- Ganglion cells.** **Ganglion cells** are the largest neurons of the retina, arranged in a single layer close to the vitreous body. They are the second-order neurons of the visual pathway. Most ganglion cells receive input from multiple bipolar cells. Their axons form the optic nerve. Some ganglion cells absorb light directly and transmit signals to brainstem nuclei that control pupillary diameter and the body's circadian rhythms. They do not contribute to visual images but detect only light intensity. Their sensory pigment is called **melanopsin**.

There are approximately 130 million rods and 6.5 million cones in one retina, but only 1.2 million nerve fibers in the optic nerve. With a ratio averaging 114 receptor cells

to one optic nerve fiber, it is obvious that there must be substantial *neural convergence* and information processing in the retina itself before signals are conducted to the brain proper. Convergence begins where multiple rod or cone cells synapse with one bipolar cell, and occurs again where multiple bipolar cells feed into one ganglion cell. Later we will examine how convergence functions in visual resolution and night vision.

There are other retinal cells, but they do not form layers of their own. **Horizontal cells** and **amacrine⁶² cells** form horizontal connections among rod, cone, and bipolar cells and intervene in the pathways from receptor cells to ganglion cells. They play diverse roles in enhancing the perception of contrast, the edges of objects, and changes in light intensity. In addition, much of the mass of the retina is composed of astrocytes and other types of glial cells.

Visual Pigments

The visual pigment of the rods is called **rhodopsin** (ro-DOP-sin), or **visual purple**. Each molecule consists of two major parts (moieties): a protein called **opsin** and a vitamin A derivative called **retinal** (rhymes with “pal”), also known as **retinene** (fig. 16.36). Opsin is embedded in the disc membranes of the rod's outer segment. All rod cells contain a single kind of rhodopsin with an absorption peak at a wavelength of 500 nm. The rods are less sensitive to light of other wavelengths and cannot distinguish one color from another.

In cones, the pigment is called **photopsin (iodopsin)**. Its retinal moiety is the same as that of rhodopsin, but the opsin moiety has a different amino acid sequence that determines which wavelengths of light the pigment absorbs. There are three kinds of cones, which are identical in appearance but optimally absorb different wavelengths of light. These differences enable us to perceive different colors.

Generating the Optic Nerve Signal

The events of sensory transduction are probably the same in rods and cones, but are better known in rods. In the dark, their retinal has a bent shape called **cis-retinal**. When it absorbs light, it changes to a straight form called **trans-retinal** and breaks away from the opsin (fig. 16.37). This is called **bleaching**, because purified rhodopsin changes from violet to colorless in the light. For a rod

⁶⁰scot = dark + op = vision

⁶¹phot = light + op = vision

⁶²a = without + macr = long + in = fiber (lacking axons)

FIGURE 16.36 Structure and Location of the Visual Pigments. (a) A rod cell. (b) Detail of the rod outer segment. (c) One disc of the outer segment showing the membrane studded with pigment molecules. (d) A pigment molecule, embedded in the unit membrane of the disc, showing the protein moiety, opsin, and the vitamin A derivative, retinal. (e) *Cis*-retinal, the isomer present in the absence of light. (f) *Trans*-retinal, the isomer produced when the pigment absorbs a photon of light.

FIGURE 16.37 The Bleaching and Regeneration of Rhodopsin. Numbers 1 through 4 indicate the bleaching events that occur in the light; numbers 5 and 6 indicate the regenerative events that are independent of light. The regenerative events occur in light and dark, but in the light, they are outpaced by bleaching.

FIGURE 16.38 Mechanism of Generating Visual Signals. In complete darkness (a), rod cells are active whereas certain bipolar cells and the ganglion cells are not. As rod cells absorb light (b), they are inhibited and these bipolar cells and ganglion cells are activated. Cones are believed to function similarly. Some bipolar cells behave differently from the type used in this example.

to continue functioning, *trans*-retinal has to be converted back to the *cis* form and reunited with opsin, producing functional rhodopsin at a rate that keeps pace with bleaching. Fifty percent of the bleached rhodopsin is regenerated in about 5 minutes. Cones are faster and their photopsin is 50% regenerated in about 90 seconds.

In the dark, rods do not sit quietly doing nothing. They steadily release the neurotransmitter glutamate from the basal end of the cell (fig. 16.38a). When a rod absorbs light, glutamate secretion ceases (fig. 16.38b). We will not delve into the mechanistic details of why this occurs. The important point is that the bipolar cells, next in line, are

sensitive to these on and off pulses of glutamate secretion. Some bipolar cells are inhibited by glutamate and excited when its secretion stops; these cells are therefore excited by rising light intensities. Other bipolar cells are excited by glutamate and therefore respond when light intensity drops. As your eye scans a scene, it passes areas of greater and lesser brightness. Their images on the retina cause a rapidly changing pattern of bipolar cell responses as the light intensity on a patch of retina rises and falls.

When bipolar cells detect fluctuations in light intensity, they stimulate ganglion cells either directly (by synapsing with them) or indirectly (via pathways that go

through amacrine cells). Ganglion cells are the only retinal cells that produce action potentials; all other retinal cells produce only graded local potentials. Ganglion cells respond to the bipolar cells with rising and falling firing frequencies. Via the optic nerve, these changes provide visual signals to the brain.

Light and Dark Adaptation

Light adaptation is an adjustment in vision that occurs when you go from a dark or dimly lit area into brighter light. If you wake up in the night and turn on a lamp, at first you see a harsh glare; you may experience discomfort from the overstimulated retinas. Your pupils quickly constrict to reduce the intensity of stimulation, but color vision and visual acuity (the ability to see fine detail) remain below normal for 5 to 10 minutes—the time needed for pigment bleaching to adjust retinal sensitivity to this light intensity. The rods bleach quickly in bright light, and cones take over. Even in typical indoor light, rod vision is nonfunctional.

On the other hand, suppose you are sitting in a bright room at night, and there is a power failure. Your eyes must undergo **dark adaptation** before you can see well enough to find your way in the dark. There is not enough light for cone (photopic) vision, and it takes a little time for the rods (scotopic vision) to adjust to the dark. Your rod pigment was bleached by the lights in the room while the power was on, but now in the relative absence of light, rhodopsin regenerates faster than it bleaches. In a minute or two, scotopic vision begins to function, and after 20 to 30 minutes, the amount of regenerated rhodopsin is sufficient for your eyes to reach essentially maximum sensitivity. Dilation of the pupils also helps by admitting more light to the eye.

The Dual Visual System

You may wonder why we have both rods and cones. Why can't we simply have one type of receptor cell that produces detailed color vision, both day and night? The **duplicity theory** of vision holds that a single type of receptor system cannot produce both high sensitivity and high resolution. It takes one type of cell and neural circuit to provide sensitive night vision and a different type to provide high-resolution daytime vision.

The high sensitivity of rods in dim light stems partly from the extensive neural convergence that occurs between the rods and ganglion cells. Up to 600 rods converge on each bipolar cell, and many bipolar cells converge on each ganglion cell. This allows for a high degree of *spatial summation* in the scotopic system (fig. 16.39a). Weak stimulation of numerous rod cells can produce an additive effect on one bipolar cell, and several bipolar cells can collaborate to excite one ganglion cell. Thus, a ganglion cell can respond in dim light that only weakly stimulates any individual rod. Scotopic vision is functional

even at a light intensity less than starlight reflected from a sheet of white paper. A shortcoming of this system is that it cannot resolve finely detailed images. One ganglion cell receives input from all the rods in about 1 mm² of retina—its receptive field. What the brain perceives is therefore a coarse, grainy image similar to an overenlarged newspaper photograph.

Around the edges of the retina, receptor cells are especially large and widely spaced. If you fixate on the middle of this page, you will notice that you cannot read the words near the margins. Visual acuity decreases rapidly as the image falls away from the fovea centralis. Our peripheral vision is a low-resolution system that serves mainly to alert us to motion in the periphery and to stimulate us to look that way to identify what is there.

When you look directly at something, its image falls on the fovea, which is occupied by about 4,000 tiny cones and no rods. The other neurons of the fovea are displaced to one side so they won't interfere with light falling on the cones. The smallness of these cones is like the smallness of the dots in a fine-grained photograph; it is partially responsible for the high-resolution images formed at the fovea. In addition, the cones here show no neural convergence. Each cone synapses with only one bipolar cell and each bipolar cell with only one ganglion cell. This gives each foveal cone a “private line to the brain,” and each ganglion cell of the fovea reports to the brain on a receptive field of just 2 μm² of retinal area (fig. 16.39b). Cones distant from the fovea exhibit some neural convergence but not nearly as much as rods do. The price of this lack of convergence at the fovea, however, is that cone cells are incapable of spatial summation, and the cone system is therefore less sensitive to light. The threshold of photopic (cone) vision lies between the intensity of starlight and moonlight reflected from white paper.

Think About It

If you look directly at a dim star in the night sky, it disappears, and if you look slightly away from it, it reappears. Why?

Color Vision

Most nocturnal vertebrates have only rod cells, but many diurnal animals are endowed with cones and color vision. Color vision is especially well developed in primates for evolutionary reasons discussed in chapter 1. It is based on three kinds of cones named for the absorption peaks of their photopsins: **short-wavelength (S) cones**, with peak sensitivity at a wavelength of 420 nm; **medium-wavelength (M) cones**, which peak at 531 nm; and **long-wavelength (L) cones**, which peak at 558 nm. These were formerly called *blue*, *green*, and *red cones*—a less accurate terminology. “Red” cones, for example, do not peak in the red part of the

FIGURE 16.39 Retinal Circuitry and Visual Sensitivity. (a) In the scotopic (night vision) system, many rods converge on each bipolar cell and many bipolar cells converge on each ganglion cell. This allows rods to combine their effects through spatial summation and stimulate the ganglion cell, generating a nerve signal even in dim light. However, it means that each ganglion cell (and its optic nerve fiber) represents a relatively large area of retina and produces a grainy image. (b) In the photopic (day vision) system, there is little neural convergence. In the fovea, represented here, each cone has a “private line” to the brain, so each optic nerve fiber represents a tiny area of retina, and vision is relatively sharp. However, the lack of convergence means photopic vision cannot function well in dim light because weakly stimulated cones cannot collaborate to stimulate a ganglion cell.

spectrum (558 nm light is perceived as orange-yellow), but they are the only cones that respond at all to red light.

Our perception of different colors is based on a mixture of nerve signals representing cones with different absorption peaks. In figure 16.40, note that light at 400 nm excites only the S cones. At 500 nm, all three types of cones are stimulated; the L cones respond at 60% of their maximum capacity, M cones at 82% of their maximum, and S cones at 20%. The brain interprets this mixture of signals as blue-green. The table in figure 16.40 shows how some other color sensations are generated by other response ratios.

Some individuals have a hereditary atteration or lack of one photopsin or another and consequently exhibit **color blindness**. The most common form is *red-green color blindness*, which results from a lack of either L or M cones and causes difficulty distinguishing these and related shades from each other. For example, a person with normal *trichromatic* color vision sees figure 16.41 as showing the number 16,

whereas a person with red-green color blindness sees no number. Red-green color blindness is a sex-linked recessive trait. It occurs in about 8% of males and 0.5% of females. (See p. 145 to review sex linkage and the reason such traits are more common in males.)

Stereoscopic Vision

Stereoscopic vision (stereopsis) is depth perception—the ability to judge how far away objects are. It depends on having two eyes with overlapping visual fields, which allows each eye to look at the same object from a different angle. Stereoscopic vision contrasts with the *panoramic vision* of mammals such as rodents and horses, in which the eyes are on opposite sides of the head. Although stereoscopic vision covers a smaller visual field than panoramic vision and provides less alertness to sneaky predators, it has the advantage of depth perception. The evolutionary basis of depth perception in primates was considered in chapter 1 (p. 11).

Wavelength (nm)	Percentage of maximum cone response (S : M : L)	Perceived hue
400	50 : 0 : 0	Violet
450	72 : 30 : 0	Blue
500	20 : 82 : 60	Blue-green
550	0 : 85 : 97	Green
625	0 : 3 : 35	Orange
675	0 : 0 : 5	Red

FIGURE 16.40 Absorption Spectra of the Retinal Cells.

In the middle column of the table, each number indicates how strongly the respective cone cells respond as a percentage of their maximum capability. At 550 nm, for example, L cones respond at 97% of their maximum, M cones at 85%, and S cones not at all. The result is a perception of green light.

❖ If you were to add another row to this table for 600 nm, what would you enter in the middle and right-hand columns?

When you fixate on something within 30 m (100 ft), each eye views it from a slightly different angle and focuses its image on the fovea centralis. The point in space on which the eyes are focused is called the *fixation point*. Objects farther away than the *fixation point* cast an image somewhat medial to the foveas, and closer objects cast their images more laterally (fig. 16.42). The distance of an image from the two foveas provides the brain with information used to judge the position of other points relative to the fixation point.

The Visual Projection Pathway

The first-order neurons in the visual pathway are the bipolar cells of the retina. The second-order neurons are the retinal ganglion cells, whose axons are the fibers of the optic nerve. The optic nerves leave each orbit through the optic foramen and then converge to form

FIGURE 16.41 A Test for Red-Green Color Blindness.

Persons with normal vision see the number 16. Persons with red-green color blindness see no discernible number. Reliable tests for color vision defects require the use of original charts. Source: *Ishihara's Tests for Colour Deficiency*, Kanehara Trading Inc., Tokyo, Japan.

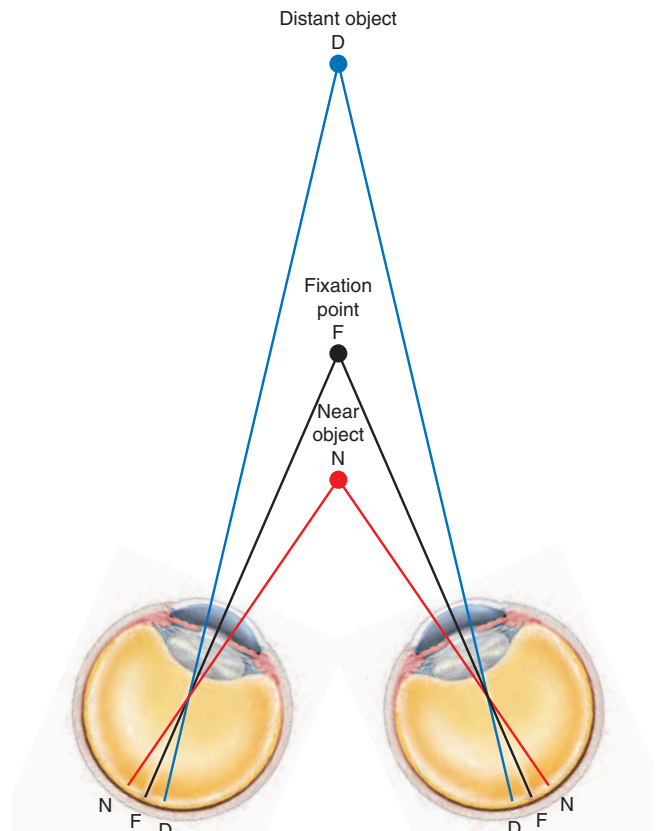

FIGURE 16.42 The Retinal Basis of Stereoscopic Vision (Depth Perception).

When the eyes converge on the fixation point (F), more distant objects (D) are focused on the retinas medial to the fovea and the brain interprets them as being farther away than the fixation point. Nearby objects (N) are focused lateral to the fovea and interpreted as being closer.

an X, the **optic chiasm**⁶³ (ky-AZ-um), inferior to the hypothalamus and anterior to the pituitary. Beyond this, the fibers continue as a pair of **optic tracts**.

Within the chiasm, half of the fibers from each optic nerve cross over to the opposite side of the brain (fig. 16.43). This is called **hemidecussation**,⁶⁴ since only half of the fibers decussate. As a result, the right cerebral hemisphere sees objects in the left visual field, because their images fall on the right half of each retina (the medial half of the left eye and lateral half of the right eye). You can trace the nerve fibers from each half retina in figure 16.43 to see that they lead to the right hemisphere. Conversely, the left hemisphere sees objects in the right visual field. Since the right brain controls motor responses on the left side of the body and vice versa, each side of the

brain needs to see what is on the side of the body where it exerts motor control. In animals with panoramic vision, nearly 100% of the optic nerve fibers of the right eye decussate to the left brain and vice versa.

The optic tracts pass laterally around the hypothalamus, and most of their axons end in the **lateral geniculate**⁶⁵ (jeh-NIC-you-late) **nucleus** of the thalamus. Third-order neurons arise here and form the **optic radiation** of fibers in the white matter of the cerebrum. These project to the primary visual cortex of the occipital lobe, where conscious visual sensation occurs. A lesion in the occipital lobe can cause blindness even if the eyes are fully functional.

A few optic nerve fibers take a different route in which they project to the midbrain and terminate in the superior colliculi and pretectal nuclei. The superior colliculi

⁶³chiasm = cross, X

⁶⁴hemi = half + decuss = to cross, form an X

⁶⁵geniculate = bent like a knee

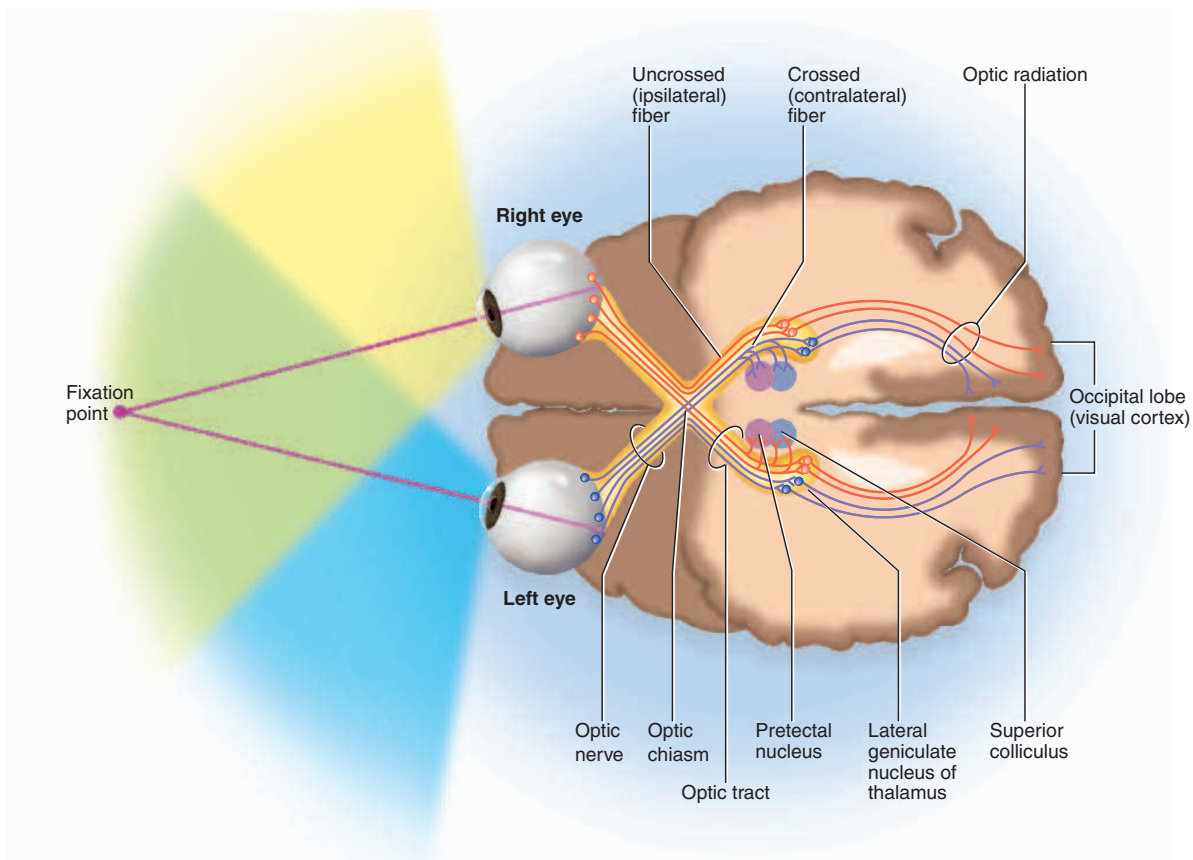

FIGURE 16.43 The Visual Projection Pathway. Diagram of hemidecussation and projection to the primary visual cortex. Blue and yellow indicate the receptive fields of the left and right eyes; green indicates the area of overlap and stereoscopic vision. Nerve fibers from the medial side of the right eye (red) decussate to the left side of the brain, while fibers from the lateral side remain on the right side of the brain. The converse is true of the left eye. The right occipital lobe thus monitors the left side of the visual field and the left occipital lobe monitors the right side.

• If a stroke destroyed the optic radiation of the right cerebral hemisphere, how would it affect a person's vision? Would it affect the person's visual reflexes?

control the visual reflexes of the extrinsic eye muscles, and the pretectal nuclei are involved in the photopupillary and accommodation reflexes.

Space does not allow us to consider much about the very complex processes of visual information processing in the brain. Some processing, such as contrast, brightness, motion, and stereopsis, begins in the retina. The primary visual cortex in the occipital lobe is connected by association tracts to nearby visual association areas in the posterior part of the parietal lobe and inferior part of the temporal lobe. These association areas process retinal data in ways beyond our present consideration to extract information about the location, motion, color, shape, boundaries, and other qualities of the objects we look at. They also store visual memories and enable the brain to identify what we are seeing—for example, to recognize printed words or name the objects we see. What is yet to be learned about visual processing promises to have important implications for biology, medicine, psychology, and even philosophy.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

22. Why can't we see wavelengths below 350 nm or above 750 nm?
23. Why are light rays bent (refracted) more by the cornea than by the lens?
24. List as many structural and functional differences between rods and cones as you can.
25. Explain how the absorption of a photon of light leads to depolarization of a bipolar retinal cell.
26. Discuss the duplicity theory of vision, summarizing the advantage of having separate types of retinal photoreceptor cells and neural circuits for photopic and scotopic vision.

INSIGHT 16.5 Medical History

Anesthesia—From Ether Frolics to Modern Surgery

Surgery is as old as civilization. People from the Stone Age to the pre-Columbian civilizations of the Americas practiced *trephination*—cutting a hole in the skull to let out “evil spirits” that were thought to cause headaches. The ancient Hindus were expert surgeons for their time, and the Greeks and Romans pioneered military surgery. But until the nineteenth century, surgery was a miserable and dangerous business, done only as a last resort and with little hope of the patient’s survival. Surgeons rarely attempted anything more complex than amputations or kidney stone removal. A surgeon had to be somewhat indifferent to the struggles and screams of his patient. Most operations had to be completed in 3 minutes or less, and a strong arm and stomach were more important qualifications for a surgeon than extensive anatomical knowledge.

At least three things were needed for surgery to be more effective: better knowledge of anatomy, *asepsis*⁶⁶ for the control of infection, and *anesthesia*⁶⁷ for the control of pain. Early efforts to control surgical pain were crude and usually ineffective, such as choking a patient into unconsciousness and trying to complete the surgery before he or she awoke. Alcohol and opium were often used as anesthetics, but the dosage was poorly controlled; some patients were underanesthetized and suffered great pain anyway, and others died of overdoses. Often there was no alternative but for a few strong men to hold the struggling patient down as the surgeon worked. Charles Darwin originally intended to become a physician, but left medical school because he was sickened by observing “two very bad operations, one on a child,” in the days before anesthesia.

In 1799, Sir Humphry Davy suggested using nitrous oxide to relieve pain. His student, Michael Faraday, suggested ether. Neither of these ideas caught on for several decades, however. Nitrous oxide (“laughing gas”) was a popular amusement in the 1800s, when traveling showmen went from town to town demonstrating its effects on volunteers from the audience. In 1841, at a medicine show in Georgia, some students were impressed with the volunteers’ euphoric giggles and antics and asked a young local physician, Crawford W. Long, if he could make some nitrous oxide for them. Long lacked the equipment to synthesize it, but he recommended they try ether. Ether was commonly used in small oral doses for toothaches and “nervous ailments,” but its main claim to popularity was its use as a party drug for so-called ether frolics. Long himself was a bit of a bon vivant who put on demonstrations for some of the young ladies, with the disclaimer that he could not be held responsible for whatever he might do under the influence of ether (such as stealing a kiss).

At these parties, Long noted that people sometimes fell and suffered considerable cuts and bruises without feeling pain. In 1842, he had a patient who was terrified of pain but needed a

tumor removed from his neck. Long excised the tumor without difficulty as his patient sniffed ether from a towel. The operation created a sensation in town, but other physicians ridiculed Long and pronounced anesthesia dangerous. His medical practice declined as people grew afraid of him, but over the next 4 years he performed eight more minor surgeries on patients under ether. Struggling to overcome criticisms that the effects he saw were due merely to hypnotic suggestion or individual variation in sensitivity to pain, Long even compared surgeries done on the same person with and without ether.

Long failed to publish his results quickly enough, and in 1844 he was scooped by a Connecticut dentist, Horace Wells, who had tried nitrous oxide as a dental anesthetic. Another dentist, William Morton of Boston, had tried everything from champagne to opium to kill pain in his patients. He too became interested in ether and gave a public demonstration at Massachusetts General Hospital, where he etherized a patient and removed a tumor. Within a month of this successful and sensational demonstration, ether was being used in other cities of the United States and England. Morton patented a “secret formula” he called Morton’s Letheon,⁶⁸ which smelled suspiciously of ether, but eventually he went broke in a greedy effort to monopolize ether anesthesia, and he died a pauper. His grave near Boston bears the epitaph:

WILLIAM T. G. MORTON
*Inventor and Revealer of Anaesthetic Inhalation
Before Whom, in All Time, Surgery Was Agony.
By Whom Pain in Surgery Was Averted and Annulled.
Since Whom Science Has Control of Pain.*

Wells, who had engaged in a bitter feud to establish himself as the inventor of ether anesthesia, committed suicide at the age of 33. Crawford Long ran a successful medical practice in Athens, Georgia, but to his death he remained disappointed that he had not received credit as the first to perform surgery on etherized patients.

Ether and chloroform became obsolete when safer anesthetics such as cyclopropane, ethylene, and nitrous oxide were developed. These are *general anesthetics* that render a patient unconscious by crossing the blood-brain barrier and blocking nervous transmission through the brainstem. General anesthetics deaden pain by activating GABA receptors and causing an inflow of Cl⁻, which hyperpolarizes neurons and makes them less likely to fire. Diazepam (Valium) also employs this mechanism. *Local anesthetics* such as procaine (Novocain) and tetracaine selectively deaden specific nerves. They decrease the permeability of membranes to Na⁺, thereby reducing their ability to produce action potentials.

A sound knowledge of anatomy, control of infection and pain, and development of better tools converged to allow surgeons time to operate more carefully. As a result, surgery became more intellectually challenging and interesting. It attracted a more educated class of practitioner, which put it on the road to becoming the remarkable lifesaving approach that it is today.

⁶⁶a = without + *sepsis* = infection

⁶⁷an = without + *esthesia* = feeling, sensation

⁶⁸lethe = oblivion, forgetfulness

CHAPTER REVIEW

Review of Key Concepts

16.1 Properties and Types of Sensory Receptors (p. 587)

1. Sensory *receptors* range from simple nerve endings to complex sense organs.
2. *Sensory transduction* is the conversion of stimulus energy into a pattern of action potentials.
3. Transduction begins with a *receptor potential* that, if it reaches threshold, triggers the production of action potentials.
4. Receptors transmit four kinds of information about stimuli: *modality*, *location*, *intensity*, and *duration*.
5. Receptors can be classified by modality as *chemoreceptors*, *thermoreceptors*, *nociceptors*, *mechanoreceptors*, and *photoreceptors*.
6. Receptors can also be classified by the origins of their stimuli as *interoceptors*, *proprioceptors*, and *exteroceptors*.
7. *General (somesthetic) senses* have receptors widely distributed over the body and include the senses of touch, pressure, stretch, temperature, and pain. *Special senses* have receptors in the head only and include vision, hearing, equilibrium, taste, and smell.

16.2 The General Senses (p. 589)

1. Unencapsulated nerve endings are simple sensory nerve fibers not enclosed in specialized connective tissue; they include *free nerve endings*, *tactile discs*, and *hair receptors*.
2. Encapsulated nerve endings are nerve fibers enclosed in glial cells or connective tissues that modify their sensitivity. They include *muscle spindles*, *tendon organs*, *tactile corpuscles*, *end bulbs*, *lamellar corpuscles*, and *bulbous corpuscles*.
3. Somesthetic signals from the head travel the trigeminal and other cranial nerves to the brainstem, and those below the head travel up the spinothalamic tract and other pathways. Most signals reach the contralateral primary somesthetic cortex, but

- proprioceptive signals travel to the cerebellum.
4. Pain is a sensation that occurs when nociceptors detect tissue damage or potentially injurious situations.
 5. *Fast pain* is a relatively quick, localized response mediated by myelinated nerve fibers; it may be followed by a less localized *slow pain* mediated by unmyelinated fibers.
 6. *Somatic pain* arises from the skin, muscles, and joints, and may be *superficial* or *deep pain*. *Visceral pain* arises from the viscera; it is less localized and is often associated with nausea.
 7. Injured tissues release bradykinin, serotonin, prostaglandins, and other chemicals that stimulate nociceptors.
 8. Pain signals travel from the receptor to the cerebral cortex by way of *first-through third-order neurons*. Signals from the head travel through the trigeminal, facial, glossopharyngeal, and vagus nerves to the medulla oblongata, and are then relayed through the thalamus to the cerebrum. Signals from below the head ascend the spinothalamic and spino-reticular tracts and gracile fasciculus of the spinal cord. The thalamus relays pain signals to the postcentral gyrus of the cerebrum.
 9. Pain signals in the spinoreticular tract travel to the reticular formation and from there to the hypothalamus and limbic system, producing visceral and emotional responses to pain.
 10. *Referred pain* is the brain's misidentification of the location of pain resulting from convergence in sensory pathways.
 11. Pain awareness can be reduced by *spinal gating* mechanisms that block the transmission of pain signals up the spinal cord. Analgesic neuropeptides (*endogenous opioids*) called *enkephalins*, *endorphins*, and *dynorphins* exert pain-blocking effects at multiple levels of the spinal cord and brainstem.

16.3 The Chemical Senses (p. 595)

1. Taste (*gustation*) results from the action of chemicals on the *taste buds*, which are groups of sensory cells located on some of the *lingual papillae* and in the palate, pharynx, and epiglottis.
2. *Foliate*, *fungiform*, and *vallate papillae* have taste buds; *filiiform papillae* lack taste buds but sense the texture of food.
3. The primary taste sensations are salty, sweet, sour, bitter, and umami. Flavor is a combined effect of these tastes and the texture, aroma, temperature, and appearance of food. Some flavors result from the stimulation of free nerve endings.
4. Some taste chemicals (sugars, alkaloids, and glutamate) bind to surface receptors on the taste cells and activate second messengers in the cell; sodium and acids penetrate into the taste cell and depolarize it.
5. Taste signals travel from the tongue through the facial and glossopharyngeal nerves, and from the palate, pharynx, and epiglottis through the vagus nerve. They travel to the medulla oblongata and then by one route to the hypothalamus and amygdala, and by another route to the thalamus and cerebral cortex.
6. Smell (*olfaction*) results from the action of chemicals on *olfactory cells* in the roof of the nasal cavity.
7. Odor molecules bind to surface receptors on the *olfactory hairs* of the olfactory cells and activate second messengers in the cell.
8. Nerve fibers from the olfactory cells assemble into fascicles that collectively constitute cranial nerve I. They pass through foramina of the cribriform plate and end in the olfactory bulbs beneath the frontal lobes of the cerebrum.
9. Olfactory signals travel the *olfactory tracts* from the bulbs to the temporal lobes, and are relayed to the insula, orbitofrontal cortex, hippocampus, amygdala, and hypothalamus.

The cerebral cortex also sends signals back to the bulbs that moderate one's perception of smell.

16.4 Hearing and Equilibrium (p. 600)

1. Sound is generated by vibrating objects. The *amplitude* of the vibration determines the *loudness* of a sound, measured in *decibels (db)*, and the *frequency* of vibration determines the *pitch*, measured in *hertz (Hz)*.
2. Humans hear best at frequencies of 1,500 to 5,000 Hz, but sensitive ears can hear sounds from 20 Hz to 20,000 Hz. The threshold of hearing is 0 db and the threshold of pain is about 140 db; most conversation is about 60 db.
3. The *outer ear* consists of the *auricle* and *auditory canal*. The *middle ear* consists of the *tympanic membrane* and an air-filled *tympanic cavity* containing three bones (*malleus*, *incus*, and *stapes*) and two muscles (*tensor tympani* and *stapedius*). The inner ear consists of fluid-filled chambers and tubes (the *membranous labyrinth*) including the *vestibule*, *semicircular ducts*, and *cochlea*.
4. The most important part of the cochlea, the organ of hearing, is the *spiral organ*, which includes sensory *hair cells*. A row of 3,500 *inner hair cells* generates the signals we hear, and three rows of *outer hair cells* tune the cochlea to enhance its pitch discrimination.
5. Vibrations in the ear move the *basilar membrane* of the cochlea up and down. As the hair cells move up and down, their stereocilia bend against the relatively stationary tectorial membrane above them. This opens K^+ gates at the tip of each stereocilium, and the inflow of K^+ depolarizes the cell. This triggers neurotransmitter release, which initiates a nerve signal.
6. *Loudness* determines the amplitude of basilar membrane vibration and the firing frequency of the associated auditory neurons. *Pitch* determines which regions of the basilar membrane vibrate more than others, and which auditory nerve fibers respond most strongly.
7. The cochlear nerve joins the vestibular nerve to become cranial nerve VIII. Cochlear nerve fibers project to the pons and from there to the inferior colliculi of the midbrain, then the thalamus, and finally the primary auditory cortex of the temporal lobes.
8. The pons transmits excitatory nerve signals back to the outer hair cells of the cochlea and inhibitory nerve signals back to the sensory dendrites associated with the inner hair cells, acting in both cases to sharpen the contrast between responses in adjacent regions of the spiral organ. This “tunes” the cochlea to enhance one's ability to discriminate between sounds of similar pitch.
9. *Static equilibrium* is the sense of the orientation of the head; *dynamic equilibrium* is the sense of linear or angular acceleration of the head.
10. The *saccul*e and *utricle* are chambers in the vestibule of the inner ear, each with a *macula* containing sensory hair cells. The *macula sacculi* is nearly vertical and the *macula utriculi* is nearly horizontal.
11. The hair cell stereocilia are capped by a weighted gelatinous *otolithic membrane*. When pulled by gravity or linear acceleration of the body, these membranes stimulate the hair cells.
12. Any orientation of the head causes a combination of stimulation to the four maculae, sending signals to the brain that enable it to sense the orientation. Vertical acceleration also stimulates each macula sacculi, and horizontal acceleration stimulates each macula utriculi.
13. Each inner ear also has three *semicircular ducts* with a sensory patch of hair cells, the *crista ampullaris*, in each duct. The stereocilia of these hair cells are embedded in a gelatinous *cupula*.
14. Tilting or rotation of the head moves the ducts relative to the fluid (endolymph) within, causing the fluid to push the cupula and stimulate the hair cells. The brain detects angular acceleration of the head from the combined input from the six ducts.
15. Signals from the utricle, saccul, and semicircular ducts travel the *vestibular nerve*, which joins the cochlear nerve in cranial nerve VIII. Vestibular nerve fibers lead to four pairs of *vestibular nuclei* in the pons and medulla. These nuclei relay signals to the cerebellum; nuclei that control eye movements; the reticular formation; the spinal cord; and via the thalamus to the cerebrum.

16.5 Vision (p. 614)

1. Vision is a response to electromagnetic radiation with wavelengths from about 400 to 700 nm.

2. Accessory structures of the orbit include the eyebrows, eyelids, conjunctiva, lacrimal apparatus, and extrinsic eye muscles.
3. The wall of the eyeball is composed of an outer *fibrous layer* composed of *sclera* and *cornea*; a middle *vascular layer* composed of *choroid*, *ciliary body*, and *iris*; and an *inner layer* composed of the *retina* and beginning of the *optic nerve*.
4. The optical components of the eye admit and bend (refract) light rays and bring images to a focus on the retina. They include the *cornea*, *aqueous humor*, *lens*, and *vitreous body*. Most refraction occurs at the air–cornea interface, but the lens adjusts the focus.
5. The neural components of the eye absorb light and encode the stimulus in action potentials transmitted to the brain. They include the *retina* and *optic nerve*. The sharpest vision occurs in a region of retina called the *fovea centralis*, whereas the *optic disc*, where the optic nerve originates, is a blind spot with no receptor cells.
6. The relaxed (*emmetropic*) eye focuses on objects 6 m or more away. A *near response* is needed to focus on closer objects. This includes convergence of the eyes, constriction of the pupil, and *accommodation* (thickening) of the lens.
7. Light falling on the retina is absorbed by visual pigments in the *outer segments* of the *rod* and *cone* cells. Rods contain the visual pigment *rhodopsin*, whereas there are three types of cones with variations of the pigment *photopsin*.
8. Rods function at low light intensities (producing night, or *scotopic*, vision) but produce monochromatic images with poor resolution. Cones require higher light intensities (producing day, or *photopic*, vision) and produce color images with finer resolution.
9. Rods secrete glutamate from the base of the cell in the dark. When rhodopsin absorbs light, it *bleaches* and the cell stops emitting glutamate. *Bipolar cells*, which synapse with the rods and cones, respond to on-and-off pulses of glutamate secretion by stimulating *ganglion cells*, the next neurons in the neural pathway. Ganglion cells then generate action potentials, which constitute the signal in the optic nerve.

10. The eyes respond to changes in light intensity by *light adaptation* (pupillary constriction and pigment bleaching) and *dark adaptation* (pupillary dilation and pigment regeneration).
11. The *duplicity theory* explains that a single type of receptor cell cannot produce both high light sensitivity (like the rods) and high resolution (like the cones). The neural convergence responsible for the sensitivity of rod pathways limits resolution, while the lack of convergence responsible for the high resolution of cones limits light sensitivity.
12. Three types of cones—*short-, medium-, and long-wavelength cones*—have slight differences in their photopsins that result in peak absorption in different regions of the spectrum. This results in the ability to distinguish colors.
13. *Stereoscopic vision* (depth perception) results from each eye viewing an object from a slightly different angle, so its image falls on different areas of the two retinas.
14. Fibers of the optic nerves *hemidecussate* at the *optic chiasm*, so images in the left visual field project from both eyes to the right cerebral hemisphere, and images on the right project to the left hemisphere.
15. Beyond the optic chiasm, most nerve fibers end in the *lateral geniculate nucleus* of the thalamus. Here they synapse with third-order neurons whose fibers form the *optic radiation* leading to the primary visual cortex of the occipital lobe.
16. Some fibers of the optic nerve lead to the superior colliculi and pretectal nuclei of the midbrain. These midbrain nuclei control visual reflexes of the extrinsic eye muscles, pupillary reflexes, and accommodation of the lens in near vision.

Testing Your Recall

1. Hot and cold stimuli are detected by
 - a. free nerve endings.
 - b. proprioceptors.
 - c. Krause end bulbs.
 - d. lamellar corpuscles.
 - e. tactile corpuscles.
2. _____ is a neurotransmitter that transmits pain sensations to second-order spinal neurons.
 - a. Endorphin
 - b. Enkephalin
 - c. Substance P
 - d. Acetylcholine
 - e. Norepinephrine
3. _____ is a neuromodulator that blocks the conduction of pain signals by second-order spinal neurons.
 - a. Endorphin
 - b. Enkephalin
 - c. Substance P
 - d. Acetylcholine
 - e. Norepinephrine
4. Most taste buds occur in
 - a. the vallate papillae.
 - b. the fungiform papillae.
 - c. the filiform papillae.
 - d. the palate.
 - e. the lips.
5. The higher the frequency of a sound,
 - a. the louder it sounds.
 - b. the harder it is to hear.
 - c. the more it stimulates the distal end of the spiral organ.
 - d. the faster it travels through air.
 - e. the higher its pitch.
6. Cochlear hair cells rest on
 - a. the tympanic membrane.
 - b. the secondary tympanic membrane.
 - c. the tectorial membrane.
 - d. the vestibular membrane.
 - e. the basilar membrane.
7. The acceleration you feel when an elevator begins to rise is sensed by
 - a. the anterior semicircular duct.
 - b. the spiral organ.
 - c. the crista ampullaris.
 - d. the macula sacculi.
 - e. the macula utriculi.
8. The color of light is determined by
 - a. its velocity.
 - b. its amplitude.
 - c. its wavelength.
 - d. refraction.
 - e. how strongly it stimulates the rods.
9. The retina receives its oxygen supply from
 - a. the hyaloid artery.
 - b. the vitreous body.
 - c. the choroid.
 - d. the pigment epithelium.
 - e. the scleral venous sinus.
10. Which of the following statements about photopic vision is false?
 - a. It is mediated by the cones.
 - b. It has a low threshold.
 - c. It produces fine resolution.
 - d. It does not function in starlight.
 - e. It does not employ rhodopsin.
11. The most finely detailed vision occurs when an image falls on a pit in the retina called the _____.
12. The only cells of the retina that generate action potentials are the _____ cells.
13. The visual pigment of a cone cell is _____.
14. The gelatinous membranes of the macula sacculi and macula utriculi are weighted by calcium carbonate and protein granules called _____.
15. Three rows of _____ in the cochlea have V-shaped arrays of stereocilia and tune the frequency sensitivity of the cochlea.
16. The _____ is a tiny bone that vibrates in the oval window and thereby transfers sound vibrations to the inner ear.
17. The _____ of the midbrain receives auditory input and triggers the head-turning auditory reflex.
18. The function of the _____ in a taste bud is to replace dead taste cells.
19. Olfactory neurons synapse with mitral cells and tufted cells in the _____, which lies inferior to the frontal lobe.
20. In the phenomenon of _____, pain from the viscera is perceived as coming from an area of the skin.

True or False

Determine which five of the following statements are false, and briefly explain why.

- The sensory (afferent) nerve fibers for touch end in the thalamus.
- Things we touch with the left hand are perceived only in the right cerebral hemisphere.
- Things we see with the left eye are perceived only in the right cerebral hemisphere.
- Some chemoreceptors are interoceptors and some are exteroceptors.
- The vitreous body occupies the posterior chamber of the eye.
- Descending analgesic fibers prevent pain signals from reaching the spinal cord.
- Cranial nerve VIII carries signals for both hearing and balance.
- The tympanic cavity is filled with air, but the membranous labyrinth is filled with liquid.
- Rods and cones release their neurotransmitter in the dark, not in the light.
- All of the extrinsic muscles of the eye are controlled by the oculomotor nerve.

Answers in appendix B

Testing Your Comprehension

- The principle of neural convergence is explained on page 472. Discuss its relevance to referred pain and scotopic vision.
- What type of cutaneous receptor enables you to feel an insect crawling through your hair? What type enables you to palpate a patient's pulse? What type enables a blind person to read braille?
- Contraction of a muscle usually puts more tension on a structure, but contraction of the ciliary muscle puts less tension on the lens. Explain how.
- Janet has terminal ovarian cancer and is in severe pelvic pain that has not yielded to any other treatment. A neurosurgeon performs an *anterolateral cordotomy*, cutting across the anterolateral region of her lumbar spinal cord. Explain the rationale of this treatment and its possible side effects.
- What would be the benefit of a drug that blocks the receptors for substance P?

Chapter Review 679

INSIGHTS

- 17.1 Clinical Application:** Melatonin, SAD, and PMS 650
- 17.2 Clinical Application:** Hormone Receptors and Therapy 664
- 17.3 Clinical Application:** Anti-Inflammatory Drugs 671
- 17.4 Medical History:** The Discovery of Insulin 676

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Structure and function of the plasma membrane (p. 91)
- G proteins, cAMP, and other second messengers (p. 94)
- Active transport and the transport maximum (p. 104)
- Protein synthesis and secretion (pp. 131–136)
- Monoamines, especially catecholamines (p. 463)
- The hypothalamus (p. 531)

If the body is to function as an integrated whole, its organs must communicate with each other and coordinate their activities. Even very simple organisms composed of only a few cells have mechanisms for intercellular communication, suggesting that such mechanisms evolved very early in the history of life. In humans, two such systems are especially prominent—the nervous and endocrine systems, which communicate with neurotransmitters and hormones, respectively.

Nearly everyone has heard of at least some hormones—growth hormone, thyroid hormone, estrogen, and insulin, for example. At least passingly familiar, too, are some of the glands that secrete them (such as the pituitary and thyroid glands) and some disorders that result from hormone deficiency, excess, or dysfunction (such as diabetes, goiter, and dwarfism).

This chapter is primarily about the *endocrine* (hormonal) *system* of communication. We will start with the relatively familiar and large-scale aspects of this system—a survey of the endocrine glands, their hormones, and the principal effects of those hormones. We will then work our way down to the finer and less familiar details—the chemical identity of hormones, how they are made and transported, and how they produce their effects on their target cells. Shorter sections at the end of the chapter discuss the role of the endocrine system in adapting to stress, some hormonelike *paracrine* secretions, and the pathologies that result from endocrine dysfunction.

The body has four principal avenues of communication from cell to cell:

1. **Gap junctions** join single-unit smooth muscle, cardiac muscle, epithelial, and other cells to each other. They enable cells to pass nutrients, electrolytes, and signaling molecules directly from the cytoplasm of one cell to the cytoplasm of the next through pores in their plasma membranes (fig. 5.28, p. 173).
2. **Neurotransmitters** are released by neurons, diffuse across a narrow synaptic cleft, and bind to receptors on the surface of the next cell.
3. **Paracrines**¹ are secreted by one cell, diffuse to nearby cells in the same tissue, and stimulate their physiology. Some call them *local hormones*.
4. **Hormones**,² in the strict sense, are chemical messengers that are transported by the bloodstream and stimulate physiological responses in cells of another tissue or organ, often a considerable distance away. Certain hormones produced by the pituitary gland in the head, for example, act on organs in the abdominopelvic cavity.

This chapter is concerned mainly with hormones and, to some extent, paracrine secretions. The glands, tissues, and cells that secrete hormones constitute the **endocrine³ system**; the study of this system and the diagnosis and treatment of its disorders is called **endocrinology**. The most familiar hormone sources are the organs traditionally recognized as **endocrine glands**, such as the pituitary, thyroid, and adrenal glands, among others (fig. 17.1). Growing knowledge of endocrinology has revealed, however, that hormones are also secreted by numerous organs and tissues not usually thought of as glands, such as the brain, heart, small intestine, bones, and adipose tissue.

Comparison of Endocrine and Exocrine Glands

In chapter 5, we examined another category of glands, the *exocrine* glands. The classical distinction between exocrine and endocrine glands has been the presence or absence of ducts. Most exocrine glands secrete their products by way of a duct onto an epithelial surface such as the skin or the mucosa of the digestive tract (see fig. 5.29, p. 175). Endocrine glands, by contrast, are ductless and release their secretions into the bloodstream. For this reason, hormones were originally called the body's “internal secretions”; the word *endocrine* still alludes to this fact. Exocrine secretions have extracellular effects such as the digestion of food, whereas endocrine secretions have intracellular effects—they alter the metabolism of their target cells.

17.1 Overview of the Endocrine System

Objectives

When you have completed this section, you should be able to

- define *hormone* and *endocrine system*;
- name several organs of the endocrine system;
- contrast endocrine with exocrine glands;
- recognize the standard abbreviations for many hormones; and
- compare and contrast the nervous and endocrine systems.

¹*para* = next + *crin* = to secrete

²*hormone* = to excite, set in motion

³*endo* = into + *crin* = to secrete

FIGURE 17.1 Major Organs of the Endocrine System. This system also includes gland cells in many other organs not shown here.
 After reading this chapter, name at least three hormone-secreting organs that are not shown in this illustration.

Endocrine glands have an unusually high density of blood capillaries, which serve to pick up and carry away their hormones. These vessels are an especially permeable type called *fenestrated capillaries*, which have patches of large pores in their walls allowing for the easy uptake of matter from the gland tissue (see fig. 20.6, p. 761).

Some glands and secretory cells defy simple classification as endocrine or exocrine. Liver cells, for example, behave as exocrine cells in the traditional sense by secreting bile into ducts that lead ultimately to the small

intestine. However, they also secrete hormones directly into the blood, and in this respect they act as endocrine cells. They secrete albumin and blood-clotting factors directly into the blood as well. These do not fit the traditional concept of exocrine secretions, because they are not released by way of ducts or onto epithelial surfaces; nor do they fit the concept of endocrine secretions, because they are not hormones. Liver cells are just one of nature's myriad ways of confounding our impulse to rigidly classify things.

TABLE 17.1 Comparison of the Nervous and Endocrine Systems

Nervous System	Endocrine System
Communicates by means of electrical impulses and neurotransmitters	Communicates by means of hormones
Releases neurotransmitters at synapses at specific target cells	Releases hormones into bloodstream for general distribution throughout body
Usually has relatively local, specific effects	Sometimes has very general, widespread effects
Reacts quickly to stimuli, usually within 1–10 msec	Reacts more slowly to stimuli, often taking seconds to days
Stops quickly when stimulus stops	May continue responding long after stimulus stops
Adapts relatively quickly to continual stimulation	Adapts relatively slowly; may respond for days to weeks

Comparison of the Nervous and Endocrine Systems

Although the nervous and endocrine systems both serve for internal communication, they are not redundant; they complement rather than duplicate each other's function (table 17.1). The systems differ in their means of communication—both electrical and chemical in the nervous system and solely chemical in the endocrine system (fig. 17.2)—yet as we shall see, they have many similarities on this point as well. They differ also in how quickly they start and stop responding to stimuli. The nervous system typically responds in just a few

milliseconds, whereas hormone release may follow from several seconds to days after the stimulus that caused it. Furthermore, when a stimulus ceases, the nervous system stops responding almost immediately, whereas some endocrine effects persist for several days or even weeks. On the other hand, under long-term stimulation, most neurons quickly adapt and their response declines. The endocrine system shows more persistent responses. For example, thyroid hormone secretion rises in cold weather and remains elevated as long as it remains cold.

Another difference between the two systems is that an efferent nerve fiber innervates only one organ and a limited number of cells within that organ; its effects, therefore, are precisely targeted and relatively specific. Hormones, by contrast, circulate throughout the body and some of them, such as growth hormone, epinephrine, and thyroid hormone, have more widespread effects than does the output of any one nerve fiber.

But these differences should not blind us to the similarities between the two systems. Several chemicals function as both neurotransmitters and hormones, including norepinephrine, cholecystokinin, thyrotropin-releasing hormone, dopamine, and antidiuretic hormone (vasopressin). Some hormones, such as oxytocin and epinephrine, are secreted by **neuroendocrine cells**—neurons that release their secretions into the bloodstream. Some hormones and neurotransmitters produce overlapping effects on the same target cells. For example, glucagon and norepinephrine stimulate the liver

(a) Nervous system

(b) Endocrine system

FIGURE 17.2 Communication by the Nervous and Endocrine Systems. (a) A neuron has a long fiber that delivers its neurotransmitter to the immediate vicinity of its target cells. (b) Endocrine cells secrete a hormone into the bloodstream (left). At a point often remote from its origin, the hormone leaves the bloodstream and enters or binds to its target cells (right).

to break down glycogen and release glucose into the blood. The nervous and endocrine systems continually regulate each other as they coordinate the activities of other organ systems. Neurons often trigger hormone secretion, and hormones often stimulate or inhibit neurons.

We have seen that neurotransmitters depend on receptors in the receiving cell; they cannot exert any effect unless the receiving cell is equipped to bind and respond to them. This is true of hormones as well. When a hormone enters the bloodstream, it goes wherever the blood goes; there is no way to send it selectively to a particular organ. However, only those organs or cells that have receptors for it can respond to it. We call these the **target organs** or **target cells**. Thyroid-stimulating hormone, for example, circulates everywhere the blood goes, but only the thyroid gland responds to it.

Hormone Nomenclature

Many hormones are denoted by standard abbreviations that are used repeatedly in this chapter. These are listed alphabetically in table 17.2 for use as a convenient reference while you work through the chapter. This list is by no means complete. It omits hormones that have no abbreviation, such as estrogen and insulin, and hormones that are not discussed much in this chapter. Synonyms used by many authors are indicated in parentheses, but the first name listed is the one used in this book.

Abbreviation	Name	Source
ACTH	Adrenocorticotrophic hormone (corticotropin)	Anterior pituitary
ADH	Antidiuretic hormone (vasopressin)	Posterior pituitary
ANP	Atrial natriuretic peptide	Heart
CRH	Corticotropin-releasing hormone	Hypothalamus
DHEA	Dehydroepiandrosterone	Adrenal cortex
EPO	Erythropoietin	Kidney, liver
FSH	Follicle-stimulating hormone	Anterior pituitary
GH	Growth hormone (somatotropin)	Anterior pituitary
GHRH	Growth hormone-releasing hormone	Hypothalamus
GnRH	Gonadotropin-releasing hormone	Hypothalamus
IGFs	Insulin-like growth factors (somatomedins)	Liver, other tissues
LH	Luteinizing hormone	Anterior pituitary
NE	Norepinephrine	Adrenal medulla
OT	Oxytocin	Posterior pituitary
PIH	Prolactin-inhibiting hormone (dopamine)	Hypothalamus
PRL	Prolactin	Anterior pituitary
PTH	Parathyroid hormone (parathormone)	Parathyroids
T ₃	Triiodothyronine	Thyroid
T ₄	Thyroxine (tetraiodothyronine)	Thyroid
TH	Thyroid hormone (T ₃ and T ₄)	Thyroid
TRH	Thyrotropin-releasing hormone	Hypothalamus
TSH	Thyroid-stimulating hormone (thyrotropin)	Anterior pituitary

17.2 The Hypothalamus and Pituitary Gland

Objectives

When you have completed this section, you should be able to

- describe the anatomical relationships between the hypothalamus and pituitary gland;
- distinguish between the anterior and posterior lobes of the pituitary;
- list the hormones produced by the hypothalamus and each lobe of the pituitary, and identify the functions of each hormone;
- explain how the pituitary is controlled by the hypothalamus and its target organs; and
- describe the effects of growth hormone.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Define the word hormone and distinguish a hormone from a neurotransmitter. Why is this an imperfect distinction?
2. Name some sources of hormones other than purely endocrine glands.
3. Describe some distinctions between endocrine and exocrine glands.
4. List some similarities and differences between the endocrine and nervous systems.

There is no master control center that regulates the entire endocrine system, but the pituitary gland and hypothalamus have a more wide-ranging influence than any other part of the system, and several other endocrine glands cannot be adequately understood without first knowing how the pituitary influences them. This is therefore an appropriate place to begin a survey of the endocrine system.

Anatomy

The hypothalamus, shaped like a flattened funnel, forms the floor and walls of the third ventricle of the brain; we studied its structure and function in chapter 14 (see figs. 14.2, p. 517, and 14.12b, p. 532). It regulates primitive functions of the body ranging from water balance and thermoregulation to sex drive and childbirth. Many of its functions are carried out by way of the pituitary gland, which is closely associated with it both anatomically and physiologically.

The **pituitary gland (hypophysis⁴)** is suspended from the floor of the hypothalamus by a stalk (*infundibulum⁵*) and housed in a depression of the sphenoid bone, the sella turcica. This gland is roughly the size and shape of a kidney bean, usually about 1.3 cm wide; it grows about 50% larger in pregnancy. It is actually composed of two structures—the *adenohypophysis* and *neurohypophysis*—with independent origins and separate functions. The adenohypophysis arises from a *hypophyseal pouch* that grows upward from the embryonic pharynx, while the neurohypophysis arises as a downgrowth of the brain, the *neurohypophyseal bud* (fig. 17.3). They come to lie side by side and are so closely joined that they look like a single gland.

The **adenohypophysis⁶** (AD-eh-no-hy-POFF-ih-sis) constitutes the anterior three-quarters of the pituitary (figs. 17.4a, 17.5a). It has two parts: a large **anterior lobe**,

⁴*hypo* = below + *physis* = growth

⁵*infundibulum* = funnel

⁶*adeno* = gland

FIGURE 17.3 Embryonic Development of the Pituitary Gland. (a) Sagittal section of the head showing the neural and pharyngeal origins of the pituitary. (b) Pituitary development at 8 weeks. The hypophyseal pouch, destined to become the anterior pituitary, has now separated from the pharynx. (c) Development at 16 weeks. The two lobes are now encased in bone and so closely associated they appear to be a single gland.

FIGURE 17.4 Anatomy of the Pituitary Gland. (a) Major structures of the pituitary and hormones of the neurohypophysis. Note that these hormones are produced by two nuclei in the hypothalamus and later released from the posterior lobe of the pituitary. (b) The hypophyseal portal system, which regulates the anterior lobe of the pituitary. The hormones in the violet box are secreted by the hypothalamus and travel in the portal system to the anterior pituitary. The hormones in the pink box are secreted by the anterior pituitary under the control of the hypothalamic releasers and inhibitors.

Which lobe of the pituitary is essentially composed of brain tissue?

FIGURE 17.5 Histology of the Pituitary Gland. (a) The anterior lobe. Basophils include gonadotropes, thyrotropes, and corticotropes. Acidophils include somatotropes and lactotropes. These subtypes are not distinguishable with this histological stain. The chromophobes resist staining, and their function is not yet known. (b) The posterior lobe, composed of nervous tissue.

also called the *pars distalis* (“distal part”) because it is most distal to the pituitary stalk, and a less important *pars tuberalis*, a small mass of cells that wraps around the stalk. In the fetus, it also has a *pars intermedia*, a strip of tissue between the anterior lobe and neurohypophysis. During subsequent development, however, most of its cells mingle with those of the anterior lobe. All that remains of the *pars intermedia* after birth is a narrow, rudimentary zone with epithelium-lined, cystlike pockets of little-known function.

The anterior pituitary has no nervous connection to the hypothalamus but is linked to it by a complex of

blood vessels called the **hypophyseal portal system** (fig. 17.4b). This system consists of a network of *primary capillaries* in the hypothalamus, a group of small veins called *portal venules* that travel down the stalk, and a complex of *secondary capillaries* in the anterior pituitary. The hypothalamus controls the anterior pituitary by secreting hormones that enter the primary capillaries, travel down the portal venules, and diffuse out of the secondary capillaries into the pituitary tissue. The hypothalamic hormones regulate secretion by various types of pituitary cells that we will study later.

The **neurohypophysis** constitutes the posterior one-quarter of the pituitary. It has three parts: the *median eminence*, an extension of the floor of the brain; the *infundibulum* mentioned earlier; and the largest part, the **posterior lobe (pars nervosa)**. The neurohypophysis is actually nervous tissue (nerve fibers and neuroglia, fig. 17.5b), not a true gland. The nerve fibers arise from certain cell bodies in the hypothalamus, pass down the stalk as a bundle called the **hypothalamo-hypophyseal tract**, and end in the posterior lobe (fig. 17.4a). The hypothalamic neurons synthesize hormones and transport them down the axons to the posterior pituitary. Here they are stored until a nerve signal coming down those same axons triggers their release into the blood.

Hereafter, we can largely disregard all parts of the pituitary except the anterior and posterior lobes, which secrete all the pituitary hormones of interest. References to the anterior and posterior pituitary should be understood as referring only to these two lobes.

Hypothalamic Hormones

To understand the physiology of the hypothalamic-pituitary system, we must begin with the hormones produced in the hypothalamus. There are eight of these (fig. 17.4)—six to regulate the anterior pituitary and two that are stored in the posterior pituitary and released on demand. The first six are described as *releasing hormones* if they stimulate pituitary cells to secrete hormones of their own, or *inhibiting hormones* if they suppress pituitary secretion (table 17.3).

TABLE 17.3

Hypothalamic Releasing and Inhibiting Hormones That Regulate the Anterior Pituitary

Hormone	Principal Effects
Thyrotropin-releasing hormone (TRH)	Promotes secretion of thyroid-stimulating hormone (TSH) and prolactin (PRL)
Corticotropin-releasing hormone (CRH)	Promotes secretion of adrenocorticotropic hormone (ACTH)
Gonadotropin-releasing hormone (GnRH)	Promotes secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
Growth hormone-releasing hormone (GHRH)	Promotes secretion of growth hormone (GH)
Prolactin-inhibiting hormone (PIH)	Inhibits secretion of prolactin (PRL)
Somatostatin	Inhibits secretion of growth hormone (GH) and thyroid-stimulating hormone (TSH)

The releasing or inhibiting effect is identified in the names of most of these. *Somatostatin* is also known as growth hormone–inhibiting hormone, though it also inhibits secretion of thyroid-stimulating hormone. Its name derives from *somatotropin*, a synonym for growth hormone, and *stat*, meaning to halt something (in this case, growth hormone secretion).

The other two hypothalamic hormones are **oxytocin (OT)** and **antidiuretic hormone (ADH)**. These are stored and released by the posterior pituitary. OT comes mainly from neurons in the right and left **paraventricular⁷ nuclei** of the hypothalamus, so called because they lie in the walls of the third ventricle. ADH comes mainly from the **supraoptic⁸ nuclei**, named for their location just above the optic chiasm. Each nucleus also produces small quantities of the other hormone. ADH and OT are treated as posterior pituitary hormones for convenience even though the posterior lobe does not synthesize them.

Anterior Pituitary Hormones

The anterior lobe of the pituitary synthesizes and secretes six principal hormones, as follows (summarized in table 17.4). The first two of these are collectively called **gonadotropins⁹** because they both target the gonads (ovaries and testes).

1. **Follicle-stimulating hormone (FSH)**. FSH is secreted by pituitary cells called *gonadotropes*. In the ovaries, it stimulates the secretion of ovarian sex hormones

and the development of the bubblelike *follicles* that contain the eggs. In the testes, it stimulates sperm production.

2. **Luteinizing hormone (LH)**. LH is also secreted by the gonadotropes. In females, it stimulates *ovulation*, the release of an egg. It is named for the fact that after ovulation, the follicle becomes a yellowish body called the *corpus luteum*.¹⁰ LH also stimulates the corpus luteum to secrete progesterone, a hormone important in pregnancy. In males, LH stimulates the testes to secrete testosterone.
3. **Thyroid-stimulating hormone (TSH), or thyrotropin**. TSH is secreted by pituitary cells called *thyrotropes*. It stimulates growth of the thyroid gland and the secretion of thyroid hormone, which has widespread effects on metabolic rate, body temperature, and other functions detailed later.
4. **Adrenocorticotrophic hormone (ACTH), or corticotropin**. ACTH is secreted by cells called *corticotropes*. Its target organ and the basis for its name is the adrenal cortex, studied later in this chapter. ACTH stimulates the cortex to secrete hormones called glucocorticoids (especially *cortisol*), which regulate glucose, protein, and fat metabolism and are important in the body's response to stress.
5. **Prolactin¹¹ (PRL)**. PRL is secreted by pituitary cells called *lactotropes (mammotropes)*. The hormone and these cells are named for the role of PRL in lactation. During pregnancy, the lactotropes increase greatly in size and number, and PRL secretion rises

⁷*para* = next to + *ventricular* = pertaining to the ventricle

TABLE 17.4 Pituitary Hormones		
Hormone	Target Organ or Tissue	Principal Effects
Anterior Pituitary		
Follicle-stimulating hormone (FSH)	Ovaries, testes	Female: growth of ovarian follicles and secretion of estrogen Male: sperm production
Luteinizing hormone (LH)	Ovaries, testes	Female: ovulation, maintenance of corpus luteum Male: testosterone secretion
Thyroid-stimulating hormone (TSH)	Thyroid gland	Growth of thyroid, secretion of thyroid hormone
Adrenocorticotrophic hormone (ACTH)	Adrenal cortex	Growth of adrenal cortex, secretion of glucocorticoids
Prolactin (PRL)	Mammary glands, testes	Female: milk synthesis Male: increased LH sensitivity and testosterone secretion
Growth hormone (GH)	Liver, bone, cartilage, muscle, fat	Widespread tissue growth, especially in the stated tissues
Posterior Pituitary		
Antidiuretic hormone (ADH)	Kidneys	Water retention
Oxytocin (OT)	Uterus, mammary glands	Labor contractions, milk release; possibly involved in ejaculation, sperm transport, sexual affection, and mother–infant bonding

proportionately, but it has no effect until after a woman gives birth. Then, it stimulates the mammary glands to synthesize milk. In males, PRL has a gonadotropic effect that makes the testes more sensitive to LH. Thus, it indirectly enhances the secretion of testosterone.

6. **Growth hormone (GH), or somatotropin.** GH is secreted by *somatotropes*, the most numerous cells of the anterior pituitary. The pituitary produces at least a thousand times as much GH as any other hormone. The general effect of GH is to stimulate mitosis and cellular differentiation and thus to promote tissue growth throughout the body. The physiology of GH will be considered in more detail shortly.

You can see that the anterior pituitary is involved in a chain of events linked by hormones: the hypothalamus secretes a releasing or inhibiting hormone; this induces a specific type of pituitary cell to secrete its hormone; that hormone is usually targeted to another endocrine gland elsewhere in the body; and finally that gland secretes a hormone with an effect of its own. For example, the hypothalamus secretes thyrotropin-releasing hormone (TRH); this induces the anterior pituitary to secrete thyroid-stimulating hormone (TSH, or thyrotropin); TSH, in turn, stimulates the thyroid gland to release thyroid hormone (TH); and finally, thyroid hormone exerts its metabolic effects throughout the body. Figure 17.6 summarizes these relationships between the hypothalamus, anterior pituitary, and more “downstream” target organs.

The Pars Intermedia

As mentioned earlier, the pars intermedia is absent from the adult human pituitary, but present in other animals and the human fetus. In other species, it secretes *melanocyte-stimulating hormone (MSH)*, which influences pigmentation of the skin, hair, or feathers. It was once thought to have a similar effect on human skin, but evidence now

FIGURE 17.6 Hypothalamo-Pituitary-Target Organ Relationships. Hypothalamic releasing hormones, shown at the top, trigger secretion of all of the anterior pituitary hormones (bottom) except prolactin (PRL).

indicates that humans have no circulating MSH. Some anterior lobe cells derived from the fetal pars intermedia produce a large polypeptide called *proopiomelanocortin (POMC)*. POMC is not secreted, but is processed within the pituitary to yield smaller fragments such as ACTH and pain-inhibiting endorphins.

Posterior Pituitary Hormones

The two posterior lobe hormones are ADH and OT. As we have already seen, they are synthesized in the hypothalamus, then transported to the posterior pituitary and stored until their release on command. Their functions are as follows:

1. **Antidiuretic hormone (ADH).** ADH increases water retention by the kidneys, reduces urine volume, and helps prevent dehydration. It is also called *vasopressin* because it can cause vasoconstriction.

This requires concentrations so unnaturally high for the human body, however, that this effect is of doubtful significance except in pathological states. ADH also functions as a brain neurotransmitter and is usually called vasopressin, or arginine vasopressin (AVP), in the neuroscience literature.

2. **Oxytocin (OT).** OT has a variety of reproductive functions in situations ranging from intercourse to breast-feeding. It surges in both sexes during sexual arousal and orgasm, possibly aiding in the propulsion of semen through the male reproductive tract and stimulating uterine contractions that help transport sperm up the female reproductive tract. OT also evidently functions in feelings of sexual satisfaction and emotional bonding between partners. In childbirth, it stimulates labor contractions, and in lactating mothers, it stimulates the flow of milk from the mammary gland acini deep in the breast to the nipple, where it is accessible to the infant. It may also promote emotional bonding between the mother and infant. In the absence of oxytocin, other female mammals tend to neglect their helpless infants.

Control of Pituitary Secretion

Pituitary hormones are not secreted at constant rates. GH is secreted mainly at night, LH peaks at the middle of the menstrual cycle, and OT surges during labor and nursing, for example. The timing and amount of pituitary secretion are regulated by the hypothalamus, other brain centers, and feedback from the target organs.

Hypothalamic and Cerebral Control

Both lobes of the pituitary gland are strongly subject to control by the brain. Hypothalamic control enables the brain to monitor conditions within and outside of the body and to stimulate or inhibit the release of anterior lobe hormones appropriately. For example, in cold weather, the hypothalamus stimulates the pituitary to secrete TSH, which leads to thyroid hormone secretion and elevated generation of body heat. In times of stress, the hypothalamus triggers ACTH secretion, which leads to the secretion of cortisol and the mobilization of materials needed for tissue repair. During pregnancy, the hypothalamus induces prolactin secretion so a woman will be prepared to lactate after the baby is born.

The posterior pituitary is controlled by **neuroendocrine reflexes**—the release of hormones in response to signals from the nervous system. For example, the suckling of an infant stimulates nerve endings in the nipple. Sensory signals are transmitted through the mother's spinal cord and brainstem to the hypothalamus and from there to the posterior pituitary. This causes the release of oxytocin, which results in milk ejection.

Antidiuretic hormone is also controlled by a neuroendocrine reflex. Dehydration raises the osmolarity of the blood, which is detected by hypothalamic neurons called *osmoreceptors*. They trigger ADH release, and ADH promotes water conservation. Excessive blood pressure, by contrast, stimulates stretch receptors in the heart and certain arteries. By another neuroendocrine reflex, this inhibits ADH release, increases urine output, and brings blood volume and pressure back to normal.

Neuroendocrine reflexes can also involve higher brain centers. For example, the milk-ejection reflex can be triggered when a lactating mother simply hears a baby cry. Emotional stress can affect the secretion of gonadotropins, thus disrupting ovulation, the menstrual rhythm, and fertility.

Think About It

Which of the unifying themes at the end of chapter 1 (p. 22) is best exemplified by the neuroendocrine reflexes that govern ADH secretion?

Feedback from Target Organs

The regulation of other endocrine glands by the pituitary is not simply a system of “command from the top down.” Those target organs also regulate the pituitary and hypothalamus through various feedback loops.

Most often, this takes the form of **negative feedback inhibition**—the pituitary stimulates another endocrine gland to secrete its hormone, and that hormone feeds back to the pituitary or hypothalamus and inhibits further secretion of the pituitary hormone. Figure 17.7 shows negative feedback inhibition in the pituitary–thyroid system as an example. The figure is numbered to correspond to the following description:

- 1 The hypothalamus secretes thyrotropin-releasing hormone (TRH).
- 2 TRH stimulates the anterior pituitary to secrete thyroid-stimulating hormone (TSH).
- 3 TSH stimulates the thyroid gland to secrete thyroid hormone (TH).
- 4 TH stimulates the metabolism of most cells throughout the body.
- 5 TH also *inhibits* the release of TSH by the pituitary.
- 6 To a lesser extent, TH also *inhibits* the release of TRH by the hypothalamus.

The negative feedback inhibition in this process consists of steps 5 and 6. It ensures that when the TH level is high, TSH secretion remains moderate. If thyroid hormone secretion drops, TSH secretion rises and stimulates the thyroid to secrete more hormone. This feedback keeps thyroid hormone levels oscillating around a set point in typical homeostatic fashion.

FIGURE 17.7 Negative Feedback Inhibition of the Pituitary Gland by the Thyroid Gland. See text for explanation of numbered steps.

Think About It

If the thyroid gland was removed from a cancer patient, would you expect the level of TSH to rise or fall? Why?

Feedback from a target organ is not always inhibitory. As we saw in chapter 1, oxytocin triggers a positive feedback cycle during labor (see fig. 1.12, p. 19). Uterine stretching sends a nerve signal to the brain that stimulates OT release. OT stimulates uterine contractions, which push the infant downward. This stretches the lower end of the uterus some more, which results in a nerve signal that stimulates still more OT release. This positive feedback cycle continues until the infant is born.

A Further Look at Growth Hormone

The ultimate effects of most pituitary hormones are exerted through endocrine glands farther downstream, such as the thyroid, adrenal cortex, and gonads. Thus, we will study those effects in the following section as we survey those glands. Growth hormone is a different matter and warrants further exploration at this point.

Unlike the other pituitary hormones, GH is not targeted to just one or a few organs but has widespread effects on the body, especially on cartilage, bone, muscle, and fat. It exerts its effects both directly and indirectly. GH itself directly stimulates these tissues, but it also induces the liver and other tissues to produce growth stimulants called **insulin-like growth factors (IGF-I and IGF-II)**, or **somatomedins**,¹² which then stimulate target cells in diverse tissues (fig. 17.6). Most of these effects are caused by IGF-I, but IGF-II is important in fetal growth.

One effect of IGF is to prolong the action of GH. All hormones have a **half-life**, the time required for 50% of the hormone to be cleared from the blood. GH is short-lived; its half-life is only 6 to 20 minutes. IGFs, by contrast, have half-lives of about 20 hours. The mechanisms of GH–IGF action include:

- **Protein synthesis.** Tissue growth requires protein synthesis, and protein synthesis needs two things: amino acids for building material, and messenger RNA (mRNA) for instructions. Within minutes of its secretion, GH boosts the translation of existing mRNA, and within a few hours, it also boosts the transcription of DNA and thus the production of more mRNA. GH also enhances amino acid transport into cells; and to ensure that protein synthesis outpaces breakdown, it suppresses protein catabolism.
- **Lipid metabolism.** To provide energy for growing tissues, GH stimulates adipocytes to catabolize fat and release fatty acids and glycerol into the blood. By providing these fuels, GH makes it unnecessary for cells to consume their proteins. This is called the **protein-sparing effect**.
- **Carbohydrate metabolism.** GH also has a **glucose-sparing effect**. Its role in mobilizing fatty acids reduces the dependence of most cells on glucose so they will not compete with the brain, which is highly glucose-dependent. GH also makes more glucose available for glycogen synthesis and storage.
- **Electrolyte balance.** GH promotes Na^+ , K^+ , and Cl^- retention by the kidneys, enhances Ca^{2+} absorption by the small intestine, and makes these electrolytes available to the growing tissues.

The most conspicuous effects of GH are on bone, cartilage, and muscle growth, especially during childhood and adolescence. IGF-I accelerates bone growth at the epiphyseal plates. It stimulates the multiplication of chondrocytes and osteogenic cells as well as protein deposition in the cartilage and bone matrix. In adulthood, it stimulates osteoblast activity and the appositional growth of bone; thus, it continues to influence bone thickening and remodeling.

¹²Acronym for *somatotropin mediating protein*

GH secretion fluctuates greatly over the course of a day. It rises to 20 nanograms per milliliter of blood plasma (ng/mL) or higher during the first 2 hours of deep sleep, and may reach 30 ng/mL in response to vigorous exercise. Smaller peaks occur after high-protein meals, but a high-carbohydrate meal tends to suppress GH secretion. Trauma, hypoglycemia (low blood sugar), and other conditions also stimulate GH secretion.

GH levels decline gradually with age. Its concentration averages about 6 ng/mL in adolescence and one-quarter of that in very old age. The resulting decline in protein synthesis may contribute to aging of the tissues, including wrinkling of the skin and reduced muscular mass and strength. At age 30, the average adult body is 10% bone, 30% muscle, and 20% fat; at age 75, it averages 8% bone, 15% muscle, and 40% fat.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What are two good reasons for considering the pituitary to be two separate glands?
2. Briefly contrast hypothalamic control of the anterior pituitary with its control of the posterior pituitary.
3. Name three anterior lobe hormones that have reproductive functions and three that have nonreproductive roles. What target organs are stimulated by each of these hormones?
4. In what sense does the pituitary “take orders” from the target organs under its command?
5. How does the liver promote GH function? How does GH affect the metabolism of proteins, fats, and carbohydrates?

17.3 Other Endocrine Glands

Objectives

When you have completed this section, you should be able to

- describe the structure and location of the remaining endocrine glands;
- name the hormones these endocrine glands produce and state their functions; and
- discuss the hormones produced by organs and tissues other than the classical endocrine glands.

The Pineal Gland

The **pineal**¹³ (PIN-ee-ul) **gland** is attached to the roof of the third ventricle of the brain, beneath the posterior

end of the corpus callosum (see figs. 17.1 and 17.4a). Its name alludes to a shape resembling a pine cone. The philosopher René Descartes (1596–1650) thought it was the seat of the human soul. If so, children must have more soul than adults—a child’s pineal gland is about 8 mm long and 5 mm wide, but after age 7 it regresses rapidly and is no more than a tiny shrunken mass of fibrous tissue in the adult. Such shrinkage of an organ is called **involution**.¹⁴ Pineal secretion peaks between the ages of 1 and 5 years and declines 75% by the end of puberty.

We no longer look for the human soul in the pineal gland, but this little organ remains an intriguing mystery. It may play a role in establishing 24-hour *circadian rhythms* of physiological function synchronized with the cycle of daylight and darkness. During the night, it synthesizes **melatonin**, a monoamine, from serotonin. Melatonin has been implicated in some human mood disorders, although the evidence remains inconclusive (see Insight 17.1). Its secretion fluctuates seasonally with changes in day length, and in animals with seasonal breeding, it regulates the gonads and the annual breeding cycle. Melatonin may suppress gonadotropin secretion; removal of the pineal from animals causes premature sexual maturation. Some physiologists think that the pineal gland may regulate the timing of puberty in humans, but a clear demonstration of its role has remained elusive. Pineal tumors cause premature onset of puberty in boys, but such tumors also damage the hypothalamus, so we cannot be sure the effect is due specifically to pineal damage.

The Thymus

The **thymus** plays a role in three systems: endocrine, lymphatic, and immune. It is a bilobed gland in the mediastinum superior to the heart, behind the sternal manubrium. In the fetus and infant, it is enormous in comparison to adjacent organs, sometimes protruding between the lungs nearly as far as the diaphragm and extending upward into the neck (fig. 17.8a). It continues to grow until the age of 5 or 6 years. In adults, the gland weighs about 20 g up to age 60, but it becomes increasingly fatty and less glandular with age. In the elderly, it is a small fibrous and fatty remnant barely distinguishable from the surrounding mediastinal tissues (fig. 17.8b).

The thymus is a site of maturation for certain white blood cells called T cells that are critically important for immune defense. It secretes several hormones (**thymopoietin**, **thymosin**, and **thymulin**) that stimulate the development of other lymphatic organs and regulate the development and activity of T cells. Its histology and immune function are discussed more fully in chapter 21.

¹³pineal = pine cone

¹⁴in = inward + *volution* = rolling or turning

INSIGHT 17.1 Clinical Application**Melatonin, SAD, and PMS**

There seems to be a relationship between melatonin and mood disorders, including depression and sleep disturbances. Some people experience a mood dysfunction called *seasonal affective disorder (SAD)*, especially in winter when the days are shorter and they get less exposure to sunlight, and in extreme northern and southern latitudes where sunlight may be dim to nonexistent for months at a time. SAD thus affects about 20% of the population in Alaska but only 2.5% in Florida. The symptoms—which include depression, sleepiness, irritability, and carbohydrate craving—can be relieved by 2 or 3 hours of exposure to bright light each day (*phototherapy*). Premenstrual syndrome (PMS) is similar to SAD and is also relieved by phototherapy. The melatonin level is elevated in both SAD and PMS and is reduced by phototherapy. However, there is also evidence that casts doubt on any causal link between melatonin and these mood disorders, so for now, “the jury is still out.” Many people are taking melatonin for jet lag, and it is quite effective, but it is also risky to use when we know so little, as yet, about its potential effect on reproductive function.

The Thyroid Gland

The **thyroid gland** is the largest endocrine gland in adults, weighing about 25 g. It is composed of two lobes that lie adjacent to the trachea immediately below the larynx. It is named for the nearby shieldlike thyroid¹⁵ cartilage of the larynx. Near the inferior end, the two lobes are usually joined by a narrow anterior bridge of tissue, the **isthmus** (figs. 17.8, 17.9a). The thyroid gland receives one of the

body’s highest rates of blood flow per gram of tissue and has a dark reddish brown color owing to its abundant blood vessels (fig. 17.9a).

Histologically, the thyroid is composed mostly of sacs called **thyroid follicles** (fig. 17.9b). Each is filled with a protein-rich colloid and lined by a simple cuboidal epithelium of **follicular cells**. These cells secrete mainly the hormone **thyroxine**, also known as **T₄** or **tetraiodothyronine** (TET-ra-EYE-oh-doe-THY-ro-nee) because of its four iodine atoms. It also produces **triiodothyronine (T₃)**, with three iodine atoms. The expression **thyroid hormone (TH)** refers to T₄ and T₃ collectively. The average adult thyroid secretes about 80 micrograms (μg) of TH daily, about 98% of which is in the T₄ form. Most T₄ is converted to T₃ in the target cells, and T₃ is the more physiologically active form (see p. 665).

Thyroid hormone is secreted in response to TSH from the pituitary. The primary effect of TH is to increase the body’s metabolic rate. As a result, it raises oxygen consumption and has a **calorigenic**¹⁶ **effect**—it increases heat production. TH secretion rises in cold weather and thus helps to compensate for increased heat loss. To ensure an adequate blood and oxygen supply to meet this increased metabolic demand, thyroid hormone raises the respiratory rate, heart rate, and strength of the heartbeat. It stimulates the appetite and accelerates the breakdown of carbohydrates, fats, and protein for fuel. Thyroid hormone also promotes alertness and quicker reflexes; growth hormone secretion; growth of the bones, skin, hair, nails, and teeth; and development of the fetal nervous system.

The thyroid gland also contains nests of **C (clear) cells**, or **parafollicular cells**, between the follicles. They respond to rising levels of blood calcium by secreting the

¹⁵thyr = shield + oid = resembling¹⁶calor = heat + genic = producing

FIGURE 17.8 Thymuses of the Newborn and Adult. (a) The neonatal thymus is deeper red because of a richer blood flow. (b) In the thymus of an older adult, circulation is greatly reduced and much of the glandular tissue is replaced with fat and fibrous tissue.

(b) Adult

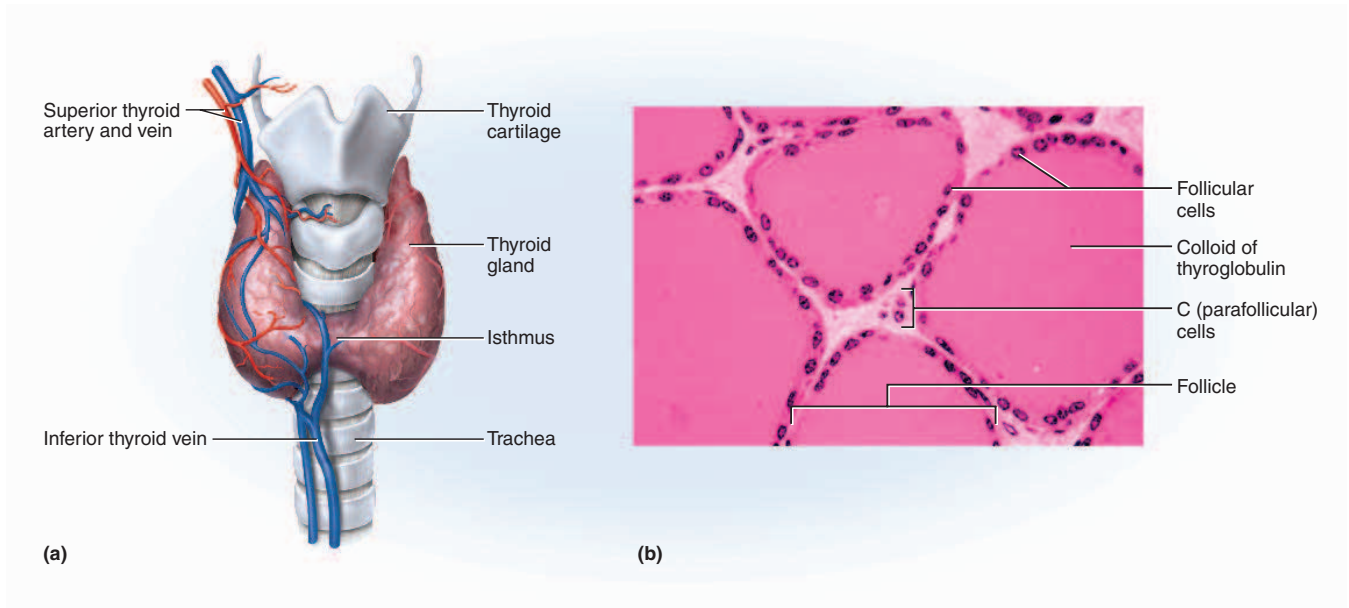

FIGURE 17.9 Anatomy of the Thyroid Gland. (a) Gross anatomy, anterior view. (b) Histology, showing the saccular thyroid follicles (source of thyroid hormone) and a nest of C cells (source of calcitonin).

hormone **calcitonin**. Calcitonin antagonizes the action of parathyroid hormone (discussed shortly) and stimulates osteoblast activity, thus promoting calcium deposition and bone formation. It is important mainly in children, having relatively little effect in adults (see p. 231).

The Parathyroid Glands

The **parathyroid glands** are ovoid glands measuring about 3 to 8 mm long and 2 to 5 mm wide. Usually there are four of them, partially embedded in the posterior surface of the thyroid; a thin fibrous capsule separates them from the thyroid tissue (fig. 17.10). Often, however, they occur in other locations ranging from as high as the hyoid bone to as low as the aortic arch, and about 5% of people have more than four parathyroids. They secrete **parathyroid hormone (PTH)** in response to hypocalcemia. PTH raises blood calcium levels by mechanisms detailed in chapter 7 (see p. 231).

The Adrenal Glands

An **adrenal**¹⁷ (**suprarenal**) **gland** sits like a cap on the superior to superomedial surface of each kidney (fig. 17.11). Like the kidneys, they are retroperitoneal, lying outside the peritoneal cavity between the peritoneum and posterior body wall. The adult adrenal gland measures about 5 cm vertically, 3 cm wide, and 1 cm from

anterior to posterior. It weighs about 8 to 10 g in the newborn, but loses half of this weight by the age of 2 years, mainly because of involution of its outer layer, the adrenal cortex. It remains at 4 to 5 g in adults.

Like the pituitary, the adrenal gland forms by the merger of two fetal glands with different origins and functions. Its inner core, the **adrenal medulla**, is 10% to 20% of the gland. Depending on blood flow, its color ranges from the gray to dark red. Surrounding it is a much thicker **adrenal cortex**, constituting 80% to 90% of the gland and having a yellowish color due to its high concentration of cholesterol and other lipids.

The Adrenal Medulla

The **adrenal medulla** has a dual nature, acting as both an endocrine gland and a ganglion of the sympathetic nervous system (see p. 572). Sympathetic preganglionic nerve fibers penetrate through the cortex to reach **chromaffin (cro-MAFF-in) cells** in the medulla. These cells, named for their tendency to stain brown with certain dyes, are essentially sympathetic postganglionic neurons, but they have no dendrites or axon and they release their products directly into the bloodstream like any other endocrine gland. Thus they are considered to be neuroendocrine cells.

Upon stimulation by the nerve fibers—usually in a situation of fear, pain, or other stress—the chromaffin cells release a mixture of catecholamines that we have previously encountered as neurotransmitters (see fig. 12.21, p. 464): about three-quarters **epinephrine**, one-quarter

¹⁷*ad* = to, toward, near + *ren* = kidney + *al* = pertaining to

FIGURE 17.10 The Parathyroid Glands. (a) Location on the posterior surface of the thyroid. (b) Histology.

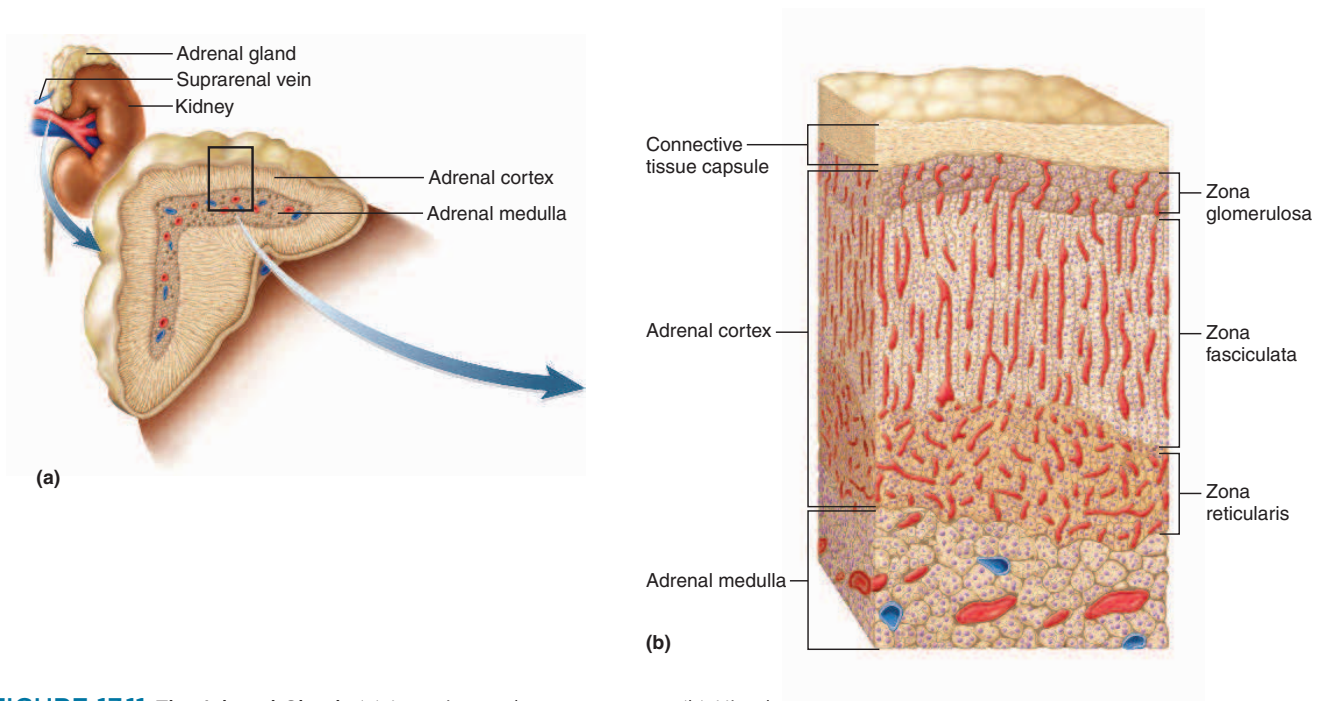

FIGURE 17.11 The Adrenal Gland. (a) Location and gross anatomy. (b) Histology.

norepinephrine, and a trace of **dopamine**. Now we find them acting as hormones. They increase alertness and prepare the body in several ways for physical activity. They mobilize high-energy fuels such as lactate, fatty acids, and glucose. Glucose levels are boosted by **glycogenolysis** (hydrolysis of glycogen to glucose) and **gluconeogenesis** (conversion of fats, amino acids, and other noncarbohydrates to glucose).

Epinephrine is said to have a **glucose-sparing effect**. It inhibits the secretion of insulin, so the muscles and other insulin-dependent organs absorb and consume less glucose. They fall back on alternative fuels such as fatty acids, while the blood glucose is left for use by the brain, which is more glucose-dependent.

The adrenal catecholamines also raise the heart rate and blood pressure, stimulate circulation to the muscles, increase pulmonary airflow, and raise the metabolic rate. At the same time, they *inhibit* such temporarily inessential functions as digestion and urine production so that they do not compete for blood flow and energy.

The Adrenal Cortex

The **adrenal cortex**, which surrounds the medulla, produces more than 25 steroid hormones, known collectively as the **corticosteroids** or **corticoids**. Only five of them, however, are produced in physiologically significant amounts; the others are either negligible in quantity or, if more abundant, are in chemically less active forms. The five most important corticosteroids fall into three categories: **mineralocorticoids**, which regulate the body's electrolyte balance; **glucocorticoids**, which regulate the metabolism of glucose and other organic fuels; and **sex steroids**, with various developmental and reproductive functions. These three classes of steroids are secreted, respectively, by the following three layers of glandular tissue (fig. 17.11b):

1. The **zona glomerulosa**¹⁸ (glo-MER-you-LO-suh) is a thin layer, less developed in humans than in many other mammals, located just beneath the capsule at the gland surface. The name *glomerulosa* (“full of little balls”) refers to the fact that many of its cells are arranged in rounded clusters. The zona glomerulosa secretes mainly **aldosterone**, a mineralocorticoid that stimulates the kidneys to retain sodium in the body fluids and excrete potassium in the urine. Since water is retained with sodium by osmosis, aldosterone helps to maintain blood volume and pressure.
2. The **zona fasciculata**¹⁹ (fah-SIC-you-LAH-ta) is a thick middle layer constituting about three-quarters of the adrenal cortex. Here the cells are arranged in parallel cords (fascicles), separated by blood capillaries, perpendicular to the gland surface. The cells are

called **spongiocytes** because of a foamy appearance imparted by an abundance of cytoplasmic lipid droplets. The zona fasciculata secretes glucocorticoids in response to ACTH from the pituitary. The most potent of these is **cortisol (hydrocortisone)**, but some effect is due to the less potent **corticosterone**. They stimulate fat and protein catabolism, gluconeogenesis, and the release of fatty acids and glucose into the blood. This helps the body adapt to stress and repair damaged tissues. Glucocorticoids also have an anti-inflammatory effect and are widely used in ointments to relieve swelling and other signs of inflammation. Long-term secretion, however, suppresses the immune system for reasons we will see later in the discussion of stress physiology.

3. The **zona reticularis**²⁰ (reh-TIC-you-LAR-iss) is the narrow, innermost layer, adjacent to the adrenal medulla. Its cells form a branching network for which the layer is named. They secrete sex steroids, including **androgens** and smaller amounts of **estrogen**. Androgens control many aspects of male development and reproductive physiology. The adrenal androgens are **dehydroepiandrosterone (DHEA)** (de-HY-dro-EP-ee-an-DROSS-tur-own) and a lesser amount of **androstenedione** (AN-dro-STEEN-di-own). These are weak androgens with little biological activity in themselves, but many tissues convert them to the much more potent androgen, testosterone. DHEA is produced in tremendous quantities by the large adrenal glands of the male fetus and plays an important role in the prenatal development of the male reproductive tract. In both sexes, androgens induce the growth of pubic and axillary hair and their associated apocrine scent glands in puberty and stimulate the libido (sex drive) throughout adolescent and adult life. In men, the large amount of testosterone secreted by the testes overshadows that produced by conversion of adrenal DHEA. In women, however, the adrenal glands meet about 50% of the androgen requirement.

The main adrenal estrogen is **estradiol**. It is normally of minor importance to women of reproductive age because its quantity is small compared with estrogen from the ovaries. After menopause, however, the ovaries no longer function and only the adrenals secrete estrogen. However, several other tissues, such as fat, convert androgens into additional estrogen. Both androgens and estrogens promote adolescent skeletal growth and help to sustain adult bone mass.

The medulla and cortex are not as functionally independent as once thought; each of them stimulates the other. Without stimulation by cortisol, the adrenal medulla

¹⁸zona = zone + glomerul = little balls + osa = full of

¹⁹fascicul = little cords + ata = possessing

²⁰reticul = little network + aris = like

atrophies significantly. Conversely, some chromaffin cells of medullary origin extend into the cortex. When stress activates the sympathetic nervous system, these cells stimulate the cortex to secrete corticosterone and perhaps other corticosteroids.

Think About It

The zona fasciculata thickens significantly in pregnant women. What do you think would be the benefit of this phenomenon?

The Pancreatic Islets

The **pancreas** is an elongated, spongy gland located below and behind the stomach, mostly superficial to the peritoneum (fig. 17.12). It is primarily an exocrine digestive gland, and its gross anatomy is described in chapter 25. Scattered throughout the exocrine tissue, however, are 1 to 2 million endocrine cell clusters called **pancreatic islets (islets of Langerhans²¹)**. Although they are less than 2% of the pancreatic tissue, the islets secrete hormones of vital importance, especially in the regulation

of **glycemia**, the blood glucose concentration. A typical islet measures about $75 \times 175 \mu\text{m}$ and contains from a few to 3,000 cells. These are about 20% alpha cells, 70% beta cells, 5% delta cells, and small numbers of PP and G cells, whose functions are as follows:

- **Alpha (α) cells, or A cells**, secrete **glucagon** between meals when the blood glucose concentration is falling. In the liver, glucagon stimulates gluconeogenesis, glycogenolysis, and the release of glucose into circulation, thus raising the blood glucose level. In adipose tissue, it stimulates fat catabolism and the release of free fatty acids. Glucagon is also secreted in response to rising amino acid levels in the blood after a high-protein meal. It promotes amino acid absorption and thereby provides cells with the raw material for gluconeogenesis.
- **Beta (β) cells, or B cells**, secrete **insulin** during and immediately following a meal, when glucose and amino acid levels are rising. In such times of plenty, insulin stimulates cells to absorb these nutrients and store or metabolize them, therefore it lowers the blood glucose level. It promotes the synthesis of glycogen, fat, and protein, thereby promoting the

(PP and G cells are not shown; they are few in number and cannot be distinguished with ordinary histological staining.) (c) Light micrograph of a pancreatic islet amid the darker exocrine acini, which produce digestive enzymes.

storage of excess nutrients for later use and enhancing cellular growth and differentiation. It also antagonizes the effects of glucagon, thus suppressing the use of already-stored fuels. The brain, liver, kidneys, and red blood cells absorb and use glucose without need of insulin, but insulin does promote glycogen synthesis in the liver. Insulin insufficiency or inaction is well known as the cause of diabetes mellitus, detailed later in this chapter.

- **Delta (δ) cells, or D cells, secrete **somatostatin (growth hormone-inhibiting hormone)** concurrently with the release of insulin by the beta cells. Somatostatin inhibits some digestive enzyme secretion and nutrient absorption, and acts locally in the pancreas as a paracrine secretion that modulates the other types of islet cells. It partially suppresses the secretion of glucagon and insulin by the alpha and beta cells. The reason for this is still a matter of speculation. It has been hypothesized that it serves to prolong the absorption of nutrients by the tissues and to thereby prevent excessively quick depletion of blood-borne nutrients.**
- **PP cells, or F cells, secrete pancreatic polypeptide.** This hormone inhibits gallbladder contraction and the secretion of pancreatic digestive enzymes.
- **G cells secrete gastrin, which stimulates the stomach's acid secretion, motility, and emptying.** The small intestine and stomach itself also secrete gastrin.

Any hormone that raises blood glucose concentration is called a *hyperglycemic hormone*. You may have noticed that glucagon is not the only hormone that does so; so do growth hormone, epinephrine, norepinephrine, cortisol, and corticosterone. Insulin is called a *hypoglycemic hormone* because it lowers blood glucose levels.

The Gonads

Like the pancreas, the **gonads** (ovaries and testes) are both endocrine and exocrine. Their exocrine products are whole cells—eggs and sperm—and in this respect they are sometimes called *cytogenic*²² glands. Their endocrine products are the gonadal hormones, most of which are steroids. Their gross anatomy is described in chapters 27 and 28.

The ovaries secrete chiefly **estradiol, progesterone, and inhibin**. Each egg develops in its own follicle, which is lined by a wall of **granulosa cells** and surrounded by a capsule, the **theca** (fig. 17.13a). Theca cells synthesize the androgen *androstenedione*, and both theca and granulosa cells convert this to estradiol and lesser amounts of two other estrogens, *estriol* and *estrone*. In the middle of the monthly ovarian cycle, a mature follicle ruptures and releases the egg. The remains of the follicle become the

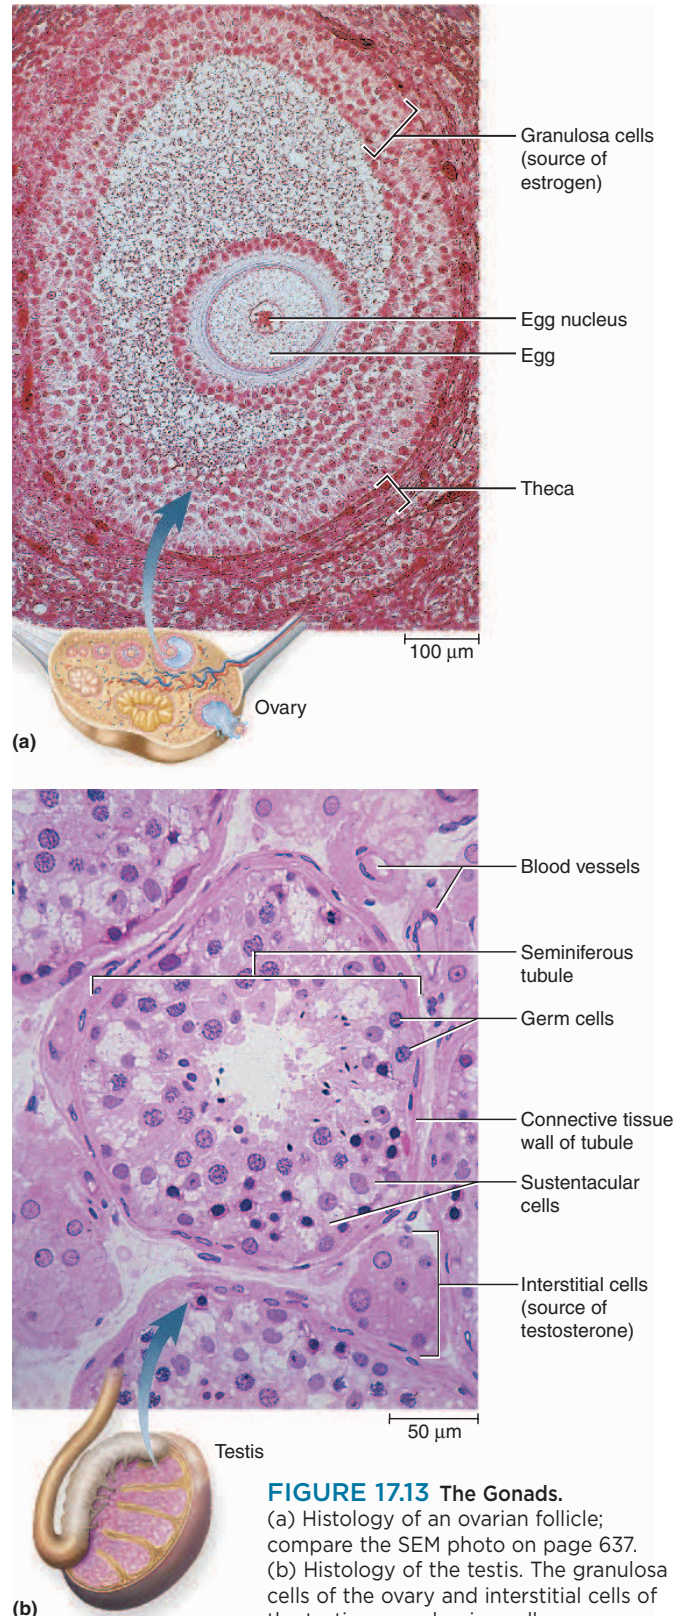

FIGURE 17.13 The Gonads.

(a) Histology of an ovarian follicle; compare the SEM photo on page 637. (b) Histology of the testis. The granulosa cells of the ovary and interstitial cells of the testis are endocrine cells.

²²cyto = cell + genic = producing

corpus luteum, which secretes progesterone for the next 12 days or so in a typical cycle (several weeks in the event of pregnancy).

The functions of estradiol and progesterone are detailed in chapter 28. In brief, they contribute to the development of the reproductive system and feminine physique, promote adolescent bone growth, regulate the menstrual cycle, sustain pregnancy, and prepare the mammary glands for lactation. Inhibin, which is also secreted by the follicle and corpus luteum, suppresses the secretion of FSH by means of negative feedback inhibition of the anterior pituitary.

The testis consists mainly of microscopic *seminiferous tubules* that produce sperm. Its endocrine secretions are **testosterone**, lesser amounts of weaker androgens and estrogens, and inhibin. Inhibin comes from **sustentacular (Sertoli²³) cells** that form the walls of the seminiferous tubules. By limiting FSH secretion, it regulates the rate of sperm production. Nestled between the tubules are clusters of **interstitial cells (cells of Leydig²⁴)**, the source of testosterone and the other sex steroids (fig. 17.13b). Testosterone stimulates development of the male reproductive system in the fetus and adolescent, the development of the masculine physique in adolescence, and the sex drive. It sustains sperm production and the sexual instinct throughout adult life.

Endocrine Functions of Other Tissues and Organs

Several other tissues and organs beyond the classical endocrine glands secrete hormones or hormone precursors:

- **The skin.** Keratinocytes of the epidermis convert a cholesterol-like steroid into **cholecalciferol** (COAL-eh-cal-SIF-er-ol), using UV radiation from the sun. The liver and kidneys further convert cholecalciferol to a calcium-regulating hormone, **calcitriol** (see the following paragraphs).
- **The liver.** The liver is involved in the production of at least five hormones: (1) It converts the cholecalciferol from the skin into **calcidiol**, the next step in calcitriol synthesis. (2) It secretes a protein called **angiotensinogen**, which the kidneys, lungs, and other organs convert to a hormone called *angiotensin II*, a regulator of blood pressure. (See fig. 23.15, p. 919, for details of its production and actions.) (3) It secretes about 15% of the body's **erythropoietin (EPO)** (er-RITH-ro-POY-eh-tin), a hormone that stimulates the red bone marrow to produce red blood cells (erythrocytes). It is therefore important in regulating the oxygen-carrying capacity of the blood. (4) It secretes **hepcidin**, a hormone discovered in 2003 and now regarded as

the body's principal hormonal mechanism of iron homeostasis. Hecpidin promotes the intestinal absorption of dietary iron and the mobilization of iron for hemoglobin synthesis and other uses. (5) It secretes **insulin-like growth factor I (IGF-I)**, a hormone that mediates the action of growth hormone.

- **The kidneys.** The kidneys play endocrine roles in the production of three hormones—calcitriol, angiotensin II, and erythropoietin. (1) The kidneys convert calcidiol into **calcitriol (vitamin D₃)**, thus completing the three-step process begun by the skin and liver. Calcitriol raises the blood concentration of calcium by promoting its intestinal absorption and slightly inhibiting its loss in the urine. This makes more calcium available for bone deposition and other uses. (2) They secrete an enzyme called **renin (REE-nin)**, which converts angiotensinogen to angiotensin I. As angiotensin I circulates through the lungs and other organs, *angiotensin-converting enzyme (ACE)* on the linings of the blood capillaries converts it to **angiotensin II**, a small peptide. This is a very potent hormone that constricts blood vessels throughout the body and thereby raises blood pressure. (3) The kidneys secrete about 85% of the body's erythropoietin.
- **The heart.** Rising blood pressure stretches the heart wall and stimulates cardiac muscle in the atria to secrete **atrial natriuretic²⁵ peptide (ANP)** and muscle in the ventricles to secrete **brain natriuretic peptide (BNP)**. BNP was so named because it was first discovered in the brain. Its effect is similar to that of ANP, but the heart produces about five times as much ANP as BNP. Both of these increase sodium excretion and urine output and oppose the action of angiotensin II, described above. Together, these effects lower the blood pressure.
- **The stomach and small intestine.** These have various *enteroendocrine cells*,²⁶ which secrete at least 10 **enteric hormones**. One role of these hormones is to coordinate different regions and glands of the digestive system with each other. For example, **cholecystokinin²⁷ (CCK)** (COAL-eh-SIS-toe-KY-nin) is secreted by enteroendocrine cells of the small intestine in response to arriving fats. Among other effects, it stimulates the gallbladder to release bile. **Gastrin²⁸** is secreted by enteroendocrine cells of the stomach upon the arrival of food and stimulates other cells of the stomach to secrete hydrochloric acid. Some enteric hormones act on the hypothalamus of the brain. **Ghrelin²⁹** (GRELL-in), secreted by the stomach

²⁵natri = sodium + uretic = pertaining to urine

²⁶entero = intestine

²⁷chole = bile + cysto = sac (gallbladder) + kin = action, motion

²⁸gastr = stomach

²⁹ghre = growth

²³Enrico Sertoli (1824–1910), Italian histologist

²⁴Franz von Leydig (1821–1908), German histologist

when it is empty, produces the sensation of hunger. **Peptide YY (PYY)**, secreted by enteroendocrine cells of the small and large intestines, signals satiety (fullness) and tends to terminate eating. CCK also has an appetite-suppressant effect on the brain.

- **Adipose tissue.** Fat cells secrete the hormone **leptin**, which has long-term effects on appetite-regulating centers of the hypothalamus. A low level of leptin, signifying a low level of body fat, increases appetite and food intake, whereas a high level of leptin tends to blunt the appetite. Leptin also serves as a signal for the onset of puberty, which is delayed in persons with abnormally low body fat. Leptin, as well as some of the aforementioned enteric hormones, is discussed more extensively in chapter 26.
- **Osseous tissue.** Osteoblasts secrete the hormone **osteocalcin**, which increases the number of pancreatic beta cells, pancreatic output of insulin, and the insulin sensitivity of other body tissues. Osteocalcin also seems to inhibit weight gain (fat deposition) and the onset of type 2 diabetes mellitus.
- **The placenta.** This organ performs many functions in pregnancy, including fetal nutrition and waste removal. But it also secretes estrogen, progesterone, and other hormones that regulate pregnancy and

stimulate development of the fetus and the mother's mammary glands (see chapter 28).

You can see that the endocrine system is extensive. It includes numerous discrete glands as well as individual cells in the tissues of other organs. The endocrine organs and tissues other than the hypothalamus and pituitary are reviewed in table 17.5.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

10. Identify three endocrine glands that are larger or more functional in infants or children than in adults. What is the term for the shrinkage of a gland with age?
11. What is the value of the calorogenic effect of thyroid hormone?
12. Name a glucocorticoid, a mineralocorticoid, and a catecholamine secreted by the adrenal gland.
13. Does the action of glucocorticoids more closely resemble that of glucagon or insulin? Explain.
14. Define hypoglycemic and hyperglycemic hormone and give an example of each.
15. What is the difference between a gonadal hormone and a gonadotropin?

TABLE 17.5 Hormones from Sources Other than the Hypothalamus and Pituitary

Source	Hormone	Target Organs and Tissues	Principal Effects
Pineal gland	Melatonin	Brain	Uncertain; may influence mood and sexual maturation
Thymus	Thymopoietin, thymosin, thymulin	Immune cells (T lymphocytes)	Stimulate T lymphocyte development and activity
Thyroid gland	Thyroxine (T ₄) and triiodothyronine (T ₃)	Most tissues	Elevate metabolic rate and heat production; increase respiratory rate, heart rate, and strength of heartbeat; stimulate appetite and accelerate breakdown of nutrients; promote alertness and quicken reflexes; stimulate growth hormone secretion and growth of skin, hair, nails, teeth, and fetal nervous system
	Calcitonin	Bone	Stimulates bone deposition, mainly in children
Parathyroid glands	Parathyroid hormone (PTH)	Bone, kidneys, small intestine	Raises blood Ca ²⁺ level by stimulating bone resorption and inhibiting deposition, reducing urinary Ca ²⁺ excretion, and enhancing calcitriol synthesis
Adrenal medulla	Epinephrine, norepinephrine, dopamine	Most tissues	Promote alertness; mobilize organic fuels; raise metabolic rate; stimulate circulation and respiration; increase blood glucose level; inhibit insulin secretion and glucose uptake by insulin-dependent organs (sparing glucose for brain)
Adrenal cortex	Aldosterone	Kidney	Promotes Na ⁺ and water retention and K ⁺ excretion; maintains blood pressure and volume
	Cortisol and corticosterone	Most tissues	Stimulate fat and protein catabolism, gluconeogenesis, stress resistance, and tissue repair
	Dehydroepiandrosterone	Bone, muscle, integument, brain, many other tissues	Precursor of testosterone; indirectly promotes growth of bones, pubic and axillary hair, apocrine glands, and fetal male reproductive tract; stimulates libido

(continued)

TABLE 17.5		Hormones from Sources Other than the Hypothalamus and Pituitary (<i>cont.</i>)	
Source	Hormone	Target Organs and Tissues	Principal Effects
Pancreatic islets	Glucagon	Primarily liver	Stimulates amino acid absorption, gluconeogenesis, glycogen and fat breakdown; raises blood glucose and fatty acid levels
	Insulin	Most tissues	Stimulates glucose and amino acid uptake; lowers blood glucose level; promotes glycogen, fat, and protein synthesis
	Somatostatin	Stomach, intestines, pancreatic islet cells	Modulates digestion, nutrient absorption, and glucagon and insulin secretion
	Pancreatic polypeptide	Pancreas, gallbladder	Inhibits release of bile and digestive enzymes
	Gastrin	Stomach	Stimulates acid secretion and gastric motility
Ovaries	Estradiol	Many tissues	Stimulates female reproductive development and adolescent growth; regulates menstrual cycle and pregnancy; prepares mammary glands for lactation
	Progesterone	Uterus, mammary glands	Regulates menstrual cycle and pregnancy; prepares mammary glands for lactation
	Inhibin	Anterior pituitary	Inhibits FSH secretion
Testes	Testosterone	Many tissues	Stimulates fetal and adolescent reproductive development, musculoskeletal growth, sperm production, and libido
	Inhibin	Anterior pituitary	Inhibits FSH secretion
Skin	Cholecalciferol	—	Precursor of calcitriol (see kidneys)
Liver	Calcidiol	—	Precursor of calcitriol (see kidneys)
	Angiotensinogen	—	Precursor of angiotensin II (see kidneys)
	Erythropoietin	Red bone marrow	Promotes red blood cell production, increases oxygen-carrying capacity of blood
	Hepcidin	Small intestine, liver	Promotes iron absorption and mobilization
	Insulin-like growth factor I	Many tissues	Prolongs and mediates action of growth hormone
Kidneys	Angiotensin I	—	Precursor of angiotensin II, a vasoconstrictor
	Calcitriol	Small intestine	Increases blood calcium level mainly by promoting intestinal absorption of Ca^{2+}
	Erythropoietin	Red bone marrow	Promotes red blood cell production, increases oxygen-carrying capacity of blood
Heart	Atrial natriuretic peptide and brain natriuretic peptide	Kidney	Lower blood volume and pressure by promoting Na^+ and water loss
Stomach and small intestine	Cholecystokinin	Gallbladder, brain	Bile release; appetite suppression
	Gastrin	Stomach	Stimulates acid secretion
	Ghrelin	Brain	Stimulates hunger, initiates feeding
	Peptide YY	Brain	Produces sense of satiety, terminates feeding
	Other enteric hormones	Stomach, intestines	Coordinate secretion and motility in different regions of digestive tract
Adipose tissue	Leptin	Brain	Limits appetite over long term
Osseous tissue	Osteocalcin	Pancreas, adipose tissue	Stimulates pancreatic beta cells to multiply, increases insulin secretion, enhances insulin sensitivity of various tissues, and reduces fat deposition
Placenta	Estrogen, progesterone	Many tissues of mother and fetus	Stimulate fetal development and maternal bodily adaptations to pregnancy; prepare mammary glands for lactation

17.4 Hormones and Their Actions

Objectives

When you have completed this section, you should be able to

- identify the chemical classes to which various hormones belong;
- describe how hormones are synthesized and transported to their target organs;
- describe how hormones stimulate their target cells;
- explain how target cells regulate their sensitivity to circulating hormones;
- describe how hormones affect each other when two or more of them stimulate the same target cells; and
- discuss how hormones are removed from circulation after they have performed their roles.

Having surveyed the body's major hormones and their effects, we are left with some deeper questions: Exactly what is a hormone? How are hormones synthesized and transported to their destinations? How does a hormone produce its effects on a target organ? Thus, we now address endocrinology at the molecular and cellular levels.

Hormone Chemistry

Most hormones fall into three chemical classes: *steroids*, *peptides*, and *monoamines* (table 17.6, fig. 17.14).

1. **Steroid hormones** are derived from cholesterol. They include sex steroids produced by the testes and ovaries (such as estrogens, progesterone, and testosterone) and corticosteroids produced by the adrenal gland (such as cortisol, corticosterone, aldosterone, and DHEA). Calcitriol, the calcium-regulating hormone, is not a steroid but is derived from one and has the same hydrophobic character and mode of action as the steroids.
2. **Peptide hormones** are chains of 3 to 200 or more amino acids. The two posterior pituitary hormones, oxytocin and antidiuretic hormone, are very similar oligopeptides; they differ in only two of their nine amino acids (fig. 17.15). Except for dopamine, the releasing and inhibiting hormones produced by the hypothalamus are polypeptides. Most hormones of the anterior pituitary are polypeptides or glycoproteins—polypeptides conjugated with short carbohydrate chains. Most glycoprotein hormones have an identical alpha chain of 92 amino acids and a variable beta chain that distinguishes them from each other.
3. **Monoamines (biogenic amines)** were introduced in chapter 12, since this class also includes several

TABLE 17.6

Chemical Classification of Hormones

Steroids and Steroid Derivatives

Aldosterone
Androgens
Calcitriol
Corticosterone
Cortisol
Estrogens
Progesterone

Peptides

Oligopeptides (3–10 amino acids)

Angiotensin II
Antidiuretic hormone
Cholecystokinin
Gonadotropin-releasing hormone
Oxytocin
Thyrotropin-releasing hormone

Polypeptides (more than 10 amino acids)

Adrenocorticotropic hormone	Hepcidin
Atrial natriuretic peptide	Insulin
Calcitonin	Leptin
Corticotropin-releasing hormone	Pancreatic polypeptide
Gastrin	Parathyroid hormone
Ghrelin	Prolactin
Glucagon	Somatostatin
Growth hormone	Thymic hormones

Growth hormone-releasing hormone

Glycoproteins (protein-carbohydrate complexes)

Erythropoietin	Luteinizing hormone
Follicle-stimulating hormone	Thyroid-stimulating hormone

Inhibin

Monoamines

Dopamine	Norepinephrine
Epinephrine	Thyroid hormone
Melatonin	

neurotransmitters (see fig. 12.21, p. 464). The monoamine hormones include dopamine, epinephrine, norepinephrine, melatonin, and thyroid hormone. The first three of these are also called *catecholamines*. Monoamines are made from amino acids and retain an amino group, from which this hormone class gets its name.

FIGURE 17.14 The Chemical Classes of Hormones. (a) Two steroid hormones, defined by their four-membered rings derived from cholesterol. (b) Two monoamines, derived from amino acids. (c) Two peptides—an oligopeptide (angiotensin II) and a protein (insulin). The three-letter labels are standard symbols for the various amino acids (see table 2.8, p. 76).

Hormone Synthesis

All hormones are made from either cholesterol or amino acids, with carbohydrate added in the case of glycoproteins.

Steroids

Steroid hormones are synthesized from cholesterol and differ mainly in the functional groups attached to the four-ringed steroid backbone. Figure 17.16 shows the synthetic pathway for several steroid hormones. Notice that while estrogen and progesterone are typically thought of as “female” hormones and testosterone as a “male” hormone, these sex steroids are interrelated in their synthesis and thus have roles in both sexes.

Peptides

Peptide hormones are synthesized the same way as any other protein. The gene for the hormone is transcribed to form a molecule of mRNA, and ribosomes translate the mRNA and assemble amino acids in the right order to make the hormone. The newly synthesized polypeptide is an inactive **preprohormone**. Its first several amino acids serve as a *signal peptide* that guides it into the cisterna of the rough endoplasmic reticulum. Here, the signal peptide is split off and the remainder of the polypeptide is now a **prohormone**. The prohormone is transferred to the Golgi complex, which may further cut and splice it and then package the hormone for secretion.

Insulin, for example, begins as *preproinsulin*. When the signal peptide is removed, the chain folds back on itself and forms three disulfide bridges. It is now called *proinsulin*. This is packaged into a secretory vesicle, where enzymes remove a large middle segment called the *connecting (C) peptide*. The remainder is now insulin, composed of two polypeptide chains totaling 51 amino acids, connected to each other by two of the three disulfide bridges (fig. 17.17).

Think About It

During the synthesis of glycoprotein hormones, where in the cell would the carbohydrate be added? (See chapter 4.)

FIGURE 17.15 Oxytocin and Antidiuretic Hormone. Note the structural similarity of these two oligopeptide hormones of the posterior pituitary. They differ only in the two amino acids in blue.

Monoamines

Melatonin is synthesized from the amino acid tryptophan and the other monoamines from the amino acid tyrosine. Thyroid hormone is unusual in that each molecule is composed of *two* tyrosines. Figure 17.18 shows the synthesis, storage, and secretion of thyroxine at a cellular level, numbered to correspond to the following description:

- 1 Follicular cells absorb iodide (I^-) ions from the blood plasma and secrete them into the lumen of the follicle. Here, iodide is oxidized to a reactive form symbolized I^* in the figure.
- 2 Meanwhile, the follicular cells synthesize a large protein called **thyroglobulin**

through the usual mechanism involving the rough endoplasmic reticulum and Golgi complex. They release this into the follicular lumen by exocytosis; in the lumen, it forms the colloid seen as the pink-staining material in figure 17.9b. Each thyroglobulin molecule has 123 tyrosines in its amino acid chain, but only 4 to 8 of them are destined to become thyroid hormone.

- 3 In the lumen, tyrosine and iodine combine to form thyroxine (T_4) through a process to be described shortly. However, thyroxine remains bound to thyroglobulin and stored in the follicle until the

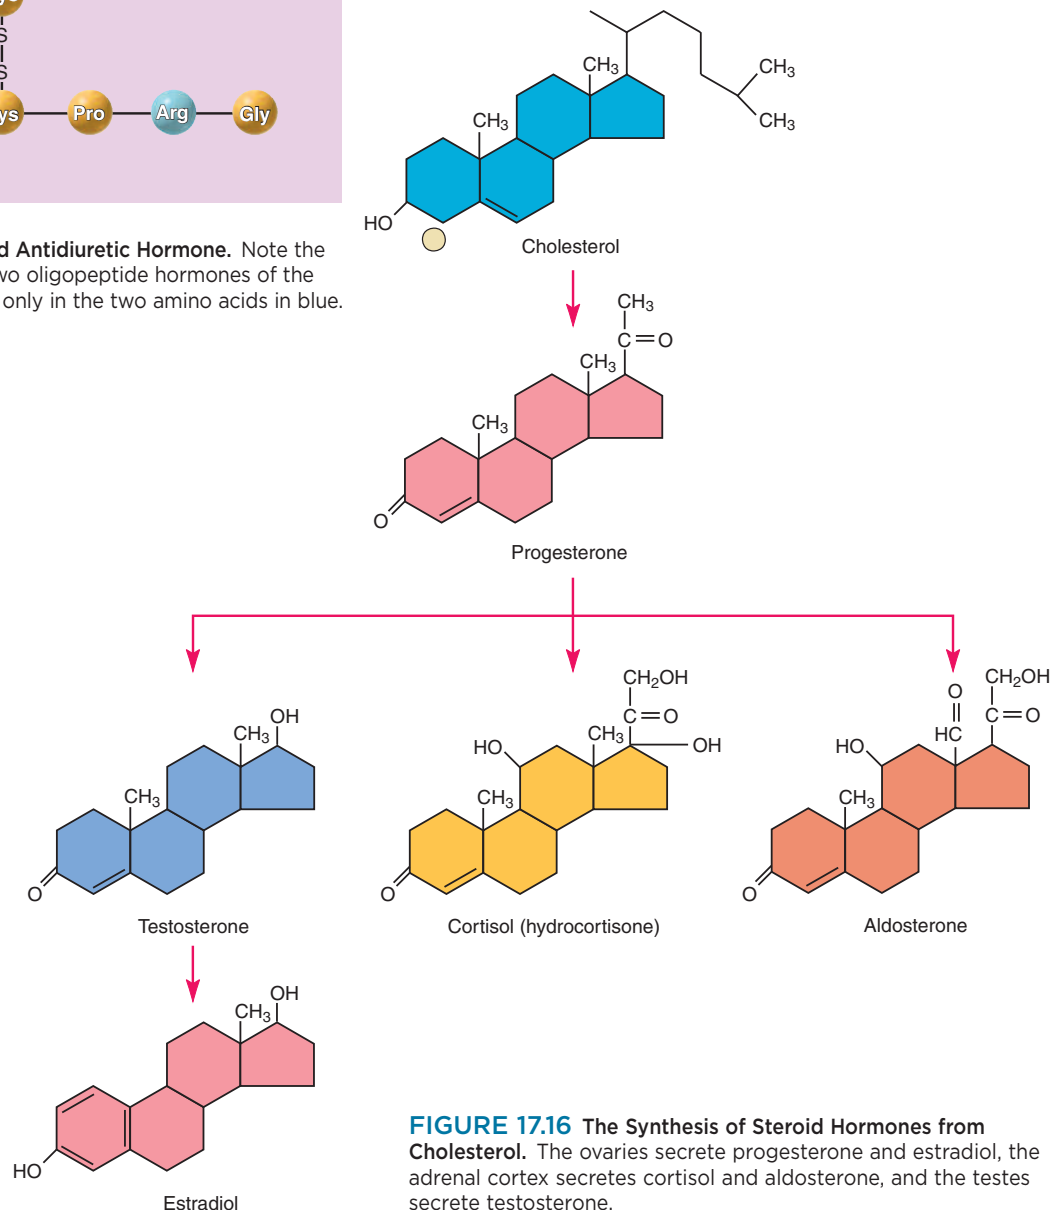

FIGURE 17.16 The Synthesis of Steroid Hormones from Cholesterol. The ovaries secrete progesterone and estradiol, the adrenal cortex secretes cortisol and aldosterone, and the testes secrete testosterone.

cell receives a signal (thyroid-stimulating hormone) inducing it to secrete the hormone.

- 4 When stimulated by TSH, the follicular cells absorb droplets of thyroglobulin by pinocytosis. A lysosome fuses with the pinocytotic vesicle and contributes an enzyme that hydrolyzes the thyroglobulin chain, liberating thyroxine.
- 5 Thyroxine is released into the blood and binds to various transport proteins in the blood plasma, which carry it to its target cells. The thyroid gland also synthesizes a small amount of triiodothyronine (T_3), with one iodine atom fewer, but its output is about 95% T_4 and only 5% T_3 . The respective physiological roles of T_3 and T_4 are explained later.

FIGURE 17.17 The Synthesis of Insulin, a Representative Polypeptide Hormone. Proinsulin has a connecting (C) peptide, 31 amino acids long, that is removed to leave insulin. Insulin has two polypeptide chains, 30 and 21 amino acids long, joined by two disulfide (—S—S—) bridges. A third disulfide bridge creates a loop in the short chain.

- 1 Iodide absorption and oxidation
- 2 Thyroglobulin synthesis and secretion
- 3 Iodine added to tyrosines of thyroglobulin
- 4 Thyroglobulin uptake and hydrolysis
- 5 Release of T_4 and a small amount of T_3 into the blood

FIGURE 17.18 Thyroid Hormone Synthesis, Storage, and Secretion. The thyroid gland secretes mainly thyroxine (T_4). A small amount of T_3 comes from the thyroid, but most is produced in the target cells by removing an iodine from T_4 . See figure 17.19 for details of steps 3 and 4.

Figure 17.19 takes a closer look at the processes that occur in the follicular lumen to combine iodine and tyrosine into thyroxine.

- 1 An iodine atom binds to the tyrosine ring, converting it to *monoiodotyrosine* (MON-oh-eye-OH-do-TY-ro-seen), or *MIT*.
- 2 MIT binds a second iodine atom, becoming *diiodotyrosine* (*DIT*).
- 3 Two DITs become linked through an oxygen atom of one of their rings, forming thyroxine. The rest of the peptide chain splits away from one of the tyrosines, but the thyroxine remains temporarily bound to thyroglobulin through the other tyrosine.
- 4 When the cell is signaled to release thyroid hormone, the lysosomal enzyme mentioned earlier degrades the peptide chain of thyroglobulin and releases thyroxine.

T_3 is synthesized in small amounts by the binding of an MIT and a DIT at step 3. Most T_3 , however, is produced in the liver and other tissues by removing an iodine from circulating T_4 .

Hormone Transport

To get from an endocrine cell to a target cell, a hormone must travel in the blood, which is mostly water. Most of the monoamines and peptides are hydrophilic, so mixing with the blood plasma presents no problem for them. Steroids and thyroid hormone, however, are hydrophobic and must bind to hydrophilic **transport proteins** to get to their destination. The transport proteins are albumins and globulins synthesized by the liver. A hormone attached to a transport protein is called **bound hormone**, and one that is not attached is an **unbound (free) hormone**. Only the unbound hormone can leave a blood capillary and get to a target cell (fig. 17.20).

Transport proteins not only enable hydrophobic hormones to travel in the blood, but also prolong their half-lives. They protect circulating hormones from being broken down by enzymes in the blood plasma and liver and from being filtered out of the blood by the kidneys. Free hormone may be broken down or

FIGURE 17.19 Chemistry of Thyroxine Synthesis. These processes occur at steps 3 and 4 of figure 17.18. T_3 can be made by combining a DIT and an MIT instead of two DITs at step 3. T_3 lacks one of the iodines from the lower tyrosine ring.

FIGURE 17.20 Transport and Action of Hormones.

Hydrophilic hormones (yellow squares) usually travel in the blood as free (unbound) hormone. Upon leaving the blood, they bind to receptors on the target cell surface and activate second messengers. Hydrophobic hormones (blue triangles) are carried in the blood by transport proteins. Upon dissociating from a protein, they leave the blood, diffuse into the target cell, and bind to receptors in the nucleus or cytoplasm.

removed from the blood in a few minutes, whereas bound hormone may circulate for hours to weeks.

Thyroid hormone binds to three transport proteins in the blood plasma: *albumin*, an albumin-like protein called *thyretin*, and an alpha globulin named *thyroxine-binding globulin (TBG)*. TBG binds the greatest amount. More than 99% of circulating TH is protein-bound. Bound TH serves as a long-lasting blood reservoir, so even if the thyroid is surgically removed (as for cancer), no signs of TH deficiency appear for about 2 weeks.

Steroid hormones bind to globulins such as *transcortin*, the transport protein for cortisol. Aldosterone is unusual. It has no specific transport protein but binds weakly to albumin and others. However, 85% of it remains unbound, and correspondingly, it has a half-life of only 20 minutes.

Hormone Receptors and Mode of Action

Hormones stimulate only those cells that have receptors for them. The receptors are protein or glycoprotein molecules located on the plasma membrane, in the cytoplasm, or in the nucleus. They act like switches to turn certain metabolic pathways on or off when the hormone binds to them.

INSIGHT 17.2 Clinical Application

Hormone Receptors and Therapy

In treating endocrine disorders, it is essential to understand the role of hormone receptors. For example, type 2 diabetes mellitus has long been thought to result from an insulin receptor defect or deficiency (among other possible causes). No amount of insulin replacement can correct this. And while growth hormone is now abundantly available thanks to genetic engineering, it is useless to children with *Laron dwarfism*, who have a hereditary defect in their GH receptors. *Androgen insensitivity syndrome* is due to an androgen receptor defect or deficiency; it causes genetic males to develop feminine genitalia and other features (see Insight 27.1, p. 1049). Estrogen stimulates the growth of some malignant tumors with estrogen receptors. For this reason, estrogen replacement therapy should not be used for women with estrogen-dependent cancer.

A target cell usually has a few thousand receptors for a given hormone. Receptor defects lie at the heart of several endocrine diseases (see Insight 17.2).

Receptor–hormone interactions are similar to the enzyme–substrate interactions described in chapter 2. Unlike enzymes, receptors do not chemically change their ligands, but they do exhibit enzymelike specificity and saturation. *Specificity* means that the receptor for one hormone will not bind other hormones. *Saturation* is the condition in which all the receptor molecules are occupied by hormone molecules. Adding more hormone cannot produce any greater effect.

Steroids and Thyroid Hormone

Some hormones enter the target cell nucleus and act directly on the genes, changing target cell physiology by either activating or inhibiting transcription of the gene for a metabolic enzyme or other protein. Such is the case with steroid hormones. Being hydrophobic, they diffuse easily through the phospholipid–cholesterol regions of the plasma membrane. Most of them pass directly into the nucleus and bind to a receptor there; glucocorticoids, however, bind to a receptor in the cytosol, and the hormone–receptor complex is then transported into the nucleus. In either case, the receptor associates with the target gene in the nucleus, controlling its transcription.

Estrogen and progesterone afford a good example of the action of steroid hormones. In cells of the uterine mucosa, estrogen and its nuclear receptor activate a gene for the protein that functions as the progesterone receptor. Progesterone comes later in the menstrual cycle, binds to these receptors, and stimulates transcription of the gene for a glycogen-synthesizing enzyme. The uterine cell then synthesizes and accumulates glycogen for the nourishment of an embryo in the event of pregnancy. Progesterone

has no effect on the uterine lining unless estrogen has been there earlier and prepared the way by inducing the synthesis of progesterone receptors.

Thyroid hormone also acts on nuclear receptors. It may enter a target cell by simple diffusion or facilitated diffusion. Surprisingly, 95% of the TH secreted by the thyroid gland is thyroxine (T₄), yet T₄ has very little metabolic effect. Within the target cell cytoplasm, an enzyme removes one iodine and converts it to the much more potent T₃. This T₃, as well as a smaller amount of T₃ produced by the thyroid and absorbed directly from the blood, enters the target cell nucleus and binds to receptors in the chromatin (fig. 17.21). One of the genes activated by T₃ is for the enzyme Na⁺-K⁺ ATPase, also known as the sodium-potassium pump. As we saw in chapter 3 (p. 105), one of the effects of the Na⁺-K⁺ pump is to generate heat, thus accounting for the calorogenic effect of thyroid hormone. T₃ also activates the transcription of genes for β-adrenergic receptors and a component of the muscle protein myosin, thus enhancing the responsiveness of cells such as cardiac muscle to sympathetic stimulation and increasing the strength of the heartbeat.

Steroid and thyroid hormones typically require several hours to days to show an effect. This lag is due to the time required for genetic transcription, translation, and accumulation of enough protein product to have a significant effect on target cell metabolism.

FIGURE 17.21 The Action of Thyroid Hormone on a Target Cell. T₃ and T₄ dissociate from thyroxine-binding globulin (TBG), leave the bloodstream, and enter the target cell cytoplasm. Here, T₄ is converted to T₃ by the removal of one iodine atom. T₃ enters the nucleus and activates genetic transcription.

Peptides and Catecholamines

Peptides and catecholamines are hydrophilic and cannot penetrate into a target cell, so they must stimulate its physiology indirectly. They bind to cell-surface receptors, which are linked to second-messenger systems on the other side of the plasma membrane (fig. 17.20). The best-known second messenger is cyclic adenosine monophosphate (cAMP). When glucagon binds to the surface of a liver cell, for example, its receptor activates a G protein, which in turn activates adenylate cyclase, the membrane enzyme that produces cAMP. cAMP leads ultimately to the activation of enzymes that hydrolyze glycogen stored in the cell (fig. 17.22). Somatostatin, by contrast, *inhibits* cAMP synthesis. Atrial natriuretic peptide (ANP) works through a similar second messenger, cyclic guanosine monophosphate (cGMP). Second messengers do not linger in the cell for long. cAMP, for example, is broken down very quickly by an enzyme called **phosphodiesterase**, and the hormonal effect is therefore short-lived.

Other commonly employed second messengers include **diacylglycerol (diglyceride)** and **inositol triphosphate**. These act on cell metabolism in a variety of ways. The numbered steps in figure 17.23 correspond to the following description. The diacylglycerol (DAG) pathway is depicted on the left side of the figure:

- ① A hormone binds to its receptor, which activates a G protein.
- ② The G protein migrates to a phospholipase molecule and activates it.
- ③ Phospholipase removes the phosphate-containing group from the head of a membrane phospholipid, leaving DAG, which remains embedded in the plasma membrane.
- ④ DAG activates protein kinase (PK), an enzyme that phosphorylates other enzymes. (See fig. 3.9, p. 96 for more detail on this.) By doing so, PK can turn metabolic pathways on or off and have a wide variety of effects on cell metabolism.

The inositol triphosphate (IP₃) pathway is depicted on the right side of the figure. Steps 1 and 2 are the same as in the DAG pathway. New aspects of the IP₃ pathway are:

- ⑤ The phosphate-containing group removed at step 3 is IP₃. IP₃ raises calcium concentration in the cytosol in two ways (steps 6–7).
- ⑥ IP₃ opens gated channels in the plasma membrane and admits Ca²⁺ to the cell from the ECF.
- ⑦ IP₃ opens gated channels in the endoplasmic reticulum and releases Ca²⁺ from storage. Calcium, a third messenger, can have three effects (steps 8–10).

- 1 Hormone–receptor binding activates a G protein.
- 2 G protein activates adenylate cyclase.
- 3 Adenylate cyclase produces cAMP.
- 4 cAMP activates protein kinases.
- 5 Protein kinases phosphorylate enzymes. This activates some enzymes and deactivates others.
- 6 Activated enzymes catalyze metabolic reactions with a wide range of possible effects on the cell.

FIGURE 17.22 Cyclic AMP as a Second Messenger. The green box lists some hormones that act in this manner.

Why are no steroid hormones listed in this figure?

- 8 Ca^{2+} may bind to other gated membrane channels and alter the membrane potential of the cell or its permeability to various solutes.
- 9 Ca^{2+} may activate cytoplasmic enzymes that alter cell metabolism.
- 10 Ca^{2+} may bind to the cytoplasmic receptor protein **calmodulin**, which in turn activates a protein kinase with effects the same as noted in step 4.

The general point of all this is that hydrophilic hormones such as those listed in the blue box at the left side of the figure cannot enter the target cell. Yet by merely “knocking on the door” (binding to a surface receptor), they can initiate a flurry of metabolic activity within the cell. The initial steps in this process are activation of a G protein and phospholipase. From there, divergent pathways are taken that involve DAG, IP_3 , and Ca^{2+} as second and third messengers. Ultimately these pathways

lead to metabolic pathways being switched on or off within the cell.

Hormonal effects mediated through surface receptors tend to be relatively quick, because they do not depend on the cell synthesizing new proteins before anything else can happen. As an example, oxytocin, the labor-inducing hormone, binds to a surface receptor on smooth muscle cells that activates the IP_3 pathway. Through the action of IP_3 , the intracellular calcium concentration rises sharply. As you saw in chapter 11, calcium triggers muscle contraction—in this case, in the smooth muscle of the uterus.

A given hormone doesn’t always employ the same second messenger. Antidiuretic hormone (ADH) employs the IP_3 –calcium system in smooth muscle but the cAMP system in kidney tubules. Insulin differs from all the foregoing mechanisms. Rather than using a second-messenger system, it binds to a plasma membrane enzyme, tyrosine kinase, that directly phosphorylates cytoplasmic proteins.

FIGURE 17.23 Diacylglycerol and Inositol Triphosphate (IP₃) as Second Messengers. The blue box at the left lists some hormones that act in this manner. See the text for explanation of the numbered steps.

Enzyme Amplification

Hormones are extraordinarily potent chemicals. Through a mechanism called **enzyme amplification** (or a **cascade effect**), one hormone molecule can trigger the synthesis of not just one enzyme molecule but an enormous number (fig. 17.24). To put it in a simplistic but illustrative way, suppose one glucagon molecule triggered the formation of 1,000 molecules of cAMP; cAMP activated a protein kinase; each protein kinase activated 1,000 other enzyme molecules; and each of those enzymes produced 1,000 molecules of a reaction product. These are modest numbers as chemical reactions go, and yet even at this low estimate, that one glucagon molecule would have triggered the production of 1 billion molecules of reaction product. Whatever the actual numbers may be, you can see how enzyme amplification enables a very small stimulus to produce a very large effect. Hormones are therefore powerfully effective in minute quantities. Their circulating concentrations are very

low compared with other blood substances: on the order of nanograms per deciliter. Blood glucose, for example, is about 100 million times this concentrated. Because of enzyme amplification, target cells do not need a great number of hormone receptors.

Modulation of Target Cell Sensitivity

Target cells can adjust their sensitivity to a hormone by changing the number of receptors for it. In **up-regulation**, a cell increases the number of hormone receptors and becomes more sensitive to the hormone (fig. 17.25a). In late pregnancy, for example, the uterus produces oxytocin receptors, preparing itself for the surge of oxytocin that will occur during childbirth.

Down-regulation is the process in which a cell reduces its receptor population and thus becomes less sensitive to a hormone (fig. 17.25b). This sometimes happens in response to long-term exposure to a high hormone concentration. For example, adipocytes down-regulate when

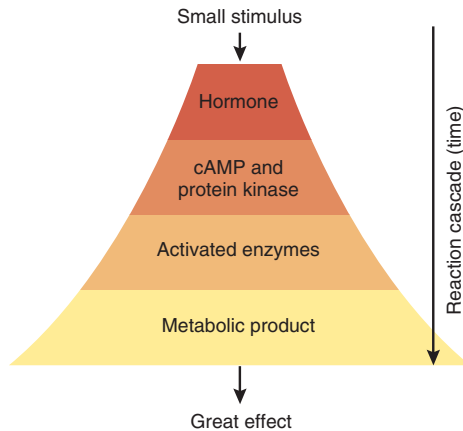

FIGURE 17.24 Enzyme Amplification. A single hormone molecule can trigger the production of many cAMP molecules and activation of many molecules of protein kinase. Every protein kinase molecule can phosphorylate and activate many other enzymes. Each of those enzyme molecules can produce many molecules of a metabolic product. Amplification of the process at each step allows for a very small hormonal stimulus to cause a very large metabolic effect.

exposed to high concentrations of insulin, and cells of the testis down-regulate in response to high concentrations of luteinizing hormone.

Hormone therapy often involves long-term use of abnormally high *pharmacological doses* of hormone, which may have undesirable side effects. Long-term treatment of inflammation with hydrocortisone, for example, has undesirable effects on bone metabolism. These come about in two ways: (1) excess hormone may bind to receptor sites for other related hormones and mimic their effects; and (2) a target cell may convert one hormone into another, such as testosterone to estrogen. Thus, long-term high doses of testosterone can, paradoxically, have feminizing effects.

Hormone Interactions

No hormone travels in the bloodstream alone, and no cell is exposed to only one hormone. Rather, there are many hormones in the blood and tissue fluid at once. Cells ignore the majority of them because they have no receptors for them, but most cells are sensitive to more than one. In these cases, the hormones may have three kinds of interactive effects:

1. **Synergistic effects**, in which two or more hormones act together to produce an effect that is greater than the sum of their separate effects. Neither FSH nor testosterone alone, for example, can stimulate significant sperm production. When they act together, however, the testes produce some 300,000 sperm per minute.

(a) Up-regulation

(b) Down-regulation

FIGURE 17.25 Modulation of Target Cell Sensitivity.

(a) Up-regulation, in which a cell produces more receptors and increases its own sensitivity to a hormone. (b) Down-regulation, in which a cell reduces the density of its receptors and lessens its sensitivity to a hormone.

2. **Permissive effects**, in which one hormone enhances the target organ's response to a second hormone that is secreted later. Estrogen stimulates the up-regulation of progesterone receptors in the uterus. The uterus would respond poorly to progesterone, if at all, had it not been primed by the first hormone. Estrogen thus has a permissive effect on progesterone action.
3. **Antagonistic effects**, in which one hormone opposes the action of another. For example, insulin lowers blood glucose level and glucagon raises it. During pregnancy, estrogen from the placenta inhibits the mammary glands from responding to prolactin; thus milk is not secreted until the placenta is shed at birth.

Hormone Clearance

Hormonal signals, like nervous signals, must be turned off when they have served their purpose. Most hormones are taken up and degraded by the liver and kidneys and then excreted in the bile or urine. Some are degraded by their

target cells. As noted earlier, hormones that bind to transport proteins are removed from the blood much more slowly than hormones that do not employ transport proteins. The rate of hormone removal is called the *metabolic clearance rate (MCR)*, and the length of time required to clear 50% of the hormone from the blood is the half-life. The faster the MCR, the shorter is the half-life.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. What are the three chemical classes of hormones? Name at least one hormone in each class.
17. Why do corticosteroids and thyroid hormones require transport proteins to travel in the bloodstream?
18. Explain how MIT, DIT, T_3 , and T_4 relate to each other structurally.
19. Where are hormone receptors located in target cells? Name one hormone that employs each receptor location.
20. Explain how one hormone molecule can activate millions of enzyme molecules.

17.5 Stress and Adaptation

Objectives

When you have completed this section, you should be able to

- give a physiological definition of stress; and
- discuss how the body adapts to stress through its endocrine and sympathetic nervous systems.

Stress affects us all from time to time, and we react to it in ways that are mediated mainly by the endocrine and sympathetic nervous systems. **Stress** is defined as any situation that upsets homeostasis and threatens one's physical or emotional well-being. Physical causes of stress (*stressors*) include injury, surgery, hemorrhage, infection, intense exercise, temperature extremes, pain, and malnutrition. Emotional causes include anger, grief, depression, anxiety, and guilt.

Whatever the cause, the body reacts to stress in a fairly consistent way called the **stress response** or **general adaptation syndrome (GAS)**. The response typically involves elevated levels of epinephrine and glucocorticoids, especially cortisol; some physiologists now define stress as any situation that raises the cortisol level. A pioneering researcher on stress physiology, Canadian biochemist Hans Selye, showed in 1936 that the GAS typically occurs in three stages, which he called the *alarm reaction*, the *stage of resistance*, and the *stage of exhaustion*.

The Alarm Reaction

The initial response to stress is an **alarm reaction** mediated mainly by norepinephrine from the sympathetic nervous system and epinephrine from the adrenal medulla. These catecholamines prepare the body to take action such as fighting or escaping danger. One of their effects, the consumption of stored glycogen, is particularly important to the transition to the next stage of the stress response. Aldosterone and angiotensin levels also rise during the alarm reaction. Angiotensin helps to raise the blood pressure, and aldosterone promotes sodium and water conservation, which helps to offset possible losses by sweating and bleeding.

The Stage of Resistance

After a few hours, the body's glycogen reserves are exhausted, yet the nervous system continues to demand glucose. If a stressful situation is not resolved before the glycogen is gone, the body enters the **stage of resistance**, in which the first priority is to provide alternative fuels for metabolism. This stage is dominated by cortisol. The hypothalamus secretes corticotropin-releasing hormone (CRH); the pituitary responds by secreting adrenocorticotropic hormone (ACTH); and this, in turn, stimulates the adrenal cortex to secrete cortisol and other glucocorticoids. Cortisol promotes the breakdown of fat and protein into glycerol, fatty acids, and amino acids, providing the liver with raw material for gluconeogenesis. Like epinephrine, cortisol inhibits glucose uptake by most organs and thus has a glucose-sparing effect. It also inhibits protein synthesis, leaving the free amino acids available for gluconeogenesis.

Unfortunately, this has adverse effects on the immune system, which depends heavily on the synthesis of antibodies and other proteins. Immunity is depressed by long-term cortisol exposure (see Insight 21.4, p. 856). Lymphoid tissues atrophy, antibody levels drop, the number of circulating leukocytes declines, and inflammatory cells such as *mast cells* release less histamine and other inflammatory chemicals. Wounds heal poorly, and a person under chronic stress becomes more susceptible to infections and some forms of cancer. Stress can aggravate peptic ulcers because of reduced resistance to the bacteria that cause them and because circulating epinephrine reduces secretion of the gastric mucus and pancreatic bicarbonate that normally protect the stomach lining.

Cortisol suppresses the secretion of sex hormones such as estrogen, testosterone, and luteinizing hormone, causing disturbances of fertility and sexual function.

The Stage of Exhaustion

The body's fat reserves can carry it through months of stress, but when fat is depleted, stress overwhelms homeostasis. The **stage of exhaustion** sets in, often marked by

670 PART THREE Integration and Control

rapid decline and death. With its fat stores gone, the body now relies primarily on protein breakdown to meet its energy needs. Thus, there is a progressive wasting away of the muscles and weakening of the body. After prolonged stimulation, the adrenal cortex may stop producing glucocorticoids, making it all the more difficult to maintain glucose homeostasis. Aldosterone sometimes promotes so much water retention that it creates a state of hypertension, and while it conserves sodium, it hastens the elimination of potassium and hydrogen ions. This creates a state of hypokalemia (potassium deficiency in the blood) and alkalosis (excessively high blood pH), resulting in nervous and muscular system dysfunctions. Death frequently results from heart failure, kidney failure, or overwhelming infection.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Define stress from the standpoint of endocrinology.
- Describe the stages of the general adaptation syndrome.
- List six hormones that show increased secretion in the stress response. Describe how each one contributes to recovery from stress.

17.6 Eicosanoids and Paracrine Signaling

Objectives

When you have completed this section, you should be able to

- explain what eicosanoids are and how they are produced;
- identify some classes and functions of eicosanoids; and
- describe several physiological roles of prostaglandins.

Neurotransmitters and hormones are not the only chemical messengers in the body. Here we briefly consider the *paracrine* messengers. These are chemical signals released by cells into the tissue fluid; they do not travel to their target cells by way of the blood, but diffuse from their source to nearby cells in the same tissue. Histamine, for example, is released by mast cells that lie alongside the blood vessels in a connective tissue. It diffuses to the smooth muscle of the blood vessel, relaxing it and allowing vasodilation. Nitric oxide, another paracrine vasodilator, is released by the endothelial cells of the blood vessel itself. In the pancreas, somatostatin acts as a paracrine signal when it is released by delta cells and diffuses to the alpha and beta cells in the same islet, inhibiting their

secretion of glucagon and insulin. Catecholamines diffuse from the adrenal medulla to the cortex to stimulate corticosterone secretion. A single chemical can act as a hormone, a paracrine, or even a neurotransmitter in different locations and circumstances.

The **eicosanoids**³⁰ (eye-CO-sah-noyds) are an important family of paracrine secretions. They have 20-carbon backbones derived from a polyunsaturated fatty acid called **arachidonic** (ah-RACK-ih-DON-ic) **acid**. Some peptide hormones and other stimuli liberate arachidonic acid from one of the phospholipids of the plasma membrane, and the following two enzymes then convert it to various eicosanoids (fig. 17.26).

³⁰eicosa (variation of *icosa*) = 20

FIGURE 17.26 Eicosanoid Synthesis and Related Drug Actions. NSAIDs are nonsteroidal anti-inflammatory drugs such as aspirin and ibuprofen. A representative leukotriene and a prostaglandin are shown at the bottom.

How would the body be affected by a drug that selectively inhibited lipoxygenase?

Lipoxygenase helps to convert arachidonic acid to **leukotrienes**, eicosanoids that mediate allergic and inflammatory reactions (see chapter 21). **Cyclooxygenase** converts arachidonic acid to three other types of eicosanoids:

1. **Prostacyclin** is produced by the walls of the blood vessels, where it inhibits blood clotting and vasoconstriction.
2. **Thromboxanes** are produced by blood platelets. In the event of injury, they override prostacyclin and stimulate vasoconstriction and clotting. Prostacyclin and thromboxanes are further discussed in chapter 18.
3. **Prostaglandins (PGs)** are the most diverse eicosanoids. They have a five-sided carbon ring in their backbone. They are named PG for *prostaglandin*, plus a third letter that indicates the type of ring structure (PGE, PGF, etc.) and a subscript that indicates the number of C=C double bonds in the side chain—such as the PGE_{2α} shown in figure 17.26. They were first found in bull semen and the prostate gland, hence their name, but they are now thought to be produced in most organs of the body. The PGEs are usually antagonized by PGFs. For example, the PGE family relaxes smooth muscle in the bladder, intestines, bronchioles, and uterus and stimulates contraction of the smooth muscle of blood vessels. PGF_{2α} has precisely the opposite effects. Some other roles of prostaglandins are described in table 17.7.

Understanding the pathways of eicosanoid synthesis makes it possible to understand the action of some familiar drugs (see Insight 17.3). The roles of prostaglandins and other eicosanoids are further explored in later chapters on blood, immunity, and reproduction.

TABLE 17.7

Some of the Roles of Prostaglandins

Inflammatory: Promote fever and pain, two cardinal signs of inflammation

Endocrine: Mimic effects of TSH, ACTH, and other hormones; alter sensitivity of anterior pituitary to hypothalamic hormones; work with glucagon, catecholamines, and other hormones in regulation of fat mobilization

Nervous: Function as neuromodulators, altering the release or effects of neurotransmitters in the brain

Reproductive: Promote ovulation and formation of corpus luteum; induce labor contractions

Gastrointestinal: Inhibit gastric secretion

Vascular: Act as vasodilators and vasoconstrictors

Respiratory: Constrict or dilate bronchioles

Renal: Promote blood circulation through the kidney, increase water and electrolyte excretion

INSIGHT 17.3 Clinical Application

Anti-Inflammatory Drugs

Cortisol and corticosterone are used as *steroidal anti-inflammatory drugs (SAIDs)*. They inhibit inflammation by blocking the release of arachidonic acid from the plasma membrane, thus inhibiting the synthesis of all eicosanoids. Their main disadvantage is that prolonged use causes side effects that mimic Cushing syndrome (see p. 673). Aspirin, ibuprofen (Motrin), and celecoxib (Celebrex) are *nonsteroidal anti-inflammatory drugs (NSAIDs)*, also called *COX inhibitors* because they block the action of cyclooxygenase (COX). Their advantage is that they do not affect lipoxygenase function or leukotriene production. One form of cyclooxygenase, COX-2, is specific to the cells of inflammation, so there has been a particular interest in developing safe COX-2 inhibitors that can treat inflammation without undesirable side effects such as gastrointestinal damage.

COX inhibitors are also useful in the treatment of fever and thrombosis (undesirable blood clotting). Fever is thought to result from the action of prostaglandins on the hypothalamus. Aspirin exerts its antipyretic (fever-reducing) effect by inhibiting prostaglandin synthesis and its antithrombotic effect by inhibiting thromboxane synthesis (see chapter 18).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

24. What are eicosanoids and how do they differ from neurotransmitters and hormones?
25. Distinguish between a paracrine and endocrine effect.
26. State four functions of prostaglandins.

17.7 Endocrine Disorders

Objectives

When you have completed this section, you should be able to

- explain some general causes and examples of hormone hyposecretion and hypersecretion;
- briefly describe some common disorders of pituitary, thyroid, parathyroid, and adrenal function; and
- in more detail, describe the causes and pathology of diabetes mellitus.

As we saw in the discussion of enzyme amplification, a little hormone can have a great effect. It is therefore necessary to tightly regulate hormone secretion and blood concentration. Variations in hormone concentration and target cell sensitivity often have very noticeable effects on the

body. This section deals with some of the better-known dysfunctions of the endocrine system. The effects of aging on the endocrine system are described on page 1142.

Hyposecretion and Hypersecretion

Inadequate hormone release is called **hyposecretion**. It can result from tumors or lesions that destroy an endocrine gland or interfere with its ability to receive signals from another gland. For example, a fractured sphenoid bone can sever the hypothalamo–hypophyseal tract and thus prevent the transport of oxytocin and antidiuretic hormone (ADH) to the posterior pituitary. The resulting ADH hyposecretion disables the water-conserving capability of the kidneys and leads to **diabetes insipidus**, a condition of chronic polyuria without glucose in the urine. (*Insipidus* means “without taste” and refers to the lack of sweetness of the glucose-free urine, in contrast to the sugary urine of diabetes mellitus.) Autoimmune diseases can also lead to hormone hyposecretion when endocrine cells are attacked by *autoantibodies*—antibodies that fail to distinguish foreign matter from one’s own tissues. This is one of the causes of diabetes mellitus.

Excessive hormone release, called **hypersecretion**, has multiple causes. Some tumors result in the overgrowth of functional endocrine tissue. A **pheochromocytoma** (FEE-o-CRO-mo-sy-TOE-muh), for example, is a tumor of the adrenal medulla that secretes excessive amounts of epinephrine and norepinephrine (table 17.8, p. 676). Some tumors in nonendocrine organs produce hormones. For example, some lung tumors secrete ACTH and thus overstimulate cortisol secretion by the adrenal gland. Whereas certain autoimmune disorders can cause endocrine hyposecretion, others cause hypersecretion. An example of this

is **toxic goiter** (Graves³¹ disease), in which autoantibodies mimic the effect of TSH on the thyroid, causing thyroid hypersecretion (table 17.8). Endocrine hypersecretion disorders can also be mimicked by excess or long-term clinical administration of hormones such as cortisol.

Following are brief descriptions of some of the better-known disorders of the major endocrine glands. Table 17.8 provides further details on some of these and lists some additional endocrine disorders.

Pituitary Disorders

The hypersecretion of growth hormone (GH) in adults causes **acromegaly**—thickening of the bones and soft tissues with especially noticeable effects on the hands, feet, and face (fig. 17.27). When it begins in childhood or adolescence, GH hypersecretion causes **gigantism** and hyposecretion causes **pituitary dwarfism** (table 17.8). Now that growth hormone is plentiful, made by genetically engineered bacteria containing the human GH gene, pituitary dwarfism has become rare.

Thyroid and Parathyroid Disorders

Congenital hypothyroidism is thyroid hyposecretion present from birth; it was formerly called *cretinism*, now regarded as an insensitive term. Severe or prolonged adult hypothyroidism can cause **myxedema** (MIX-eh-DEE-muh). Both syndromes are described in table 17.8, and both can be treated with oral thyroid hormone.

A *goiter* is any pathological enlargement of the thyroid gland. **Endemic goiter** (fig. 17.28) is due to a dietary

● How would she have been affected if GH hypersecretion began at age 9?

FIGURE 17.28 Endemic Goiter. An iodine deficiency in this person's diet resulted in a lack of thyroid hormone and extremely large goiter. For lack of negative feedback inhibition, the pituitary secreted elevated levels of thyroid-stimulating hormone (TSH). This resulted in hypertrophy of the thyroid gland.

iodine deficiency. There is little iodine in soil or most foods, but seafood and iodized salt are good sources. Without iodine, the gland cannot synthesize TH. Without TH, the pituitary gland receives no feedback and acts as if the thyroid were understimulated. It produces extra TSH, which stimulates hypertrophy of the thyroid gland. In the earlier-described toxic goiter, by contrast, the overgrown thyroid produces functional TH.

Because of their location and small size, the parathyroids are sometimes accidentally removed in thyroid surgery. Without hormone replacement therapy, the resulting **hypoparathyroidism** causes a rapid decline in blood

calcium level and leads to fatal tetany within 3 or 4 days. **Hyperparathyroidism**, excess PTH secretion, is usually caused by a parathyroid tumor. It causes the bones to become soft, deformed, and fragile; it raises the blood levels of calcium and phosphate ions; and it promotes the formation of *renal calculi* (kidney stones) composed of calcium phosphate. Chapter 7 further describes the relationship among parathyroid function, blood calcium, and bone tissue.

Adrenal Disorders

Cushing³² syndrome is excess cortisol secretion owing to any of several causes: ACTH hypersecretion by the pituitary, ACTH-secreting tumors, or hyperactivity of the adrenal cortex independently of ACTH. Cushing syndrome disrupts carbohydrate and protein metabolism, leading to hyperglycemia, hypertension, muscular weakness, and edema. Muscle and bone mass are lost rapidly as protein is catabolized. Some patients exhibit abnormal fat deposition between the shoulders ("buffalo hump") or in the face ("moon face") (fig. 17.29). Long-term hydrocortisone therapy can have similar effects.

Adrenogenital syndrome (AGS), the hypersecretion of adrenal androgens, commonly accompanies Cushing syndrome. In children, AGS often causes enlargement of the penis or clitoris and the premature onset of puberty. Prenatal AGS can result in newborn girls exhibiting masculinized genitalia and being misidentified as boys (fig. 17.30). In women, AGS produces such masculinizing effects as increased body hair, deepening of the voice, and beard growth.

³²Harvey Cushing (1869–1939), American physician

(b)

FIGURE 17.29 Cushing Syndrome. (a) Patient before the onset of the syndrome. (b) The same boy, only 4 months later, showing the "moon face" characteristic of Cushing syndrome.

FIGURE 17.30 Adrenogenital Syndrome (AGS). These are the genitals of a baby girl with AGS, masculinized by prenatal hypersecretion of adrenal androgens. Note the fusion of the labia majora to resemble a scrotum and enlargement of the clitoris to resemble a penis. Such infants are easily mistaken for boys and raised as such.

Diabetes Mellitus

The world's most prevalent metabolic disease is diabetes mellitus, occurring in about 7% of the U.S. population and even more in areas such as Scandinavia and the Pacific Islands. It is the leading cause of adult blindness, renal failure, gangrene, and the necessity for limb amputations, and warrants a more extended discussion than the less common endocrine diseases. The pathology of DM is described here, and the chapter ends with an essay on the history of the discovery of insulin (see Insight 17.4).

Diabetes mellitus³³ (DM) can be defined as a disruption of carbohydrate, fat, and protein metabolism resulting from the hyposecretion or inaction of insulin. Its classic signs and symptoms are “the three polys”: **polyuria**³⁴ (excessive urine output), **polydipsia**³⁵ (intense thirst), and **polyphagia**³⁶ (ravenous hunger). Three further clinical signs are revealed by blood and urine tests: **hyperglycemia**³⁷ (elevated blood glucose), **glycosuria**³⁸ (glucose in the urine), and **ketonuria** (ketones in the urine). DM was originally named for the sweetness of the urine stemming from glycosuria.

A little knowledge of kidney physiology is necessary to understand why glycosuria and polyuria occur. The

kidneys filter blood plasma and convert the filtrate to urine. In a healthy person, the kidney tubules remove all glucose from the filtrate and return it to the blood, so there is little or no glucose in the urine. Water follows the glucose and other solutes by osmosis, so the tubules also reclaim most of the water in the filtrate.

But like any other carrier-mediated transport system, there is a limit to how fast the glucose transporters of the kidney can work. The maximum rate of reabsorption is called the *transport maximum*, T_m (see p. 104). In diabetes mellitus, glucose enters the tubules so rapidly that it exceeds the T_m and the tubules cannot reabsorb it fast enough. The excess passes through into the urine. Glucose and ketones in the tubules also raise the osmolarity of the tubular fluid and cause **osmotic diuresis**—water remains in the tubules with these solutes, so large amounts of water are passed in the urine. This accounts for the polyuria, dehydration, and thirst of diabetes. A person with untreated DM may pass 10 to 15 L of urine per day, compared with 1 or 2 L in a healthy person.

Types and Treatment

There are two forms of diabetes mellitus: type 1 and type 2. These were formerly called, respectively, juvenile onset or insulin-dependent DM, and adult onset or non-insulin-dependent DM. These terms have lately been abandoned because they are too misleading. Although insulin is always used to treat type 1, it is frequently used for type 2 diabetes as well, and either type can occur at any age. Indeed, with the burgeoning problem of childhood obesity, nearly half of all new cases of childhood diabetes are now type 2.

Type 1 diabetes mellitus accounts for 5% to 10% of cases in the United States. What causes it? It begins with heredity. Several genes have been identified that predispose a person to type 1 DM. Then, when a genetically susceptible individual is infected by certain viruses (rubella, cytomegalovirus, or a few others), the body produces autoantibodies that destroy pancreatic beta cells. To a great extent, this destruction is tolerated and produces no disease, but when 80% to 90% of the beta cells are gone, insulin falls to such a critically low level that it can no longer regulate glycemia, the blood glucose level. Now comes the problematic hyperglycemia and all of its insidious complications. Type 1 diabetes is usually diagnosed before the age of 30, but may occur later. Its victims require insulin to survive—usually periodic injections or continual subcutaneous delivery by a small insulin pump worn on the body. A dry insulin inhaler is now available, but is not suitable for all patients. Meal planning, exercise, and self-monitoring of blood glucose levels are also important aspects of the treatment regimen.

Ninety percent to 95% of diabetics, however, have **type 2 DM**. Here, the chief problem is not lack of insulin, but *insulin resistance*—unresponsiveness of the target

³³ *diabet* = to flow through + *melli* = honey

³⁴ *poly* = much, excessive + *uri* = urine

³⁵ *dipsia* = drinking

³⁶ *phagia* = eating

³⁷ *hyper* = excess + *glyc* = sugar, glucose + *emia* = blood condition

³⁸ *glyco* = glucose, sugar + *uria* = urine condition

cells to the hormone. The level of insulin may actually be very high in the early stage of the disease, although it later tends to fall to normal or subnormal levels. Again, heredity is one of the causes. Although no type 2 DM genes have yet been specifically identified, there is clear evidence of a hereditary component: There are great differences in incidence from one ethnic group to another; it is relatively high, for example, among people of Native American, Hispanic, and Asian descent. It also has a tendency to run in families, and shows very high concordance between genetically identical twins—if one twin develops type 2 DM, there is more than a 90% probability that the other will too. Other important risk factors are age, obesity, and a sedentary lifestyle. All of these are accompanied by the progressive replacement of muscular tissue with fat. Muscle plays a highly important role in absorbing blood glucose and buffering glycemia, so as muscle mass diminishes, a person becomes less and less able to regulate glycemia. Type 2 DM develops slowly and is usually diagnosed after age 40, but it is becoming increasingly prevalent in young people because of childhood obesity. Aside from the loss of the glucose-buffering role of muscle, another apparent factor in type 2 DM is that adipose tissue secretes chemical signals that indirectly interfere with glucose transport into most kinds of cells—so the more body fat, the less efficient is glucose uptake. It is no surprise, then, that type 2 DM can often be successfully managed through a weight-loss program of diet and exercise, supplemented if necessary with oral glycemia-lowering medications. If these approaches prove inadequate, insulin therapy is also employed.

Pathogenesis

When cells cannot absorb glucose, they must get their energy someplace else; they metabolize fat and protein. In time, this leads to muscular atrophy, emaciation, and weakness. Before insulin therapy was introduced in 1922, the victims of type 1 DM wasted away to an astonishing extent (see Insight 17.4). Diabetes was described in the first century as “a melting down of the flesh and limbs into urine.” Adult patients weighed as little as 27 to 34 kg (60–75 lb) and looked like victims of severe famine. Their breath had a sickeningly sweet ketone smell, like rotten apples. One typical patient was described by medical historian Michael Bliss as “barely able to lift his head from his pillow, crying most of the time from pain, hunger, and despair.” In the terminal stage, patients became increasingly drowsy, gasped for air, became comatose, and then died within a few hours. Most diabetic children lived less than 1 year after diagnosis—a year of utmost misery at that. Such was the natural course of the disease in the centuries before insulin therapy.

Rapid fat catabolism elevates blood levels of free fatty acids and their breakdown products, the ketone bodies (acetoacetic acid, acetone, and β -hydroxybutyric

acid). Ketonuria promotes osmotic diuresis, flushing Na^+ and K^+ from the body and creating electrolyte deficiencies that can lead to abdominal pain, vomiting, irregular heartbeat, and neurological dysfunction. As acids, ketones lower the pH of the blood and produce a condition called **ketoacidosis**. This causes a deep, gasping breathing called *Kussmaul*³⁹ *respiration*, typical of terminal diabetes. It also depresses the nervous system and produces diabetic coma.

DM also leads to long-term degenerative cardiovascular and neurological diseases—signs that were seldom seen before insulin therapy, when patients died too quickly to show the chronic effects. Through multiple, complex mechanisms, chronic hyperglycemia has devastating effects on small to medium blood vessels (*microvascular disease*), including *atherosclerosis*, the obstruction of blood vessels by plaques of lipid and overgrown smooth muscle (see p. 750). Two of the common complications of long-term DM are blindness and renal failure, brought on by arterial degeneration in the retinas and kidneys. Death from kidney failure is much more common in type 1 DM than in type 2. In type 2, the most common cause of death is heart failure stemming from coronary artery disease. Another complication is *diabetic neuropathy*—nerve damage resulting from impoverished blood flow. This can lead to erectile dysfunction, incontinence, and loss of sensation from affected areas of the body. Microvascular disease in the skin results in poor healing of skin wounds, so even a minor break easily becomes ulcerated, infected, and gangrenous. This is especially common in the feet, because people take less notice of foot injuries; circulation is poorer in the feet (farthest from the heart) than anywhere else; pressure on the feet makes them especially susceptible to tissue injury; and neuropathy may make a person unaware of skin lesions or reluctant to consent to amputation of toes, or more, from which they feel no pain. DM outweighs all other reasons for the amputation of gangrenous appendages.

Diabetes mellitus is not the only kind of diabetes. Diabetes insipidus, a disease with no relation to insulin, has already been mentioned (p. 672), and other forms are discussed with the urinary system in chapter 23 (see p. 930).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

27. Explain some causes of hormone hyposecretion, and give examples. Do the same for hypersecretion.
28. In diabetes mellitus, explain the chain of events that lead to (a) osmotic diuresis, (b) ketoacidosis and coma, and (c) gangrene of the lower limbs.

³⁹Adolph Kussmaul (1822–1902), German physician

TABLE 17.8 Some Disorders of the Endocrine System

Addison ⁴⁰ disease	Hyposecretion of adrenal glucocorticoids and mineralocorticoids, causing hypoglycemia, hypotension, weight loss, weakness, loss of stress resistance, darkening or bronzing (metallic discoloration) of the skin, and potentially fatal dehydration and electrolyte imbalances	
Congenital hypothyroidism	Thyroid hormone hyposecretion present from birth, resulting in stunted physical development, thickened facial features, low body temperature, lethargy, and irreversible brain damage in infancy	
Hyperinsulinism	Insulin excess caused by islet hypersecretion or injection of excess insulin, causing hypoglycemia, weakness, hunger, and sometimes <i>insulin shock</i> , which is characterized by disorientation, convulsions, or unconsciousness	
Myxedema	A syndrome occurring in severe or prolonged adult hypothyroidism, characterized by low metabolic rate, sluggishness and sleepiness, weight gain, constipation, dry skin and hair, abnormal sensitivity to cold, hypertension, and tissue swelling	
Pheochromocytoma	A tumor of the adrenal medulla that secretes excess epinephrine and norepinephrine. Causes hypertension, elevated metabolic rate, nervousness, indigestion, hyperglycemia, and glycosuria	
Toxic goiter (Graves disease)	Thyroid hypertrophy and hypersecretion, occurring when autoantibodies mimic the effect of TSH and overstimulate the thyroid. Results in elevated metabolic rate and heart rate, nervousness, sleeplessness, weight loss, abnormal heat sensitivity and sweating, and bulging of the eyes (exophthalmos) resulting from eyelid retraction and edema of the orbital tissues	
Disorders described elsewhere		
Acromegaly p. 672	Diabetes insipidus p. 672	Hyperparathyroidism p. 673
Adrenogenital syndrome p. 673	Endemic goiter p. 672	Hypoparathyroidism p. 673
Androgen-insensitivity syndrome p. 1049	Gigantism p. 672	Pituitary dwarfism p. 672
Cushing syndrome p. 673		

⁴⁰Thomas Addison (1793–1860). English physician**INSIGHT 17.4** Medical History**The Discovery of Insulin**

At the start of the twentieth century, physicians felt nearly helpless in the face of diabetes mellitus. They put patients on useless diets—the oatmeal cure, the potato cure, and others—or on starvation diets as low as 750 Cal per day so as not to “stress the system.” They were resigned to the fact that their patients were doomed to die, and simple starvation seemed to produce the least suffering.

After the cause of diabetes was traced to the pancreatic islets in 1901, European researchers tried treating patients and experimental animals with extracts of pancreas, but became discouraged by the severe side effects of impurities in the extracts. They lacked the resources to pursue the problem to completion, and by 1913, the scientific community showed signs of giving up on diabetes.

But in 1920, Frederick Banting (1891–1941), a young Canadian physician with a failing medical practice, became intrigued with a possible method for isolating the islets from the pancreas and testing extracts of the islets alone. He returned to his alma mater, the University of Toronto, to present his idea to Professor J. J. R. Macleod (1876–1935), a leading authority on carbohydrate metabolism. Macleod was unimpressed with Banting, finding his knowledge of the diabetes literature and scientific

method superficial. Nevertheless, he felt Banting’s idea was worth pursuing and thought that with his military surgical training, Banting might be able to make some progress where others had failed. He offered Banting laboratory space for the summer, giving him a marginal chance to test his idea. Banting was uncertain whether to accept, but when his fiancée broke off their engagement and an alternative job offer fell through, he closed his medical office, moved to Toronto, and began work. Little did either man realize that in two years’ time, they would share a Nobel Prize and yet so thoroughly detest each other they would scarcely be on speaking terms.

A Modest Beginning

Macleod advised Banting on an experimental plan of attack and gave him an assistant, Charles Best (1899–1978). Best had just received his B.A. in physiology and looked forward to an interesting summer job with Banting before starting graduate school. Over the summer of 1921, they removed the pancreases from some dogs to render them diabetic and tied off the pancreatic ducts in other dogs to make most of the pancreas degenerate while leaving the islets intact. Their plan was to treat the diabetic dogs with extracts made from the degenerated pancreases of the others.

It was a difficult undertaking. Their laboratory was tiny, filthy, and unbearably hot, and reeked of dog excrement. The pancreatic ducts were very small and difficult to tie, and it was hard to tell if all pancreatic tissue had been removed from the

dogs intended to become diabetic, Several dogs died of over-anesthesia, infection, and bleeding from Banting's clumsy surgical technique. Banting was also careless in reading his data and interpreting the results and had little interest in reading the literature to see what other researchers were doing. In Banting and Best's first publication, in early 1922, the data in their discussion disagreed with the data in the tables, and both disagreed with the data in their laboratory notebooks. These were not the signs of promising researchers.

In spite of themselves, Banting and Best achieved modest positive results over the summer. Crude extracts brought one dog back from a diabetic coma and reduced the hyperglycemia and glycosuria of others. Buoyed by these results, Banting demanded a salary, a better laboratory, and another assistant. Macleod grudgingly obtained salaries for the pair, but Banting began to loathe him for their disagreement over his demands, and he and Macleod grew in mutual contempt as the project progressed.

Success and Conflict

Macleod brought biochemist J. B. Collip (1892-1965) into the project that fall in hopes that he could produce purer extracts. More competent in experimental science, Collip was the first to show that pancreatic extracts could eliminate ketosis and restore the liver's ability to store glycogen. He obtained better and better results in diabetic rabbits until, by January 1922, the group felt ready for human trials. Banting was happy to have Collip on the team initially, but grew intensely jealous of him as Collip not only achieved better results than he had, but also developed a closer relationship with Macleod. Banting, who had no qualifications to perform human experiments, feared he would be pushed aside as the project moved to its clinical phase. At one point, the tension between Banting and Collip nearly erupted into a fistfight in the laboratory.

Banting insisted that the first human trial be done with an extract he and Best prepared, not with Collip's. The patient was a 14-year-old boy who weighed only 29 kg (65 lb) and was on the verge of death. He was injected on January 11 with the Banting and Best extract, described by one observer as "a thick brown muck." The trial was an embarrassing failure, with only a slight lowering of his blood glucose and a severe reaction to the impurities in the extract. On January 23, the same boy was treated again, but with Collip's extract. This time, his ketonuria and glycosuria were almost completely eliminated and his blood sugar dropped 77%. This was the first successful clinical trial of insulin. Six more patients were treated in February 1922 and quickly became stronger, more alert, and in better spirits. In April, the Toronto group began calling the product *insulin*, and at a medical conference in May, they gave the first significant public report of their success.

But Banting felt increasingly excluded from the project. He quit coming to the laboratory, stayed drunk much of the time, and day-dreamed of leaving diabetes research to work on

cancer. He remained only because Best pleaded with him to stay. Banting briefly operated a private diabetes clinic, but fearful of embarrassment over alienating the discoverer of insulin, the university soon lured him back with a salaried appointment and hospital privileges.

Banting had a number of high-profile, successful cases in 1922, such as 14-year-old Elizabeth Hughes, who weighed only 20 kg (45 lb) before treatment. She began treatment in August and showed immediate, dramatic improvement. She was a spirited, optimistic, and articulate girl who kept enthusiastic diaries of being allowed to eat bread, potatoes, and macaroni and cheese for the first time since the onset of her illness. "Oh it is simply too wonderful for words this stuff," she exuberantly wrote to her mother—even though the still-impure extracts caused her considerable pain and swelling. The world quickly beat a path to Toronto begging for insulin. The pharmaceutical firm of Eli Lilly and Company entered into an agreement with the University of Toronto for the mass production of insulin, and by the fall of 1923, over 25,000 patients were being treated at more than 60 Canadian and U.S. clinics.

The Bitter Fruits of Success

Banting's self-confidence was restored. He had become a public hero, and the Canadian Parliament awarded him an endowment generous enough to ensure him a life of comfort. Several distinguished physiologists nominated Banting and Macleod for the 1923 Nobel Prize, and they won. When the award was announced, Banting was furious about having to share it with Macleod. At first, he threatened to refuse it, but when he cooled down, he announced that he would split his share of the prize money with Best. Macleod quickly announced that half of his share would go to Collip.

Banting subsequently made life at the university so unbearable that Macleod left in 1928 to accept a university post in Scotland. Banting stayed on at Toronto. Although now wealthy and surrounded by admiring students, he achieved nothing significant in science for the rest of his career. He was killed in a plane crash in 1941. Best replaced Macleod on the Toronto faculty, led a distinguished career, and developed the anticoagulant heparin. Collip went on to play a lead role in the isolation of PTH, ACTH, and other hormones.

Insulin made an industry giant of Eli Lilly and Company. It became the first protein whose amino acid sequence was determined, for which Frederick Sanger received a Nobel Prize in 1958. Diabetics today no longer depend on a limited supply of insulin extracted from beef and pork pancreas. Human insulin is now in plentiful supply, made by genetically engineered bacteria. Paradoxically, while insulin has dramatically reduced the suffering caused by diabetes mellitus, it has increased the number of people who have the disease—because thanks to insulin, diabetics are now able to live long enough to raise families and pass on the diabetes genes.

CONNECTIVE ISSUES

Interactions Between the ENDOCRINE SYSTEM and Other Organ Systems

← indicates ways in which this system affects other systems

← indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

Sex hormones affect skin pigmentation, development of body hair and apocrine glands, and subcutaneous fat deposition
Skin synthesizes calcitriol precursor

SKELETAL SYSTEM

Many hormones affect bone development
Protects some endocrine glands; stores calcium needed for endocrine function

MUSCULAR SYSTEM

Growth hormone and testosterone stimulate muscular growth; insulin regulates carbohydrate metabolism in muscle; other hormones affect electrolyte balance, which is critical to muscle function

Skeletal muscles protect some endocrine glands

NERVOUS SYSTEM

Exerts negative feedback inhibition on hypothalamus; several hormones affect nervous system development, mood, and behavior; hormones regulate electrolyte balance, which is critical to neuron function

Hypothalamus regulates secretion of pituitary hormones and synthesizes the posterior pituitary hormones; sympathetic nervous system triggers secretion by adrenal medulla

CIRCULATORY SYSTEM

Angiotensin II, aldosterone, ADH, ANP, and BNP regulate blood volume and pressure; epinephrine, TH, and other hormones affect heart rate and contraction force

Blood transports hormones to their target organs; blood pressure and osmolarity variations trigger secretion of some hormones

ALL SYSTEMS

The integumentary system serves all other systems by providing a physical barrier to environmental hazards

LYMPHATIC/IMMUNE SYSTEM

Thymosin and other hormones activate immune cells; glucocorticoids suppress immunity and inflammation

Lymphatic system maintains fluid balance in endocrine glands; lymphocytes protect endocrine glands from infection

RESPIRATORY SYSTEM

Epinephrine and norepinephrine increase pulmonary airflow

Provides O₂ and removes CO₂; lungs convert angiotensin I to angiotensin II

URINARY SYSTEM

ADH regulates water excretion; PTH, calcitriol, and aldosterone regulate electrolyte excretion

Kidneys secrete EPO and produce angiotensin I and calcitriol; degrade and excrete other hormones

DIGESTIVE SYSTEM

Insulin and glucagon modulate nutrient storage and metabolism; enteric hormones regulate gastrointestinal secretion and motility

Provides nutrients; nutrient absorption triggers insulin secretion; gut-brain peptides act on hypothalamus and stimulate specific hungers; liver secretes several hormones, and degrades and excretes others

REPRODUCTIVE SYSTEM

Gonadotropins and sex steroids regulate sexual development, sperm and egg production, sex drive, menstrual cycle, pregnancy, fetal development, and lactation

Sex hormones inhibit secretion by hypothalamus and pituitary gland

CHAPTER REVIEW

Review of Key Concepts

17.1 Overview of the Endocrine System (p. 638)

1. Intercellular communication is necessary for homeostasis. Cells communicate through gap junctions, neurotransmitters, paracrines, and hormones.
2. *Endocrinology* is the study of the endocrine system, which is composed of hormone-secreting cells and *endocrine glands*.
3. Endocrine glands have no ducts, but secrete their products into the bloodstream.
4. The nervous and endocrine systems collaborate and have several overlapping functions and properties, but are not redundant. Differences are listed in table 17.1.
5. Hormones circulate throughout the body but stimulate only *target cells*, which have receptors for them.

17.2 The Hypothalamus and Pituitary Gland (p. 641)

1. The hypothalamus and pituitary gland have a more wide-ranging influence on the body than any other endocrine glands.
2. The pituitary gland is connected to the hypothalamus by a stalk. It is divided into an anterior *adenohypophysis*, whose main part is the *anterior lobe*, and a posterior *neurohypophysis*, whose main part is the *posterior lobe*.
3. The adenohypophysis is connected to the hypothalamus by a system of blood vessels called the *hypophyseal portal system*. The neurohypophysis is connected to the hypothalamus by a bundle of nerve fibers, the *hypothalamo-hypophyseal tract*.
4. The hypothalamus secretes six hormones that travel through the portal system and regulate the anterior lobe. Four of these trigger hormone release and two of them inhibit hormone release by the anterior lobe (see table 17.3).
5. The hypothalamus synthesizes two other hormones that are stored in the

posterior pituitary and released in response to nerve signals: *oxytocin (OT)* and *antidiuretic hormone (ADH)*.

6. The anterior lobe secretes *follicle-stimulating hormone (FSH)*, *luteinizing hormone (LH)*, *thyroid-stimulating hormone (TSH)*, *adrenocorticotropic hormone (ACTH)*, *prolactin (PRL)*, and *growth hormone (GH)*. Their functions are summarized in table 17.4.
7. The posterior lobe stores OT and ADH until the brain stimulates their release. OT promotes labor contractions and milk release and possibly contributes to semen propulsion, uterine contractions, and sexual emotion. ADH promotes water conservation. The secretion of OT and ADH is controlled by *neuroendocrine reflexes*.
8. The hypothalamus and pituitary are regulated by positive and negative feedback from their target organs.
9. GH has an especially broad effect on the body, notably to stimulate the growth of cartilage, bone, muscle, and fat through its influence on protein, lipid, and carbohydrate metabolism. Many of its effects are mediated through insulin-like growth factors (IGFs) secreted by the liver.

17.3 Other Endocrine Glands (p. 649)

1. The *pineal gland* secretes *melatonin* and may influence mood and sexual maturation.
2. The *thymus* secretes *thymopoietin*, *thymosins*, and *thymulin*, which regulate the immune system.
3. The *thyroid gland* secretes mainly *thyroxine (T₄)*, which stimulates catabolism and heat production, tissue growth, nervous system development, and alertness. It also secretes calcitonin, which promotes bone deposition and lowers blood Ca²⁺ levels in children.
4. The four *parathyroid glands* secrete *parathyroid hormone*, which acts in several ways to increase blood Ca⁺ levels.
5. The *adrenal medulla* secretes mainly *epinephrine* and *norepinephrine*,

which raise blood glucose levels and help the body adapt to physical activity and stress.

6. The *adrenal cortex* secretes *aldosterone*, which promotes Na⁺ retention and K⁺ excretion; *cortisol* and *corticosterone*, which raise blood glucose and fatty acid levels and aid in stress adaptation and tissue repair; and *androgens* and *estrogens*, which contribute to reproductive development and physiology.
7. The *pancreatic islets* secrete *insulin*, which promotes glucose uptake by the tissues; *glucagon*, which stimulates the release of glucose from storage; *somatostatin*, which regulates the insulin- and glucagon-secreting cells and inhibits some digestive functions; *pancreatic polypeptide*, which inhibits the gallbladder and exocrine pancreas; and *gastrin*, which stimulates the stomach.
8. The ovaries secrete *estradiol* and *progesterone*, which regulate reproductive development and physiology, and *inhibin*, which suppresses FSH secretion by the pituitary. The testes secrete *testosterone* and *inhibin*, with corresponding roles in the male.
9. Many other hormones are also produced by tissues and organs other than the conventional endocrine glands: the skin, liver, kidneys, heart, stomach, small intestine, adipose tissue, osseous tissue, and placenta (see table 17.5).

17.4 Hormones and Their Actions (p. 659)

1. There are three main chemical classes of hormones: steroids, peptides, and monoamines (table 17.6).
2. The steroids are synthesized from cholesterol.
3. Peptide hormones are synthesized by ribosomes and pass through inactive stages called the *preprohormone* and *prohormone* before being converted to active hormone.
4. Monoamines are synthesized from the amino acids tryptophan and tyrosine. Thyroid hormone is an unusual

case in that its synthesis begins with a large protein, thyroglobulin. Iodine is added to its tyrosine residues, the modified tyrosines are linked in pairs, and then the tyrosines are cleaved from the protein to yield thyroxine (T_4) and a small amount of triiodothyronine T_3 .

- Peptides and most monoamines travel easily in the watery blood plasma, but the hydrophobic steroids and thyroid hormone are carried by *transport proteins*, which also prolong the half-life of the hormones.
- Hormone receptors are found in the plasma membranes, in the cytoplasm, and in the nuclei of the target cells. Steroids and thyroid hormone bind to nuclear receptors, and peptides and catecholamines to plasma membrane receptors, which activate formation of second messengers in the cytosol. Target cells convert most T_4 to the more physiologically active T_3 before it binds to its receptor.
- Second messengers for hormone action include cAMP, cGMP, *diacylglycerol (DAG)*, and *inositol triphosphate (IP₃)*.
- Because of *enzyme amplification*, small amounts of hormone can have great physiological effects.
- Target cells can adjust their sensitivity to a hormone by *up-regulation* (increasing the number of hormone receptors) and *down-regulation* (decreasing the number of receptors).
- Hormones do not act in isolation, but influence each other. One hormone can have *synergistic*, *permissive*, or *antagonistic effects* on the action of another.
- Hormones are cleared from the blood by metabolism in the liver and kidneys and excretion in the bile and urine.

17.5 Stress and Adaptation (p. 669)

- Stress* is any situation that upsets homeostasis and threatens well-being.
- Regardless of the cause of stress, the body reacts in a fairly consistent way called the *stress response (general adaptation syndrome)*.
- The first stage of the stress response, the *alarm reaction*, is characterized by elevated levels of norepinephrine, epinephrine, aldosterone, and angiotensin, resulting in glycogen breakdown, fluid and electrolyte retention, and elevated blood pressure.
- The second stage, the *stage of resistance*, sets in when stored glycogen is exhausted. It is characterized by elevated levels of ACTH and cortisol, and the breakdown of fat and protein for fuel.
- The third stage, the *stage of exhaustion*, sets in if fat reserves are depleted. It is characterized by increasing protein breakdown, weakening of the body, and often death.

17.6 Eicosanoids and Paracrine Signaling (p. 670)

- Paracrines* are hormonelike messengers that travel only short distances and stimulate nearby cells.
- Many paracrines are *eicosanoids*, which have 20-carbon backbones and are derived from arachidonic acid. Eicosanoids include *leukotrienes*, *prostacyclin*, *thromboxanes*, and *prostaglandins*.

17.7 Endocrine Disorders (p. 671)

- Endocrine dysfunctions often stem from hormone hyposecretion or hypersecretion.
- Some pituitary disorders include *acromegaly* and *gigantism* from GH hypersecretion, *pituitary dwarfism*

from GH hyposecretion, and *diabetes insipidus* from ADH hyposecretion.

- Myxedema* and *endemic goiter* are thyroid hyposecretion disorders and *toxic goiter* is a thyroid hypersecretion disorder.
- Hypoparathyroidism* leads to low blood Ca^{2+} level and sometimes fatal tetany; *hyperparathyroidism* leads to excessive blood Ca^{2+} and bone fragility.
- Hypersecretion by the adrenal cortex can result in *Cushing syndrome* (excess cortisol) or *adrenogenital syndrome* (excess androgen).
- Diabetes mellitus (DM)* is the most common endocrine dysfunction, resulting from the hyposecretion or inaction of insulin—called type 1 and type 2 DM, respectively.
- DM is characterized by *polyuria*, *polydipsia*, and *polyphagia* and clinically confirmed by findings of *hyperglycemia*, *glycosuria*, and *ketonuria*. Glycosuria and osmotic diuresis result in the extreme polyuria, dehydration, and thirst typical of DM.
- Type 1 DM results from destruction of insulin-secreting beta cells of the pancreas and is treated with insulin, dietary management, and exercise. Type 2 results from insensitivity of target cells to insulin. It is sometimes manageable through diet and exercise alone, but may require glycemia-lowering drugs or insulin.
- Untreated DM results in severe wasting away of the body, degenerative cardiovascular and neurological disease, gangrene, blindness, kidney failure, ketoacidosis, coma, and death.

Testing Your Recall

- CRH secretion would *not* raise the blood concentration of
 - ACTH.
 - thyroxine.
 - cortisol.
 - corticosterone.
 - glucose.
- Which of the following hormones has the least in common with the others?
 - adrenocorticotrophic hormone
 - follicle-stimulating hormone
 - thyrotropin
 - thyroxine
 - prolactin
- Which hormone would no longer be secreted if the hypothalamo–hypophyseal tract were destroyed?
 - oxytocin
 - follicle-stimulating hormone
 - growth hormone
 - adrenocorticotrophic hormone
 - corticosterone
- Which of the following is *not* a hormone?
 - prolactin
 - prolactin-inhibiting hormone
 - thyroxine-binding globulin
 - atrial natriuretic peptide
 - cortisol
- Where are the receptors for insulin located?
 - in the pancreatic beta cells
 - in the blood plasma
 - on the target cell membrane
 - in the target cell cytoplasm
 - in the target cell nucleus
- What would be the consequence of defective ADH receptors?
 - diabetes mellitus
 - adrenogenital syndrome
 - dehydration
 - seasonal affective disorder
 - none of these
- Which of these has more exocrine than endocrine tissue?
 - the pineal gland
 - the adenohypophysis
 - the thyroid gland
 - the pancreas
 - the adrenal gland
- Which of these cells stimulate bone deposition?
 - alpha cells
 - beta cells
 - C cells
 - G cells
 - T cells
- Which of these hormones relies on cAMP as a second messenger?
 - ACTH
 - progesterone
 - thyroxine
 - testosterone
 - estrogen
- Prostaglandins are derived from
 - proopiomelanocortin.
 - cyclooxygenase.
 - leukotriene.
 - lipoygenase.
 - arachidonic acid.
- The _____ develops from the hypophyseal pouch of the embryo.
- Thyroxine (T_4) is synthesized by combining two iodinated molecules of the amino acid _____.
- Growth hormone hypersecretion in adulthood causes a disease called _____.
- The dominant hormone in the stage of resistance of the stress response is _____.
- Adrenal steroids that regulate glucose metabolism are collectively called _____.
- Testosterone is secreted by the _____ cells of the testis.
- Target cells can reduce pituitary secretion by a process called _____.
- Hypothalamic releasing factors are delivered to the anterior pituitary by way of a network of blood vessels called the _____.
- A hormone is said to have a/an _____ effect when it stimulates the target cell to develop receptors for other hormones to follow.
- _____ is a process in which a cell increases its number of receptors for a hormone.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Castration would raise a man's blood gonadotropin concentration.
- Hormones in the glycoprotein class cannot have cytoplasmic or nuclear receptors in their target cells.
- Epinephrine and thyroid hormone have the same effects on metabolic rate and blood pressure.
- Tumors can lead to either hyposecretion or hypersecretion of various hormones.
- All hormones are secreted by endocrine glands.
- An atherosclerotic deposit that blocked blood flow in the hypophyseal portal system would cause the testes and ovaries to malfunction.
- The pineal gland and thymus are larger in adults than in children.
- A deficiency of dietary iodine would lead to negative feedback inhibition of TSH synthesis.
- The tissue at the center of the adrenal gland is called the zona reticularis.
- Of the endocrine organs covered in this chapter, only the adrenal glands are paired; the rest are single.

Answers in appendix B

Testing Your Comprehension

1. Propose a model of enzyme amplification for the effect of a steroid hormone and construct a diagram similar to figure 17.24 for your model. A review of protein synthesis in chapter 4 may help.
2. Suppose you were browsing in a health-food store and saw a product advertised: "Put an end to heart disease. This herbal medicine will rid your body of cholesterol!" Would you buy it? Why or why not? If the product were as effective as claimed, what are some other effects it would produce?
3. A person with toxic goiter tends to sweat profusely. Explain this in terms of homeostasis.
4. How is the action of a peptide hormone similar to the action of the neurotransmitter norepinephrine?
5. Review the effects of anabolic steroid abuse (see Insight 2.5, p. 83), and explain how some of them relate to the concept of down-regulation explained in this chapter.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Polypeptides and conjugated proteins (pp. 75–76)
- Filtration (p. 100)
- Osmosis and osmolarity (pp. 101–103)
- Dominant and recessive alleles (p. 143)
- Sex linkage (p. 145)

Blood has always had a special mystique. From time immemorial, people have seen blood flow from the body and with it, the life of the individual. People thus presumed that blood carried a mysterious “vital force”; Roman gladiators drank it to fortify themselves for battle. Even today, we become especially alarmed when we find ourselves bleeding, and the emotional impact of blood is enough to make many people faint at the sight of it. From ancient Egypt to nineteenth-century America, physicians drained “bad blood” from their patients to treat everything from gout to headaches, from menstrual cramps to mental illness. It was long thought that hereditary traits were transmitted through the blood, and people still use such unfounded expressions as “I have one-quarter Cherokee blood.”

Scarcely anything meaningful was known about blood until its cells were seen with the first microscopes. Even though blood is a uniquely accessible tissue, most of what we know about it dates only to the last 50 years. Recent developments in this field have empowered us to save and improve the lives of countless people who would otherwise suffer or die.

18.1 Introduction

Objectives

When you have completed this section, you should be able to

- describe the functions and major components of the circulatory system;
- describe the components and physical properties of blood;
- describe the composition of blood plasma;
- explain the significance of blood viscosity and osmolarity; and
- describe in general terms how blood is produced.

Functions of the Circulatory System

The **circulatory system** consists of the heart, blood vessels, and blood. The term **cardiovascular¹ system** refers only to the heart and vessels, which are the subject of chapters 19 and 20. The study of blood, specifically, is called **hematology²**.

The fundamental purpose of the circulatory system is to transport substances from place to place in the body. Blood

is the liquid medium in which these materials travel, blood vessels ensure the proper routing of blood to its destinations, and the heart is the pump that keeps the blood flowing.

More specifically, the functions of the circulatory system are as follows:

Transport

- The blood carries oxygen from the lungs to all of the body’s tissues, while it picks up carbon dioxide from those tissues and carries it to the lungs to be removed from the body.
- It picks up nutrients from the digestive tract and delivers them to all of the body’s tissues.
- It carries metabolic wastes to the kidneys for removal.
- It carries hormones from endocrine cells to their target organs.
- It transports a variety of stem cells from the bone marrow and other origins to the tissues where they lodge and mature.

Protection

- The blood plays several roles in inflammation, a mechanism for limiting the spread of infection.
- White blood cells destroy microorganisms and cancer cells.
- Antibodies and other blood proteins neutralize toxins and help to destroy pathogens.
- Platelets secrete factors that initiate blood clotting and other processes for minimizing blood loss.

Regulation

- By absorbing or giving off fluid under different conditions, the blood capillaries help to stabilize fluid distribution in the body.
- By buffering acids and bases, blood proteins help to stabilize the pH of the extracellular fluids.
- Shifts in blood flow help to regulate body temperature by routing blood to the skin for heat loss or retaining it deeper in the body to conserve heat.

Considering the importance of efficiently transporting nutrients, wastes, hormones, and especially oxygen from place to place, it is easy to understand why an excessive loss of blood is quickly fatal, and why the circulatory system needs mechanisms for minimizing such losses.

Components and General Properties of Blood

All of the foregoing functions depend, of course, on the characteristics of the blood. Adults generally have about 4 to 6 liters of blood. It is a liquid connective tissue composed, like other connective tissues, of cells and an extracellular matrix. The matrix is the blood **plasma**, a clear, light yellow fluid constituting a little over half of

¹cardio = heart + vas = vessel

²hem, hemato = blood + logy = study of

FIGURE 18.1 The Formed Elements of Blood.

What do erythrocytes and platelets lack that the other formed elements have?

the blood volume. Suspended in the plasma are the **formed elements**—cells and cell fragments including the red blood cells, white blood cells, and platelets (fig. 18.1). The term *formed element* alludes to the fact that these are membrane-enclosed bodies with a definite structure visible with the microscope. Strictly speaking, they cannot all be called cells because the platelets, as explained later, are merely fragments torn from certain bone marrow cells. The formed elements are classified as follows:

- Erythrocytes³ (red blood cells, RBCs)
- Platelets
- Leukocytes⁴ (white blood cells, WBCs)
 - Granulocytes
 - Neutrophils
 - Eosinophils
 - Basophils
 - Agranulocytes
 - Lymphocytes
 - Monocytes

Thus, there are seven kinds of formed elements: the erythrocytes, platelets, and five kinds of leukocytes. The five

leukocyte types are divided into two categories, the *granulocytes* and *agranulocytes*, on grounds explained later.

The ratio of formed elements to plasma can be seen by taking a sample of blood in a tube and spinning it for a few minutes in a centrifuge (fig. 18.2). Erythrocytes, the densest elements, settle to the bottom of the tube and typically constitute about 37% to 52% of the total volume. (This value is called the *hematocrit*.) WBCs and platelets make up a narrow cream- or buff-colored zone called the *buffy coat* just above the RBCs; they total 1% or less of the blood volume. At the top of the tube is the plasma, which accounts for about 47% to 63% of the volume.

Table 18.1 lists several properties of the blood. Some of the terms in that table are defined later in the chapter.

Think About It

Based on your body weight, estimate the volume (in liters) and weight (in kilograms) of your own blood, using the data in table 18.1.

Blood Plasma

Even though blood plasma has no anatomy that we can study visually, we cannot ignore its importance as the matrix of this liquid connective tissue we call blood. Plasma is a complex mixture of water, proteins, nutrients, electrolytes, nitrogenous

³erythro = red + cyte = cell

⁴leuko = white + cyte = cell

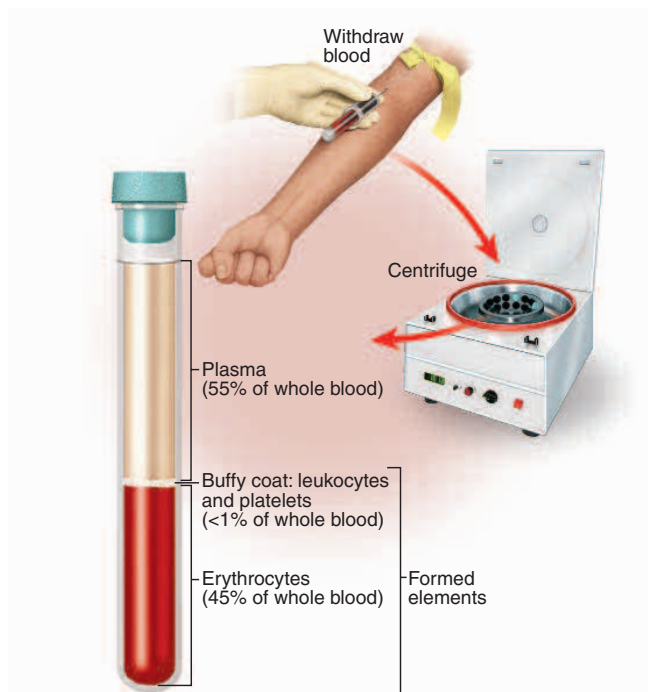

FIGURE 18.2 The Components of Blood. Centrifuging a sample of blood separates the erythrocytes from the white cells and platelets (buffy coat) and plasma. The hematocrit is the percentage of the volume composed of erythrocytes.

TABLE 18.1		General Properties of Blood
Characteristic	Typical Values for Healthy Adults*	
Mean fraction of body weight	8%	
Volume in adult body	Female: 4–5 L; male: 5–6 L	
Volume/body weight	80–85 mL/kg	
Mean temperature	38°C (100.4°F)	
pH	7.35–7.45	
Viscosity (relative to water)	Whole blood: 4.5–5.5; plasma: 2.0	
Osmolarity	280–296 mOsm/L	
Mean salinity (mainly NaCl)	0.9%	
Hematocrit (packed cell volume)	Female: 37% to 48% Male: 45% to 52%	
Hemoglobin	Female: 12–16 g/dL Male: 13–18 g/dL	
Mean RBC count	Female: 4.2–5.4 million/ μ L Male: 4.6–6.2 million/ μ L	
Platelet count	130,000–360,000/ μ L	
Total WBC count	5,000–10,000/ μ L	

*Values vary slightly depending on the testing methods used.

wastes, hormones, and gases (table 18.2). When the blood clots and the solids are removed, the remaining fluid is the blood **serum**. Serum is essentially identical to plasma except for the absence of the clotting protein fibrinogen.

Protein is the most abundant plasma solute by weight, totaling 6 to 9 g/dL. Plasma proteins play a variety of roles including clotting, defense, and transport of other solutes such as iron, copper, lipids, and hydrophobic hormones. There are three major categories of plasma proteins: the albumins, globulins, and fibrinogen (table 18.3). Many other plasma proteins are indispensable to survival, but they account for less than 1% of the total.

Albumin is the smallest and most abundant plasma protein. It serves to transport various solutes and buffer the pH of the plasma. It also makes a major contribution to two physical properties of blood: its *viscosity* and *osmolarity*, discussed shortly. Through its effects on these two variables, changes in albumin concentration can significantly affect blood volume, pressure, and flow. **Globulins** are divided into three subclasses; from smallest to largest in molecular weight, they are the alpha (α), beta (β), and gamma (γ) globulins. Globulins play various roles in solute transport, clotting, and immunity. **Fibrinogen** is a soluble precursor of *fibrin*, a sticky protein that forms the framework of a blood clot. Some of the other plasma proteins are enzymes involved in the clotting process.

The liver produces as much as 4 g of plasma protein per hour, contributing all of the major proteins except gamma globulins. The gamma globulins come from *plasma cells*—connective tissue cells that are descended from white blood cells called *B lymphocytes*.

Think About It

How could a disease such as liver cancer or hepatitis result in impaired blood clotting?

In addition to protein, the blood plasma contains such nitrogen-containing compounds as free amino acids and nitrogenous wastes. **Nitrogenous wastes** are toxic end products of catabolism. The most abundant is *urea*, a product of amino acid catabolism. These wastes are normally excreted by the kidneys at a rate that balances their production.

The plasma also transports nutrients absorbed by the digestive tract, including glucose, amino acids, fats, cholesterol, phospholipids, vitamins, and minerals. It transports dissolved oxygen, carbon dioxide, and nitrogen (see table 18.2). The dissolved nitrogen normally has no physiological role in the body (but see Insight 22.4, p. 899).

Electrolytes are another important component of the blood plasma. Sodium ions constitute about 90% of the plasma cations. Sodium is more important than any other solute for the osmolarity of the blood. As such, it has a major influence on blood volume and pressure; people with high blood pressure are often advised to limit their sodium intake. Electrolyte concentrations are carefully regulated by the body and have rather stable concentrations in the plasma.

TABLE 18.2		Composition of Blood Plasma
Blood Component*	Typical Values for Healthy Adults	
<i>Water</i>	92% by weight	
<i>Proteins</i>	Total 6–9 g/dL	
Albumin	60% of total protein, 3.2–5.5 g/dL	
Globulins	36% of total protein, 2.3–3.5 g/dL	
Fibrinogen	4% of total protein, 0.2–0.3 g/dL	
<i>Nutrients</i>		
Glucose (dextrose)	70–110 mg/dL	
Amino acids	33–51 mg/dL	
Lactic acid	6–16 mg/dL	
Total lipid	450–850 mg/dL	
Cholesterol	120–220 mg/dL	
Fatty acids	190–420 mg/dL	
High-density lipoprotein (HDL)	30–80 mg/dL	
Low-density lipoprotein (LDL)	62–185 mg/dL	
Triglycerides (neutral fats)	40–150 mg/dL	
Phospholipids	6–12 mg/dL	
Iron	50–150 µg/dL	
Trace elements	Traces	
Vitamins	Traces	
<i>Electrolytes</i>		
Sodium (Na ⁺)	135–145 mEq/L	
Calcium (Ca ²⁺)	9.2–10.4 mEq/L	
Potassium (K ⁺)	3.5–5.0 mEq/L	
Magnesium (Mg ²⁺)	1.3–2.1 mEq/L	
Chloride (Cl ⁻)	100–106 mEq/L	
Bicarbonate (HCO ₃ ⁻)	23.1–26.7 mEq/L	
Phosphate (HPO ₄ ²⁻)	1.4–2.7 mEq/L	
Sulfate (SO ₄ ²⁻)	0.6–1.2 mEq/L	
<i>Nitrogenous wastes</i>		
Urea	10–20 mg/dL	
Uric acid	1.5–8.0 mg/dL	
Creatinine	0.6–1.5 mg/dL	
Creatine	0.2–0.8 mg/dL	
Ammonia	0.02–0.09 mg/dL	
Bilirubin	0–1.0 mg/dL

Blood Viscosity and Osmolarity

Two important properties of blood—viscosity and osmolarity—arise from the formed elements and plasma composition. **Viscosity** is the resistance of a fluid to flow, resulting from the cohesion of its particles. Loosely speaking, it is the thickness or stickiness of a fluid. At a given temperature, mineral oil is more viscous than water, for example, and honey is more viscous than mineral oil. Whole blood is 4.5 to 5.5 times as viscous as water, mainly because of the RBCs; plasma alone is 2.0 times as viscous as water, mainly because of its protein. Viscosity is important in circulatory function because it partially governs the flow of blood through the vessels. An RBC or protein deficiency reduces viscosity and causes blood to flow too easily, whereas an excess causes blood to flow too sluggishly. Either of these conditions puts a strain on the heart that may lead to serious cardiovascular problems if not corrected.

The **osmolarity** of blood (total molarity of those dissolved particles that cannot pass through the blood vessel wall) is another important factor in cardiovascular function. In order to nourish surrounding cells and remove their wastes, substances must pass between the bloodstream and tissue fluid through the capillary walls. This transfer of fluids depends on a balance between the filtration of fluid from the capillary and its reabsorption by osmosis (see fig. 3.15, p. 102). The rate of reabsorption is governed by the relative osmolarity of the blood versus the tissue fluid. If the osmolarity of the blood is too high, the

bloodstream absorbs too much water. This raises the blood volume, resulting in elevated blood pressure and a potentially dangerous strain on the heart and arteries. If its osmolarity drops too low, too much water remains in the tissues. They become edematous (swollen) and the blood pressure may drop to dangerously low levels because of the amount of water lost from the bloodstream.

It is therefore important that the blood maintain an optimal osmolarity. The osmolarity of the blood is a product mainly of its sodium ions, protein, and erythrocytes. The contribution of protein to blood osmotic pressure—called the **colloid osmotic pressure (COP)**—is especially important, as we see from the effects of extremely low-protein diets (see Insight 18.1).

How Blood Is Produced

We lose blood continually, not only from bleeding but also as blood cells grow old and die and plasma components are consumed or excreted from the body. Therefore, we must continually replace it. An adult typically produces 400 billion platelets, 200 billion RBCs, and 10 billion WBCs every day. The production of blood, especially its formed elements, is called **hemopoiesis**⁵ (HE-mo-poy-EE-sis). A knowledge of this process provides an indispensable foundation for understanding leukemia, anemia, and other blood disorders.

The tissues that produce blood cells are called **hemopoietic tissues**. The first hemopoietic tissues of the human embryo form in the *yolk sac*, a membrane associated with all vertebrate embryos. In most vertebrates (fish, amphibians, reptiles, and birds), this sac encloses the egg yolk, transfers its nutrients to the growing embryo, and produces the fore-runners of the first blood cells. Even animals that don't lay eggs, however, have a yolk sac that retains its hemopoietic function. (It is also the source of cells that later produce eggs and sperm.) Cell clusters called *blood islands* form here by the third week of human development. They produce primitive *stem cells* that migrate into the embryo proper and colonize the bone marrow, liver, spleen, and thymus. Here, the stem cells multiply and give rise to blood cells throughout fetal development. The liver stops producing blood cells around the time of birth. The spleen stops producing RBCs soon after, but it continues to produce lymphocytes for life.

From infancy onward, the red bone marrow produces all seven kinds of formed elements, while lymphocytes are produced not only there but also in the lymphatic tissues and organs—especially the thymus, tonsils, lymph nodes, spleen, and patches of lymphatic tissue in the mucous membranes. Blood formation in the bone marrow and lymphatic organs is called, respectively, **myeloid**⁶ and **lymphoid hemopoiesis**.

All formed elements trace their origins to a common type of bone marrow stem cell, the **pluripotent**⁷ **stem cell**

⁵hemo = blood + poiesis = formation

⁶myel = bone marrow

⁷pluri = many, multiple + potent = able

INSIGHT 18.1 Clinical Application

Starvation and Plasma Protein Deficiency

Several conditions can lead to *hypoproteinemia*, a deficiency of plasma protein: extreme starvation or dietary protein deficiency, liver diseases that interfere with protein synthesis, kidney diseases that result in protein loss through the urine, and severe burns that result in protein loss through the body surface. As the protein content of the blood plasma drops, so does its osmolarity. The bloodstream loses more fluid to the tissues than it reabsorbs by osmosis. Thus, the tissues become edematous and a pool of fluid may accumulate in the abdominal cavity—a condition called *ascites* (ah-SY-teez).

Children who suffer severe dietary protein deficiencies often exhibit a condition called *kwashiorkor* (KWASH-ee-OR-cor) (fig. 18.3). The arms and legs are emaciated for lack of muscle, the skin is shiny and tight with edema, and the abdomen is swollen by ascites. *Kwashiorkor* is an African word for a “deposed” or “displaced” child who is no longer breast-fed. Symptoms appear when a child is weaned and placed on a diet consisting mainly of rice or other cereals. Children with kwashiorkor often die of diarrhea and dehydration.

FIGURE 18.3 Children of Angola with Kwashiorkor. Note the thin limbs and fluid-distended abdomens.

(**PPSC**) (or **hemopoietic stem cell**; formerly called a *hemocytoblast*⁸). PPSCs are so named because they have the potential to develop into multiple mature cell types. They multiply at a relatively slow rate and thus maintain only a small population in the bone marrow. Some of them go on to differentiate into a variety of more specialized cells called **colony-forming units (CFUs)**, each type destined to produce one or another class of formed elements. The specific processes leading from a PPSC to RBCs, WBCs, and platelets are described at later points in this chapter.

Blood plasma also requires continual replacement. It is composed mainly of water, which it obtains primarily

⁸hemo = blood + cyto = cell + blast = precursor

by absorption from the digestive tract. Its electrolytes and organic nutrients are also acquired there, and its gamma globulins come from connective tissue plasma cells and its other proteins from the liver.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Identify at least two each of the transport, protective, and regulatory functions of the circulatory system.
2. What are the two principal components of the blood?
3. List the three major classes of plasma proteins. Which one is absent from blood serum?
4. Define the viscosity and osmolarity of blood. Explain why each of these is important for human survival.
5. What does hemopoiesis mean? After birth, what one cell type is the starting point for all hemopoiesis?

18.2 Erythrocytes

Objectives

When you have completed this section, you should be able to

- discuss the structure and function of erythrocytes (RBCs);
- describe the structure and function of hemoglobin;
- state and define some clinical measurements of RBC and hemoglobin quantities;
- describe the life cycle of erythrocytes; and
- name and describe the types, causes, and effects of RBC excesses and deficiencies.

Erythrocytes, or red blood cells (RBCs), have two principal functions: (1) to pick up oxygen from the lungs and deliver it to tissues elsewhere, and (2) to pick up carbon dioxide from the tissues and unload it in the lungs. RBCs are the most abundant formed elements of the blood and therefore the most obvious things one sees upon its microscopic examination. They are also the most critical to survival; although a severe deficiency of leukocytes or platelets can be fatal within a few days, a severe deficiency of erythrocytes can be fatal within a few minutes. It is the lack of life-giving oxygen, carried by erythrocytes, that leads rapidly to death in cases of major trauma or hemorrhage.

Form and Function

An erythrocyte is a discoidal cell with a thick rim and a thin sunken center. It is about $7.5\ \mu\text{m}$ in diameter and $2.0\ \mu\text{m}$ thick at the rim (fig. 18.4). Although most cells,

FIGURE 18.4 The Structure of Erythrocytes. (a) Dimensions and shape of an erythrocyte. (b) Erythrocytes on the tip of a hypodermic needle (SEM). (c) Erythrocytes in a blood capillary (TEM). Note the absence of organelles or other internal features in the cells.

• Why are erythrocytes caved in at the center?

including white blood cells, have an abundance of organelles, RBCs lose nearly all organelles during their development and are thus remarkably devoid of internal structure. When viewed with the transmission electron microscope, the interior of an RBC appears uniformly gray. Lacking mitochondria, RBCs rely exclusively on anaerobic fermentation to produce ATP. The lack of aerobic respiration prevents them from consuming the oxygen that they must transport to other tissues. Erythrocytes are the only cells in the body that carry on anaerobic fermentation indefinitely. Lacking a nucleus and DNA, RBCs also are incapable of protein synthesis and mitosis.

The plasma membrane of a mature RBC has glycoproteins and glycolipids on the outer surface that determine a person's blood type. On its inner surface are two cytoskeletal proteins, *spectrin* and *actin*, that give the membrane resilience and durability. This is especially important when RBCs pass through small blood capillaries and sinusoids. Many of these passages are narrower than the diameter of an RBC, forcing the RBCs to stretch, bend, and fold as they squeeze through. When they enter larger vessels, RBCs spring back to their discoid shape like an air-filled inner tube.

The cytoplasm of an RBC consists mainly of a 33% solution of **hemoglobin** (about 280 million molecules per cell). This is the red pigment that gives an RBC its color and name. It is known especially for its oxygen-transport function, but it also aids in the transport of carbon dioxide and the buffering of blood pH. Although the lack of a nucleus makes an RBC unable to repair itself, it has an overriding advantage: The biconcave shape gives the cell a much greater ratio of surface area to volume, which enables O_2 and CO_2 to diffuse quickly to and from the hemoglobin.

The cytoplasm also contains an enzyme, *carbonic anhydrase (CAH)*, that catalyzes the reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$. The role of CAH in gas transport and pH balance is discussed in chapters 22 and 24.

Hemoglobin

Hemoglobin consists of four protein chains called **globins** (fig. 18.5). Two of these, the *alpha* (α) chains, are 141 amino acids long, and the other two, the *beta* (β) chains, are 146 amino acids long. Each chain is conjugated with a nonprotein moiety called the **heme** group, which binds oxygen to a ferrous ion (Fe^{2+}) at its center. Each heme can carry one molecule of O_2 ; thus, the hemoglobin molecule as a whole can transport up to 4 O_2 . About 5% of the CO_2 in the bloodstream is also transported by hemoglobin but is bound to the globin moiety rather than to the heme. Gas transport by hemoglobin is discussed in detail in chapter 22.

Hemoglobin exists in several forms with slight differences in the globin chains. The form just described is called *adult hemoglobin (HbA)*. About 2.5% of an adult's hemoglobin, however, is of a form called HbA_2 , which has two *delta* (δ) chains in place of the beta chains. The fetus produces a form called *fetal hemoglobin (HbF)*, which has

FIGURE 18.5 The Structure of Hemoglobin. (a) The hemoglobin molecule consists of two alpha proteins and two beta proteins, each conjugated to a nonprotein heme group. (b) Structure of the heme group. Oxygen binds to Fe^{2+} at the center of the heme.

◀ In what way does this exemplify a quaternary protein structure? What is the prosthetic group of hemoglobin?

two *gamma* (γ) chains in place of the beta chains. The delta and gamma chains are the same length as the beta chains but differ in amino acid sequence. HbF binds oxygen more tightly than HbA does; thus, it enables the fetus to extract oxygen from the mother's bloodstream.

Quantities of Erythrocytes and Hemoglobin

The RBC count and hemoglobin concentration are important clinical data because they determine the amount of oxygen the blood can carry. Three of the most common measurements are hematocrit, hemoglobin concentration, and RBC count. The **hematocrit**⁹ (**packed cell volume, PCV**) is the percentage of whole blood volume composed of RBCs (see fig. 18.2). In men, it normally ranges between 42% and 52%; in women, between 37% and 48%. The **hemoglobin concentration** of whole blood is normally

⁹hemato = blood + crit = to separate

INSIGHT 18.2 Evolutionary Medicine

The Packaging of Hemoglobin

The gas-transport pigments of earthworms, snails, and many other animals are dissolved in the plasma rather than contained in blood cells. You might wonder why human hemoglobin must be contained in RBCs. The main reason is osmotic. Remember that the osmolarity of blood depends on the number of particles in solution. A “particle,” for this purpose, can be a sodium ion, an albumin molecule, or a whole cell. If all the hemoglobin contained in the RBCs were free in the plasma, it would drastically increase blood osmolarity, since each RBC contains about 280 million molecules of hemoglobin. The circulatory system would become enormously congested with fluid, and circulation would be severely impaired. The blood simply could not contain that much free hemoglobin and support life. On the other hand, if it contained a safe level of free hemoglobin, it could not transport enough oxygen to support the high metabolic demand of the human body. By having our hemoglobin packaged in RBCs, we are able to have much more of it and hence to have more efficient gas transport and more active metabolism.

Another reason for packaging the hemoglobin in RBCs is that some of the body’s capillaries (*fenestrated capillaries* found in the kidneys and endocrine glands, for example) are permeable to proteins. Hemoglobin would leak out into the tissues if it were not contained in cells too big to pass through the capillary wall. Hemoglobin liberated by the rapid breakdown of RBCs can plug the kidney tubules and cause renal failure.

13 to 18 g/dL in men and 12 to 16 g/dL in women. The RBC count is normally 4.6 to 6.2 million RBCs/ μ L in men and 4.2 to 5.4 million/ μ L in women. This is often expressed as cells per cubic millimeter (mm^3); 1 μ L = 1 mm^3 .

Notice that these values tend to be lower in women than in men. There are three physiological reasons for this: (1) androgens stimulate RBC production, and men have higher androgen levels than women; (2) women of reproductive age have periodic menstrual losses; and (3) the hematocrit is inversely proportional to percentage body fat, which is higher in women than in men. In men, the blood also clots faster and the skin has fewer

blood vessels than in women. Such differences are not limited to humans. From the evolutionary standpoint, the adaptive value of these differences may lie in the fact that male animals fight more than females and suffer more injuries. The traits described here may serve to minimize or compensate for their blood loss.

Think About It

Explain why the hemoglobin concentration could appear deceptively high in a patient who is dehydrated.

The Erythrocyte Life Cycle

An erythrocyte lives for an average of 120 days from the time it is produced in the red bone marrow until it dies and breaks up. In a state of balance and stable RBC count, the birth and death of RBCs amount to about 2.5 million cells per second, or a packed cell volume of 20 mL of RBCs per day.

Erythrocyte Production

Erythrocyte production is called **erythropoiesis** (eh-RITH-ro-poy-EE-sis). The process normally takes 3 to 5 days and involves four major developments: a reduction in cell size, an increase in cell number, the synthesis of hemoglobin, and the loss of the nucleus and most other organelles. It begins when a pluripotent stem cell (PPSC) becomes an *erythrocyte colony-forming unit (ECFU)* (fig. 18.6), which has receptors for the hormone **erythropoietin (EPO)**. EPO stimulates the ECFU to transform into an *erythroblast* (*normoblast*). Erythroblasts multiply and synthesize hemoglobin. When this task is completed, the nucleus shrivels and is discharged from the cell. The cell is now called a *reticulocyte*, named for a temporary network (reticulum) composed of ribosome clusters (polyribosomes).

Reticulocytes leave the bone marrow and enter the circulating blood. In a day or two, the last of the polyribosomes disintegrate and disappear, and the cell is a mature erythrocyte. Normally, about 0.5% to 1.5% of the circulating RBCs are reticulocytes, but this percentage rises under certain circumstances. Blood loss, for

FIGURE 18.6 Erythropoiesis. Stages in the development of a red blood cell.

example, stimulates accelerated erythropoiesis and leads to an increasing number of reticulocytes in circulation—as if the bone marrow is in such a hurry to replenish the lost RBCs that it releases many developing RBCs into circulation a little early.

Iron Metabolism

Iron is a critical part of the hemoglobin molecule and therefore one of the key nutritional requirements for erythropoiesis. Men lose about 0.9 mg of iron per day through the urine, feces, and bleeding, and women of reproductive age lose an average of 1.7 mg/day through these routes and the added factor of menstruation. Since we absorb only a fraction of the iron in our food, we must consume 5 to 20 mg/day to replace our losses. A pregnant woman needs 20 to 48 mg/day, especially in the last 3 months, to meet not only her own need but also that of the fetus.

Dietary iron exists in two forms: ferric (Fe^{3+}) and ferrous (Fe^{2+}) ions. Stomach acid converts most Fe^{3+} to Fe^{2+} , the only form that can be absorbed by the small intestine (fig. 18.7). A protein called **gastroferritin**,¹⁰ produced by the stomach, then binds Fe^{2+} and transports it to the small intestine. Here, it is absorbed into the blood, binds to a plasma protein called **transferrin**, and travels to the bone marrow, liver, and other tissues. Bone marrow uses Fe^{2+} for hemoglobin synthesis; muscle uses it to make the oxygen-storage protein myoglobin; and nearly all cells use iron to make electron-transport molecules called cytochromes in their mitochondria. The liver binds surplus iron to a protein called **apoferritin**,¹¹ forming an

iron-storage complex called **ferritin**. It releases Fe^{2+} into circulation when needed.

Some other nutritional requirements for erythropoiesis are vitamin B_{12} and folic acid, required for the rapid cell division and DNA synthesis that occurs in erythropoiesis, and vitamin C and copper, which are cofactors for some of the enzymes that synthesize hemoglobin. Copper is transported in the blood by an alpha globulin called **ceruloplasmin**.¹²

Erythrocyte Homeostasis

The RBC count is maintained in a classic negative feedback manner (fig. 18.8). If the count should drop (for example, because of hemorrhaging), it may result in a state of **hypoxemia**¹³ (oxygen deficiency in the blood). The kidneys detect this and increase their EPO output. Three or four days later, the RBC count begins to rise and reverses the hypoxemia that started the process.

Hypoxemia has many causes other than blood loss. Another cause is a low level of oxygen in the atmosphere. If you were to move from Miami to Denver, for example, the lower O_2 level at the high altitude of Denver would produce temporary hypoxemia and stimulate EPO secretion and erythropoiesis. The blood of an average adult has about 5 million RBCs/ μL , but people who live at high altitudes may have counts of 7 to 8 million RBCs/ μL . Another cause of hypoxemia is an abrupt increase in the body's oxygen consumption. If a lethargic person suddenly takes up tennis or aerobics, for example, the muscles consume oxygen more rapidly and create a state of

¹⁰*gastro* = stomach + *ferrit* = iron + *in* = protein

¹¹*apo* = separated from + *ferrit* = iron + *in* = protein

FIGURE 18.7 Iron Metabolism.

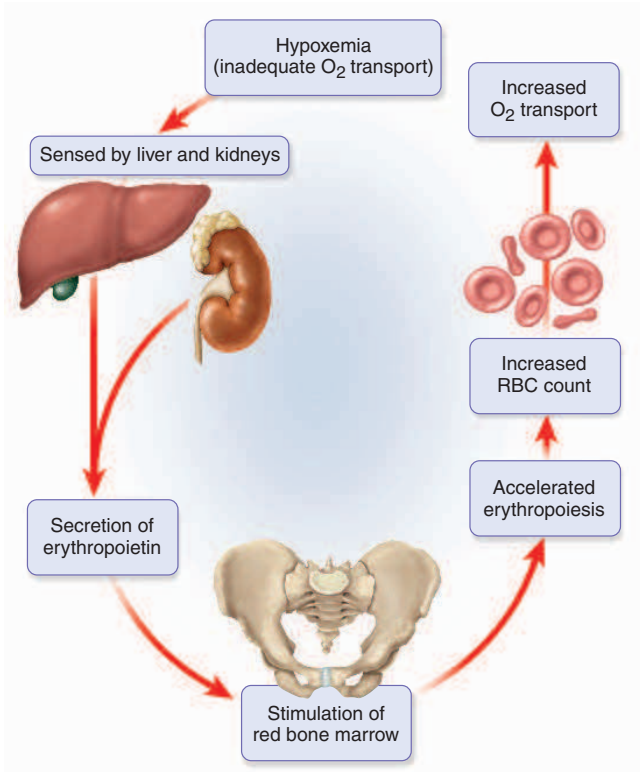

FIGURE 18.8 Correction of Hypoxemia by a Negative Feedback Loop.

hypoxemia that stimulates erythropoiesis. Endurance-trained athletes commonly have RBC counts as high as 6.5 million RBCs/ μ L.

Not all hypoxemia can be corrected by increasing erythropoiesis. In emphysema, for example, less lung tissue is available to oxygenate the blood. Raising the RBC count cannot correct this, but the kidneys and bone marrow have no way of knowing this. The RBC count continues to rise in a futile attempt to restore homeostasis, resulting in a dangerous excess called *polycythemia*, discussed shortly.

Erythrocyte Death and Disposal

The life of an RBC is summarized in figure 18.9. As an RBC ages and its membrane proteins (especially spectrin) deteriorate, the membrane grows increasingly fragile. Without a nucleus or ribosomes, an RBC cannot synthesize new spectrin. Many RBCs die in the spleen, which has been called the “erythrocyte graveyard.” The spleen has channels as narrow as 3 μ m that severely test the ability of old, fragile RBCs to squeeze through the organ. Old cells become trapped, broken up, and destroyed. An enlarged and tender spleen may indicate diseases in which RBCs are rapidly breaking down.

Hemolysis¹⁴ (he-MOLL-ih-sis), the rupture of RBCs, releases hemoglobin and leaves empty plasma membranes.

FIGURE 18.9 The Life and Death of Erythrocytes. Note especially the stages of hemoglobin breakdown and disposal.

The membrane fragments are easily digested by macrophages in the liver and spleen, but hemoglobin disposal is a bit more complicated. It must be disposed of efficiently, however, or it can block kidney tubules and cause renal failure. Macrophages begin the disposal process by separating the heme from the globin. They hydrolyze the globin into free amino acids, which become part of the body’s general pool of amino acids available for protein synthesis or energy-releasing catabolism.

Disposing of the heme is another matter. First, the macrophage removes the iron and releases it into the blood, where it combines with transferrin and is used or stored in the same way as dietary iron. The macrophage converts the rest of the heme into a greenish pigment called **biliverdin**¹⁵ (BIL-ih-VUR-din), then further converts most of this to a yellow-green pigment called **bilirubin**.¹⁶ Bilirubin is released by the macrophages and binds to albumin in the blood plasma. The liver removes it from the

¹⁴hemo = blood + lysis = splitting, breakdown

¹⁵bili = bile + verd = green + in = substance

¹⁶bili = bile + rub = red + in = substance

albumin and secretes it into the bile, to which it imparts a dark green color as the bile becomes concentrated in the gallbladder. Biliverdin and bilirubin are collectively known as **bile pigments**. The gallbladder discharges the bile into the small intestine, where bacteria convert bilirubin to *urobilinogen*, responsible for the brown color of the feces. Another hemoglobin breakdown pigment, *urochrome*, produces the yellow color of urine. A high level of bilirubin in the blood causes *jaundice*, a yellowish cast in light-colored skin and the whites of eyes. Jaundice may be a sign of rapid hemolysis or a liver disease or bile duct obstruction that interferes with bilirubin disposal.

Erythrocyte Disorders

Any imbalance between the rates of erythropoiesis and RBC destruction may produce an excess or deficiency of red cells. An RBC excess is called *polycythemia*¹⁷ (POL-ee-sy-THÉE-me-uh), and a deficiency of either RBCs or hemoglobin is called *anemia*.¹⁸

Polycythemia

Primary polycythemia (polycythemia vera) is due to cancer of the erythropoietic line of the red bone marrow. It can result in an RBC count as high as 11 million RBCs/ μ L and a hematocrit as high as 80%. Polycythemia from all other causes, called **secondary polycythemia**, is characterized by RBC counts as high as 6 to 8 million RBCs/ μ L. It can result from dehydration because water is lost from the bloodstream while erythrocytes remain and become abnormally concentrated. More often, it is caused by smoking, air pollution, emphysema, high altitude, excessive aerobic exercise, or other factors that create a state of hypoxemia and stimulate erythropoietin secretion.

The principal dangers of polycythemia are increased blood volume, pressure, and viscosity. Blood volume can double in primary polycythemia and cause the circulatory system to become tremendously engorged. Blood viscosity may rise to three times normal. Circulation is poor, the capillaries are clogged with viscous blood, and the heart is dangerously strained. Chronic (long-term) polycythemia can lead to embolism, stroke, or heart failure. The deadly consequences of emphysema and some other lung diseases are due in part to polycythemia.

TABLE 18.4

Causes of Anemia

Categories of Anemia	Causes or Examples
Inadequate erythropoiesis	
Iron-deficiency anemia	Dietary iron deficiency
Other nutritional anemias	Dietary folic acid, vitamin B ₁₂ , or vitamin C deficiency
Anemia due to renal insufficiency	Deficiency of EPO secretion
Pernicious anemia	Deficiency of intrinsic factor leading to inadequate vitamin B ₁₂ absorption
Hypoplastic and aplastic anemia	Destruction of myeloid tissue by radiation, viruses, some drugs and poisons (arsenic, benzene, mustard gas), or autoimmune disease
Anemia of old age	Declining erythropoiesis due to nutritional deficiencies, reduced physical activity, gastric atrophy (reduced intrinsic factor secretion), or renal atrophy (depressed EPO secretion)
Blood loss (hemorrhagic anemia)	Trauma, hemophilia, menstruation, ulcer, ruptured aneurysm, etc.
RBC destruction (hemolytic anemia)	
Drug reactions	Penicillin allergy
Poisoning	Mushroom toxins, snake and spider venoms
Parasitic infection	RBC destruction by malaria parasites
Hereditary hemoglobin defects	Sickle cell disease, thalassemia
Blood type incompatibilities	Hemolytic disease of the newborn, transfusion reactions

Anemia

The causes of **anemia** fall into three categories: (1) inadequate erythropoiesis or hemoglobin synthesis, (2) **hemorrhagic anemia** from bleeding, and (3) **hemolytic anemia** from RBC destruction. Table 18.4 gives specific examples and causes for each category. We give special attention to the deficiencies of erythropoiesis and some forms of hemolytic anemia.

Anemia often results from kidney failure, because RBC production depends on erythropoietin, which is produced mainly by the kidneys. Erythropoiesis also declines with age, simply because the kidneys atrophy and produce less and less EPO as we get older. Compounding this problem, elderly people tend to get less exercise and eat less well, and both of these factors reduce erythropoiesis.

Nutritional anemia results from a dietary deficiency of any of the requirements for erythropoiesis discussed earlier. Its most common form is **iron-deficiency anemia**, characterized by small pale erythrocytes. Iron-deficiency anemia is usually caused by blood loss without sufficiently compensatory iron ingestion. A deficiency of vitamin B₁₂ can cause **pernicious anemia**, but B₁₂ is so abundant in meat that a deficiency is rare except in strict vegetarians. More often, it occurs when glands of the stomach fail to produce a substance called **intrinsic factor**

¹⁷poly = many + cyt = cell + hem = blood + ia = condition

¹⁸an = without + em = blood + ia = condition

that the small intestine needs to absorb vitamin B₁₂. This becomes more common in old age because of atrophy of the stomach. Pernicious anemia can also be hereditary. It is treatable with vitamin B₁₂ injections; oral B₁₂ would be useless because the digestive tract cannot absorb it without intrinsic factor.

Hypoplastic¹⁹ anemia is caused by a decline in erythropoiesis, whereas the complete failure or destruction of the myeloid tissue produces **aplastic anemia**, a complete cessation of erythropoiesis. Aplastic anemia leads to grotesque tissue necrosis and blackening of the skin. Barring successful treatment, most victims die within a year. About half of all cases are of unknown or hereditary cause, especially in adolescents and young adults. Other causes are given in table 18.4.

Anemia has three potential consequences:

1. The tissues suffer **hypoxia** (oxygen deprivation). The individual is lethargic and becomes short of breath upon physical exertion. The skin is pallid because of the deficiency of hemoglobin. Severe anemic hypoxia can cause life-threatening necrosis of brain, heart, and kidney tissues.
2. Blood osmolarity is reduced. More fluid thus transfers from the bloodstream to the intercellular spaces, resulting in edema.
3. Blood viscosity is reduced. Because the blood puts up so little resistance to flow, the heart beats faster than normal and cardiac failure may ensue. Blood pressure also drops because of the reduced volume and viscosity.

Sickle-Cell Disease

Sickle-cell disease and thalassemia (see table 18.8) are hereditary hemoglobin defects that occur mostly among people of African and Mediterranean descent, respectively. **Sickle-cell disease** afflicts about 1.3% of people of African American descent. It is caused by a recessive allele that modifies the structure of hemoglobin. Sickle-cell hemoglobin (HbS) differs from normal HbA only in the sixth amino acid of the beta chain, where HbA has glutamic acid and HbS has valine. People who are homozygous for HbS exhibit sickle-cell disease. People who are heterozygous for it—about 8.3% of African Americans—have *sickle-cell trait* but rarely have severe symptoms. However, if two carriers reproduce, their children each have a 25% chance of being homozygous and having the disease.

HbS does not bind oxygen very well. At low oxygen concentrations, it becomes deoxygenated, polymerizes, and forms a gel that causes the erythrocytes to become elongated and pointed at the ends (fig. 18.10), hence the name of the disease. Sickled erythrocytes are sticky; they

agglutinate²⁰ (clump together) and block small blood vessels, causing intense pain in oxygen-starved tissues. Blockage of the circulation can also lead to kidney or heart failure, stroke, rheumatism, or paralysis. Hemolysis of the fragile cells causes anemia and hypoxemia, which triggers further sickling in a deadly positive feedback loop. Chronic hypoxemia also causes fatigue, weakness, mental deficiency, and deterioration of the heart and other organs. In a futile effort to counteract the hypoxemia, the hemopoietic tissues become so active that bones of the cranium and elsewhere become enlarged and misshapen. The spleen reverts to a hemopoietic role, while also disposing of dead RBCs, and becomes enlarged and fibrous. Sickle-cell disease is a prime example of *pleiotropy*—the occurrence of multiple phenotypic effects from a change in a single gene (see p. 145).

Without treatment, a child with sickle-cell disease has little chance of living to age 2. Advances in treatment, however, have steadily raised life expectancy to a little beyond age 50.

Why does sickle-cell disease exist? In Africa, where it originated, vast numbers of people die of malaria. Malaria is caused by a parasite that invades the RBCs and feeds on hemoglobin. Sickle-cell hemoglobin is detrimental to the parasites, and people heterozygous for sickle-cell disease are resistant to malaria. The lives saved by this gene far outnumber the deaths of homozygous individuals, so the gene persists in the population.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe the size, shape, and contents of an erythrocyte, and explain how it acquires its unusual shape.
- What is the function of hemoglobin? What are its protein and nonprotein moieties called?
- Define hematocrit, hemoglobin concentration, and RBC count, and give the units of measurement in which each is expressed.
- List the stages in the production of an RBC and describe how each stage differs from the previous one.
- What is the role of erythropoietin in the regulation of RBC count? What is the role of gastroferritin?
- What happens to each component of an RBC and its hemoglobin when it dies and disintegrates?
- What are the three primary causes or categories of anemia? What are its three primary consequences?

18.3 Blood Types

Objectives

When you have completed this section, you should be able to

- explain what determines a person's ABO and Rh blood types and how this relates to transfusion compatibility;
- describe the effect of an incompatibility between mother and fetus in Rh blood type; and
- list some blood groups other than ABO and Rh and explain how they may be useful.

Blood types and transfusion compatibility are a matter of interactions between plasma proteins and erythrocytes. Ancient Greek physicians attempted to transfuse blood from one person to another by squeezing it from a pig's bladder through a porcupine quill into the recipient's vein. Although some patients benefited from the procedure, it was fatal to others. The reason some people have compatible blood and some don't remained obscure until 1900, when Karl Landsteiner discovered blood types A, B, and O—a discovery that won him a Nobel Prize in 1930; type AB was discovered later. World War II stimulated great improvements in transfusions, blood banking, and blood substitutes (see Insight 18.3).

Blood types are based on interactions between large molecules called *antigens* and *antibodies*. Explained more fully in chapter 21, these will be introduced only briefly here. **Antigens** are complex molecules such as proteins, glycoproteins, and glycolipids that are genetically

unique to each individual (except identical twins). They occur on the surfaces of all cells and enable the body to distinguish its own cells from foreign matter. When the body detects an antigen of foreign origin, it activates an immune response. This response consists partly of the *plasma cells*, mentioned earlier, secreting proteins (gamma globulins) called **antibodies**.

Antibodies bind to antigens and mark them, or the cells bearing them, for destruction. One method of antibody action is **agglutination**, in which each antibody molecule binds to two or more antigen molecules and sticks them together. Repetition of this process produces large **antigen-antibody complexes** that immobilize the antigens until certain immune cells can break them down. Whole cells may become immobilized and clumped together when antibodies bind to their surface antigens.

Blood types are based on antigens called **agglutinogens** (ah-glue-TIN-oh-jens) on the surfaces of the RBCs, and antibodies called **agglutinins** (ah-GLUE-tih-nins) in the blood plasma. These names refer to the fact that they interact to agglutinate RBCs in the event of a mismatched transfusion.

The ABO Group

Blood types A, B, AB, and O form the **ABO blood group** (table 18.5). Your ABO blood type is determined by the hereditary presence or absence of antigens A and B on your RBCs. The genetic determination of blood types is explained on page 144. Figure 18.12 shows how the carbohydrate moieties of RBC surface antigens determine the ABO blood types.

Antibodies of the ABO group begin to appear in the plasma 2 to 8 months after birth. They reach their maximum concentrations between 8 and 10 years of age and then slowly decline for the rest of one's life. They are produced mainly in response to bacteria that inhabit the intestines, but they cross-react with RBC antigens and are therefore best known for their significance in transfusions.

Antibodies of the ABO group react against any A or B antigen except those on one's own RBCs. The antibody that reacts against antigen A is called *alpha agglutinin*, or *anti-A*; it is present in the plasma of people with type O or type B blood—that is, anyone who does *not* possess antigen A. The antibody that reacts against antigen B is *beta agglutinin*, or *anti-B*, and is present in type O and type A individuals—those who do not possess antigen B. Each antibody molecule has 10 binding sites where it can attach to either an A or B antigen. An antibody can therefore attach to several RBCs at once and agglutinate them (fig. 18.13).

A person's ABO blood type can be determined by placing one drop of blood in a pool of anti-A serum and another drop in a pool of anti-B serum. Blood type AB exhibits conspicuous agglutination in both antisera; type

INSIGHT 18.3 Medical History

Charles Drew—Blood-Banking Pioneer

Charles Drew (fig. 18.11) was a scientist who lived and died in the grip of irony. After receiving his M.D. from McGill University of Montreal in 1933, Drew became the first black person to pursue the advanced degree of Doctor of Science in Medicine, for which he studied transfusion and blood banking at Columbia University. He became the director of a new blood bank at Columbia Presbyterian Hospital in 1939 and organized numerous blood banks during World War II.

Drew saved countless lives by convincing physicians to use plasma rather than whole blood for battlefield and other emergency transfusions. Whole blood could be stored for only a week and given only to recipients with compatible blood types. Plasma could be stored longer and was less likely to cause transfusion reactions.

When the U.S. War Department issued a directive forbidding the mixing of Caucasian and Negro blood in military blood banks, Drew denounced the order and resigned his position. He became a professor of surgery at Howard University in Washington, D.C., and later chief of staff at Freedmen's Hospital. He was a mentor for numerous young black physicians and campaigned to get them accepted into the medical community. The American Medical Association, however, firmly refused to admit black members, even Drew himself.

Late one night in 1950, Drew and three colleagues set out to volunteer their medical services to an annual free clinic in Tuskegee, Alabama. Drew fell asleep at the wheel and was critically injured in the resulting accident. Doctors at the nearest

hospital administered blood and attempted unsuccessfully to revive him. For all the lives he saved through his pioneering work in blood transfusion, Drew himself bled to death at the age of 45.

FIGURE 18.11 Charles Drew (1904–50).

TABLE 18.5 The ABO Blood Group

Characteristics	ABO Blood Type			
	Type O	Type A	Type B	Type AB
Possible genotypes*	<i>ii</i>	<i>I^A I^A or I^A i</i>	<i>I^B I^B or I^B i</i>	<i>I^A I^B</i>
RBC antigen	None	A	B	A,B
Plasma antibody	Anti-A, anti-B	Anti-B	Anti-A	None
May safely receive RBCs of type	O	O, A	O, B	O, A, B, AB
May safely donate RBCs to	O, A, B, AB	A, AB	B, AB	AB
Frequency in U.S. population				
White	45%	40%	11%	4%
Black	49%	27%	20%	4%
Hispanic	63%	14%	20%	3%
Japanese	31%	38%	22%	9%
Native American	79%	16%	4%	< 1%

**I^A* is the dominant allele for agglutinin A; *I^B* is the dominant allele for agglutinin B; and allele *i* is recessive to both of these.

FIGURE 18.12 Chemical Basis of the ABO Blood Types. The terminal carbohydrates of the antigenic glycolipids are shown. All of them end with galactose and fucose (not to be confused with fructose). In type A, the galactose also has an *N*-acetylgalactosamine added to it; in type B, it has another galactose; and in type AB, both of these chain types are present.

A or B agglutinates only in the corresponding antiserum; and type O does not agglutinate in either one (fig. 18.14).

Type O blood is the most common and AB is the rarest in the United States. Percentages differ from one region of the world to another and among ethnic groups because people tend to marry within their locality and ethnic group and perpetuate statistical variations particular to that group (see table 18.5).

In giving transfusions, it is imperative that the donor's RBCs not agglutinate as they enter the recipient's bloodstream. For example, if type B blood were transfused into a type A recipient, the recipient's anti-B antibodies would immediately agglutinate the donor's RBCs (fig. 18.15). A mismatch causes a **transfusion reaction**—the agglutinated RBCs block small blood vessels, hemolyze, and release their hemoglobin over the next few hours to days. Free hemoglobin can block the kidney tubules and cause death from acute renal failure within a week or so. For this reason, a person with type A (anti-B) blood must never be given a transfusion of type B or AB blood. A person with type B (anti-A) must never receive type A or AB blood. Type O (anti-A and anti-B) individuals cannot safely receive type A, B, or AB blood.

Type AB is sometimes called the *universal recipient* because this blood type lacks both anti-A and anti-B antibodies; thus, it will not agglutinate donor RBCs of any

FIGURE 18.13 Agglutination of RBCs by an Antibody. Anti-A and anti-B have 10 binding sites, located at the 2 tips of each of the 5 Ys, and can therefore bind multiple RBCs to each other.

ABO type. However, this overlooks the fact that the *donor's* plasma can agglutinate the *recipient's* RBCs if it contains anti-A, anti-B, or both. For similar reasons, type O is sometimes called the *universal donor*. The plasma of a type O donor, however, can agglutinate the RBCs of a type A, B, or AB recipient. There are procedures for reducing the risk of a transfusion reaction in certain mismatches, however, such as giving packed RBCs with a minimum of plasma.

Contrary to some people's belief, blood type is not changed by transfusion. It is fixed at conception and remains the same for life.

Think About It

Scientists have recently developed a method of enzymatically splitting *N*-acetylgalactosamine off the glycolipid of type A blood cells (fig. 18.12). What potential benefit do you think they saw as justifying their research effort?

The Rh Group

The **Rh blood group** is named for the rhesus monkey, in which the Rh antigens were discovered in 1940. This group includes numerous RBC antigens, of which the principal types are antigens C, D, and E. Antigen D is by far the most reactive of these, so a person is considered *Rh-positive* (Rh^+) if he or she has the D antigen (genotype DD or Dd) and *Rh-negative* (Rh^-) if it is lacking (genotype dd). The Rh blood type is tested by using an anti-D reagent. The Rh type is usually combined with the ABO type in a single expression such as O^+ for type O, Rh-positive, or AB^- for type AB, Rh-negative. About 85% of white Americans are Rh^+ and 15% are Rh^- . ABO blood type has no influence on Rh type, or vice versa. If the frequency of type O whites in the United States is 45%, and 85% of these are also Rh^- , then the frequency of O^+ individuals is the product of these separate frequencies: $0.45 \times 0.85 = 0.38$, or 38%. Rh frequencies vary among ethnic groups just as ABO frequencies do. About 99% of Asians are Rh^+ , for example.

FIGURE 18.14 ABO Blood Typing. Each row shows the appearance of a drop of blood mixed with anti-A and anti-B antisera. Blood cells become clumped if they possess the antigens for the antiserum (top row left, second row right, third row both) but otherwise remain uniformly mixed. Thus, type A agglutinates only in anti-A; type B agglutinates only in anti-B; type AB agglutinates in both; and type O agglutinates in neither of them. The antisera in the vials at the top are artificially colored to make them more easily distinguishable.

Think About It

Predict what percentage of Japanese Americans have type B⁻ blood.

In contrast to the ABO group, anti-D antibodies are not normally present in the blood. They form only in Rh⁻ individuals who are exposed to Rh⁺ blood. If an Rh⁻ person receives an Rh⁺ transfusion, the recipient produces anti-D. Since anti-D does not appear instantaneously, this presents little danger in the first mismatched transfusion. But if that person should later receive another Rh⁺ transfusion, his or her anti-D could agglutinate the donor's RBCs.

A related condition sometimes occurs when an Rh⁻ woman carries an Rh⁺ fetus. The first pregnancy is likely to be uneventful because the placenta normally prevents maternal and fetal blood from mixing. However, at the time of birth, or if a miscarriage occurs, placental tearing exposes the mother to Rh⁺ fetal blood. She then begins to produce anti-D antibodies (fig. 18.16). If she becomes pregnant again with an Rh⁺ fetus, her anti-D antibodies may pass through the placenta and agglutinate the fetal erythrocytes. Agglutinated RBCs hemolyze, and the baby is born with a severe anemia called **hemolytic disease of the newborn (HDN)**, or **erythroblastosis fetalis**. Not all HDN is due to Rh incompatibility, however. About 2% of cases result from incompatibility of ABO and other blood

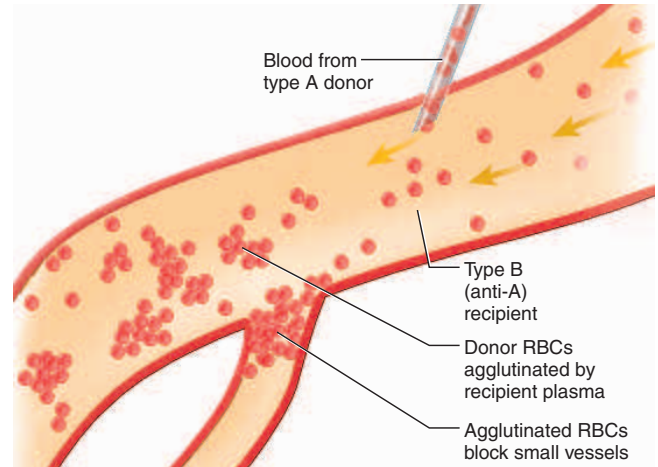

FIGURE 18.15 Effects of a Mismatched Transfusion. Donor RBCs become agglutinated in the recipient's blood plasma. The agglutinated RBCs lodge in smaller blood vessels downstream from this point and cut off the blood flow to vital tissues.

types. About 1 out of 10 cases of ABO incompatibility between mother and fetus results in HDN.

HDN, like so many other disorders, is easier to prevent than to treat. If an Rh⁻ woman gives birth to (or miscarries) an Rh⁺ child, she can be given an *Rh immune globulin* (sold under such trade names as RhoGAM and Gamulin). The immune globulin binds fetal RBC antigens so they cannot stimulate her immune system to produce anti-D. It is now common to give immune globulin at 28 to 32 weeks' gestation and at birth in any pregnancy in which the mother is Rh⁻.

If an Rh⁻ woman has had one or more previous Rh⁺ pregnancies, her subsequent Rh⁺ children have about a 17% probability of being born with HDN. Infants with HDN are usually severely anemic. As the fetal hemopoietic tissues respond to the need for more RBCs, erythroblasts (immature RBCs) enter the circulation prematurely—hence the name *erythroblastosis fetalis*. Hemolyzed RBCs release hemoglobin, which is converted to bilirubin. High bilirubin levels can cause *kernicterus*, a syndrome of toxic brain damage that may kill the infant or leave it with motor, sensory, and mental deficiencies. HDN can be treated with *phototherapy*—exposing the infant to ultraviolet radiation, which degrades bilirubin as blood passes through the capillaries of the skin. In more severe cases, an *exchange transfusion* may be given to completely replace the infant's Rh⁺ blood with Rh⁻. In time, the infant's hemopoietic tissues will replace the donor's RBCs with Rh⁺ cells, and by then the mother's antibody will have disappeared from the infant's blood.

Think About It

A baby with HDN typically has jaundice and an enlarged spleen. Explain these effects.

FIGURE 18.16 Hemolytic Disease of the Newborn (HDN). (a) When an Rh⁻ woman is pregnant with an Rh⁺ fetus, she is exposed to D (Rh) antigens, especially during childbirth. (b) Following that pregnancy, her immune system produces anti-D antibodies. (c) If she later becomes pregnant with another Rh⁺ fetus, her anti-D antibodies can cross the placenta and agglutinate the blood of that fetus, causing that child to be born with HDN.

Other Blood Groups

In addition to the ABO and Rh groups, there are at least 100 other known blood groups with a total of more than 500 antigens, including the MN, Duffy, Kell, Kidd, and Lewis groups. These rarely cause transfusion reactions, but they are useful for such legal purposes as paternity and criminal cases and for research in anthropology and population genetics. Reactions in the Kell, Kidd, and Duffy groups occasionally cause HDN.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

13. What are antibodies and antigens? How do they interact to cause a transfusion reaction?
14. What antibodies and antigens are present in people with each of the four ABO blood types?
15. Describe the cause, prevention, and treatment of HDN.
16. Why might someone be interested in determining a person's blood type other than ABO/Rh?

18.4 Leukocytes

Objectives

When you have completed this section, you should be able to

- explain the function of leukocytes in general and the individual role of each leukocyte type;
- describe the appearance and relative abundance of each type of leukocyte;
- describe the formation and life history of leukocytes; and
- discuss the types, causes, and effects of leukocyte excesses and deficiencies.

Form and Function

Leukocytes, or **white blood cells (WBCs)**, are the least abundant formed elements, totaling only 5,000 to 10,000 WBCs/ μ L. Yet we cannot live long without them, because

they afford protection against infectious microorganisms and other pathogens. WBCs are easily recognized in stained blood films because they have conspicuous nuclei that stain from light violet to dark purple with the most common blood stains. They are much more abundant in the body than their low number in blood films would suggest, because they spend only a few hours in the bloodstream, then migrate through the walls of the capillaries and venules and spend the rest of their lives in the connective tissues. It's as if the bloodstream were merely the subway that the WBCs take to work; in blood films, we see only the ones on their way to work, not the WBCs already at work in the tissues.

Leukocytes differ from erythrocytes in that they retain their organelles throughout life; thus, when viewed with the transmission electron microscope, they show a complex internal structure (fig. 18.17). Among these organelles are the usual instruments of protein synthesis—the nucleus, rough endoplasmic reticulum, ribosomes, and Golgi complex—for leukocytes must synthesize proteins in order to carry out their functions. Some of these proteins are packaged into lysosomes and other organelles, which appear as conspicuous cytoplasmic granules that distinguish one WBC type from another.

Types of Leukocytes

As outlined at the beginning of this chapter, there are five kinds of leukocytes (table 18.6). They are distinguished from each other by their relative size and abundance, the size and shape of their nuclei, the presence or absence of certain cytoplasmic granules, the coarseness and staining properties of those granules, and most importantly by their functions.

All WBCs have lysosomes called **nonspecific (azurophilic²¹) granules** in the cytoplasm, so named because they absorb the blue or violet dyes of blood stains. Three of the five WBC types—neutrophils, eosinophils, and basophils—are called **granulocytes** because they also have various types of **specific granules** that stain conspicuously and distinguish each cell type from the others. These granules contain enzymes and other chemicals employed in defense against pathogens. The two remaining WBC types—monocytes and lymphocytes—are called **agranulocytes** because they lack specific granules. Nonspecific granules are inconspicuous to the light microscope, and these cells therefore have relatively clear-looking cytoplasm.

Granulocytes

- **Neutrophils** (NEW-tro-fills) are the most abundant WBCs—generally about 4,150 cells/ μ L and constituting 60% to 70% of the circulating leukocytes. The nucleus is clearly visible and, in a mature

FIGURE 18.17 The Structure of a Leukocyte (TEM). This example is an eosinophil. The lysosomes seen here are the coarse pink granules seen in the cytoplasm of the eosinophil in table 18.6.

neutrophil, typically consists of three to five lobes connected by slender nuclear strands. These strands are sometimes so delicate that they are scarcely visible, and the neutrophil may seem as if it had multiple nuclei. Young neutrophils have an undivided band-shaped nucleus and are called *band cells* or *stab cells*. Neutrophils are also called *polymorphonuclear leukocytes (PMNs)* because of their varied nuclear shapes.

The cytoplasm contains fine reddish to violet specific granules, which contain lysozyme and other antibiotic agents. Neutrophils are named for the way these granules take up histological stains at pH 7—some stain with acidic dyes and others with basic dyes. The individual granules are barely visible with the light microscope, but their combined effect gives the cytoplasm a pale lilac color.

The neutrophil count rises—a condition called *neutrophilia*—in response to bacterial infections. The primary task is to destroy bacteria, which they achieve in ways detailed in chapter 21.

- **Eosinophils** (EE-oh-SIN-oh-fills) are harder to find in a blood film because they are only 2% to 4% of the WBC total, typically numbering about 170 cells/ μ L. The eosinophil count fluctuates greatly, however, from day to night, seasonally, and with the phase of the menstrual cycle. It rises (*eosinophilia*) in allergies, parasitic infections, collagen diseases, and diseases of the spleen and central nervous system. Although

²¹azuro = blue + philic = loving

TABLE 18.6 The White Blood Cells (Leukocytes)**Neutrophils**

Percentage of WBCs	60% to 70%
Mean count	4,150 cells/ μL
Diameter	9–12 μm

Appearance*

- Nucleus usually with 3–5 lobes in S- or C-shaped array
- Fine reddish to violet granules in cytoplasm

Differential count

- Increases in bacterial infections

Functions

- Phagocytize bacteria
- Release antimicrobial chemicals

**Neutrophils**10 μm **Eosinophils**

Percentage of WBCs	2% to 4%
Mean count	165 cells/ μL
Diameter	10–14 μm

Appearance*

- Nucleus usually has two large lobes connected by thin strand
- Large orange-pink granules in cytoplasm

Differential count

- Fluctuates greatly from day to night, seasonally, and with phase of menstrual cycle
- Increases in parasitic infections, allergies, collagen diseases, and diseases of spleen and central nervous system

Functions

- Phagocytize antigen-antibody complexes, allergens, and inflammatory chemicals
- Release enzymes that weaken or destroy parasites such as worms

**Eosinophil**10 μm **Basophils**

Percentage of WBCs	< 0.5% to 1%
Mean count	44 cells/ μL
Diameter	8–10 μm

Appearance*

- Nucleus large and U- to S-shaped, but typically pale and obscured from view
- Coarse, abundant, dark violet granules in cytoplasm

Differential count

- Relatively stable
- Increases in chickenpox, sinusitis, diabetes mellitus, myxedema, and polycythemia

Functions

- Secrete histamine (a vasodilator), which increases blood flow to a tissue
- Secrete heparin (an anticoagulant), which promotes mobility of other WBCs by preventing clotting

**Basophil**10 μm

TABLE 18.6 The White Blood Cells (Leukocytes) (*cont.*)**Lymphocytes**

Percentage of WBCs	25% to 33%
Mean count	2,185 cells/ μ L
Diameter	
Small class	5–8 μ m
Medium class	10–12 μ m
Large class	14–17 μ m

Appearance*

- Nucleus round, ovoid, or slightly dimpled on one side, of uniform or mottled dark violet color
- In small lymphocytes, nucleus fills nearly all of the cell and leaves only a scanty rim of clear, light blue cytoplasm
- In larger lymphocytes, cytoplasm is more abundant; large lymphocytes may be hard to differentiate from monocytes

Differential count

- Increases in diverse infections and immune responses

Functions

- Several functional classes usually indistinguishable by light microscopy
- Destroy cancer cells, cells infected with viruses, and foreign cells
- “Present” antigens to activate other cells of immune system
- Coordinate actions of other immune cells
- Secrete antibodies
- Serve in immune memory

**Lymphocyte**10 μ m**Monocytes**

Percentage of WBCs	3% to 8%
Mean count	456 cells/ μ L
Diameter	12–15 μ m

Appearance*

- Nucleus ovoid, kidney-shaped, or horseshoe-shaped; violet
- Abundant cytoplasm with sparse, fine granules
- Sometimes very large with stellate or polygonal shapes

Differential count

- Increases in viral infections and inflammation

Functions

- Differentiate into macrophages (large phagocytic cells of the tissues)
- Phagocytize pathogens, dead neutrophils, and debris of dead cells
- “Present” antigens to activate other cells of immune system

**Monocyte**10 μ m

*Appearance pertains to blood films dyed with Wright's stain.

relatively scanty in the blood, eosinophils are abundant in the mucous membranes of the respiratory, digestive, and lower urinary tracts. The eosinophil nucleus usually has two large lobes connected by a thin strand, and the cytoplasm has an abundance of coarse rosy to orange-colored specific granules.

Eosinophils secrete chemicals that weaken or destroy relatively large parasites such as hookworms and tapeworms, too big for any one WBC to phagocytize. They also phagocytize and dispose of inflammatory chemicals, antigen–antibody complexes, and allergens (foreign antigens that trigger allergies).

- **Basophils** are the rarest of the WBCs and, indeed, of all formed elements. They number about 40 cells/ μL and constitute from less than 0.5% to about 1% of the WBC count. They can be recognized mainly by an abundance of very coarse, dark violet specific granules. The nucleus is largely hidden from view by these granules, but is large, pale, and typically S- or U-shaped.

Basophils secrete two chemicals that aid in the body's defense processes: (1) **histamine**, a vasodilator that widens the blood vessels, speeds the flow of blood to an injured tissue, and makes the blood vessels more permeable so that blood components such as neutrophils and clotting proteins can get into the connective tissues more quickly; and (2) **heparin**, an anticoagulant that inhibits blood clotting and thus promotes the mobility of other WBCs in the area. They also release chemical signals that attract eosinophils and neutrophils to a site of infection.

Agranulocytes

- **Lymphocytes** (LIM-fo-sites) are second to neutrophils in abundance and are thus quickly spotted when you examine a blood film. They number about 2,200 cells/ μL and are 25% to 33% of the WBC count. They include the smallest WBCs; at 5 to 17 μm in diameter, they range from smaller than RBCs to two and a half times as large. They are sometimes classified into three size classes (table 18.6), but there are gradations between them. Medium and large lymphocytes are usually seen in fibrous connective tissues and only occasionally in the circulating blood (see fig. 18.1). The lymphocytes seen in blood films are mostly in the small size class. The lymphocyte nucleus is round, ovoid, or slightly dimpled on one side, and usually stains dark violet. In small lymphocytes, it fills nearly the entire cell and leaves only a narrow rim of light blue cytoplasm, often barely detectable, around the cell perimeter. The cytoplasm is more abundant in medium and large lymphocytes.

Small lymphocytes are sometimes difficult to distinguish from basophils, but most basophils are conspicuously grainy, whereas the lymphocyte nucleus is uniform or merely mottled. Basophils also lack the rim of clear cytoplasm seen in most lymphocytes. Large lymphocytes are sometimes difficult to distinguish from monocytes.

There are several subclasses of lymphocytes with different immune functions (see chapter 21), but they look alike through the light microscope.

- **Monocytes** (MON-oh-sites) are the largest WBCs, often two or three times the diameter of an RBC. They number about 460 cells/ μL and about 3% to 8% of the WBC count. The nucleus is large and clearly

visible, often a relatively light violet, and typically ovoid, kidney-shaped, or horseshoe-shaped. The cytoplasm is abundant and contains sparse, fine granules. In prepared blood films, monocytes often assume sharply angular to spiky shapes (see fig. 18.1).

The monocyte count rises in inflammation and viral infections. Monocytes go to work only after leaving the bloodstream and transforming into large tissue cells called **macrophages** (MAC-ro-fay-jez). Macrophages are highly phagocytic cells that consume up to 25% of their own volume per hour. They destroy dead or dying host and foreign cells, pathogenic chemicals and microorganisms, and other foreign matter. They also chop up or "process" foreign antigens and "display" fragments of them on the cell surface to alert the immune system to the presence of a pathogen. Thus, they and a few other cells are called *antigen-presenting cells* (APCs). The functions of macrophages are further detailed in chapter 21.

The Leukocyte Life Cycle

Leukopoiesis (LOO-co-poy-EE-sis), the production of white blood cells, begins with the same pluripotent stem cells (PPSCs) as erythropoiesis. Some PPSCs differentiate into distinct types of colony-forming units (CFUs) and then go on to produce the following cell lines (fig. 18.18), each of them now irreversibly committed to a certain outcome.

1. *Myeloblasts*, which ultimately differentiate into the three types of granulocytes (neutrophils, eosinophils, and basophils).
2. *Monoblasts*, which look identical to myeloblasts but lead ultimately to monocytes.
3. *Lymphoblasts*, which give rise to all types of lymphocytes.

Committed cells have receptors for colony-stimulating factors (CSFs). Mature lymphocytes and macrophages secrete several types of CSFs in response to infections and other immune challenges. Each CSF stimulates a different WBC type to develop in response to specific needs. Thus, a bacterial infection may trigger the production of neutrophils, whereas an allergy triggers the production of eosinophils, each process working through its own CSF.

The red bone marrow stores granulocytes and monocytes until they are needed and contains 10 to 20 times more of these cells than the circulating blood does. Lymphocytes begin developing in the bone marrow but do not stay there. Some types mature there and others migrate to the thymus to complete their development. Mature lymphocytes from both locations then colonize the spleen, lymph nodes, and other lymphoid organs and tissues.

Circulating leukocytes do not stay in the blood for very long. Granulocytes circulate for 4 to 8 hours and then migrate into the tissues, where they live another 4 or 5 days. Monocytes travel in the blood for 10 to 20 hours, then migrate

FIGURE 18.18 Leukopoiesis. Stages in the development of white blood cells. The pluripotent stem cell at the left also is the ultimate source of red blood cells (see fig. 18.6) and platelet-producing cells.

● Explain the meaning and relevance of the combining form *myelo-* seen in so many of these cell names.

into the tissues and transform into a variety of macrophages, which can live as long as a few years. Lymphocytes, responsible for long-term immunity, survive from a few weeks to decades; they leave the bloodstream for the tissues and eventually enter the lymphatic system, which empties them back into the bloodstream. Thus, they are continually recycled from blood to tissue fluid to lymph and back to the blood.

When leukocytes die, they are generally phagocytized and digested by macrophages. Dead neutrophils, however, are responsible for the creamy color of pus, and are sometimes disposed of by the rupture of a blister onto the skin surface. The biology of leukocytes is discussed more extensively in chapter 21.

Think About It

It is sometimes written that RBCs do not live as long as WBCs because RBCs do not have a nucleus and therefore cannot repair and maintain themselves. Explain the flaw in this argument.

Leukocyte Disorders

The total WBC count is normally 5,000 to 10,000 WBCs/ μ L. A count below this range, called **leukopenia**²² (LOO-co-PEE-nee-uh), is seen in lead, arsenic, and mercury poisoning; radiation sickness; and such infectious diseases as measles, mumps, chickenpox, poliomyelitis, influenza, typhoid fever, and AIDS. It can also be produced by glucocorticoids, anticancer drugs, and immunosuppressant drugs given to organ transplant patients. Since WBCs are protective cells, leukopenia presents an elevated risk of infection and cancer. A count above 10,000 WBCs/ μ L, called **leukocytosis**,²³ usually indicates infection, allergy, or other diseases but can also occur in response to dehydration or emotional disturbances. More useful than a total WBC count is a *differential WBC count*, which identifies what percentage of the total WBC count consists of each type of leukocyte (see Insight 18.4).

Leukemia is a cancer of the hemopoietic tissues that usually produces an extraordinarily high number of circulating leukocytes and their precursors (fig. 18.19). Leukemia is classified as myeloid or lymphoid, acute or chronic. **Myeloid leukemia** is marked by uncontrolled granulocyte production, whereas **lymphoid leukemia** involves uncontrolled lymphocyte or monocyte production. **Acute leukemia** appears suddenly, progresses rapidly, and causes death within a few months if it is not treated. **Chronic leukemia** develops more slowly and may go undetected for many months; if untreated, the typical survival time is about 3 years. Both myeloid and lymphoid leukemia occur in acute and chronic forms. The greatest success in treatment and cure has been with acute lymphoblastic leukemia, the most common type of child-

INSIGHT 18.4 Clinical Application

The Complete Blood Count

One of the most common clinical procedures in both routine physical examinations and the diagnosis of disease is a *complete blood count (CBC)*. The CBC yields a highly informative profile of data on multiple blood values: the number of RBCs, WBCs, and platelets per microliter of blood; the relative numbers (percentages) of each WBC type, called a *differential WBC count*; hematocrit; hemoglobin concentration; and various *RBC indices* such as RBC size (*mean corpuscular volume, MCV*) and hemoglobin concentration per RBC (*mean corpuscular hemoglobin, MCH*).

RBC and WBC counts used to require the microscopic examination of films of diluted blood on a calibrated slide, and a differential WBC count required examination of stained blood films. Today, most laboratories use *electronic cell counters*. These devices draw a blood sample through a very narrow tube with sensors that identify cell types and measure cell sizes and hemoglobin content. These counters give faster and more accurate results based on much larger numbers of cells than the old visual methods. However, cell counters still misidentify some cells, and a medical technologist must review the results for suspicious abnormalities and identify cells that the instrument cannot.

The wealth of information gained from a CBC is too vast to give more than a few examples here. Various forms of anemia are indicated by low RBC counts or abnormalities of RBC size, shape, and hemoglobin content. A platelet deficiency can indicate an adverse drug reaction. A high neutrophil count suggests bacterial infection, and a high eosinophil count suggests an allergy or parasitic infection. Elevated numbers of specific WBC types or WBC stem cells can indicate various forms of leukemia. If a CBC does not provide enough information or if it suggests other disorders, additional tests may be done, such as coagulation time and bone marrow biopsy.

hood cancer. Treatment employs chemotherapy and marrow transplants along with the control of side effects such as anemia, hemorrhaging, and infection.

As leukemic cells proliferate, they replace normal bone marrow and a person suffers from a deficiency of normal granulocytes, erythrocytes, and platelets. Although enormous numbers of leukocytes are produced and spill over into the bloodstream, they are immature cells incapable of performing their normal defensive roles. The deficiency of competent WBCs leaves the patient vulnerable to *opportunistic infection*—the establishment of pathogenic organisms that usually cannot get a foothold in people with healthy immune systems. The RBC deficiency renders the patient anemic and fatigued, and the platelet deficiency results in hemorrhaging and impaired blood clotting. The immediate cause of death is usually hemorrhage or infection. Cancerous hemopoietic tissue often metastasizes from the bone marrow or lymph nodes to other organs of the body, where the cells displace or compete with normal cells. Metastasis to the bone tissue itself is common and leads to bone and joint pain.

²²leuko = white + penia = deficiency

²³leuko = white + cyt = cell + osis = condition

(a)

(b)

FIGURE 18.19 Normal and Leukemic Blood. (a) A normal blood smear. (b) Blood from a patient with acute monocytic leukemia. Note the abnormally high number of white blood cells, especially monocytes, in part (b).

• With all these extra white cells, why isn't the body's infection-fighting capability increased in leukemia?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

17. What is the overall function of leukocytes?
18. List the five kinds of leukocytes in order of abundance, identify whether each is a granulocyte or agranulocyte, and describe how to identify each one.
19. What does leukopoiesis have in common with erythropoiesis? How does it differ?
20. What can cause an abnormally high or low WBC count?
21. WBCs fight infection, and leukemia is an abnormally high WBC count. Yet leukemia patients are very vulnerable to infection. Explain this seeming paradox.

18.5 Platelets and Hemostasis—The Control of Bleeding

Objectives

When you have completed this section, you should be able to

- describe the body's mechanisms for controlling bleeding;
- list the functions of platelets;
- describe two reaction pathways that produce blood clots;
- explain what happens to blood clots when they are no longer needed;
- explain what keeps blood from clotting in the absence of injury; and
- describe some disorders of blood clotting.

Circulatory systems developed very early in animal evolution, and with them evolved mechanisms for stopping leaks, which are potentially fatal. **Hemostasis**²⁴ is the cessation of bleeding. Although hemostatic mechanisms may not stop a hemorrhage from a large blood vessel, they are quite effective at closing breaks in small ones. Platelets play multiple roles in hemostasis, so we begin with a consideration of their form and function.

Platelet Form and Function

Platelets are not cells but small fragments of marrow cells called *megakaryocytes*. Platelets are the second most abundant formed elements, after erythrocytes; a normal platelet count in blood from a fingerstick ranges from 130,000 to 400,000 platelets/μL (averaging about 250,000). The platelet count can vary greatly, however, under different physiological conditions and in blood samples taken from various places in the body. In spite of their numbers, platelets are so small (2 to 4 μm in diameter) that they contribute even less than the WBCs to the blood volume.

Platelets have a complex internal structure that includes lysosomes, mitochondria, microtubules and microfilaments, **granules** filled with platelet secretions, and a system of channels called the **open canalicular system**, which open onto the platelet surface (fig. 18.20a). They have no nucleus. When activated, they form pseudopods and are capable of ameboid movement.

Despite their small size, platelets have a greater variety of functions than any of the true blood cells:

- They secrete *vasoconstrictors*, chemicals that stimulate spasmodic constriction of broken vessels and thus help reduce blood loss.

²⁴hemo = blood + stasis = stability

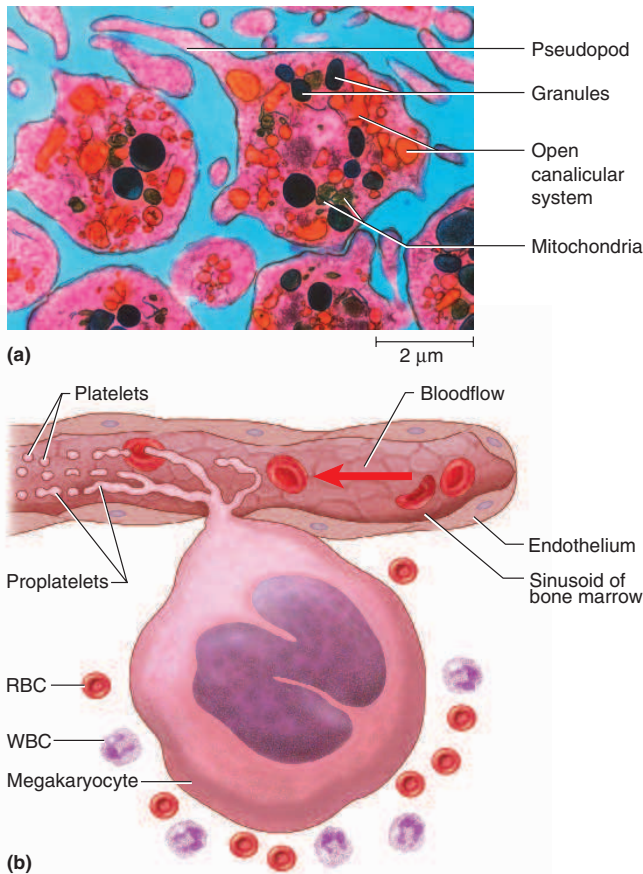

FIGURE 18.20 Platelets. (a) Structure of blood platelets (TEM). (b) Platelets being produced by the shredding of the peripheral cytoplasm of a megakaryocyte. Note the sizes of the megakaryocyte and platelets relative to RBCs and WBCs.

- They stick together to form temporary *platelet plugs* that seal small breaks in injured blood vessels.
- They secrete *procoagulants*, or clotting factors, which promote blood clotting.
- They initiate the formation of a clot-dissolving enzyme that dissolves blood clots that have outlasted their usefulness.
- They secrete chemicals that attract neutrophils and monocytes to sites of inflammation.
- They internalize and destroy bacteria.
- They secrete *growth factors* that stimulate mitosis in fibroblasts and smooth muscle and thus help to maintain and repair blood vessels.

Platelet Production

The production of platelets is a division of hemopoiesis called **thrombopoiesis**. (Platelets are occasionally called *thrombocytes*,²⁵ but this term is now usually reserved for

nucleated true cells in other animals such as birds and reptiles.) Some pluripotent stem cells produce receptors for the hormone *thrombopoietin*, thus becoming megakaryoblasts, cells committed to the platelet-producing line. The megakaryoblast duplicates its DNA repeatedly without undergoing nuclear or cytoplasmic division. The result is a **megakaryocyte**²⁶ (MEG-ah-CAR-ee-oh-site), a gigantic cell up to 150 μm in diameter, visible to the naked eye, with a huge multilobed nucleus and multiple sets of chromosomes (fig. 18.20b). Most megakaryocytes live in the red bone marrow adjacent to blood-filled spaces called *sinusoids*, lined with a thin simple squamous epithelium called the *endothelium* (see fig. 21.9, p. 823).

A megakaryocyte sprouts long tendrils called *proplatelets* that protrude through the endothelium into the blood of the sinusoid. The blood flow shears off the proplatelets, which break up into platelets as they travel in the bloodstream. Much of this breakup is thought to occur when they pass through the small vessels of the lungs, because blood counts show more proplatelets entering the lungs than leaving and more platelets exiting. About 25% to 40% of the platelets are stored in the spleen and released as needed. The remainder circulate freely in the blood and live for about 10 days.

Hemostasis

There are three hemostatic mechanisms—*vascular spasm*, *platelet plug formation*, and *blood clotting* (coagulation) (fig. 18.21). Platelets play an important role in all three.

Vascular Spasm

The most immediate protection against blood loss is **vascular spasm**, a prompt constriction of the broken vessel. Several things trigger this reaction. An injury stimulates pain receptors, some of which directly innervate nearby blood vessels and cause them to constrict. This effect lasts only a few minutes, but other mechanisms take over by the time it subsides. Injury to the smooth muscle of the blood vessel itself causes a longer-lasting vasoconstriction, and platelets release serotonin, a chemical vasoconstrictor. Thus, the vascular spasm is maintained long enough for the other two hemostatic mechanisms to come into play.

Platelet Plug Formation

Platelets do not adhere to the endothelium (inner lining) of undamaged blood vessels. The endothelium is normally very smooth and coated with **prostacyclin**, a platelet repellent. When a vessel is broken, however, collagen fibers of its wall are exposed to the blood. Upon contact with collagen or other rough surfaces, platelets grow long spiny pseudopods that adhere to the vessel and to other platelets; the pseudopods then contract and draw the walls of

²⁵*thrombo* = clotting + *cyte* = cell

²⁶*mega* = giant + *karyo* = nucleus + *cyte* = cell

FIGURE 18.21 Hemostasis. (a) Vasoconstriction of a broken vessel reduces bleeding. (b) A platelet plug forms as platelets adhere to exposed collagen fibers of the vessel wall. The platelet plug temporarily seals the break. (c) A blood clot forms as platelets become enmeshed in fibrin threads. This forms a longer-lasting seal and gives the vessel a chance to repair itself.

How does a blood clot differ from a platelet plug?

the vessel together. The mass of platelets thus formed, called a **platelet plug**, may reduce or stop minor bleeding.

As platelets aggregate, they undergo **degranulation**—the exocytosis of their cytoplasmic granules and release of factors that promote hemostasis. Among these are serotonin, a vasoconstrictor; adenosine diphosphate (ADP), which attracts more platelets to the area and stimulates their degranulation; and **thromboxane A₂**, an eicosanoid that promotes platelet aggregation, degranulation, and vasoconstriction. Thus, a positive feedback cycle is activated that can quickly seal a small break in a blood vessel.

Coagulation

Coagulation (clotting) of the blood is the last but most effective defense against bleeding. It is important for the blood to clot quickly when a vessel has broken, but equally important for it not to clot in the absence of vessel damage. Because of this delicate balance, coagulation is one of the most complex processes in the body, involving over 30 chemical reactions. It is presented here in a very simplified form.

Perhaps clotting is best understood if we first consider its goal. The objective is to convert the plasma protein fibrinogen into **fibrin**, a sticky protein that adheres to the walls of a vessel. As blood cells and platelets arrive, they stick to the fibrin like insects in a spider web (fig. 18.22). The resulting mass of fibrin, blood cells, and platelets ideally seals the break in the blood vessel. The complexity of clotting lies in how the fibrin is formed.

There are two reaction pathways to coagulation (fig. 18.23). One of them, the **extrinsic mechanism**, is initiated by clotting factors released by the damaged blood vessel and perivascular²⁷ tissues. The word *extrinsic*

refers to the fact that these factors come from sources other than the blood itself. Blood may also clot, however, without these tissue factors—for example, when platelets adhere to a fatty plaque of atherosclerosis or to a test tube. The reaction pathway in this case is called the **intrinsic mechanism** because it uses only clotting factors found in

FIGURE 18.22 A Blood Clot (SEM). Platelets (orange) are seen trapped in a sticky protein mesh.

What is the name of this protein?

²⁷peri = around + vas = vessel + cular = pertaining to

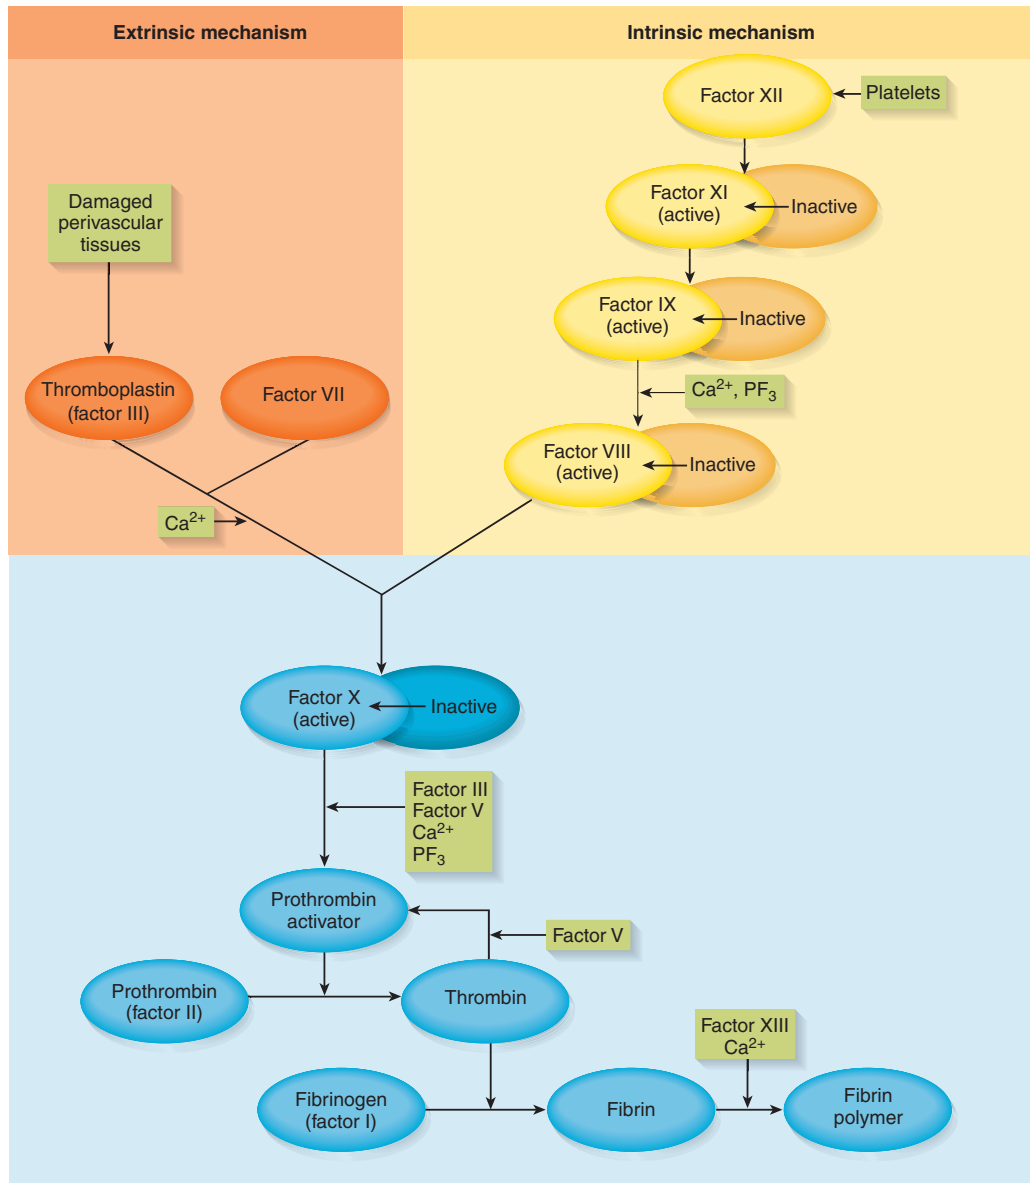

FIGURE 18.23 The Pathways of Coagulation. Most clotting factors act as enzymes that convert the next factor from an inactive form to an active form. One enzyme molecule at any given level activates many enzyme molecules at the next level down, so the overall effect becomes amplified at each step.

Would hemophilia C affect the extrinsic mechanism, the intrinsic mechanism, or both?

the blood itself. In most cases of bleeding, both the extrinsic and intrinsic mechanisms work simultaneously to contribute to hemostasis.

Clotting factors (table 18.7) are called **procoagulants**, in contrast to the **anticoagulants** discussed later (see Insight 18.6, p. 715). Most procoagulants are proteins produced by the liver. They are always present in the plasma in inactive form, but when one factor is activated, it functions as an enzyme that activates the next one in

the pathway. That factor activates the next, and so on, in a sequence called a **reaction cascade**—a series of reactions, each of which depends on the product of the preceding one. Many of the clotting factors are identified by roman numerals, which indicate the order in which they were discovered, not the order of the reactions. Factors IV and VI are not included in table 18.7. These terms were abandoned when it was found that factor IV was calcium and factor VI was activated factor V. The last four

TABLE 18.7 Clotting Factors (Procoagulants)

Number	Name	Origin	Function
I	Fibrinogen	Liver	Precursor of fibrin
II	Prothrombin	Liver	Precursor of thrombin
III	Tissue thromboplastin	Perivascular tissue	Activates factor VII
V	Proaccelerin	Liver	Activates factor VII; combines with factor X to form prothrombin activator
VII	Proconvertin	Liver	Activates factor X in extrinsic pathway
VIII	Antihemophilic factor A	Liver	Activates factor X in intrinsic pathway
IX	Antihemophilic factor B	Liver	Activates factor VIII
X	Thrombokinese	Liver	Combines with factor V to form prothrombin activator
XI	Antihemophilic factor C	Liver	Activates factor IX
XII	Hageman factor	Liver, platelets	Activates factor XI and plasmin; converts prekallikrein to kallikrein
XIII	Fibrin-stabilizing factor	Platelets, plasma	Cross-links fibrin filaments to make fibrin polymer and stabilize clot
PF ₁	Platelet factor 1	Platelets	Same role as factor V; also accelerates platelet activation
PF ₂	Platelet factor 2	Platelets	Accelerates thrombin formation
PF ₃	Platelet factor 3	Platelets	Aids in activation of factor VIII and prothrombin activator
PF ₄	Platelet factor 4	Platelets	Binds heparin during clotting to inhibit its anticoagulant effect

procoagulants in the table are called *platelet factors* (PF₁ through PF₄) because they are produced by the platelets.

Initiation of Coagulation The extrinsic mechanism is diagrammed on the top left side of figure 18.23. The damaged blood vessel and perivascular tissues release a lipoprotein mixture called **tissue thromboplastin²⁸ (factor III)**. Factor III combines with factor VII to form a complex that, in the presence of Ca²⁺, activates factor X. The extrinsic and intrinsic pathways differ only in how they arrive at active factor X. Therefore, before examining their common pathway from factor X to the end, let's consider how the intrinsic pathway reaches this step.

The intrinsic mechanism is diagrammed on the top right side of figure 18.23. Everything needed to initiate it is present in the plasma or platelets. When platelets degranulate, they release factor XII (Hageman factor, named for the patient in whom it was discovered). Through a cascade of reactions, this leads to activated factors XI, IX, and VIII, in that order—each serving as an enzyme that catalyzes the next step—and finally to factor X. This pathway also requires Ca²⁺ and PF₃.

Completion of Coagulation Once factor X is activated, the remaining events are identical in the intrinsic and extrinsic mechanisms. Factor X combines with factors III and V in the presence of Ca²⁺ and PF₃ to produce *prothrombin activator*. This enzyme acts on a globulin called **prothrombin (factor II)** and converts it to the enzyme **thrombin**. Thrombin then chops up fibrinogen into shorter

strands of fibrin. Factor XIII cross-links these *fibrin* strands to create a dense aggregation called *fibrin polymer*, which forms the structural framework of the blood clot.

Once a clot begins to form, it launches a self-accelerating positive feedback process that seals off the damaged vessel more quickly. Thrombin works with factor V to accelerate the production of prothrombin activator, which in turn produces more thrombin.

The cascade of enzymatic reactions acts as an amplifying mechanism to ensure the rapid clotting of blood (fig. 18.24). Each activated enzyme in the pathway produces a larger number of enzyme molecules at the following step. One activated molecule of factor XII at the start of the intrinsic pathway, for example, causes thousands of fibrin molecules to be produced very quickly. Note the similarity of this process to the *enzyme amplification* that occurs in hormone action (see fig. 17.24, p. 668).

Notice that the extrinsic mechanism requires fewer steps to activate factor X than the intrinsic mechanism does; it is a “shortcut” to coagulation. It takes 3 to 6 minutes for a clot to form by the intrinsic pathway but only 15 seconds or so by the extrinsic pathway. For this reason, when a small wound bleeds, you can stop the bleeding sooner by massaging the site. This releases thromboplastin from the perivascular tissues and activates or speeds up the extrinsic pathway.

A number of laboratory tests are used to evaluate the efficiency of coagulation. Normally, the bleeding of a fingerstick should stop within 2 to 3 minutes, and a sample of blood in a clean test tube should clot within 15 minutes. Other techniques are available that can separately assess the effectiveness of the intrinsic and extrinsic mechanisms.

²⁸thrombo = clot + plast = forming + in = substance

FIGURE 18.24 The Reaction Cascade in Blood Clotting. Each clotting factor produces many molecules of the next one, so the number of active clotting factors increases rapidly and a large amount of fibrin is quickly formed. The example shown here is for the intrinsic mechanism.

How does this compare with enzyme amplification in hormone action (chapter 17)?

The Fate of Blood Clots

After a clot has formed, spinous pseudopods of the platelets adhere to strands of fibrin and contract. This pulls on the fibrin threads and draws the edges of the broken vessel together, like a drawstring closing a purse. Through this process of **clot retraction**, the clot becomes more compact within about 30 minutes.

Platelets and endothelial cells secrete a mitotic stimulant named **platelet-derived growth factor (PDGF)**. PDGF stimulates fibroblasts and smooth muscle cells to multiply and repair the damaged blood vessel. Fibroblasts also invade the clot and produce fibrous connective tissue, which helps to strengthen and seal the vessel while the repairs take place.

Eventually, tissue repair is completed and the clot must be disposed of. **Fibrinolysis**, the dissolution of a clot, is achieved by a small cascade of reactions with a positive feedback component (fig. 18.25). In addition to promoting clotting, factor XII catalyzes the formation of a plasma enzyme called **kallikrein** (KAL-ih-KREE-in).

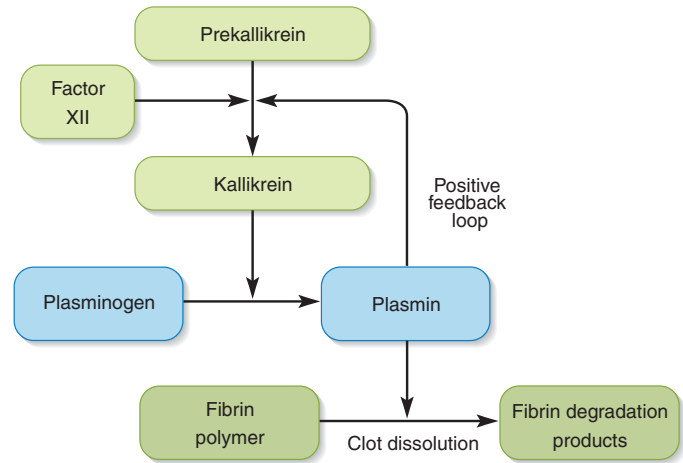

FIGURE 18.25 The Mechanism for Dissolving Blood Clots. Prekallikrein is converted to kallikrein. Kallikrein is an enzyme that catalyzes the formation of plasmin. Plasmin is an enzyme that dissolves the blood clot.

Kallikrein, in turn, converts the inactive protein *plasminogen* into **plasmin**, a fibrin-dissolving enzyme that breaks up the clot. Thrombin also activates plasmin, and plasmin indirectly promotes the formation of more kallikrein, thus completing a positive feedback loop.

Prevention of Inappropriate Clotting

Precise controls are required to prevent coagulation when it is not needed. These include the following:

- **Platelet repulsion.** As noted earlier, platelets do not adhere to the smooth prostacyclin-coated endothelium of undamaged blood vessels.
- **Dilution.** Small amounts of thrombin form spontaneously in the plasma, but at normal rates of blood flow, the thrombin is diluted so quickly that a clot has little chance to form. If flow decreases, however, enough thrombin can accumulate to cause clotting. This can happen in circulatory shock, for example, when output from the heart is diminished and circulation slows down.
- **Anticoagulants.** Thrombin formation is suppressed by anticoagulants that are present in the plasma. **Antithrombin**, secreted by the liver, deactivates

INSIGHT 18.5 Clinical Application**Liver Disease and Blood Clotting**

Proper blood clotting depends on normal liver function for two reasons. First, the liver synthesizes most of the clotting factors. Therefore, diseases such as hepatitis, cirrhosis, and cancer that degrade liver function result in a deficiency of clotting factors. Second, the synthesis of clotting factors II, VII, IX, and X require vitamin K. The absorption of vitamin K from the diet requires bile, a liver secretion. Gallstones can lead to a clotting deficiency by obstructing the bile duct and thus interfering with bile secretion and vitamin K absorption. Efficient blood clotting is especially important in childbirth, since both the mother and infant bleed from the trauma of birth. Therefore, pregnant women should take vitamin K supplements to ensure fast clotting, and newborn infants may be given vitamin K injections.

thrombin before it can act on fibrinogen. **Heparin**, secreted by basophils and mast cells, interferes with the formation of prothrombin activator, blocks the action of thrombin on fibrinogen, and promotes the action of antithrombin. Heparin is given by injection to patients with abnormal clotting tendencies.

Clotting Disorders

In a process as complex as coagulation, it is not surprising that things can go wrong. Clotting deficiencies can result from causes as diverse as malnutrition, leukemia, and gallstones (see Insight 18.5).

A deficiency of any clotting factor can shut down the coagulation cascade. This happens in **hemophilia**, a family of hereditary diseases characterized by deficiencies of one factor or another. Because of its sex-linked recessive mechanism of heredity, most hemophilia occurs predominantly in males. They can inherit it only from their mothers, however, as happened with the descendants of Queen Victoria. The lack of factor VIII causes *classical hemophilia* (*hemophilia A*), which accounts for about 83% of cases and afflicts 1 in 5,000 males worldwide. Lack of factor IX causes *hemophilia B*, which accounts for 15% of cases and occurs in about 1 out of 30,000 males. Factors VIII and IX are therefore known as *antihemophilic factors A and B*. A rarer form called *hemophilia C* (factor XI deficiency) is autosomal and not sex-linked, so it occurs equally in both sexes.

Before purified factor VIII became available in the 1960s, more than half of those with hemophilia died before age 5 and only 10% lived to age 21. Physical exertion causes bleeding into the muscles and joints. Excruciating pain and eventual joint immobility can result from intramuscular and joint **hematomas**²⁹ (masses of clotted blood in the tissues). Hemophilia varies in severity, however. Half of the normal level of clotting factor is enough to prevent the symptoms, and the symptoms are mild even in individuals with as little as 30% of the normal amount. Such cases may go undetected even into adulthood. Bleeding can be relieved for a few days by transfusion of plasma or purified clotting factors.

Think About It

Why is it important for people with hemophilia not to use aspirin? (Hint: See p. 671.)

Far more people die from unwanted blood clotting than from clotting failure. Most strokes and heart attacks are due to **thrombosis**—the abnormal clotting of blood in an unbroken vessel. A **thrombus** (clot) may grow large enough to obstruct a small vessel, or a piece of it may break loose and begin to travel in the bloodstream as an **embolus**.³⁰ An embolus may lodge in a small artery and block blood flow from that point on. If that vessel supplies a vital organ such as the heart, brain, lung, or kidney, *infarction* (tissue death) may result. About 650,000 Americans die annually of *thromboembolism* (traveling blood clots) in the cerebral, coronary, and pulmonary arteries.

Thrombosis is more likely to occur in veins than in arteries because blood flows more slowly in the veins and does not dilute thrombin and fibrin as rapidly. It is especially common in the leg veins of inactive people and patients immobilized in a wheelchair or bed. Most venous blood flows directly to the heart and then to the lungs. Therefore, blood clots arising in the limbs commonly lodge in the lungs and cause *pulmonary embolism*. When blood cannot circulate freely through the lungs, it cannot receive oxygen and a person may die of hypoxia.

Table 18.8 describes some additional disorders of the blood. The effects of aging on the blood are described on page 1142.

²⁹hemato = blood + oma = mass

³⁰em = in, within + bolus = ball, mass

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

22. What are the three basic mechanisms of hemostasis?
23. How do the extrinsic and intrinsic mechanisms of coagulation differ? What do they have in common?
24. In what respect does blood clotting represent a negative feedback loop? What part of it is a positive feedback loop?
25. Describe some of the mechanisms that prevent clotting in undamaged vessels.
26. Describe a common source and effect of pulmonary embolism.

TABLE 18.8 Some Disorders of the Blood

Disseminated intravascular coagulation (DIC)	Widespread clotting within unbroken vessels, limited to one organ or occurring throughout the body. Usually triggered by septicemia but also occurs when blood circulation slows markedly (as in cardiac arrest). Marked by widespread hemorrhaging, congestion of the vessels with clotted blood, and tissue necrosis in blood-deprived organs.
Infectious mononucleosis	Infection of B lymphocytes with Epstein-Barr virus, most commonly in adolescents and young adults. Usually transmitted by exchange of saliva, as in kissing. Causes fever, fatigue, sore throat, inflamed lymph nodes, and leukocytosis. Usually self-limiting and resolves within a few weeks.
Septicemia	Bacteremia (bacteria in the bloodstream) accompanying infection elsewhere in the body. Often causes fever, chills, and nausea, and may cause DIC or septic shock (see p. 776).
Thalassemia	A group of hereditary anemias most common in Greeks, Italians, and others of Mediterranean descent; shows a deficiency or absence of alpha or beta hemoglobin and RBC counts that may be less than 2 million/ μ L.
Thrombocytopenia	A platelet count below 100,000/mL. Causes include bone marrow destruction by radiation, drugs, poisons, or leukemia. Signs include small hemorrhagic spots in the skin or hematomas in response to minor trauma.

INSIGHT 18.6 Clinical Application

Clinical Management of Blood Clotting

For many cardiovascular patients, the goal of treatment is to prevent clotting or to dissolve clots that have already formed. Several strategies employ inorganic salts and products of bacteria, plants, and animals with anticoagulant and clot-dissolving effects.

Preventing Clots from Forming

Since calcium is an essential requirement for blood clotting, blood samples can be kept from clotting by adding a few crystals of sodium oxalate, sodium citrate, or EDTA³¹—salts that bind calcium ions and prevent them from participating in the coagulation reactions. Blood-collection equipment such as hematocrit tubes may also be coated with heparin, a natural anticoagulant whose action was explained earlier.

Since vitamin K is required for the synthesis of clotting factors, anything that antagonizes vitamin K usage makes the blood clot less readily. One vitamin K antagonist is *coumarin*³² (COO-muh-rin), a sweet-smelling extract of tonka beans, sweet clover, and other plants, used in perfume. Taken orally by patients at risk for thrombosis, coumarin takes up to 2 days to act, but it has longer-lasting effects than heparin. A similar vitamin K antagonist is the pharmaceutical preparation *warfarin*³³ (*Coumadin*), which was originally developed as a pesticide—it makes rats bleed to death. Obviously, such anticoagulants must be used in humans with great care.

As explained in chapter 17, aspirin suppresses the formation of the eicosanoid thromboxane A₂, a factor in platelet aggregation. Low daily doses of aspirin can therefore suppress thrombosis and help to prevent heart attacks.

Many parasites feed on the blood of vertebrates and secrete anticoagulants to keep the blood flowing. Among these are segmented worms known as leeches. Leeches secrete a local anesthetic that makes their bites painless; therefore, as early as 1567 BCE, physicians used them for bloodletting. This method was less painful and repugnant to their patients than *phlebotomy*³⁴—cutting a vein—and indeed, leeching became very popular. In seventeenth-century France, it was quite the rage; tremendous numbers of leeches were used to treat headaches, insomnia, whooping cough, obesity, tumors, menstrual cramps, mental illness, and almost anything else doctors or their patients imagined to be caused by “bad blood.”

The first known anticoagulant was discovered in the saliva of the medicinal leech, *Hirudo medicinalis*, in 1884. Named *hirudin*, it is a polypeptide that prevents clotting by inhibiting thrombin. It causes the blood to flow freely while the leech feeds and for as long as an hour thereafter. While the doctrine of bad blood is now discredited, leeches have lately reentered medical usage (fig. 18.26). A major problem in reattaching a severed body part such as a finger or ear is that the tiny veins

FIGURE 18.26 A Modern Use of Leeching. Two medicinal leeches are being used to remove clotted blood from a post-surgical hematoma. Despite their formidable size, the leeches secrete a natural anesthetic and produce a painless bite.

How does the modern theory behind leeching differ from the theory of leeching that was popular a few centuries ago?

draining these organs are too small to reattach surgically. Since arterial blood flows into the reattached organ and cannot flow out, it pools and clots there. This inhibits the regrowth of veins and the flow of fresh blood through the organ, and thus often leads to necrosis. Some vascular surgeons now place leeches on the reattached part. Their anticoagulant keeps the blood flowing freely and allows new veins to grow. After 5 to 7 days, venous drainage is restored and leeching can be stopped.

Anticoagulants also occur in the venom of some snakes. *Arvin*, for example, is obtained from the venom of the Malayan viper. It rapidly breaks down fibrinogen and may have potential as a clinical anticoagulant.

Dissolving Clots That Have Already Formed

When a clot has already formed, it can be treated with clot-dissolving drugs such as *streptokinase*, an enzyme made by certain bacteria (streptococci). Intravenous streptokinase is used to dissolve blood clots in coronary vessels, for example. It is nonspecific, however, and digests almost any protein. Tissue *plasminogen activator (TPA)* works faster, is more specific, and is now made by transgenic bacteria. TPA converts plasminogen into the clot-dissolving enzyme plasmin. Some anticoagulants of animal origin also work by dissolving fibrin. A giant Amazon leech, *Haementeria*, produces one such anticoagulant named *hementin*. This, too, has been successfully produced by genetically engineered bacteria and used to dissolve blood clots in cardiac patients.

³⁴*phlebo* = vein + *tomy* = cutting

CHAPTER REVIEW

Review of Key Concepts

18.1 Introduction (p. 684)

1. The circulatory system consists of the heart, blood vessels, and blood.
2. Blood serves to transport O_2 , CO_2 , nutrients, wastes, hormones, and stem cells; to protect the body by means of antibodies, leukocytes, platelets, and its roles in inflammation; and it helps to stabilize the body's fluid balance, pH, and temperature.
3. Blood is a liquid connective tissue composed of about 55% *plasma* and 45% *formed elements* by volume. The formed elements include erythrocytes, platelets, and five kinds of leukocytes.
4. Blood plasma is the clear fluid in which the formed elements are suspended. It is a mixture of water, nutrients, electrolytes, wastes, hormones, gases, and proteins. Its major proteins are albumin, globulins, and fibrinogen.
5. The viscosity of blood, stemming mainly from its RBCs and proteins, is an important factor in blood flow.
6. The osmolarity of blood, stemming mainly from its RBCs, proteins, and Na^+ , governs its water content and is thus a major factor in blood volume and pressure. The protein contribution to osmolarity is the *colloid osmotic pressure*.
7. *Hemopoiesis* is production of the formed elements of blood. It begins in the embryonic yolk sac and continues in the fetal bone marrow, liver, spleen, and thymus. From infancy onward, it occurs in the bone marrow (*myeloid hemopoiesis*) and lymphoid tissues (*lymphoid hemopoiesis*).
8. All formed elements derive ultimately from a *pluripotent stem cell* in the red bone marrow.

18.2 Erythrocytes (p. 689)

1. RBCs transport O_2 and CO_2 . They are discoid cells with a sunken center and no organelles, but they do have a cytoskeleton of *spectrin* and *actin* that reinforces the plasma membrane.
2. The most important components of the cytoplasm are *hemoglobin (Hb)* and *carbonic anhydrase (CAH)*. Hb transports nearly all of the O_2 and some of the CO_2 in the blood, and CAH catalyzes the reversible reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$.

3. Hemoglobin consists of four peptide chains—two alpha and two beta—each with a *heme* moiety.
4. Oxygen binds to the Fe^{2+} at the center of each heme. About 5% of the CO_2 in the blood binds to the globin moiety for transport.
5. The quantities of RBCs and Hb are clinically important. They are measured in terms of *hematocrit* (percentage of the blood volume composed of RBCs), *hemoglobin concentration* (g/dL), and *RBC count* (RBCs/ μ L of blood). Normal averages are lower in women than in men.
6. *Erythropoiesis*, or RBC production, proceeds through the following stages: *pluripotent stem cell* \rightarrow *erythrocyte colony-forming unit* \rightarrow *erythroblast* \rightarrow *reticulocyte* \rightarrow *erythrocyte*. These transformations entail a reduction in cell size, increase in cell number, synthesis of hemoglobin, and loss of organelles.
7. Iron, in the form of ferrous ions (Fe^{2+}), is essential for hemoglobin synthesis. Dietary Fe^{3+} is converted to Fe^{2+} by stomach acid, then binds to *gastroferritin*, is absorbed into the blood, and binds with the plasma protein *transferrin*. Transferrin transports Fe^{2+} to the myeloid tissue and liver. The liver stores excess iron in *ferritin*.
8. Erythropoiesis is stimulated by the hormone *erythropoietin*. It is regulated by a negative feedback loop that responds to *hypoxemia* with increased EPO secretion, and thus increased erythropoiesis.
9. An RBC lives for about 120 days, grows increasingly fragile, and then breaks apart, especially in the spleen. *Hemolysis*, the rupture of RBCs, releases cell fragments and free hemoglobin.
10. Hemoglobin is broken down into its globin and heme moieties. The globin is hydrolyzed into its free amino acids, which are reused. The heme is broken down into its Fe^{2+} and organic components. The Fe^{2+} is recycled or stored, and the organic component eventually becomes *biliverdin* and *bilirubin* (bile pigments), which are excreted as waste.
11. An excessive RBC count is *polycythemia*. *Primary polycythemia* results from cancer of the bone

marrow, and *secondary polycythemia* from many other causes, such as dehydration, smoking, high altitude, and habitual strenuous exercise. Polycythemia increases blood volume, pressure, and viscosity to sometimes dangerous levels.

12. A deficiency of RBCs is *anemia*. Causes of anemia, classified and described in table 18.4, essentially fall into three categories: inadequate erythropoiesis, hemorrhage, or hemolysis.
13. The effects of anemia include tissue hypoxia and necrosis, reduced blood osmolarity, and reduced blood viscosity.
14. Sickle-cell disease and thalassemia are hereditary hemoglobin defects that result in severe anemia and multiple other effects.

18.3 Blood Types (p. 696)

1. Blood types are determined by antigenic glycoproteins and glycolipids on the RBC surface. Incompatibility of one person's blood with another results from the action of plasma antibodies against these RBC antigens.
2. Blood types A, B, AB, and O form the ABO blood group. The first two have antigen A or B on the RBC surface, the third has both A and B, and type O has neither.
3. A few months after birth, a person develops anti-A and anti-B antibodies against intestinal bacteria. These antibodies cross-react with foreign ABO antigens and thereby limit transfusion compatibility.
4. When anti-A reacts with type A or AB red cells, or anti-B reacts with type B or AB red cells, the red cells agglutinate and hemolyze, causing a severe *transfusion reaction* that can lead to renal failure and death.
5. The Rh blood group is based on antigens called C, D, and E, of which D is the most reactive. Persons with genotypes *DD* and *Dd* produce antigen D and are considered Rh-positive (Rh^+). Rh-negative (Rh^-) individuals have genotype *dd* and do not produce this antigen.
6. An Rh-negative (Rh^-) person who is exposed to Rh^+ RBCs through transfusion or childbirth develops an anti-D

antibody. Later exposures to Rh⁺ red cells can cause a transfusion reaction.

7. Rh incompatibility between a sensitized Rh⁻ woman and an Rh⁺ fetus can cause *hemolytic disease of the newborn*, a severe neonatal anemia that must be treated by phototherapy or transfusion.
8. Many other blood groups besides ABO and Rh exist. They rarely cause transfusion reactions but are useful in paternity and criminal cases and for studies of population genetics.

18.4 Leukocytes (p. 700)

1. WBCs play various roles in defending the body from pathogens. Neutrophils, eosinophils, and basophils are classified as *granulocytes*, and lymphocytes and monocytes are classified as *agranulocytes*. The appearance and function of each type are detailed in table 18.6.
2. *Leukopoiesis*, the production of WBCs, follows three principal lines stemming from pluripotent stem cells (PPSCs). PPSCs develop into *myeloblasts* (precursors of the granulocytes), *monoblasts* (precursors of monocytes), and *lymphoblasts* (precursors of lymphocytes).
3. Circulating WBCs remain in the bloodstream for only a matter of hours and spend most of their lives in other tissues. Lymphocytes cycle repeatedly from blood to tissue fluids to lymph and back to the blood.
4. A WBC deficiency, called *leukopenia*, may result from chemical or radiation poisoning, various infections, and certain drugs. It reduces a person's resistance to infection and cancer.
5. A WBC excess, called *leukocytosis*, may result from infection, allergy, dehydration, or emotional disorders, or from *leukemia* (cancer of the hemopoietic tissues).
6. Leukemia is classified by site of origin as *myeloid* or *lymphoid*, and by

speed of progression as *acute* or *chronic*. Leukemia increases the risk of *opportunistic infection* and is typically accompanied by RBC and platelet deficiencies.

18.5 Platelets and Hemostasis—The Control of Bleeding (p. 707)

1. Platelets are not cells but small, mobile fragments of megakaryocyte cytoplasm, second only to RBCs in abundance. They are filled with diverse organelles but have no nuclei.
2. Platelets have a wide variety of functions: secretion of vasoconstrictors, formation of platelet plugs to plug small broken blood vessels, secretion of clotting factors, dissolving old blood clots, attracting neutrophils and monocytes to inflamed tissue, destroying bacteria, and secreting growth factors that stimulate tissue repair and maintenance.
3. *Thrombopoiesis*, the production of platelets, also begins with PPSCs of the bone marrow. The hormone *thrombopoietin* induces the differentiation of large cells called *megakaryocytes*, which shed bits of cytoplasm called *proplatelets* into the bloodstream. These subsequently break up into platelets.
4. Breakage of a blood vessel leads first to *vascular spasm*, then formation of a *platelet plug*, and third but most effectively, *coagulation* (formation of a blood clot).
5. The objective of coagulation is to form a mesh of sticky protein called *fibrin*. There are two biochemical pathways to fibrin production, called the *extrinsic* and *intrinsic mechanisms*. Both pathways involve a self-amplifying chain reaction, or *reaction cascade*, of chemicals called *procoagulants*.
6. The extrinsic mechanism depends on chemicals released by damaged cells outside the bloodstream. It begins

with release of a lipoprotein called *tissue thromboplastin* and leads to activation of a procoagulant called *factor X*.

7. The intrinsic mechanism employs only factors found in the blood plasma or platelets. It begins with *factor XII* and likewise ends with the activation of factor X.
8. Beyond the activation of factor X, events are identical regardless of intrinsic or extrinsic beginnings. The remaining steps include activation of the enzyme *thrombin*, which cuts plasma fibrinogen into fibrin. Fibrin then polymerizes to form the weblike matrix of the blood clot.
9. Positive feedback and enzyme amplification ensure rapid clotting and the production of a large amount of fibrin in spite of small amounts of the other procoagulants that drive the process.
10. Once formed, a blood clot undergoes *clot retraction*, a process that helps to seal the wound. *Platelet-derived growth factor* promotes repair of the damaged blood vessel and surrounding connective tissues. Tissue repair is followed by *fibrinolysis*, in which the blood clot, no longer needed, is dissolved by the enzyme *plasmin*.
11. Inappropriate coagulation is normally prevented by the repulsion of platelets by prostacyclin on the blood vessel endothelium, dilution of the small amounts of thrombin that form spontaneously, and anticoagulants such as *heparin*.
12. Clotting deficiency can result from *thrombocytopenia* (low platelet count) or *hemophilia* (hereditary deficiency in procoagulant structure and function, especially in factor VIII).
13. Unwanted clotting in unbroken blood vessels is called *thrombosis*. A *thrombus* (clot) can break loose and become a traveling *embolus*, which can cause sometimes fatal obstruction of small blood vessels.

Testing Your Recall

1. Antibodies belong to a class of plasma proteins called
 - a. albumins.
 - b. gamma globulins.
 - c. alpha globulins.
 - d. procoagulants.
 - e. agglutinins.
2. Serum is blood plasma minus its
 - a. sodium ions.
 - b. calcium ions.
 - c. clotting proteins.
 - d. globulins.
 - e. albumins.
3. Which of the following conditions is most likely to cause hemolytic anemia?
 - a. folic acid deficiency
 - b. iron deficiency
 - c. mushroom poisoning
 - d. alcoholism
 - e. hypoxemia
4. It is impossible for a type O⁺ baby to have a type _____ mother.
 - a. AB⁻
 - b. O⁻
 - c. O⁺
 - d. A⁺
 - e. B⁺
5. Which of the following is *not* a component of hemostasis?
 - a. platelet plug formation
 - b. agglutination
 - c. clot retraction
 - d. a vascular spasm
 - e. degranulation

718 PART FOUR Regulation and Maintenance

6. Which of the following contributes most to the viscosity of blood?
 - a. albumin
 - b. sodium
 - c. globulins
 - d. erythrocytes
 - e. fibrin
7. Which of these is a granulocyte?
 - a. a monocyte
 - b. a lymphocyte
 - c. a macrophage
 - d. an eosinophil
 - e. an erythrocyte
8. Excess iron is stored in the liver as a complex called
 - a. gastroferritin.
 - b. transferrin.
 - c. ferritin.
 - d. hepatoferritin.
 - e. erythropoietin.
9. Pernicious anemia is a result of
 - a. hypoxemia.
 - b. iron deficiency.
 - c. malaria.
 - d. lack of intrinsic factor.
 - e. Rh incompatibility.
10. The first clotting factor that the intrinsic and extrinsic pathways have in common is
 - a. thromboplastin.
 - b. Hageman factor.
 - c. factor X.
 - d. prothrombin activator.
 - e. factor VIII.
11. Production of all the formed elements of blood is called _____.
12. The percentage of blood volume composed of RBCs is called the _____.
13. The extrinsic pathway of coagulation is activated by _____ from damaged perivascular tissues.
14. The RBC antigens that determine transfusion compatibility are called _____.
15. The hereditary lack of factor VIII causes a disease called _____.
16. The overall cessation of bleeding, involving several mechanisms, is called _____.
17. _____ results from a mutation that changes one amino acid in the hemoglobin molecule.
18. An excessively high RBC count is called _____.
19. Intrinsic factor enables the small intestine to absorb _____.
20. The kidney hormone _____ stimulates RBC production.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. By volume, the blood usually contains more plasma than blood cells.
2. An increase in the albumin concentration of the blood would tend to increase blood pressure.
3. Anemia is caused by a low oxygen concentration in the blood.
4. Hemostasis, coagulation, and clotting are three terms for the same process.
5. A man with blood type A⁺ and a woman with blood type B⁺ could have a baby with type O⁻.
6. Lymphocytes are the most abundant WBCs in the blood.
7. Calcium ions are required for blood clotting.
8. All formed elements of the blood come ultimately from pluripotent stem cells.
9. When RBCs die and break down, the globin moiety of hemoglobin is excreted and the heme is recycled to new RBCs.
10. Leukemia is a severe deficiency of white blood cells.

Answers in appendix B

Testing Your Comprehension

1. Why would erythropoiesis not correct the hypoxemia resulting from lung cancer?
2. People with chronic kidney disease often have hematocrits of less than half the normal value. Explain why.
3. An elderly white woman is hit by a bus and severely injured. Accident investigators are informed that she lives in an abandoned warehouse, where her few personal effects include several empty wine bottles and an expired driver's license indicating she is 72 years old. At the hospital, she is found to be severely anemic. List all the factors you can think of that may contribute to her anemia.
4. How is coagulation different from agglutination?
5. Although fibrinogen and prothrombin are equally necessary for blood clotting, fibrinogen is about 4% of the plasma protein whereas prothrombin is present only in small traces. In light of the roles of these clotting factors and your knowledge of enzymes, explain this difference in abundance.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Desmosomes and gap junctions (p. 173)
- Ultrastructure of striated muscle (pp. 405-409)
- Excitation-contraction coupling in muscle (p. 414)
- Length-tension relationship in muscle fibers (p. 420)
- Action potentials (p. 457)
- Mode of action of the sympathetic and parasympathetic nervous systems (pp. 576-579)

We are more conscious of our heart than we are of most organs, and more wary of its failure. Speculation about the heart is at least as old as written history. Some ancient Chinese, Egyptian, Greek, and Roman scholars correctly surmised that the heart is a pump for filling the vessels with blood. Aristotle's views, however, were a step backward. Perhaps because the heart quickens its pace when we are emotionally aroused, and because grief causes "heartache," he regarded it primarily as the seat of emotion, as well as a source of heat to aid digestion. During the Middle Ages, Western medical schools clung dogmatically to the ideas of Aristotle. Perhaps the only significant advance came from Arabic medicine, when thirteenth-century physician Ibn an-Nafis described the role of the coronary blood vessels in nourishing the heart. The sixteenth-century dissections and anatomical charts of Vesalius, however, greatly improved knowledge of cardiovascular anatomy and set the stage for a more scientific study of the heart and treatment of its disorders—the science we now call **cardiology**.¹

In the early decades of the twentieth century, little could be recommended for heart disease other than bed rest. Then nitroglycerin was found to improve coronary circulation and relieve the pain resulting from physical exertion, digitalis proved effective for treating abnormal heart rhythms, and diuretics were first used to reduce hypertension. Coronary bypass surgery, replacement of diseased valves, clot-dissolving enzymes, heart transplants, and artificial pacemakers, valves, and hearts have made cardiology one of the most dramatic and attention-getting fields of medicine.

19.1 Overview of the Cardiovascular System

Objectives

When you have completed this section, you should be able to

- define and distinguish between the pulmonary and systemic circuits;
- describe the general location, size, and shape of the heart; and
- describe the pericardial sac that encloses the heart.

The **cardiovascular**² system consists of the heart and the blood vessels. The heart functions as a muscular pump

FIGURE 19.1 General Schematic of the Cardiovascular System.

Are the lungs supplied by the pulmonary circuit, the systemic circuit, or both? Explain.

that keeps blood flowing through the vessels. The vessels deliver the blood to all the body's organs and then return it to the heart (fig. 19.1). The broader term *circulatory system* also includes the blood and some authorities use

¹cardio = heart + logy = study

²cardio = heart + vas = vessel

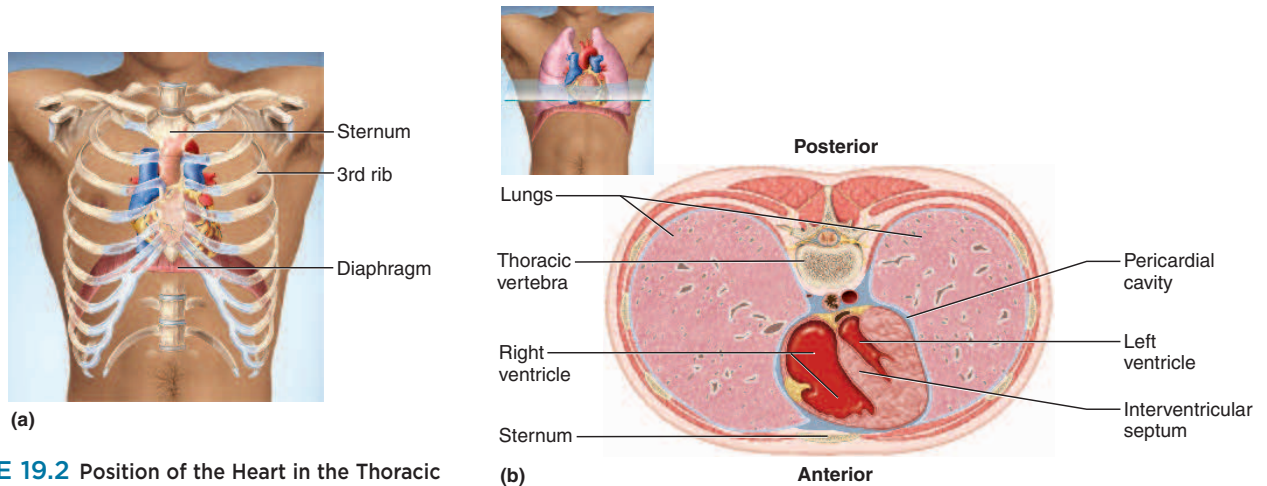

FIGURE 19.2 Position of the Heart in the Thoracic Cavity. (a) Relationship to the thoracic cage. (b) Cross section of the thorax at the level of the heart. (c) Frontal view with the lungs slightly retracted and the pericardial sac opened.

Does most of the heart lie to the right or left of the median plane?

it to include the lymphatic system as well (described in chapter 21).

The Pulmonary and Systemic Circuits

The cardiovascular system has two major divisions: a **pulmonary circuit**, which carries blood to the lungs for gas exchange and returns it to the heart, and a **systemic circuit**, which supplies blood to every organ of the body, including other parts of the lungs and the wall of the heart itself.

The right side of the heart furnishes blood to the pulmonary circuit. It receives blood that has circulated through the body, unloaded its oxygen and nutrients, and picked up a load of carbon dioxide and other wastes. It pumps this oxygen-poor blood into a large artery, the *pulmonary trunk*, which immediately divides into right and left *pulmonary arteries*. These transport blood to the air sacs (*alveoli*) of the lungs, where carbon dioxide is unloaded and oxygen is picked up. The oxygen-rich blood then flows by way of the *pulmonary veins* to the left side of the heart.

The left side supplies the systemic circuit. Blood leaves it by way of another large artery, the *aorta*. The aorta takes a sharp inverted U-turn, the *aortic arch*, and passes downward, posterior to the heart. The aortic arch gives off arteries that supply the head, neck, and upper limbs. The aorta then travels through the thoracic and abdominal cavities and issues smaller arteries to the other organs before branching into the lower limbs. After circulating

through the body, the now deoxygenated systemic blood returns to the right side of the heart mainly by way of two large veins: the *superior vena cava* (draining the upper body) and *inferior vena cava* (draining everything below the diaphragm). The major arteries and veins entering and leaving the heart are called the *great vessels* (*great arteries and veins*) because of their relatively large diameters.

Position, Size, and Shape of the Heart

The heart is located in the thoracic cavity in the mediastinum, between the lungs and deep to the sternum. From its superior to inferior midpoints, it is tilted toward the left, so about two-thirds of the heart lies to the left of the median plane (fig. 19.2; see also figs. A.18–A.19, p. 46). The broad superior portion of the heart, called the **base**,

is the point of attachment for the great vessels described previously. The inferior end tapers to a blunt point, the **apex**, immediately above the diaphragm.

The adult heart is about 9 cm (3.5 in.) wide at the base, 13 cm (5 in.) from base to apex, and 6 cm (2.5 in.) from anterior to posterior at its thickest point—roughly the size of one's fist. It weighs about 300 g (10 oz).

The Pericardium

The heart is enclosed in a double-walled sac called the **pericardium**.³ The outer wall, called the **pericardial sac (parietal pericardium)**, has a tough, superficial *fibrous layer* of dense irregular connective tissue and a deep, thin *serous layer*. The serous layer turns inward at the base of the heart and forms the **epicardium (visceral pericardium)** covering the heart surface (fig. 19.3). The pericardial sac is anchored by ligaments to the diaphragm below and the sternum anterior to it, and more loosely

anchored by fibrous connective tissue to mediastinal tissue posterior to the heart.

Between the parietal and visceral membranes is a space called the **pericardial cavity** (see figs. 19.2b and 19.3). It contains 5 to 30 mL of **pericardial fluid**, exuded by the serous pericardium. The fluid lubricates the membranes and allows the heart to beat with minimal friction. In *pericarditis*—inflammation of the pericardium—the membranes may become roughened and produce a painful *friction rub* with each heartbeat. In addition to reducing friction, the pericardium isolates the heart from other thoracic organs and allows it room to expand, yet resists excessive expansion. (See *cardiac tamponade* in table 19.3, p. 749).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Distinguish between the pulmonary and systemic circuits and state which part of the heart supplies each one.
2. Make a two-color sketch of the pericardium; use one color for the fibrous pericardium and another for the serous pericardium and show their relationship to the heart wall and pericardial cavity.

³peri = around + cardi = heart

FIGURE 19.3 The Pericardium and Heart Wall. The inset shows the layers of the heart wall in relationship to the pericardium.

19.2 Gross Anatomy of the Heart

Objectives

When you have completed this section, you should be able to

- describe the three layers of the heart wall;
- identify the four chambers of the heart;
- identify the surface features of the heart and correlate them with its internal four-chambered anatomy;
- identify the four valves of the heart;
- trace the flow of blood through the four chambers and valves of the heart and adjacent blood vessels; and
- describe the arteries that nourish the myocardium and the veins that drain it.

The Heart Wall

The heart wall consists of three layers: *epicardium*, *myocardium*, and *endocardium*.

The **epicardium**⁴ (visceral pericardium) is a serous membrane on the heart surface. It consists mainly of a simple squamous epithelium overlying a thin layer of areolar tissue. In some places, it also includes a thick

⁴epi = upon + cardi = heart

FIGURE 19.4 The Heart of a Human Cadaver.

layer of adipose tissue, whereas in other areas it is fat-free and translucent, so the muscle of the underlying myocardium shows through (figs. 19.4a and 19.5). The largest branches of the coronary blood vessels travel through the epicardium.

The **endocardium**,⁵ a similar layer, lines the interior of the heart chambers (figs. 19.3 and 19.4b). Like the epicardium, this is a simple squamous endothelium overlying a thin areolar tissue layer; however, it has no adipose

tissue. The endocardium covers the valve surfaces and is continuous with the endothelium of the blood vessels.

The **myocardium**⁶ between these two is composed of cardiac muscle. This is by far the thickest layer and performs the work of the heart. Its thickness varies greatly from one heart chamber to another and is proportional to the workload on the individual chambers. Its muscle spirals around the heart (fig. 19.6), so when the ventricles contract, they exhibit a twisting or wringing motion.

⁵endo = internal + cardi = heart

⁶myo = muscle + cardi = heart

(a) Anterior view

(b) Posterior view

FIGURE 19.5 Surface Anatomy of the Heart. The coronary blood vessels on the heart surface are identified in figure 19.10.

FIGURE 19.6 Spiral Arrangement of the Cardiac Muscle. (a) Anterior view of the heart with the epicardium rendered transparent to expose the bundles of myocardial muscle. (b) View from the apex to show the way the muscle coils around the heart. This results in a twisting motion when the ventricles contract.

The microscopic structure of the cardiac muscle cells (*cardiac myocytes* or *cardiocytes*) is detailed later.

The heart also has a framework of collagenous and elastic fibers that make up the **fibrous skeleton**. This tissue is especially concentrated in the walls between the heart chambers, in *fibrous rings* (*anuli fibrosi*) around the valves, and in sheets of tissue that interconnect these rings (see fig. 19.8). The fibrous skeleton has multiple functions: (1) It provides structural support for the heart, especially around the valves and the openings of the great vessels; it holds these orifices open and prevents them from excessively stretching when blood surges through them. (2) It anchors the cardiocytes and gives them something to pull against. (3) As a nonconductor of electricity, it serves as electrical insulation between the atria and the ventricles, so the atria cannot stimulate the ventricles directly. This insulation is important to the timing and coordination of electrical and contractile activity. (4) Some authorities think that elastic recoil of the fibrous skeleton may aid in refilling the heart with blood after each beat in a manner described later.

Think About It

Parts of the fibrous skeleton sometimes become calcified in old age. How would you expect this to affect cardiac function?

The Chambers

The heart has four chambers, best seen in a frontal section (figs. 19.4b and 19.7). The two at the superior pole (base) of the heart are the **right** and **left atria** (AY-tree-uh; singular *atrium*⁷). They are thin-walled receiving chambers for blood returning to the heart by way of the great veins. Most of the mass of each atrium is on the posterior side of the heart, so only a small portion is visible from an anterior view. Here, each atrium has a small earlike extension called an **auricle**⁸ that slightly increases its volume (see fig. 19.5a).

The two inferior chambers, the **right** and **left ventricles**,⁹ are the pumps that eject blood into the arteries and keep it flowing around the body. The right ventricle constitutes most of the anterior aspect of the heart, whereas the left ventricle forms the apex and inferoposterior aspect.

On the surface, the boundaries of the four chambers are marked by three sulci (grooves), which are largely filled by fat and the coronary blood vessels (see fig. 19.5a). The **coronary**¹⁰ (**atrioventricular**) **sulcus** encircles the heart near the base and separates the atria above from the ventricles below. It can be exposed by lifting the margins of the atria. The other two sulci extend obliquely down the heart from the coronary sulcus toward the apex—one on the front of the heart called the **anterior interventricular sulcus** and one on the back called the **posterior interventricular sulcus**. These sulci overlie an internal wall, the *interventricular septum*, that divides the right ventricle from the left. The coronary sulcus and two interventricular sulci harbor the largest of the coronary blood vessels.

The atria exhibit thin flaccid walls corresponding to their light workload—all they do is pump blood into the ventricles immediately below (fig. 19.7). They are separated from each other by a wall called the **interatrial septum**. The right atrium and both auricles exhibit internal ridges of myocardium called **pectinate**¹¹ **muscles**.

The **interventricular septum** is a much more muscular, vertical wall between the ventricles. The right ventricle pumps blood only to the lungs and back, so its wall is only moderately muscular. The wall of the left ventricle is two to four times as thick because it bears the greatest workload of all four chambers, pumping blood through the entire body. Both ventricles exhibit internal ridges called **trabeculae carneae**¹² (trah-BEC-you-lee CAR-nee-ee).

The Valves

To pump blood effectively, the heart needs valves that ensure a one-way flow. There is a valve between each atrium and its ventricle and another at the exit from each

⁷atrium = entryway

⁸auricle = little ear

⁹ventr = belly, lower part + icle = little

¹⁰coron = crown + ary = pertaining to

¹¹pectin = comb + ate = like

ventricle into its great artery (fig. 19.7), but there are no valves where the great veins empty into the atria. Each valve consists of two or three fibrous flaps of tissue called **cusps** or **leaflets**, covered with endocardium.

The **atrioventricular (AV) valves** regulate the openings between the atria and ventricles. The **right AV (tricuspid) valve** has three cusps and the **left AV (bicuspid) valve** has two (fig. 19.8). The left AV valve is also known as the **mitral (MY-trul) valve** after its resemblance to a miter, the headdress of a church bishop. Stringlike **tendinous cords (chordae tendineae)**, reminiscent of the shroud lines of a parachute, connect the valve cusps to conical **papillary¹³ muscles** on the floor of the ventricle. They prevent the AV valves from flipping inside out or bulging into the atria when the ventricles contract.

The **semilunar¹⁴ valves** (pulmonary and aortic valves) regulate the flow of blood from the ventricles into the great arteries. The **pulmonary valve** controls the opening

from the right ventricle into the pulmonary trunk, and the **aortic valve** controls the opening from the left ventricle into the aorta. Each has three cusps shaped somewhat like shirt pockets. There are no tendinous cords on the semilunar valves.

The valves do not open and close by any muscular effort of their own. The cusps are simply pushed open and closed by changes in blood pressure that occur as the heart chambers contract and relax. Later in this chapter, we will take a closer look at these pressure changes and their effect on the valves.

Blood Flow Through the Heart Chambers

Until the sixteenth century, blood was thought to flow directly from the right ventricle into the left through invisible pores in the septum. This of course is not true. Blood is kept entirely separate on the right and left sides of the heart. Figure 19.9 shows the pathway of the blood

¹³*papill* = nipple + *ary* = like, shaped

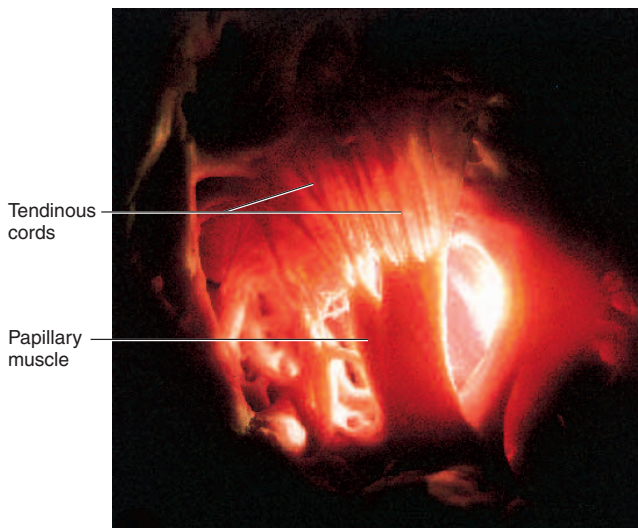

¹⁴*semi* = half + *lunar* = moonlike

as it travels from the right atrium through the body and back to the starting point.

The Coronary Circulation

If your heart lasts for 80 years and beats an average of 75 times a minute, it will beat more than 3 billion times and pump more than 200 million liters of blood. It is, in

short, a remarkably hardworking organ, and understandably, it needs an abundant supply of oxygen and nutrients. These needs are not met to any appreciable extent by the blood in the heart chambers, because the diffusion of substances from there to the myocardium would be too slow. Instead, the myocardium has its own supply of arteries and capillaries that deliver blood to every muscle cell. The blood vessels of the heart wall constitute the **coronary circulation**.

At rest, the coronary blood vessels supply the myocardium with about 250 mL of blood per minute. This constitutes about 5% of the circulating blood going to meet the metabolic needs of the heart, even though the heart is only 0.5% of the body's weight. It receives 10 times its "fair share" to sustain its strenuous workload.

Arterial Supply

The coronary circulation is the most variable aspect of cardiac anatomy. The following description covers only the largest coronary blood vessels and describes only the pattern seen in about 70% to 85% of persons.

Immediately after the aorta leaves the left ventricle, it gives off a right and left coronary artery. The orifices of these two arteries lie deep in the pockets formed by two of the aortic valve cusps (fig. 19.8a). The **left coronary artery (LCA)** travels through the coronary sulcus under the left auricle and divides into two branches (fig. 19.10):

1. The **anterior interventricular branch** travels down the anterior interventricular sulcus to the apex, rounds the bend, and travels a short distance up the posterior side of the heart. There it joins the posterior interventricular branch described shortly.

- ① Blood enters right atrium from superior and inferior venae cavae.
- ② Blood in right atrium flows through right AV valve into right ventricle.
- ③ Contraction of right ventricle forces pulmonary valve open.
- ④ Blood flows through pulmonary valve into pulmonary trunk.
- ⑤ Blood is distributed by right and left pulmonary arteries to the lungs, where it unloads CO_2 and loads O_2 .
- ⑥ Blood returns from lungs via pulmonary veins to left atrium.
- ⑦ Blood in left atrium flows through left AV valve into left ventricle.
- ⑧ Contraction of left ventricle (simultaneous with step ③) forces aortic valve open.
- ⑨ Blood flows through aortic valve into ascending aorta.
- ⑩ Blood in aorta is distributed to every organ in the body, where it unloads O_2 and loads CO_2 .
- ⑪ Blood returns to heart via venae cavae.

FIGURE 19.9 The Pathway of Blood Flow Through the Heart. The pathway from 4 through 6 is the pulmonary circuit, and the pathway from 9 through 11 is the systemic circuit. Violet arrows indicate oxygen-poor blood; orange arrows indicate oxygen-rich blood.

Clinically, it is also called the *left anterior descending (LAD) branch*. This artery supplies blood to both ventricles and the anterior two-thirds of the interventricular septum.

2. The **circumflex branch** continues around the left side of the heart in the coronary sulcus. It gives off a **left marginal branch** that passes down the left margin of the heart and furnishes blood to the left ventricle. The circumflex branch then ends on the posterior side of the heart. It supplies blood to the left atrium and posterior wall of the left ventricle.

The **right coronary artery (RCA)** supplies the right atrium and sinoatrial node (pacemaker), continues along the coronary sulcus under the right auricle, and gives off two branches of its own:

1. The **right marginal branch** runs toward the apex of the heart and supplies the lateral aspect of the right atrium and ventricle.
2. The RCA continues around the right margin of the heart to the posterior side, sends a small branch to the atrioventricular node, then gives off a large **posterior interventricular branch**. This branch travels down the corresponding sulcus and supplies the posterior

walls of both ventricles as well as the posterior portion of the interventricular septum. It ends by joining the anterior interventricular branch of the LCA.

The energy demand of the cardiac muscle is so critical that an interruption of the blood supply to any part of the myocardium can cause necrosis within minutes. A fatty deposit or blood clot in a coronary artery can cause a **myocardial infarction**¹⁵ (**MI**), or heart attack (see Insight 19.1). Some protection from MI is provided by the aforementioned points where two arteries come together and combine their blood flow to points farther downstream. Such points of convergence, called *arterial anastomoses* (ah-NASS-tih-MO-seez), provide an alternative route, called **collateral circulation**, that can supply the heart tissue with blood if the primary route becomes obstructed.

In most organs, blood flow peaks when the ventricles contract and eject blood into the arteries, and diminishes when the ventricles relax and refill. The opposite is true in the coronary arteries. There are three reasons for this. (1) Contraction of the myocardium compresses the arteries and obstructs blood flow. (2) During *ventricular systole*

¹⁵infarct = to stuff

(a) Anterior view

(b) Posterior view

(c)

FIGURE 19.10 The Principal Coronary Blood Vessels. (a) Anterior view. (b) Posterior view. (c) A polymer cast of the coronary circulation.

(contraction of the ventricles), the aortic valve is forced open and the valve cusps cover the openings to the coronary arteries, blocking blood from flowing into them. (3) During *ventricular diastole* (relaxation), blood in the aorta briefly surges back toward the heart. It fills the aortic valve cusps and some of it flows into the coronary arteries, like water pouring into a bucket and flowing out through a hole in the bottom. In the coronary blood vessels, therefore, blood flow increases during ventricular relaxation.

INSIGHT 19.1 Clinical Application

Angina and Heart Attack

An obstruction of coronary blood flow can cause a chest pain known as *angina pectoris*¹⁶ (an-JY-na PEC-toe-riss) or, more seriously, *myocardial infarction* (heart attack). Angina is a sense of heaviness or pain in the chest resulting from temporary and reversible *ischemia*¹⁷ (iss-KEE-me-ah), or deficiency of blood flow to the cardiac muscle. It typically occurs when a partially blocked coronary artery constricts. The oxygen-deprived myocardium shifts to anaerobic fermentation, producing lactic acid, which stimulates pain receptors in the heart. The pain abates when the artery relaxes and normal blood flow resumes.

Myocardial infarction (MI), on the other hand, is the sudden death of a patch of myocardium resulting from long-term obstruction of the coronary circulation. Coronary arteries often become obstructed by a blood clot or fatty deposit called an *atheroma* (see Insight 19.5). As cardiac muscle downstream from the obstruction dies, the individual commonly feels a sense of heavy pressure or squeezing pain in the chest, often “radiating” to the shoulder and left arm. Some MIs are painless, “silent” heart attacks, especially in elderly or diabetic individuals. Infarctions weaken the heart wall and disrupt electrical conduction pathways, potentially leading to fibrillation and cardiac arrest (discussed later in this chapter). MI is responsible for about half of all deaths in the United States.

¹⁶angina = to choke, strangle + *pectoris* = of the chest

¹⁷isch = holding back + *em* = blood + *ia* = condition

Venous Drainage

Venous drainage refers to the route by which blood leaves an organ. After flowing through capillaries of the heart wall, about 5% to 10% of the coronary blood empties directly from multiple small *thebesian*¹⁸ *veins* (*smallest cardiac veins*) into the heart chambers, especially the right ventricle. The rest returns to the right atrium by the following route (fig. 19.10):

- The **great cardiac vein** collects blood from the anterior aspect of the heart and travels alongside the anterior interventricular artery. It carries blood from the apex toward the coronary sulcus, then arcs around the left side of the heart and empties into the coronary sinus.
- The **posterior interventricular (middle cardiac) vein**, found in the posterior sulcus, collects blood from the posterior aspect of the heart. It, too, carries blood from the apex upward and drains into the same sinus.
- The **left marginal vein** travels from a point near the apex up the left margin, and also empties into the coronary sinus.
- The **coronary sinus**, a large transverse vein in the coronary sulcus on the posterior side of the heart, collects blood from all three of the aforementioned veins as well as some smaller ones. It empties blood into the right atrium.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

3. Name the three layers of the heart and describe their structural differences.
4. What are the functions of the fibrous skeleton?
5. Trace the flow of blood through the heart, naming each chamber and valve in order.
6. What are the three principal branches of the left coronary artery? Where are they located on the heart surface? What are the branches of the right coronary artery, and where are they located?
7. What is the medical significance of anastomoses in the coronary arterial system?
8. Why do the coronary arteries carry a greater blood flow during ventricular diastole than they do during ventricular systole?
9. What are the three major veins that empty into the coronary sinus?

¹⁸Adam Christian Thebesius (1686–1732), German physician

19.3 Cardiac Muscle and the Cardiac Conduction System

Objectives

When you have completed this section, you should be able to

- describe the unique structural and metabolic characteristics of cardiac muscle;
- explain the nature and functional significance of the intercellular junctions between cardiac muscle cells;
- describe the heart's pacemaker and internal electrical conduction system; and
- describe the nerve supply to the heart and explain its role.

The most obvious physiological fact about the heart is its rhythmicity. It contracts at regular intervals, typically about 75 beats per minute (bpm) in a resting adult. Among invertebrates such as clams, crabs, and insects, each heartbeat is triggered by a pacemaker in the nervous system. The vertebrate heartbeat, however, is said to be *myogenic*¹⁹ because the signal originates within the heart itself. Indeed, we can sever the nerves to the heart, or even remove the heart from the body and keep it in aerated saline, and it will beat for hours. Cut the heart into little pieces, and each piece continues its own rhythmic pulsations; even solitary, isolated cardiac muscle cells pulsate rhythmically, so cardiocytes are said to be inherently **autorhythmic**.²⁰ Thus the heart is obviously not dependent on the nervous system for its rhythm. It has its own pacemaker and electrical system. We now turn our attention to the cardiac muscle, the pacemaker and internal electrical system, and the heart's nerve supply—the foundations for its electrical activity and rhythmic beat.

Structure of Cardiac Muscle

The heart is mostly muscle. It is striated like skeletal muscle, but quite different from skeletal muscle in other structural and functional respects—and it has to be, if we want it to pump infallibly, more than once every second, for nine or ten decades.

Cardiocytes are relatively short, thick, branched cells, typically 50 to 100 μm long and 10 to 20 μm wide (fig. 19.11). The ends of the cell are slightly branched, like a log with deep notches in the end. Through these branches, each cardiocyte contacts several others, so collectively they form a network throughout each pair of

¹⁹*myo* = muscle + *genic* = arising from

²⁰*auto* = self

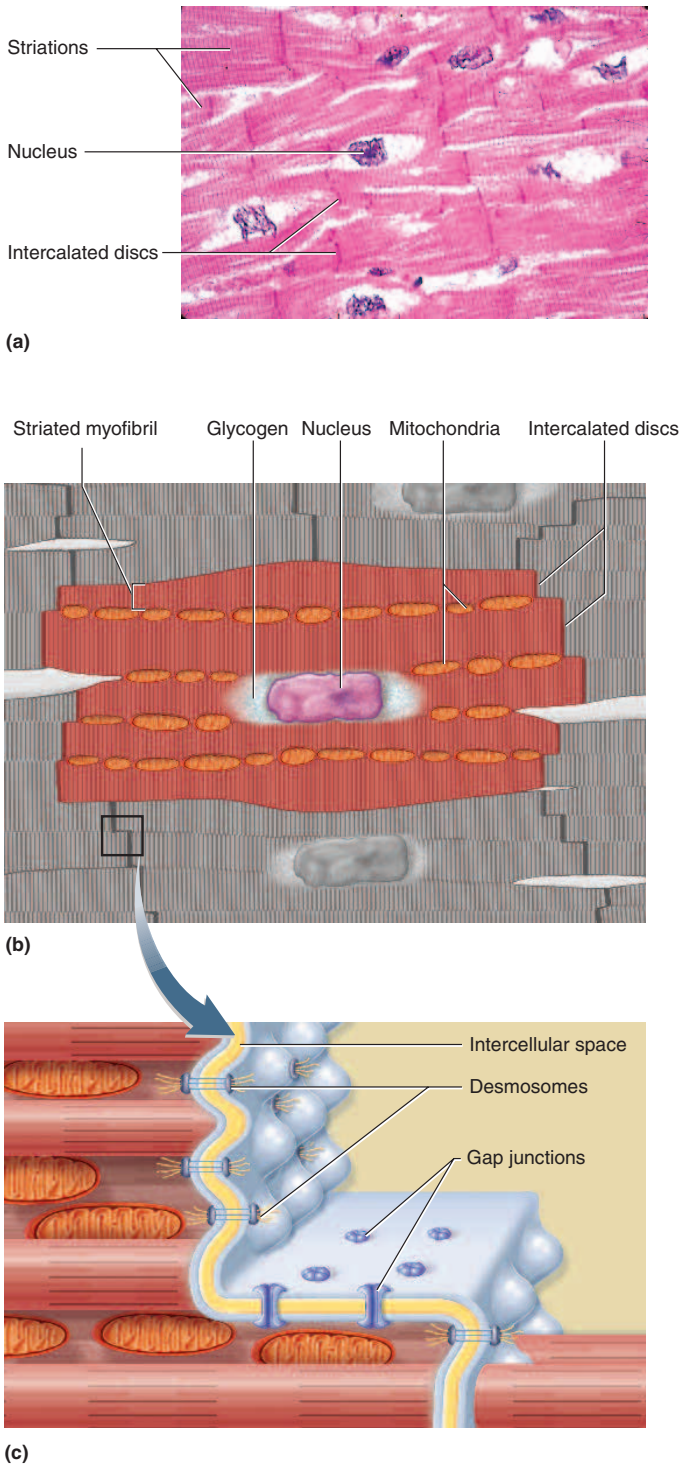

FIGURE 19.11 Cardiac Muscle. (a) Light micrograph. (b) Structure of a cardiocyte and its relationship to adjacent cardiocytes. All of the colored area is a single cell. Note that it is notched at the ends and typically linked to two or more neighboring cardiocytes by the mechanical and electrical junctions of the intercalated discs. (c) Structure of an intercalated disc.

heart chambers—one network in the atria and one in the ventricles. A cardiocyte usually has only one, centrally placed nucleus, often surrounded by a light-staining mass of glycogen. The sarcoplasmic reticulum is less developed than in skeletal muscle; it lacks terminal cisternae, although it does have footlike sacs associated with the T tubules. The T tubules are much larger than in skeletal muscle. During excitation of the cell, they admit supplemental calcium ions from the extracellular fluid to activate muscle contraction. Cardiocytes have especially large mitochondria for reasons noted shortly.

Cardiocytes are joined end to end by thick connections called **intercalated** (in-TUR-ka-LAY-ted) **discs**. With the right histological stain, these appear as dark lines thicker than the striations. An intercalated disc is a complex steplike structure with three distinctive features not found in skeletal muscle:

1. **Interdigitating folds.** The plasma membrane at the end of the cell is folded somewhat like the bottom of an egg carton. The folds of adjoining cells interlock with each other and increase the surface area of intercellular contact.
2. **Mechanical junctions.** The cells are tightly joined by two types of mechanical junctions: the fascia adherens and desmosomes. The *fascia adherens*²¹ (FASH-ee-ah ad-HEER-enz) is the most extensive. It is a broad band in which the actin of the thin myofilaments is anchored to the plasma membrane and each cell is linked to the next via transmembrane proteins. The fascia adherens is interrupted here and there by *desmosomes*. Described in more detail on p. 173, desmosomes are weldlike mechanical junctions between cells. They prevent the cardiocytes from pulling apart when they contract.
3. **Electrical junctions.** The intercalated discs also contain *gap junctions*, which form channels that allow ions to flow from the cytoplasm of one cardiocyte directly into the next (see p. 173). They enable each cardiocyte to electrically stimulate its neighbors. Thus, the entire myocardium of the two atria behaves almost like a single cell, as does the entire myocardium of the two ventricles. This unified action is essential for the effective pumping of a heart chamber.

Skeletal muscle contains satellite cells that can divide and replace dead muscle fibers to some extent. Cardiac muscle lacks these, however, so the repair of damaged cardiac muscle is almost entirely by fibrosis (scarring). A limited capacity for myocardial mitosis and regeneration was discovered in 2001, raising hope that it might one day be clinically enhanced to repair hearts damaged by myocardial infarction.

²¹fascia = band + adherens = adhering

Metabolism of Cardiac Muscle

Cardiac muscle depends almost exclusively on aerobic respiration to make ATP. It is very rich in myoglobin (a short-term source of stored oxygen for aerobic respiration; see p. 425) and glycogen (for stored energy). Its huge mitochondria fill about 25% of the cell; skeletal muscle fibers, by comparison, have much smaller mitochondria that occupy only 2% of the fiber. Cardiac muscle is relatively adaptable with respect to the organic fuels used. At rest, the heart gets about 60% of its energy from fatty acids, 35% from glucose, and 5% from other fuels such as ketones, lactic acid, and amino acids. Cardiac muscle is more vulnerable to an oxygen deficiency than it is to the lack of any specific fuel. Because it makes little use of anaerobic fermentation or the oxygen debt mechanism, it is not prone to fatigue. You can easily appreciate this fact by squeezing a rubber ball in your fist once every second for a minute or two. You will soon feel weakness and fatigue in your skeletal muscles and perhaps feel all the more grateful that cardiac muscle can maintain a rhythm like this, without fatigue, for a lifetime.

Conduction System

The heartbeat is coordinated by a **cardiac conduction system** composed of an internal pacemaker and nerverlike conduction pathways through the myocardium. There is some disagreement on the origin of this system. Some evidence indicates that it arises, like the nervous system, from the neural crest of the embryo (see p. 519); other evidence indicates that it is formed from modified cardiocytes that forfeit the ability to contract and specialize,

instead, in generating action potentials. Whatever the origin of the system may be, it generates and conducts rhythmic electrical signals in the following order (fig. 19.12):

- ① The **sinoatrial (SA) node**, a patch of modified cardiocytes in the right atrium, just under the epicardium near the superior vena cava. This is the **pacemaker** that initiates each heartbeat and determines the heart rate.
- ② Signals from the SA node spread throughout the atria, as shown by the red arrows in the figure.
- ③ The **atrioventricular (AV) node**, located near the right AV valve at the lower end of the interatrial septum. This node acts as an electrical gateway to the ventricles; the fibrous skeleton acts as an insulator to prevent currents from getting to the ventricles by any other route.
- ④ The **atrioventricular (AV) bundle (bundle of His²²)**, a pathway by which signals leave the AV node. The AV bundle soon forks into **right and left bundle branches**, which enter the interventricular septum and descend toward the apex.
- ⑤ **Purkinje²³ (pur-KIN-jee) fibers**, nerverlike processes that arise from the lower end of the bundle branches and turn upward to spread throughout the ventricular myocardium. Purkinje fibers distribute the electrical excitation to the cardiocytes of the ventricles. They form a more elaborate network in the left ventricle than in the right.

²²Wilhelm His, Jr. (1863–1934), German physiologist

²³Johannes E. Purkinje (1787–1869), Bohemian physiologist

FIGURE 19.12 The Cardiac Conduction System. Electrical signals travel along the pathways indicated by the arrows.

● Which atrium is first to receive the signal that induces atrial contraction?

Once the Purkinje fibers have delivered the electrical signal to their limits, the cardiocytes themselves perpetuate it by passing ion flows from cell to cell through their gap junctions.

Nerve Supply to the Heart

Even though the heart has its own pacemaker, it does receive both sympathetic and parasympathetic nerves that modify the heart rate and contraction strength. Sympathetic stimulation can raise the heart rate to as high as 230 bpm, and parasympathetic stimulation can slow it to as low as 20 bpm or even stop the heart for a few seconds.

The sympathetic pathway to the heart originates in the lower cervical to upper thoracic segments of the spinal cord. Preganglionic nerve fibers extend from there to the adjacent sympathetic chain ganglia, and some of them ascend to the cervical ganglia. Postganglionic fibers arise in these ganglia, pass through a **cardiac plexus** in the mediastinum (see fig. 15.4, p. 570), and continue by way of **cardiac nerves** to the heart. These fibers terminate in the SA and AV nodes and in the atrial and ventricular myocardium, as well as in the aorta, pulmonary trunk, and coronary arteries. Sympathetic stimulation increases the heart rate and contraction strength and dilates the coronary arteries to increase myocardial blood flow.

The parasympathetic pathway begins with nuclei of the vagus nerves in the medulla oblongata. Preganglionic fibers extend through the vagus nerves to the cardiac plexus, where they mingle with the sympathetic fibers, and continue to the heart by way of the cardiac nerves (see fig. 15.7, p. 574). They synapse with postganglionic neurons in the epicardial surface and within the heart wall. Postganglionic fibers from the right vagus nerve lead mainly to the SA node and those from the left vagus lead mainly to the AV node, but each has some fibers that cross over to the other target cells. There is little or no vagal parasympathetic innervation of the myocardium. Parasympathetic stimulation reduces the heart rate. Autonomic effects on heart rate and contraction strength are described in more detail later in this chapter.

From the foregoing description, you can see that the cardiac nerves from the plexus to the heart contain both sympathetic and parasympathetic efferent fibers. They also carry sensory (afferent) fibers from the heart to the CNS. Those fibers are important in cardiovascular reflexes and the transmission of pain signals from the heart.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

10. What organelle(s) are less developed in cardiac muscle than in skeletal muscle? What one(s) are more developed? What is the functional significance of these differences between muscle types?

11. What exactly is an intercalated disc, and what function is served by each of its components?
12. Cardiac muscle rarely uses anaerobic fermentation to generate ATP. What benefit do we gain from this fact?
13. Where is the pacemaker of the heart located? What is it called? Trace the path of electrical excitation from there to a cardiocyte of the left ventricle, naming each component of the conduction system along the way.
14. Why does the heart have a nerve supply, since it continues to beat even without one?

19.4 Electrical and Contractile Activity of the Heart

Objectives

When you have completed this section, you should be able to

- explain why the SA node fires spontaneously and rhythmically;
- explain how the SA node excites the myocardium;
- describe the unusual action potentials of cardiac muscle and relate them to the contractile behavior of the heart; and
- interpret a normal electrocardiogram.

In this section, we examine how the electrical events in the heart produce its cycle of contraction and relaxation. Contraction is called **systole** (SIS-toe-lee) and relaxation is **diastole** (dy-ASS-toe-lee). These terms can refer to a specific part of the heart (for example, atrial systole), but if no particular chamber is specified, they usually refer to the more conspicuous and important ventricular action, which ejects blood from the heart.

The Cardiac Rhythm

The normal heartbeat triggered by the SA node is called the **sinus rhythm**. At rest, the adult heart typically beats about 70 to 80 times per minute, although heart rates from 60 to 100 bpm are not unusual.

Stimuli such as hypoxia, electrolyte imbalances, caffeine, nicotine, and other drugs can cause other parts of the conduction system to fire before the SA node does, setting off an extra heartbeat called a *premature ventricular contraction (PVC)*, or *extrasystole*. Any region of spontaneous firing other than the SA node is called an **ectopic**²⁴ **focus**. If the SA node is damaged, an ectopic focus may take over the governance of the heart rhythm. The most common ectopic focus is the AV node, which produces a slower heartbeat of 40 to 50 bpm called a **nodal rhythm**.

²⁴ec = cut of + top = place

If neither the SA nor AV node is functioning, other ectopic foci fire at rates of 20 to 40 bpm. The nodal rhythm is sufficient to sustain life, but a rate of 20 to 40 bpm provides too little flow to the brain to be survivable. This condition calls for an artificial pacemaker.

Any abnormal cardiac rhythm is called **arrhythmia**²⁵ (see Insight 19.2). One cause of arrhythmia is a **heart block**—the failure of any part of the cardiac conduction system to transmit signals, usually as a result of disease and degeneration of conduction system fibers. A *bundle branch block*, for example, is due to damage to one or both bundle branches. Damage to the AV node causes *total heart block*, in which signals from the atria fail to reach the ventricles and the ventricles beat at their own intrinsic rhythm of 20 to 40 bpm.

Pacemaker Physiology

Why does the SA node spontaneously fire at regular intervals? Unlike skeletal muscle or neurons, the cells of the SA node do not have a stable resting membrane potential. Their membrane potential starts at about -60 mV and drifts upward, showing a gradual depolarization called the **pacemaker potential** (fig. 19.13). This results from a slow inflow of Na^+ without a compensating outflow of K^+ .

²⁵a = without + *rhythm* + *ia* = condition

INSIGHT 19.2 Clinical Application

Cardiac Arrhythmias

Atrial flutter, premature ventricular contractions, and ventricular fibrillation are common cardiac arrhythmias. *Atrial flutter* occurs when ectopic foci in the atria set off extra contractions and the atria beat 200 to 400 times per minute. *Premature ventricular contractions (PVCs)* occur singly or in bursts as a result of early firing of an ectopic focus (see fig. 19.17d). PVCs are often due to irritation of the heart by stimulants, emotional stress, or lack of sleep, but they sometimes indicate more serious pathology.

Ventricular fibrillation (see fig. 19.17e) is a serious arrhythmia caused by electrical signals arriving at different regions of the myocardium at widely different times. A fibrillating ventricle exhibits squirming, uncoordinated contractions; surgeons have described it as feeling like a “bag of worms.” Since a fibrillating heart does not pump blood, there is no coronary perfusion (blood flow) and the myocardium rapidly dies of ischemia. *Cardiac arrest* is the cessation of cardiac output, with the ventricles either motionless or in fibrillation.

Fibrillation kills quickly if it is not stopped. *Defibrillation* is an emergency procedure in which the heart is given a strong electrical shock with a pair of electrodes. The purpose is to depolarize the entire myocardium and stop the fibrillation, with the hope that the SA node will resume its sinus rhythm. This does not correct the underlying cause of the arrhythmia, but it may sustain a patient’s life long enough to allow for other corrective action.

FIGURE 19.13 Pacemaker Potentials and Action Potentials of the SA Node.

When the pacemaker potential reaches a threshold of -40 mV, voltage-regulated **fast calcium–sodium channels** open and both Ca^{2+} and Na^+ flow in from the extracellular fluid. This produces the rising (depolarizing) phase of the action potential, which peaks slightly above 0 mV. At that point, K^+ channels open and K^+ leaves the cell. This makes the cytosol increasingly negative and creates the falling (repolarizing) phase of the action potential. When repolarization is complete, the K^+ channels close and the pacemaker potential starts over, on its way to producing the next heartbeat. Each depolarization of the SA node sets off one heartbeat. When the SA node fires, it excites the other components in the conduction system; thus, the SA node serves as the system’s pacemaker. At rest, it typically fires every 0.8 second or so, creating a heart rate of about 75 bpm.

Impulse Conduction to the Myocardium

Firing of the SA node excites atrial cardiocytes and stimulates the two atria to contract almost simultaneously. The signal travels at a speed of about 1 m/sec through the atrial myocardium and reaches the AV node in about 50 msec. In the AV node, the signal slows down to about 0.05 m/sec, partly because the cardiocytes here are thinner, but more importantly because they have fewer gap junctions over which the signal can be transmitted. This delays the signal at the AV node for about 100 msec—like highway traffic slowing down at a small town. This delay is essential because it gives the ventricles time to fill with blood before they begin to contract.

The ventricular myocardium has a conduction speed of only 0.3 to 0.5 m/sec. If this were the only route of travel for the excitatory signal, some cardiocytes would be stimulated much sooner than others. Ventricular contraction would not be synchronized and the pumping effectiveness

of the ventricles would be severely compromised. But signals travel through the AV bundle and Purkinje fibers at a speed of 4 m/sec, the fastest in the conduction system. Consequently, the entire ventricular myocardium depolarizes within 200 msec after the SA node fires, causing the ventricles to contract in near unison.

Signals reach the papillary muscles before the rest of the myocardium. Thus, these muscles contract and begin taking up slack in the tendinous cords an instant before ventricular contraction causes blood to surge against the AV valves. Ventricular systole begins at the apex of the heart, which is first to be stimulated, and progresses upward—pushing the blood upward toward the semilunar valves. Because of the spiral arrangement of ventricular cardiocytes, the ventricles twist slightly as they contract, like someone wringing out a towel.

Think About It

Some people have abnormal cords or bridges of myocardium that extend from atrium to ventricle, bypassing the AV node and other parts of the conduction system. How would you expect this to affect the cardiac rhythm?

Electrical Behavior of the Myocardium

The action potentials of cardiocytes are significantly different from those of neurons and skeletal muscle fibers (fig. 19.14). Cardiocytes have a stable resting potential of -90 mV and normally depolarize only when stimulated, unlike cells of the SA node. A stimulus opens voltage-regulated sodium gates, causing a Na^+

inflow and depolarizing the cell to its threshold. The threshold voltage rapidly opens additional Na^+ gates and triggers a positive feedback cycle like the one seen in the firing of a neuron (see p. 457). The action potential peaks at nearly $+30$ mV. The Na^+ gates close quickly, and the rising phase of the action potential is very brief.

As action potentials spread over the plasma membrane, they open voltage-regulated **slow calcium channels**, which admit a small amount of Ca^{2+} from the extracellular fluid into the cell. This Ca^{2+} binds to ligand-regulated Ca^{2+} channels on the sarcoplasmic reticulum (SR), opening them and releasing a greater quantity of Ca^{2+} from the SR into the cytosol. This second wave of Ca^{2+} binds to troponin and triggers contraction in the same way as it does in skeletal muscle (see p. 414). The SR provides 90% to 98% of the Ca^{2+} needed for myocardial contraction.

In skeletal muscle and neurons, an action potential falls back to the resting potential within 2 msec. In cardiac muscle, however, the depolarization is prolonged for 200 to 250 msec (at a heart rate of 70–80 bpm), producing a long plateau in the action potential—perhaps because the Ca^{2+} channels of the SR are slow to close or because the SR is slow to remove Ca^{2+} from the cytosol.

As long as the action potential is in its plateau, the cardiocytes contract. Thus, in figure 19.14, you can see the development of muscle tension (myocardial contraction) following closely behind the depolarization and plateau. Rather than showing a brief twitch like skeletal muscle, cardiac muscle has a more sustained contraction necessary for expulsion of blood from the heart chambers. Both atrial and ventricular cardiocytes exhibit these plateaus, but they are more pronounced in the ventricles.

FIGURE 19.14 Action Potential of a Ventricular Cardiocyte. The green curve is the action potential. The red curve represents rising and falling muscle tension as the myocardium contracts and relaxes.

❏ What is the benefit of having such a long absolute refractory period in cardiac muscle?

At the end of the plateau, Ca^{2+} channels close and K^{+} channels open. Potassium diffuses rapidly out of the cell and Ca^{2+} is transported back into the extracellular fluid and SR. Membrane voltage drops rapidly, and muscle tension declines soon afterward.

Cardiac muscle has an *absolute refractory period* of 250 msec, compared with 1 to 2 msec in skeletal muscle. This long refractory period prevents wave summation and tetanus, which would stop the pumping action of the heart.

Think About It

With regard to the ions involved, how does the falling (repolarization) phase of a myocardial action potential differ from that of a neuron's action potential?

(See p. 457).

The Electrocardiogram

We can detect electrical currents in the heart by means of electrodes (leads) applied to the skin. An instrument called the *electrocardiograph* amplifies these signals and produces a record, usually on a moving paper chart,

called an **electrocardiogram**²⁶ (**ECG** or **EKG**²⁷). To record an ECG, electrodes are typically attached to the wrists, ankles, and six locations on the chest. Several simultaneous recordings can be made from electrodes at different distances from the heart; collectively, they provide a comprehensive image of the heart's electrical activity. An ECG is a composite recording of all the action potentials produced by the nodal and myocardial cells—it should not be misconstrued as a tracing of a single action potential.

Figure 19.15 shows a typical ECG. It shows three principal deflections above and below the baseline: the *P wave*, *QRS complex*, and *T wave*. Figure 19.16 shows how these correspond to regions of the heart undergoing depolarization and repolarization.

The **P wave** is produced when a signal from the SA node spreads through the atria and depolarizes them. Atrial systole begins about 100 msec after the P wave begins, during the *PQ segment*. This segment is about 160 msec long and represents the time required for impulses to travel from the SA node to the AV node.

²⁶graph = recording instrument; graphy = recording procedure; gram = record of
²⁷EKG is from the German spelling, Elektrokardiogramm

FIGURE 19.15 The Normal Electrocardiogram.

FIGURE 19.16 Relationship of the Electrocardiogram (ECG) to Electrical Activity and Contraction of the Myocardium. Each heart diagram indicates the events occurring at the time of the colored segment of the ECG. Red indicates depolarizing or depolarized myocardium, and green indicates repolarizing or repolarized myocardium. Arrows indicate the direction in which a wave of depolarization or repolarization is traveling.

The **QRS complex** consists of a small downward deflection (Q), a tall sharp peak (R), and a final downward deflection (S). It is produced when the signal from the AV node spreads through the ventricular myocardium and depolarizes the muscle. Its complex shape is due to the different sizes of the two ventricles and the different times required for them to depolarize. Ventricular systole begins shortly after the QRS complex, in the *ST segment*. Atrial repolarization and diastole also occur during the QRS interval, but atrial repolarization sends a relatively weak signal that is obscured by the electrical activity of the more muscular ventricles. The ST segment corresponds to the plateau in the myocardial action potential and thus represents the time during which the ventricles contract and eject blood.

The **T wave** is generated by ventricular repolarization immediately before diastole. The ventricles take longer to repolarize than to depolarize; the T wave is therefore smaller and more spread out than the QRS complex, and it has a rounder peak. Even when the T wave is taller than the QRS complex, it can be recognized by its relatively rounded peak.

The ECG affords a wealth of information about the normal electrical activity of the heart. Deviations from normal are invaluable for diagnosing abnormalities in the conduction pathways, myocardial infarction, enlargement of the heart, and electrolyte and hormone imbalances. A few examples of abnormal ECGs are given in table 19.1 and figure 19.17.

TABLE 19.1 Examples of the Diagnostic Interpretation of Abnormal Electrocardiograms

Appearance	Suggested Meaning
Enlarged P wave	Atrial hypertrophy, often a result of mitral valve stenosis (constriction)
Missing or inverted P wave	SA node damage; AV node has taken over pacemaker role
Two or more P waves per cycle	Extrasystole; heart block
Extra, misshapen, sometimes inverted QRS not preceded by P wave	Premature ventricular contraction (PVC) (extrasystole)
Enlarged Q wave	Myocardial infarction
Enlarged R wave	Ventricular hypertrophy
Abnormal T waves	Flattened in hypoxia; elevated in hyperkalemia (K^+ excess)
Abnormally long PQ segment	Scarring of atrial myocardium, forcing impulses to bypass normal conduction pathways and take slower alternative routes to AV node
Abnormal ST segment	Elevated above baseline in myocardial infarction; depressed in myocardial hypoxia.

(a) Sinus rhythm (normal)

(c) Heart block

(b) Nodal rhythm—no SA node activity

(d) Premature ventricular contraction

FIGURE 19.17 Normal and Pathological Electrocardiograms. (a) Normal sinus rhythm. (b) Nodal rhythm generated by the AV node in the absence of SA node activity; note the lack of P waves. (c) Heart block, in which some P waves are not transmitted through the AV node and thus fail to generate QRS complexes. (d) Premature ventricular contraction (PVC), or extrasystole; note the absence of a P wave, the inverted QRS complex, and the misshapen QRS and T. (e) Ventricular fibrillation, with grossly irregular waves of depolarization. This is typically seen in a myocardial infarction (heart attack).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

15. Define systole and diastole.
16. How does the pacemaker potential of the SA node differ from the resting membrane potential of a neuron? Why is this important in creating the heart rhythm?
17. How does excitation–contraction coupling in cardiac muscle resemble that of skeletal muscle? How is it different?
18. What produces the plateau in the action potentials of cardiocytes? Why is this important to the pumping ability of the heart?
19. Identify the portion of the ECG that coincides with each of the following events: atrial depolarization, atrial systole, atrial repolarization, ventricular depolarization, ventricular systole, ventricular repolarization, ventricular diastole.

19.5 Blood Flow, Heart Sounds, and the Cardiac Cycle

Objectives

When you have completed this section, you should be able to

- explain why blood pressure is expressed in millimeters of mercury;
- describe how changes in blood pressure operate the heart valves;
- explain what causes the sounds of the heartbeat;
- describe in detail one complete cycle of heart contraction and relaxation; and
- relate the events of the cardiac cycle to the volume of blood entering and leaving the heart.

A **cardiac cycle** consists of one complete contraction and relaxation of all four heart chambers. We will examine these events in detail to see how they relate to the entry and expulsion of blood, but first we consider two related issues: (1) some general principles of pressure changes and how they affect the flow of blood, and (2) the heart sounds produced during the cardiac cycle, which we can then relate to the stages of the cycle.

Principles of Pressure and Flow

A fluid is a state of matter that can flow in bulk from place to place. In the body, this includes both liquids and gases—blood, lymph, air, and urine, among others. Certain

basic principles of fluid movement (*fluid dynamics*) apply to all of these. In particular, flow is governed by two main variables: **pressure**, which impels a fluid to move, and **resistance**, which opposes flow. In this chapter, we will focus on how pressure changes govern the operation of the heart valves, the entry of blood into the heart chambers, and its expulsion into the arteries. In the next chapter, we will examine the roles of pressure and resistance in the flow of blood through the blood vessels, and in chapter 22, we apply the same principles to respiratory airflow.

Measurement of Pressure

Pressure is commonly measured by a device called a *manometer*. In simplest form, this is typically a J-shaped glass tube partially filled with mercury. The sealed upper end, above the mercury, contains a vacuum, whereas the lower end is open. Pressure applied at the lower end is measured in terms of how high it can push the mercury column up the evacuated end of the tube. In principle, any liquid would do, but mercury is used because it is so dense, it enables us to measure pressure with shorter columns than we would need with a less dense liquid such as water. Pressures are therefore commonly expressed in millimeters of mercury (mm Hg). Blood pressure, specifically, is usually measured with a **sphygmomanometer**²⁸ (SFIG-mo-ma-NOM-eh-tur)—a calibrated mercury manometer with its open lower end attached to an inflatable pressure cuff wrapped around the arm. Blood pressure and the method of measuring it are discussed in greater detail in chapter 20.

Pressure Gradients and Flow

A fluid flows only if it is subjected to more pressure at one point in space than at another. The difference creates a **pressure gradient**, and fluids always flow down their pressure gradients, from the high-pressure point to the low-pressure point. Before we relate this to blood flow, it may be easier to begin with an analogy—an air-filled syringe (fig. 19.18).

At rest, the air pressure within the syringe barrel and in the atmosphere surrounding it are equal. But for a given quantity (mass) of air, and assuming a constant temperature, pressure is inversely proportional to the volume of the container—the greater the volume, the lower the pressure, and vice versa. Suppose you pull back the plunger of the syringe (fig. 19.18a). This increases the volume and thus lowers the air pressure within the barrel. Now you have a pressure gradient, with pressure outside the syringe being greater than the pressure inside. Air will flow down its gradient into the syringe until the two pressures are equal. If you then push the plunger in (fig. 19.18b), pressure inside the barrel will rise above the pressure outside, and air will flow out—again going down its pressure gradient but in the reverse direction.

²⁸sphygmo = pulse + mano = rare, sparse, roomy

FIGURE 19.18 Principles of Volume, Pressure, and Flow Illustrated with a Syringe. (a) As the plunger is pulled back, the volume of the enclosed space increases, its pressure falls, and pressure inside the syringe (P_1) is lower than the pressure outside (P_2). The pressure gradient causes air to flow inward until the pressures are equal. This is analogous to the filling of an expanding heart chamber. (b) As the plunger is depressed, the volume of the enclosed space decreases, P_1 rises above P_2 , and air flows out until the pressures are equal. This is analogous to the ejection of blood from a contracting heart chamber. In both cases, fluids flow down their pressure gradients.

The syringe barrel is analogous to a heart chamber such as the left ventricle. When the ventricle is expanding, its internal pressure falls. If the AV valve is open, blood flows into the ventricle from the atrium above. When the ventricle contracts, its internal pressure rises. When the aortic valve opens, blood is ejected from the ventricle into the aorta.

The opening and closing of the heart valves are governed by these pressure changes. Remember that the valves are just soft flaps of connective tissue with no muscle.

They do not exert any effort of their own, but are passively pushed open and closed by the changes in blood pressure on the upstream and downstream sides of the valve.

When the ventricles are relaxed and their pressure is low, the AV valve cusps hang down limply and both valves are open (fig. 19.19a). Blood flows freely from the atria into the ventricles even before the atria contract. As the ventricles fill with blood, the cusps float upward toward the closed position. When the ventricles contract, their internal pressure rises sharply and blood surges against the AV valves from below. This pushes the cusps together, seals the openings, and prevents blood from flowing back into the atria. The papillary muscles contract slightly before the rest of the ventricular myocardium and tug on the tendinous cords, preventing the valves from bulging excessively (prolapsing) into the atria or turning inside out like windblown umbrellas (see *mitral valve prolapse* in Insight 19.3).

The rising pressure in the ventricles also acts on the aortic and pulmonary valves. Up to a point, pressure in the aorta and pulmonary trunk opposes their opening, but when the ventricular pressure rises above the arterial pressure, the valves open and blood is ejected from the heart. Then as the ventricles relax again and their pressure falls below that in the arteries, arterial blood briefly flows backward and fills the pocketlike cusps of the

INSIGHT 19.3 Clinical Application

Valvular Insufficiency

Valvular insufficiency (incompetence) refers to any failure of a valve to prevent *reflux* (regurgitation)—the backward flow of blood. *Valvular stenosis*²⁹ is a form of insufficiency in which the cusps are stiffened and the opening is constricted by scar tissue. It frequently results from rheumatic fever, an autoimmune disease in which antibodies produced to fight a bacterial infection also attack the mitral and aortic valves. As the valves become scarred and constricted, the heart is overworked by the effort to force blood through the openings and may become enlarged. Regurgitation of blood through the incompetent valves creates turbulence that can be heard with a stethoscope as a *heart murmur*.

Mitral valve prolapse (MVP) is an insufficiency in which one or both mitral valve cusps bulge into the atrium during ventricular contraction. It is often hereditary and affects about 1 out of 40 people, especially young women. In many cases, it causes no serious dysfunction, but in some people it causes chest pain, fatigue, and shortness of breath.

In some cases, an incompetent valve can eventually lead to heart failure. A defective valve can be surgically repaired or replaced with an artificial valve or a valve transplanted from a pig heart.

²⁹*steno* = narrow + *osis* = condition

FIGURE 19.19 Operation of the Heart Valves. (a) The atrioventricular valves. When atrial pressure is greater than ventricular pressure, the valve opens and blood flows through (green arrows). When ventricular pressure rises above atrial pressure, the blood in the ventricle pushes the valve cusps closed. (b) The semilunar valves. When the pressure in the ventricles is greater than the pressure in the great arteries, the semilunar valves are forced open and blood is ejected. When ventricular pressure is lower than arterial pressure, arterial blood holds these valves closed.

• What role do the tendinous cords play?

semilunar valves. The three cusps meet in the middle of the orifice and seal it, thereby preventing arterial blood from reentering the heart.

Think About It

How would valvular stenosis (see Insight 19.3) affect the amount of blood pumped into the aorta? How might this affect a person's physical stamina? Explain your reasoning.

Heart Sounds

As we follow events through the cardiac cycle, we will note the occurrence of two or three *heart sounds* audible with a stethoscope. Listening to sounds made by the body is called **auscultation** (AWS-cul-TAY-shun). The **first** and **second heart sounds**, symbolized S_1 and S_2 , are often described as a “lubb-dupp”— S_1 is louder and longer and S_2 a little softer and sharper. In children and adolescents, it is normal to hear a **third heart sound** (S_3). This is rarely

audible in people older than 30, but when it is, the heart-beat is said to show a *triple rhythm* or *gallop*. If the normal sounds are roughly simulated by drumming two fingers on a table, a triple rhythm sounds a little like drumming with three fingers. The heart valves themselves operate silently, but S_1 and S_2 occur in conjunction with the closing of the valves as a result of turbulence in the bloodstream and movements of the heart wall. The cause of each sound is not known with certainty, but the probable factors are discussed in the respective phases of the cardiac cycle.

Phases of the Cardiac Cycle

We now examine the phases of the cardiac cycle, the pressure changes that occur, and how the pressure changes and valves govern the flow of blood. A substantial amount of information about these events is summarized in figure 19.20, which is divided into colored bars numbered to correspond to the phases described here. Closely follow the figure as you study the following text. Where to begin when describing a circular chain of events is somewhat arbitrary. However, in this presentation, we begin with the filling of the ventricles. Remember that all these events are completed in less than 1 second.

- 1. Ventricular filling.** During diastole, the ventricles expand and their pressure drops below that of the atria. As a result, the AV valves open and blood flows into the ventricles, causing ventricular pressure to rise and atrial pressure to fall. Ventricular filling occurs in three phases: **(1a)** The first one-third is *rapid ventricular filling*, when blood enters especially quickly. **(1b)** The second one-third, called *diastasis* (di-ASS-tuh-sis), is marked by slower filling. The P wave of the electrocardiogram occurs at the end of diastasis, marking the depolarization of the atria. **(1c)** In the last one-third, *atrial systole* completes the filling process. The right atrium contracts slightly before the left because it is the first to receive the signal from the SA node. At the end of ventricular filling, each ventricle contains an **end-diastolic volume (EDV)** of about 130 mL of blood. Only 40 mL (31%) of this is contributed by atrial systole.
- 2. Isovolumetric contraction.** The atria repolarize, relax, and remain in diastole for the rest of the cardiac cycle. The ventricles depolarize, generate the QRS complex, and begin to contract. Pressure in the ventricles rises sharply and reverses the pressure gradient between atria and ventricles. The AV valves close as ventricular blood surges back against the cusps. Heart sound S_1 occurs at the beginning of this phase and is produced mainly by the left ventricle; the right ventricle is thought to make little

contribution. Causes of the sound are thought to include the tensing of ventricular tissues, acceleration of the ventricular wall, turbulence in the blood as it surges against the closed AV valves, and impact of the heart against the chest wall.

This phase is called *isovolumetric*³⁰ because even though the ventricles contract, they do not eject blood yet and there is no change in their volume. This is because pressures in the aorta (80 mm Hg) and pulmonary trunk (10 mm Hg) are still greater than the pressures in the respective ventricles and thus oppose the opening of the semilunar valves. The cardiocytes exert force, but with all four valves closed, the blood cannot go anywhere.

- 3. Ventricular ejection.** The ejection of blood begins when ventricular pressure exceeds arterial pressure and forces the semilunar valves open. The pressure peaks at typically 120 mm Hg in the left ventricle and 25 mm Hg in the right. Blood spurts out of each ventricle rapidly at first (*rapid ejection*), then flows out more slowly under less pressure (*reduced ejection*). By analogy, suppose you were to shake up a bottle of soda pop and remove the cap. The soda would spurt out rapidly at high pressure and then more would dribble out at lower pressure, much like the blood leaving the ventricles. Ventricular ejection lasts about 200 to 250 msec, which corresponds to the plateau of the myocardial action potential but lags somewhat behind it (review the red tension curve in fig. 19.14). The T wave occurs late in this phase, beginning at the moment of peak ventricular pressure.

The ventricles do not expel all their blood. In an average resting heart, each ventricle contains an EDV of 130 mL. The amount ejected, about 70 mL, is called the **stroke volume (SV)**. The percentage of the EDV ejected, about 54%, is the **ejection fraction**. The blood remaining behind, about 60 mL in this case, is called the **end-systolic volume (ESV)**. Note that $EDV - SV = ESV$. In vigorous exercise, the ejection fraction may be as high as 90%. Ejection fraction is an important measure of cardiac health. A diseased heart may eject much less than 50% of the blood it contains.

- 4. Isovolumetric relaxation.** This is early ventricular diastole, when the T wave ends and the ventricles begin to expand. There are competing hypotheses as to how they expand. One is that the blood flowing into the ventricles “inflates” them. Another is that contraction of the ventricles deforms the fibrous skeleton, which subsequently springs back like a rubber ball that has been squeezed and released. This elastic recoil and expansion would cause pressure to drop rapidly and suck blood into the ventricles.

³⁰iso = same

FIGURE 19.20 Events of the Cardiac Cycle. Two complete cycles are shown. The phases are numbered across the bottom to correspond to the text description.

● Explain why the aortic pressure curve begins to rise abruptly at about 0.5 second.

At the beginning of ventricular diastole, blood from the aorta and pulmonary trunk briefly flows backward through the semilunar valves. The backflow, however, quickly fills the cusps and closes them, creating a slight pressure rebound that appears as the *dicrotic notch* of the aortic pressure curve (the top curve in fig. 19.20). Heart sound S_2 occurs as blood rebounds from the closed semilunar valves and the ventricles expand. This phase is called *isovolumetric* because the semilunar valves are closed, the AV valves have not yet opened, and the ventricles are therefore taking in no blood. When the AV valves open, ventricular filling (phase 1) begins again. Heart sound S_3 , if it occurs, is thought to result from the transition from expansion of the empty ventricles to their sudden filling with blood.

In a resting person, atrial systole lasts about 0.1 second; ventricular systole, 0.3 second; and the *quiescent period* (when all four chambers are in diastole), 0.4 second. Total duration of the cardiac cycle is therefore 0.8 second (800 msec) in a heart beating at 75 bpm.

Overview of Volume Changes

An additional perspective on the cardiac cycle can be gained if we review the volume changes that occur. This “balance sheet” is from the standpoint of one ventricle; both ventricles have equal volumes. The volumes vary somewhat from one person to another and depend on a person’s state of activity.

End-systolic volume (ESV, left from previous heartbeat)	60 mL
Passively added to the ventricle during atrial diastole	+ 30 mL
Added by atrial systole	+ 40 mL
<hr/>	
<i>Total:</i> End-diastolic volume (EDV)	130 mL
Stroke volume (SV) ejected by ventricular systole	– 70 mL
<i>Leaves:</i> End-systolic volume (ESV)	60 mL

Notice that the ventricle pumps out as much blood as it received during diastole: 70 mL in this example.

Both ventricles eject the same amount of blood even though pressure in the right ventricle is only about one-fifth the pressure in the left. Blood pressure in the pulmonary trunk is relatively low, so the right ventricle does not need to generate very much pressure to overcome it. It is essential that both ventricles have the same output. If the right ventricle pumped more blood into the lungs than the left side of the heart could handle on return, blood would accumulate in the lungs and cause pulmonary hypertension and edema (fig. 19.21a). This would put a person at risk of suffocation as fluid filled the lungs and interfered with gas exchange. Conversely, if the left

(a) Pulmonary edema

(b) Systemic edema

FIGURE 19.21 The Necessity of Balanced Ventricular Output.

(a) If the left ventricle pumps less blood than the right, blood pressure backs up into the lungs and causes pulmonary edema. (b) If the right ventricle pumps less blood than the left, pressure backs up in the systemic circulation and causes systemic edema. To maintain homeostasis, both ventricles must pump the same average amount of blood.

INSIGHT 19.4 Clinical Application**Congestive Heart Failure**

Congestive heart failure (CHF) results from the failure of either ventricle to eject blood effectively. It is usually due to a heart weakened by myocardial infarction, chronic hypertension, valvular insufficiency, or congenital defects in cardiac structure. If the left ventricle fails, blood backs up into the lungs and causes pulmonary edema (fluid in the lungs), shortness of breath, and a sense of suffocation. If the right ventricle fails, blood backs up into the venae cavae and causes systemic, or generalized, edema (formerly called *dropsy*). Systemic edema is marked by enlargement of the liver, *ascites* (the pooling of fluid in the abdominal cavity), distension of the jugular veins, and swelling of the fingers, ankles, and feet. Failure of one ventricle eventually increases the workload on the other ventricle, which stresses it and leads to its eventual failure as well.

ventricle pumped out more blood than the right heart could handle on return, blood would accumulate in the systemic circuit and cause hypertension and edema there (fig. 19.21b). Over the long term, this could lead to aneurysms (weakened, bulging arteries), stroke, kidney failure, or heart failure (see Insight 19.4). To maintain homeostasis, the two ventricles must have equal output.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

20. Explain how a pressure gradient across a heart valve determines whether a ventricle ejects blood.
21. What factors are thought to cause the first and second heart sounds? When do these sounds occur?
22. What phases of the cardiac cycle are isovolumetric? Explain what this means.

19.6 Cardiac Output

Objectives

When you have completed this section, you should be able to

- define *cardiac output* and explain its importance;
- identify the factors that govern cardiac output;
- discuss some of the nervous and chemical factors that alter heart rate, stroke volume, and cardiac output;
- explain how the right and left ventricles achieve balanced output; and
- describe some effects of exercise on cardiac output.

The entire point of all the cardiac physiology we have considered is to eject blood from the heart. The amount ejected by each ventricle in 1 minute is called the **cardiac output (CO)**. If HR is heart rate (beats/min) and SV is stroke volume (mL/beat), $CO = HR \times SV$. At typical resting values, $CO = 75 \text{ beats/min} \times 70 \text{ mL/beat} = 5,250 \text{ mL/min}$. Thus, the body's total volume of blood (4–6 L) passes through the heart every minute; or to look at it another way, an RBC leaving the left ventricle will, on average, arrive back at the left ventricle in about 1 minute.

Cardiac output is not constant, but varies with the body's state of activity. Vigorous exercise increases CO to as much as 21 L/min in a person in good condition, and up to 35 L/min in world-class athletes. The difference between the maximum and resting cardiac output is called **cardiac reserve**. People with severe heart disease may have little or no cardiac reserve and little tolerance of physical exertion.

Given that cardiac output equals $HR \times SV$, you can see that there are only two ways to change it: change the heart rate or change the stroke volume. We will consider factors that influence each of these variables, but bear in mind that heart rate and stroke volume are somewhat interdependent. They usually change together and in opposite directions. As heart rate goes up, stroke volume goes down, and vice versa.

Heart Rate

Heart rate is most easily measured by taking a person's **pulse** at some point where an artery runs close to the body surface, such as the *radial artery* in the wrist or *common carotid artery* in the neck. Each beat of the heart produces a surge of pressure that can be felt by palpating a superficial artery with the fingertips. Heart rate can be obtained by counting the number of pulses in 15 seconds and multiplying by 4 to get the beats per minute. In newborn infants, the resting heart rate is commonly 120 bpm or greater. It declines steadily with age, averaging 72 to 80 bpm in young adult females and 64 to 72 bpm in young adult males. It rises again in the elderly.

Tachycardia³¹ is a persistent, resting adult heart rate above 100 bpm. It can be caused by stress, anxiety, drugs, heart disease, or fever. Heart rate also rises to compensate to some extent for a drop in stroke volume. Thus, the heart races when the body has lost a significant quantity of blood or when there is damage to the myocardium.

Bradycardia³² is a persistent, resting adult heart rate below 60 bpm. It is common during sleep and in endurance-trained athletes. Endurance training enlarges the heart and increases its stroke volume. Thus, the heart can maintain the same output with fewer beats. Hypothermia (low body temperature) also slows the heart rate and may be

³¹tachy = speed, fast + card = heart + ia = condition

³²brady = slow + card = heart + ia = condition

deliberately induced in preparation for cardiac surgery. Diving mammals such as whales and seals exhibit bradycardia during the dive, as do humans to some extent when the face is immersed in cool water.

Factors that raise the heart rate are called *positive chronotropic*³³ *agents*, and factors that lower it are *negative chronotropic agents*. We next consider some chronotropic effects of the autonomic nervous system, hormones, electrolytes, and blood gases.

Chronotropic Effects of the Autonomic Nervous System

Although the nervous system does not initiate the heart-beat, it does modulate its rhythm and force. The reticular formation of the medulla oblongata contains **cardiac centers**, with only vaguely defined anatomical boundaries, that initiate autonomic output to the heart. Some neurons in these centers have a *cardiostimulatory* effect and transmit signals to the heart by way of the sympathetic pathway described earlier; others have a *cardioinhibitory* effect communicated to the heart by way of the vagus nerves.

The sympathetic postganglionic fibers are adrenergic—they release norepinephrine, which binds to β -adrenergic fibers in the heart. This activates the cyclic adenosine monophosphate (cAMP) second-messenger system in the cardiocytes and nodal cells. Cyclic AMP activates an enzyme that phosphorylates and opens a calcium channel in the plasma membrane. The inflow of Ca^{2+} accelerates depolarization of the SA node and contraction of the cardiocytes, so it speeds up the heart. In addition, cAMP accelerates the uptake of Ca^{2+} by the sarcoplasmic reticulum and thereby enables cardiocytes to relax more quickly. By accelerating *both* contraction and relaxation, norepinephrine and cAMP increase the heart rate.

Adrenergic stimulation can, in fact, raise the heart rate to as high as 230 bpm. This limit is set mainly by the refractory period of the SA node, which prevents it from firing any more frequently. Cardiac output peaks, however, at a heart rate of 160 to 180 bpm. At rates any higher than this, the ventricles have too little time to fill between beats. Remember that the ventricles fill during diastole. At a resting heart rate of 65 bpm, ventricular diastole lasts about 0.62 sec, but at 200 bpm, it lasts only about 0.14 sec. Thus you can see that at excessively high heart rates, diastole is too brief to allow complete filling of the ventricles, and therefore stroke volume and cardiac output are reduced.

The parasympathetic vagus nerves, by contrast, have cholinergic, inhibitory effects on the SA and AV nodes. Acetylcholine (ACh) binds to muscarinic receptors and opens K^+ gates in the nodal cells. As K^+ exits the cells, they become hyperpolarized and fire less frequently, so the heart slows down. The vagus nerves have a faster-acting effect on the heart than the sympathetic nerves because

ACh acts directly on ion channels in the plasma membrane; sympathetic effects are somewhat delayed because of the time taken for the second-messenger system to act on the ion channels.

If all sympathetic and parasympathetic stimulation of the heart is pharmacologically blocked, or if the cardiac nerves are severed, the heart beats at a rate of about 100 bpm. This is the intrinsic “natural” firing rate of the SA node free of autonomic influence. With intact, functional innervation, however, the resting heart rate is held down to about 70 to 80 bpm by **vagal tone**, a steady background firing rate of the vagus nerves. More extreme vagal stimulation can reduce the heart rate to as low as 20 bpm or even stop the heart briefly.

There is a benefit to placing heart rate under the influence of cardiac centers in the medulla—these centers can receive input from many other sources and integrate it into a “decision” as to whether the heart should beat more quickly or slowly. Sensory and emotional stimuli can act on the cardiac centers by way of the cerebral cortex, limbic system, and hypothalamus; therefore, heart rate can climb even as you anticipate taking the first plunge on a roller coaster or competing in an athletic event, and it is influenced by emotions such as love and anger. The medulla also receives input from receptors in the muscles, joints, arteries, and brainstem:

- **Proprioceptors** in the muscles and joints provide information on changes in physical activity. Thus, the heart can increase its output even before the metabolic demands of the muscles rise.
- **Baroreceptors (pressoreceptors)** are pressure sensors found in the aorta and internal carotid arteries (see fig. 15.1, p. 567). They send a continual stream of signals to the medulla. When the heart rate rises, cardiac output increases and raises the blood pressure at the baroreceptors. The baroreceptors increase their signaling to the medulla and, depending on circumstances, the medulla may issue vagal output to lower the heart rate. Conversely, the baroreceptors also inform the medulla of drops in blood pressure. The medulla can then issue sympathetic output to increase the heart rate, bringing cardiac output and blood pressure back up to normal (see fig. 1.11, p. 18). Either way, a negative feedback loop usually prevents the blood pressure from deviating too far from normal.
- **Chemoreceptors** occur in the aortic arch, carotid arteries, and the medulla oblongata itself, and are sensitive to blood pH, carbon dioxide, and oxygen levels. They are more important in respiratory control than in cardiovascular control, but they do influence the heart rate. If circulation to the tissues is too slow to remove CO_2 as fast as the tissues produce it, then CO_2 accumulates in the blood and cerebrospinal fluid (CSF) and produces a state of *hypercapnia* (CO_2 excess). Furthermore, CO_2 generates hydrogen ions

³³*chrono* = time + *trop* = change, influence

by reacting with water: $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$. The hydrogen ions lower the pH of the blood and CSF and may create a state of *acidosis* (pH < 7.35). Hypercapnia and acidosis stimulate the cardiac centers of the medulla to increase the heart rate, thus improving perfusion of the tissues and restoring homeostasis. The chemoreceptors also respond to extreme *hypoxemia* (oxygen deficiency), as in suffocation, but the effect is usually to slow down the heart, perhaps so the heart does not compete with the brain for the limited oxygen supply.

Such responses to fluctuations in blood chemistry and blood pressure, called **chemoreflexes** and **baroreflexes**, are good examples of negative feedback loops. They are discussed more fully in the next chapter.

Chronotropic Effects of Chemicals

Heart rate is influenced by many other chemicals besides the neurotransmitters of the cardiac nerves. Blood-borne epinephrine and norepinephrine from the adrenal medulla, for example, have the same effect as epinephrine from the sympathetic nerves. The chronotropic action of some other chemicals can be understood from their relationships to this catecholamine–cAMP mechanism. Nicotine accelerates the heart by stimulating catecholamine secretion. Thyroid hormone stimulates the up-regulation of adrenergic receptors, making the heart more responsive to sympathetic stimulation; thus, hyperthyroidism commonly produces tachycardia. Caffeine and the related stimulants in tea and chocolate accelerate the heart by inhibiting cAMP breakdown, thus prolonging the adrenergic effect.

The electrolyte with the greatest chronotropic effect is potassium (K^+). In *hyperkalemia*,³⁴ a potassium excess, K^+ diffuses into the cardiocytes and keeps the membrane voltage elevated, inhibiting cardiocyte repolarization. The myocardium becomes less excitable, the heart rate becomes slow and irregular, and the heart may arrest in diastole. In *hypokalemia*, a potassium deficiency, K^+ diffuses out of the cardiocytes and they become hyperpolarized—the membrane potential is more negative than normal. This makes them harder to stimulate. These potassium imbalances are very dangerous and require emergency medical treatment.

Calcium also affects heart rate. A calcium excess (*hypercalcemia*) causes a slow heartbeat, whereas a calcium deficiency (*hypocalcemia*) elevates the heart rate. Such calcium imbalances are relatively rare, however, and when they do occur, their primary effect is on contraction strength, which is considered in the coming section on contractility. Chapter 24 further explores the causes and effects of imbalances in potassium, calcium, and other electrolytes.

Stroke Volume

The other factor in cardiac output is stroke volume. This, in turn, is governed by three variables called *preload*, *contractility*, and *afterload*. Increased preload or contractility increases stroke volume, whereas increased afterload opposes the emptying of the ventricles and reduces stroke volume.

Preload

Preload is the amount of tension in the ventricular myocardium immediately before it begins to contract. To understand how this influences stroke volume, imagine yourself engaged in heavy exercise. As active muscles massage your veins, they drive more blood back to the heart, increasing *venous return*. As more blood enters the heart, it stretches the myocardium. Because of the length–tension relationship of striated muscle (see p. 420), moderate stretch enables the cardiocytes to generate more tension when they contract—that is, stretch increases preload. When the ventricles contract more forcefully, they expel more blood, thus adjusting cardiac output to the increase in venous return.

This principle is summarized by the **Frank–Starling law of the heart**.³⁵ In a concise, symbolic way, it states that $\text{SV} \propto \text{EDV}$ —stroke volume is proportional to the end-diastolic volume. In other words, the ventricles tend to eject as much blood as they receive. Within limits, the more they are stretched, the harder they contract on the next beat.

Although relaxed skeletal muscle is normally at an optimum length for the most forceful contraction, relaxed cardiac muscle is at less than optimum length. Additional stretch therefore produces a significant increase in contraction force on the next beat. This helps balance the output of the two ventricles. For example, if the right ventricle begins to pump an increased amount of blood, this soon arrives at the left ventricle, stretches it more than before, and causes it to increase its stroke volume and match that of the right.

Contractility

Contractility refers to how hard the myocardium contracts *for a given preload*. It does not describe the increase in tension produced by stretching the muscle, but rather an increase caused by factors that make the cardiocytes more responsive to stimulation. Factors that increase contractility are called *positive inotropic*³⁶ *agents*, and those that reduce it are *negative inotropic agents*.

Calcium has a strong, positive inotropic effect—it increases the strength of each contraction of the heart. This is not surprising, because Ca^{2+} not only is essential

³⁴hyper = excess + kal = potassium (Latin, *kalium*) + emia = blood condition

³⁵Otto Frank (1865–1944), German physiologist; Ernest Henry Starling (1866–1927), English physiologist

³⁶ino = fiber + trop = change, influence

to the excitation–contraction coupling of muscle, but also prolongs the plateau of the myocardial action potential. Calcium imbalances therefore affect not only heart rate, as we have already seen, but also contraction strength. In hypercalcemia, extra Ca^{2+} diffuses into the cardiocytes and produces strong, prolonged contractions. In extreme cases, it can cause cardiac arrest in systole. In hypocalcemia, the cardiocytes lose Ca^{2+} to the extracellular fluid, leading to a weak, irregular heart-beat and potentially to cardiac arrest in diastole. However, as explained in chapter 7, severe hypocalcemia is likely to kill through skeletal muscle paralysis and suffocation before the cardiac effects are felt.

Agents that affect calcium availability have not only the chronotropic effects already examined, but also inotropic effects. We have already seen that norepinephrine increases calcium levels in the sarcoplasm; consequently, it increases not only heart rate but also contraction strength (as does epinephrine, for the same reason). The pancreatic hormone glucagon exerts an inotropic effect by stimulating cAMP production; a solution of glucagon and calcium chloride is sometimes used for the emergency treatment of heart attacks. Digitalis, a cardiac stimulant from the foxglove plant, also raises the intracellular calcium level and contraction strength; it is used to treat congestive heart failure.

Hyperkalemia has a negative inotropic effect because it reduces the strength of myocardial action potentials and thus reduces the release of Ca^{2+} into the sarcoplasm. The heart becomes dilated and flaccid. Hypokalemia, however, has little effect on contractility.

The vagus nerves have a negative inotropic effect on the atria, but they provide so little innervation to the ventricles that they have no significant effect on them.

There are other chronotropic and inotropic agents too numerous to mention here. The ones we have discussed are summarized in table 19.2.

Think About It

Suppose a person has a heart rate of 70 bpm and a stroke volume of 70 mL. A negative inotropic agent then reduces the stroke volume to 50 mL. What would the new heart rate have to be to maintain the same cardiac output?

Afterload

Afterload is the blood pressure in the aorta and pulmonary trunk immediately distal to the semilunar valves; it opposes the opening of these valves and thus limits stroke volume. Thus, hypertension increases the afterload and opposes ventricular ejection. Anything that impedes arterial circulation can also increase the afterload. For example, in some lung diseases, scar tissue forms in the lungs

TABLE 19.2

Some Chronotropic and Inotropic Agents

Chronotropic Agents (Influence Heart Rate)	
Positive	Negative
Sympathetic stimulation	Parasympathetic stimulation
Epinephrine and norepinephrine	Acetylcholine
Thyroid hormone	Hyperkalemia
Hypocalcemia	Hypokalemia
Hypercapnia and acidosis	Hypercalcemia
Digitalis	Hypoxia
Inotropic Agents (Influence Contraction Strength)	
Positive	Negative
Sympathetic stimulation	(Parasympathetic effect negligible)
Epinephrine and norepinephrine	Hyperkalemia
Hypercalcemia	Hypocalcemia
Digitalis	Myocardial hypoxia
Glucagon	Myocardial hypercapnia

and restricts pulmonary circulation. This increases the afterload in the pulmonary trunk. As the right ventricle works harder to overcome this resistance, it gets larger like any other muscle. Stress and hypertrophy of a ventricle can eventually cause it to weaken and fail. Right ventricular failure due to obstructed pulmonary circulation is called *cor pulmonale*³⁷ (CORE PUL-mo-NAY-lee). It is a common complication of emphysema, chronic bronchitis, and black lung disease (see chapter 22).

Exercise and Cardiac Output

It is no secret that exercise makes the heart work harder, and it should come as no surprise that this increases cardiac output. The main reason the heart rate increases at the beginning of exercise is that proprioceptors in the muscles and joints transmit signals to the cardiac centers, signifying that the muscles are active and will quickly need an increased blood flow. Sympathetic output from the cardiac centers then increases cardiac output to meet the expected demand. As the exercise progresses, muscular activity increases venous return. This increases the preload on the right ventricle and is soon reflected in the left ventricle as more blood flows through the pulmonary circuit and reaches the left heart. As the heart rate and stroke volume rise, cardiac output rises, which compensates for the increased venous return.

³⁷ *cor* = heart + *pulmo* = lung

TABLE 19.3 Some Disorders of the Heart

Acute pericarditis	Inflammation of the pericardium, sometimes due to infection, radiation therapy, or connective tissue disease, causing pain and friction rub	
Cardiac tamponade	Compression of the heart by an abnormal accumulation of fluid or clotted blood in the pericardial cavity, interfering with ventricular filling and potentially leading to heart failure	
Cardiomyopathy	Any disease of the myocardium not resulting from coronary artery disease, valvular dysfunction, or other cardiovascular disorders; can cause dilation and failure of the heart, thinning of the heart wall, or thickening of the interventricular septum	
Infective endocarditis	Inflammation of the endocardium, usually due to infection, especially streptococcus and staphylococcus bacterial infections	
Myocardial ischemia	Inadequate blood flow to the myocardium, usually because of coronary atherosclerosis; can lead to myocardial infarction	
Pericardial effusion	Seepage of fluid from the pericardium into the pericardial cavity, often resulting from pericarditis and sometimes causing cardiac tamponade	
Septal defects	Abnormal openings in the interatrial or interventricular septum, resulting in blood from the right atrium flowing directly into the left atrium, or blood from the left ventricle returning to the right ventricle; results in pulmonary hypertension, difficulty breathing, and fatigue. Often fatal in childhood if uncorrected	
<i>Disorders described elsewhere</i>

Congestive heart failure p. 745	Myocardial infarction p. 729	

A sustained program of exercise causes hypertrophy of the ventricles, which increases their stroke volume. As explained earlier, this allows the heart to beat more slowly and still maintain a normal resting cardiac output. Endurance athletes commonly have resting heart rates as low as 40 to 60 bpm, but because of the higher stroke volume, their resting cardiac output is about the same as that of an untrained person. Champion cyclist Lance Armstrong has an astonishingly low resting heart rate of only 32 to 34 bpm. Such athletes have greater cardiac reserve, so they can tolerate more exertion than a sedentary person can.

The effects of aging on the heart are discussed on page 1143, and some common heart diseases are listed in table 19.3. Disorders of the blood and blood vessels are described in chapters 18 and 20.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Define cardiac output in words and with a simple formula.
- Describe the cardiac center and innervation of the heart.
- Explain what is meant by positive and negative chronotropic and inotropic agents. Give two examples of each.
- How do preload, contractility, and afterload influence stroke volume and cardiac output?
- Explain the principle behind the Frank-Starling law of the heart. How does this mechanism normally prevent pulmonary or systemic congestion?

INSIGHT 19.5 Clinical Application

Coronary Artery Disease

Coronary artery disease (CAD) is a constriction of the coronary arteries usually resulting from *atherosclerosis*³⁸—an accumulation of lipid deposits that degrade the arterial wall and obstruct the lumen. The most dangerous consequence of CAD is myocardial infarction, tissue death caused by a lack of blood flow downstream from the obstruction.

Pathogenesis

CAD begins when hypertension, diabetes, or other factors damage the arterial lining. Monocytes adhere to the lining, penetrate into the tissue, and become macrophages. Macrophages and smooth muscle cells absorb cholesterol and fat from the blood, which gives them a frothy appearance. They are then called *foam cells* and form visible *fatty streaks* on the arterial wall. Seen even in infants and children, these are harmless in themselves but have the potential to grow into atherosclerotic plaques (*atheromas*³⁹).

Platelets adhere to these plaques and secrete a growth factor that stimulates local proliferation of smooth muscle and fibroblasts and deposition of collagen. The plaque grows into a bulging mass of lipid, fiber, and smooth muscle and other cells. When it obstructs 75% or more of the arterial lumen, it begins to cause such symptoms as the intermittent chest pain called *angina pectoris*. More seriously, inflammation of the plaque roughens its surface and creates a focal point for thrombosis. A blood clot can block what remains of the lumen, or break free and lodge in a smaller artery downstream. Sometimes a piece

FIGURE 19.22 Diseased Coronary Artery, Cross Section. A plaque has reduced the lumen to a very small space that can easily be blocked by thrombosis, embolism, or vasoconstriction.

of plaque breaks free and travels as a *fatty embolus*. Furthermore, the plaque can contribute to spasms of the coronary artery, cutting off blood flow to the myocardium. If the lumen is already partially obstructed by a plaque and perhaps a blood clot, such a spasm can temporarily shut off the remaining flow and precipitate an attack of angina.

Over time, the resilient muscular and elastic tissue of an inflamed artery becomes increasingly replaced with scar tissue and calcium deposits, transforming an atheroma into a hard *complicated plaque* (fig. 19.22). Hardening of the arteries by calcified plaques is called *arteriosclerosis*.⁴⁰ For reasons explained in chapter 20, this results in excessive surges of blood pressure that may weaken and rupture smaller arteries, leading to stroke and kidney failure.

Risk, Prevention, and Treatment

A paramount risk factor for CAD is excess *low-density lipoproteins (LDLs)* in the blood combined with defective LDL receptors in the arterial walls. LDLs are protein-coated droplets of cholesterol, fats, free fatty acids, and phospholipids (see p. 1020). Most cells have LDL receptors that enable them to absorb these droplets from the blood so they can metabolize the cholesterol and other lipids. CAD can occur when the arterial cells have dysfunctional LDL receptors that “don’t know when to quit,” so the cells absorb and accumulate excess cholesterol.

Some risk factors for CAD are unavoidable—for example, heredity, aging, and being male. Most risk factors, however, are preventable—obesity; smoking; lack of exercise; and a personality fraught with anxiety, stress, and aggression, all conducive to the hypertension that initiates arterial damage. Diet, of course, is very significant. Eating animal fat raises one’s LDL level and reduces the number of LDL receptors. Foods high in soluble fiber (such as beans, apples, and oat bran) lower blood cholesterol by an interesting mechanism: The liver normally converts cholesterol to bile acids and secretes them into the small intestine to aid fat digestion. The bile acids are reabsorbed farther down the intestine and recycled to the liver for reuse. Soluble fiber, however, binds bile acids and carries them out in the feces. To replace them, the liver synthesizes more, thus consuming more cholesterol.

CAD is often treated with *coronary artery bypass surgery*. Sections of the great saphenous vein of the leg or small thoracic arteries are used to construct a detour around the obstruction in the coronary artery. In *balloon angioplasty*,⁴¹ a slender catheter is threaded into the coronary artery and then a balloon at its tip is inflated to press the atheroma against the arterial wall, widening the lumen. In *laser angioplasty*, the surgeon views the interior of the diseased artery with an illuminated catheter and vaporizes the atheroma with a laser. Angioplasty is less risky and expensive than bypass surgery, but is often followed by *restenosis*—atheromas grow back and reobstruct the artery months later. Insertion of a tube called a *stent* into the artery can prevent restenosis.

³⁸*athero* = fat, *fatty* + *sclerosis* = hardening

³⁹*athero* = fat + *oma* = mass, tumor

⁴⁰*arterio* = artery + *sclerosis* = hardening

⁴¹*angio* = vessel + *plasty* = surgical repair

CHAPTER REVIEW

Review of Key Concepts

19.1 Overview of the Cardiovascular System (p. 720)

1. The cardiovascular system is divided into a pulmonary circuit supplied by the right side of the heart and a systemic circuit supplied by the left.
2. The heart is located in the mediastinum between the lungs, with about two-thirds of it to the left of the median plane.
3. The heart is enclosed in a fibrous, two-layered *pericardium*. The space between the parietal and visceral pericardium is the *pericardial cavity*, and contains lubricating *pericardial fluid*.

19.2 Gross Anatomy of the Heart (p. 722)

1. The heart wall is composed of a thin outer *epicardium*, a thick muscular *myocardium*, and a thin inner *endocardium*.
2. The heart has a connective tissue *fibrous skeleton*, which supports the myocardium and valves, anchors the cardiac muscle cells (*cardiocytes*), electrically insulates the ventricles from the atria, and may aid in ventricular filling by means of elastic recoil.
3. The two upper chambers of the heart are the *atria*, which serve to receive blood from the venae cavae and pulmonary veins. The two lower chambers are the *ventricles*, which eject blood into the pulmonary trunk and aorta. The ventricles are much more muscular than the atria. The *atrioventricular* and *interventricular sulci* on the heart surface mark the boundaries of these chambers.
4. The chambers are internally separated by an *interatrial septum* between the atria and *interventricular septum* between the ventricles.
5. The passages between the atria and ventricles are regulated by the *atrioventricular valves* (*tricuspid valve* on the right and *bicuspid*, or *mitral valve* on the left). The cusps of these valves are connected by *tendinous cords* to *papillary muscles* on the floor of the ventricles.

6. The openings into the pulmonary trunk and aorta are regulated by the *semilunar* (*pulmonary* and *aortic*) valves.
7. Systemic blood is received by the right atrium and flows into the right ventricle. The right ventricle pumps it into the pulmonary trunk, from which it flows to the lungs. Pulmonary blood returning from the lungs is received by the left atrium and flows into the left ventricle. The left ventricle pumps it into the aorta, the beginning of the systemic circulation.
8. The myocardium has a high workload and metabolic rate and needs an abundant oxygen and nutrient supply. It gets this not from the blood in its chambers but from a system of blood vessels called the *coronary circulation*.
9. The *left coronary artery* arises behind an aortic valve cusp near the beginning of the aorta, and gives rise mainly to the *anterior interventricular* and *circumflex branches*. The circumflex gives off a *left marginal branch*.
10. The *right coronary artery* arises behind another aortic valve cusp and gives off mainly a *right marginal branch* and *posterior interventricular branch*.
11. Obstruction of a coronary artery deprives the downstream myocardium of a blood supply and may cause *myocardial infarction* (heart attack). The risk of this is reduced to some extent by several *anastomoses* in the coronary circulation.
12. The myocardium is drained mainly by the *great cardiac*, *posterior interventricular*, and *left marginal veins*, all of which empty into the *coronary sinus*. The coronary sinus and several small *thebesian veins* empty into the right atrium and ventricle.

19.3 Cardiac Muscle and the Cardiac Conduction System (p. 730)

1. Cardiocytes are striated muscle cells with a single nucleus, a poorly developed sarcoplasmic reticulum, very

- large T tubules, and large abundant mitochondria. They are joined end to end by *interdigitating folds* in their *intercalated discs*. The discs also include intercellular mechanical junctions (*fascia adherens* and *desmosomes*) and electrical (gap) junctions. The latter enable cardiocytes to electrically communicate directly with each other.
2. Cardiac muscle uses almost exclusively aerobic respiration, and has large, abundant mitochondria and abundant glycogen and myoglobin to meet this demand. It employs fatty acids, glucose, and other organic fuels.
 3. The cardiac rhythm is set by its own internal pacemaker, the *sinoatrial (SA) node*. Electrical signals originating here spread through the atrial myocardium and then travel via the *atrioventricular (AV) node*, *AV bundle*, *bundle branches*, and *Purkinje fibers* to reach the ventricular cardiocytes.
 4. Although the heart can beat independently of the nervous system, it is innervated by the autonomic nervous system, which modifies the heart rate and contraction force. Sympathetic nerves supply the SA and AV nodes and the atrial and ventricular myocardium. Parasympathetic fibers from the vagus nerves supply mainly the SA and AV nodes. Sympathetic stimulation increases heart rate and contraction strength, and parasympathetic stimulation reduces the heart rate.

19.4 Electrical and Contractile Activity of the Heart (p. 733)

1. *Systole* is the contraction of any heart chamber, and *diastole* is relaxation.
2. A cardiac rhythm activated by the SA node is the *sinus rhythm*. Irritation of the heart or damage to the SA node can cause other areas to take over control. When the AV node takes over, the heart beats with a *nodal rhythm* that is slower than the sinus rhythm. Any abnormal cardiac rhythm is called *arrhythmia*.

752 PART FOUR Regulation and Maintenance

3. Cells of the SA node exhibit a *pace-maker potential* in which the membrane voltage starts at -60 mV and drifts spontaneously toward a threshold of -40 mV. At this point, *fast calcium-sodium channels* open, and the inflow of Ca^{2+} and Na^{+} sets off an action potential. A subsequent outflow of K^{+} returns the membrane voltage to its starting point. In a resting sinus rhythm of 70 to 80 beats/min, this process repeats itself about every 0.8 second.
4. Firing of the SA node excites the atria and causes atrial systole. The spreading wave of excitation slows down at the AV node, then quickly spreads down the AV bundle and Purkinje fibers to the ventricular cardiocytes, triggering ventricular systole.
5. Papillary muscles contract and pull on the tendinous cords just before the rest of the ventricle contracts; the cords prevent the AV valves from prolapsing when pressure rises in the ventricles.
6. Ordinary cardiocytes have a resting potential of -90 mV. Upon excitation, Na^{+} enters the cells and sets off an action potential that peaks around $+30$ mV. Ca^{2+} channels then open, admitting Ca^{2+} into the cytosol from the ECF and SR and triggering muscle contraction.
7. The action potential of a cardiocyte has a sustained plateau of 200 to 250 msec, causing prolonged contraction rather than a muscle twitch. The plateau ensures that contraction is sustained long enough to expel blood from the ventricles.
8. At the end of the plateau, Ca^{2+} channels close and K^{+} channels open. The membrane potential drops rapidly as K^{+} leaves the cell. Contraction is followed by a long refractory period that prevents wave summation and tetanus in the heart.
9. The electrical events of the myocardium as a whole generate the *electrocardiogram (ECG)*. The P wave of the ECG indicates atrial depolarization; atrial systole occurs during the PQ segment. The QRS complex indicates ventricular depolarization, but atrial repolarization occurs at the same time. Ventricular systole begins in the ST segment. The T wave indicates ventricular repolarization and is followed by ventricular diastole.

19.5 Blood Flow, Heart Sounds, and the Cardiac Cycle (p. 739)

1. Blood pressure is measured with a *sphygmomanometer* and expressed in millimeters of mercury (mm Hg).
2. Fluids flow down a *pressure gradient*, from a point of higher pressure to a point of lower pressure. The pressure of a fluid is inversely proportional to the volume it occupies. Therefore, when a heart ventricle expands, its pressure falls, and blood tends to flow into the chamber from the atrium. When a ventricle contracts, its pressure rises, and it tends to eject blood into the arteries.
3. Heart valves contain no muscle and exert no effort of their own. A valve is passively opened and closed by changes in the relative pressure on opposite sides of its cusps.
4. Adults normally have two heart sounds: S_1 and S_2 . Listening to these sounds is called *auscultation*.
5. A *cardiac cycle* is one complete cycle of contraction and relaxation of all four chambers. It can be divided into four phases.
6. In phase 1, *ventricular filling*, the ventricles expand, the AV valves open, and blood flows into the ventricles, rapidly at first and then more slowly. The P wave occurs, and the atria contract and contribute the last one-third of the blood to the ventricles. At the end of phase 1, each ventricle contains an *end-diastolic volume (EDV)* of about 130 mL.
7. In phase 2, *isovolumetric contraction*, the QRS wave occurs, the atria repolarize and relax, and the ventricles begin contracting. The AV valves close and heart sound S_1 occurs. The semilunar valves remain closed and no blood is expelled yet.
8. In phase 3, *ventricular ejection*, the semilunar valves open and blood is ejected, rapidly at first and then more slowly. Each ventricle ejects a *stroke volume* of about 70 mL, which is an *ejection fraction* of about 54% of the EDV. The blood remaining behind, about 60 mL, is the *end-systolic volume (ESV)*. The T wave begins around the middle of this phase.
9. In phase 4, *isovolumetric relaxation*, the ventricles repolarize and relax. The semilunar valves close and heart sound S_2 occurs. The AV valves

remain closed and no blood enters the ventricles until the next phase 1.

10. Each ventricle ejects the same amount of blood. If they ejected unequal amounts, fluid would accumulate in the tissues of either the pulmonary or systemic circuit.

19.6 Cardiac Output (p. 745)

1. *Cardiac output (CO)* is the volume of blood pumped by each ventricle in 1 minute. It is a product of heart rate \times stroke volume, and averages about 5.25 L/min.
2. Heart rate is typically about 70 to 80 bpm in young adults, but higher in children and the elderly. A persistent high resting heart rate is *tachycardia* and a persistent low resting rate is *bradycardia*.
3. Heart rate is raised or lowered, respectively, by *positive* and *negative chronotropic agents*.
4. The medulla oblongata contains *cardiac centers with cardiostimulatory and cardioinhibitory neurons*. Cardiostimulatory neurons act by way of sympathetic fibers in the cardiac nerves to increase heart rate and contraction strength. Cardioinhibitory neurons act by way of parasympathetic fibers in the vagus nerves to reduce the heart rate.
5. Norepinephrine from the sympathetic nerve fibers acts through a cAMP second-messenger system to produce a positive chronotropic effect, raising the heart rate to as high as 230 bpm. Maximum cardiac output occurs at about 160 to 180 bpm.
6. Acetylcholine from the vagus nerves acts directly on K^{+} gates in cells of the SA and AV nodes to produce a negative chronotropic effect.
7. The cardiac centers of the medulla integrate information from the cerebral cortex, muscle and joint proprioceptors, arterial baroreceptors, and arterial chemoreceptors to regulate the heart rate and contraction force.
8. Adrenal epinephrine, nicotine, thyroid hormone, and caffeine all accelerate the heart by acting on various elements of the adrenergic mechanism. Potassium and calcium imbalances also affect the heart rate, but the latter are rare.
9. Stroke volume acts with heart rate to determine cardiac output. Stroke volume is influenced by *preload*

(myocardial tension prior to contraction), *contractility* (variation in myocardial contraction strength for a given preload), and *afterload* (arterial blood pressure opposing ventricular ejection).

10. Preload is determined by the amount of blood entering the heart and stretching the myocardium during diastole.

Contractility is increased by *positive inotropic agents* such as calcium, norepinephrine, glucagon, and digitalis. It is reduced by hyperkalemia, which is therefore said to have a *negative inotropic effect*. Afterload is governed by factors that influence arterial blood pressure.

11. Exercise influences cardiac output through its effects on the proprioceptors and on the venous return of blood to the heart. Habitual endurance exercise increases ventricular size and stroke volume and reduces resting heart rate.

Testing Your Recall

- The cardiac conduction system includes all of the following *except*
 - the SA node.
 - the AV node.
 - the bundle branches.
 - the tendinous cords.
 - the Purkinje fibers.
- To get from the right atrium to the right ventricle, blood flows through
 - the pulmonary valve.
 - the tricuspid valve.
 - the bicuspid valve.
 - the aortic valve.
 - the mitral valve.
- Assume that one ventricle of a child's heart has an EDV of 90 mL, an ESV of 60 mL, and a cardiac output of 2.55 L/min. What are the child's stroke volume (SV), ejection fraction (EF), and heart rate (HR)?
 - SV = 60 mL; EF = 33%; HR = 85 bpm
 - SV = 30 mL; EF = 60%; HR = 75 bpm
 - SV = 150 mL; EF = 67%; HR = 42 bpm
 - SV = 30 mL; EF = 33%; HR = 85 bpm
 - Not enough information is given to calculate these.
- A heart rate of 45 bpm and an absence of P waves suggest
 - damage to the SA node.
 - ventricular fibrillation.
 - cor pulmonale.
 - extrasystole.
 - heart block.
- There is/are _____ pulmonary vein(s) emptying into the right atrium of the heart.
 - no
 - one
 - two
 - four
 - more than four
- The coronary blood vessels are part of the _____ circuit of the circulatory system.
 - cardiac
 - pulmonary
 - systematic
 - systemic
 - cardiovascular
- The atria contract during
 - the first heart sound.
 - the second heart sound.
 - the QRS complex.
 - the PQ segment.
 - the ST segment.
- Cardiac muscle does not exhibit tetanus because it has
 - fast Ca^{2+} channels.
 - scanty sarcoplasmic reticulum.
 - a long absolute refractory period.
 - electrical synapses.
 - exclusively aerobic respiration.
- The blood contained in a ventricle during isovolumetric relaxation is
 - the end-systolic volume.
 - the end-diastolic volume.
 - the stroke volume.
 - the ejection fraction.
 - none of these; the ventricle is empty then.
- Drugs that increase the heart rate have a _____ effect.
 - myogenic
 - negative inotropic
 - positive inotropic
 - negative chronotropic
 - positive chronotropic
- The contraction of any heart chamber is called _____ and its relaxation is called _____.
- The circulatory route from aorta to the venae cavae is the _____ circuit.
- The circumflex artery travels in a groove called the _____.
- The pacemaker potential of the SA node cells results from the slow inflow of _____.
- Electrical signals pass quickly from one cardiac myocyte to another through the _____ of the intercalated discs.
- Repolarization of the ventricles produces the _____ of the electrocardiogram.
- The _____ nerves innervate the heart and tend to reduce the heart rate.
- The death of cardiac tissue from lack of blood flow is commonly known as a heart attack, but clinically called _____.
- Blood in the heart chambers is separated from the myocardium by a thin membrane called the _____.
- The Frank–Starling law of the heart explains why the _____ of the left ventricle is the same as that of the right ventricle.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- The blood supply to the myocardium is the coronary circulation; everything else is called the systemic circuit.
- There are no valves at the point where venous blood flows into the atria.
- No blood can enter the ventricles until the atria contract.
- The vagus nerves reduce the heart rate but have little effect on the strength of ventricular contraction.
- A high blood CO₂ level and low blood pH stimulate an increase in heart rate.
- The first heart sound occurs at the time of the P wave of the electrocardiogram.
- If all nerves to the heart were severed, the heart would instantly stop beating.
- If the two pulmonary arteries were clamped shut, systemic edema would follow.
- Ventricular cardiocytes have a stable resting membrane potential but myocytes of the SA node do not.
- An electrocardiogram is a tracing of the action potential of a cardiocyte.

Answers in appendix B

Testing Your Comprehension

- Verapamil is a calcium channel blocker used to treat hypertension. It selectively blocks slow calcium channels. Would you expect it to have a positive or negative inotropic effect? Explain. (See p. 95 to review calcium channel blockers.)
- To temporarily treat tachycardia and restore the normal resting sinus rhythm, a physician may massage a patient's carotid artery near the angle of the mandible. Propose a mechanism by which this treatment would have the desired effect.
- Becky, age 2, was born with a hole in her interventricular septum (*ventricular septal defect*, or *VSD*). Considering that the blood pressure in the left ventricle is significantly higher than blood pressure in the right ventricle, predict the effect of the VSD on Becky's pulmonary blood pressure, systemic blood pressure, and long-term changes in the ventricular walls.
- In ventricular systole, the left ventricle is the first to begin contracting, but the right ventricle is the first to expel blood. Aside from the obvious fact that the pulmonary valve opens before the aortic valve, how can you explain this difference?
- In dilated cardiomyopathy of the left ventricle, the ventricle can become enormously enlarged. Explain why this might lead to regurgitation of blood through the mitral valve (blood flowing from the ventricle back into the left atrium) during ventricular systole.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Set point and dynamic equilibrium in homeostasis (p. 17)
- Diffusion (p. 100)
- Equilibrium between filtration and osmosis (p. 102)
- Transcytosis (p. 108)
- Viscosity and osmolarity of blood (p. 687)
- Principles of pressure and flow (p. 739)
- Autonomic effects on the heart (p. 746)

The route taken by the blood after it leaves the heart was a point of much confusion for many centuries. Chinese emperor Huang Ti (2697–2597 BCE) correctly believed that it flowed in a complete circuit around the body and back to the heart. But in the second century, Roman physician Claudius Galen (129–c. 199) argued that it flowed back and forth in the veins, like air in the bronchial tubes. He believed that the liver received food from the small intestine and converted it to blood, the heart pumped the blood through the veins to all other organs, and those organs consumed it.

Huang Ti was right, but the first experimental demonstration of this did not come for another 4,000 years. English physician William Harvey (1578–1657) (see p. 4) studied the filling and emptying of the heart in snakes, tied off the vessels above and below the heart to observe the effects on cardiac filling and output, and measured cardiac output in a variety of living animals. He concluded that (1) the heart pumps more blood in half an hour than there is in the entire body, (2) not enough food is consumed to account for the continual production of so much blood, and (3) since the planets orbit the sun and (as he believed) the human body is modeled after the solar system, it follows that the blood orbits the body. So for a peculiar combination of experimental and superstitious reasons, Harvey argued that the blood returns to the heart rather than being consumed by the peripheral organs. He could not explain how, since the microscope had yet to be developed to the point that enabled Antony van Leeuwenhoek (1632–1723) and Marcello Malpighi (1628–94) to discover the blood capillaries.

Harvey's work was the first experimental study of animal physiology and a landmark in the history of biology and medicine. But so entrenched were the ideas of Aristotle and Galen in the medical community, and so strange was the idea of doing experiments on living animals, that Harvey's contemporaries rejected his ideas. Indeed, some of them regarded him as a crackpot because his conclusion flew in the face of common sense—if the blood was continually recirculated and not consumed by the tissues, they reasoned, then what purpose could it serve? We now know, of course, that he was right. Harvey's case is one of the most interesting in biomedical history, for it shows how empirical science overthrows old theories and spawns better ones, and how common sense and blind allegiance to authority can interfere with the acceptance of truth. But most importantly, Harvey's contributions represent the birth of experimental physiology.

20.1 General Anatomy of the Blood Vessels

Objectives

When you have completed this section, you should be able to

- describe the structure of a blood vessel;
- describe the different types of arteries, capillaries, and veins;
- trace the general route usually taken by the blood from the heart and back again; and
- describe some variations on this route.

There are three principal categories of blood vessels: arteries, veins, and capillaries (fig. 20.1). **Arteries** are the

FIGURE 20.1 Micrographs of Blood Vessels. (a) A neurovascular bundle, composed of a small artery, vein, and nerve traveling together in a common sheath of connective tissue (LM). (b) A vascular cast of blood vessels of the eye (SEM). This was prepared by injecting the vessels with a polymer, digesting away all tissue to leave a replica of the vessels, and photographing the cast with the electron microscope.

efferent vessels of the cardiovascular system—that is, vessels that carry blood away from the heart. **Veins** are the afferent vessels—vessels that carry blood back to the heart. **Capillaries** are microscopic, thin-walled vessels that connect the smallest arteries to the smallest veins. Aside from their general location and direction of blood flow, these three categories of vessels also differ in the histological structure of their walls.

The Vessel Wall

The walls of arteries and veins are composed of three layers called *tunics* (fig. 20.2):

1. The **tunica interna (tunica intima)** lines the inside of the vessel and is exposed to the blood. It consists of a simple squamous epithelium called the **endothelium** overlying a basement membrane and a sparse layer of

FIGURE 20.2 The Structure of Arteries and Veins.

❏ Why do the arteries have so much more elastic tissue than the veins do?

loose connective tissue. The endothelium acts as a selectively permeable barrier to materials entering or leaving the bloodstream; it secretes chemicals that stimulate dilation or constriction of the vessel; and it normally repels blood cells and platelets so that they flow freely without sticking to the vessel wall. When the endothelium is damaged, however, platelets may adhere to it and form a blood clot; and when the tissue around a vessel is inflamed, the endothelial cells produce *cell-adhesion molecules* that induce leukocytes to adhere to the surface. This causes leukocytes to congregate in tissues where their defensive actions are needed.

2. The **tunica media**, the middle layer, is usually the thickest. It consists of smooth muscle, collagen, and in some cases, elastic tissue. The relative amounts of smooth muscle and elastic tissue vary greatly from one vessel to another and form a basis for classifying vessels as described in the next section. The tunica media strengthens the vessels and prevents blood pressure from rupturing them, and it provides **vasomotion**, changes in the diameter of a blood vessel.
3. The **tunica externa (tunica adventitia¹)** is the outermost layer. It consists of loose connective tissue that often merges with that of neighboring blood vessels, nerves, or other organs (fig. 20.1a). It anchors the vessel and provides passage for small nerves, lymphatic vessels, and smaller blood vessels. Small vessels called the **vasa vasorum²** (VAY-za vay-SO-rum) supply blood to at least the outer half of the wall of a larger vessel. Tissues of the inner half of the wall are thought to be nourished by diffusion from blood in the lumen.

Arteries

Arteries are sometimes called the *resistance vessels* of the cardiovascular system because they have a relatively strong, resilient tissue structure that resists high blood pressure. Each beat of the heart creates a surge of pressure in the arteries as blood is ejected into them. Arteries are built to withstand these surges. Being more muscular than veins, they retain their round shape even when empty, and they appear relatively circular in tissue sections. They are divided into three categories by size, but there is a smooth transition from one category to the next.

1. **Conducting (elastic or large) arteries** are the biggest arteries. The aorta, common carotid and subclavian arteries, pulmonary trunk, and common iliac arteries are examples of conducting arteries. They have a layer of elastic tissue called the *internal elastic lamina* at the border between the interna and media, but microscopically, it is incomplete and difficult to distinguish from the elastic tissue of the tunica

media. The tunica media consists of 40 to 70 layers of elastic sheets, perforated like slices of Swiss cheese, alternating with thin layers of smooth muscle, collagen, and elastic fibers. In histological sections, the view is dominated by this elastic tissue. There is an *external elastic lamina* at the border between the media and externa, but it, too, is difficult to distinguish from the elastic sheets of the tunica media. The tunica externa is less than half as thick as the tunica media and quite sparse in the largest arteries. It is well supplied with vasa vasorum.

Conducting arteries expand during ventricular systole to receive blood, and recoil during diastole. Their expansion takes some of the pressure off the blood so that smaller arteries downstream are subjected to less systolic stress. Their recoil between heartbeats prevents the blood pressure from dropping too low while the heart is relaxing and refilling. These effects lessen the fluctuations in blood pressure that would otherwise occur. Arteries stiffened by atherosclerosis cannot expand and recoil as freely. Consequently, the downstream vessels are subjected to greater stress and are more likely to develop aneurysms and rupture (see Insight 20.1).

2. **Distributing (muscular or medium) arteries** are smaller branches that distribute blood to specific organs. You could compare a conducting artery to an interstate highway and distributing arteries to the exit ramps and state highways that serve specific towns. Most arteries that have specific anatomical names are in these first two size classes. The brachial, femoral, renal, and splenic arteries are examples of distributing arteries. Distributing arteries typically

INSIGHT 20.1 Clinical Application

Aneurysm

An *aneurysm³* is a weak point in an artery or in the heart wall. It forms a thin-walled, bulging sac that pulsates with each beat of the heart and may eventually rupture. In a *dissecting aneurysm*, blood accumulates between the tunics of an artery and separates them, usually because of degeneration of the tunica media. The most common sites of aneurysms are the abdominal aorta, renal arteries, and the arterial circle at the base of the brain. Even without hemorrhaging, aneurysms can cause pain or death by putting pressure on brain tissue, nerves, adjacent veins, pulmonary air passages, or the esophagus. Other consequences include neurological disorders, difficulty in breathing or swallowing, chronic cough, or congestion of the tissues with blood. Aneurysms sometimes result from congenital weakness of the blood vessels and sometimes from trauma or bacterial infections such as syphilis. The most common cause, however, is the combination of atherosclerosis and hypertension.

¹advent = added to

²vasa = vessels + vasorum = of the vessels

³aneurysm = widening

have up to 40 layers of smooth muscle constituting about three-quarters of the wall thickness. In histological sections, this smooth muscle is more conspicuous than the elastic tissue. Both the internal and external elastic laminae, however, are thick and often conspicuous.

(a) Sphincters open

(b) Sphincters closed

FIGURE 20.3 Perfusion of a Capillary Bed. (a) Precapillary sphincters dilated and capillaries well perfused. (b) Precapillary sphincters closed, with most blood bypassing the capillaries.

3. **Resistance (small) arteries** are usually too variable in number and location to be given individual names. They exhibit up to 25 layers of smooth muscle and relatively little elastic tissue. Compared to large arteries, they have a thicker tunica media in proportion to the lumen. The smallest of these arteries, about 40 to 200 μm in diameter and with only one to three layers of smooth muscle, are called **arterioles**. Arterioles have very little tunica externa.

Metarterioles⁴ are short vessels that link arterioles and capillaries. Instead of a continuous tunica media, they have individual muscle cells spaced a short distance apart, each forming a **precapillary sphincter** that encircles the entrance to one capillary (fig. 20.3). Constriction of these sphincters reduces or shuts off blood flow through their respective capillaries and diverts blood to tissues or organs elsewhere.

Arterial Sense Organs

Certain major arteries above the heart have sensory structures in their walls that monitor blood pressure and chemistry (fig. 20.4). These receptors transmit information

⁴meta = beyond, next in a series

FIGURE 20.4 Baroreceptors and Chemoreceptors in the Arteries Superior to the Heart. The structures shown here in the right carotid arteries are repeated in the left carotids.

to the brainstem that serves to regulate the heartbeat, vasomotion, and respiration. They are of three kinds:

1. **Carotid sinuses.** These are *baroreceptors* (pressure sensors) that respond to changes in blood pressure. Ascending the neck on each side is a *common carotid artery*, which branches near the angle of the mandible, forming the *internal carotid artery* to the brain and *external carotid artery* to the face. The carotid sinuses are located in the wall of the internal carotid artery just above the branch point. The carotid sinus has a relatively thin tunica media and an abundance of glossopharyngeal nerve fibers in the tunica externa. A rise in blood pressure easily stretches the thin media and stimulates these nerve fibers. The glossopharyngeal nerve then transmits signals to the vasomotor and cardiac centers of the brainstem, and the brainstem responds by lowering the heart rate and dilating the blood vessels, thereby lowering the blood pressure.
2. **Carotid bodies.** Also located near the branch of the common carotid arteries, these are oval receptors about 3×5 mm in size, innervated by sensory fibers of the vagus and glossopharyngeal nerves. They are *chemoreceptors* that monitor changes in blood composition. They primarily transmit signals to the brainstem respiratory centers, which adjust breathing to stabilize the blood pH and its CO_2 and O_2 levels.
3. **Aortic bodies.** These are one to three chemoreceptors located in the aortic arch near the arteries to the head and arms. They are structurally similar to the carotid bodies and have the same function.

Capillaries

For the blood to serve any purpose, materials such as nutrients, wastes, and hormones must pass between the blood and the tissue fluids, through the walls of the vessels. There are only two places in the circulation where this occurs—the capillaries and some venules. We can think of these as the “business end” of the cardiovascular system, because all the rest of the system exists to serve the exchange processes that occur here. Since capillaries greatly outnumber venules, they are the more important of the two. Capillaries are sometimes called the *exchange vessels* of the cardiovascular system.

Blood capillaries (see figs. 20.1–20.3) are composed of only an endothelium and basal lamina. Their walls are as thin as 0.2 to $0.4 \mu\text{m}$. They average about $5 \mu\text{m}$ in diameter at the proximal end (where they receive arterial blood); they widen to about $9 \mu\text{m}$ at the distal end (where they empty into a small vein); and they often branch along the way. Since erythrocytes are about $7.5 \mu\text{m}$ in diameter, they often have to stretch into elongated shapes to squeeze through the smallest capillaries.

The number of capillaries has been estimated at a billion and their total surface area at $6,300 \text{ m}^2$. But a more

important point is that scarcely any cell in the body is more than 60 to $80 \mu\text{m}$ (about four to six cell widths) away from the nearest capillary (see photo, p. 755). There are a few exceptions: Capillaries are scarce in tendons and ligaments, found only occasionally in cartilage, and absent from epithelia and the cornea and lens of the eye.

Types of Capillaries

There are three types of capillaries, distinguished by the ease with which they allow substances to pass through their walls and by structural differences that account for their greater or lesser permeability.

1. **Continuous capillaries** (fig. 20.5) occur in most tissues, such as skeletal muscle. Their endothelial cells, held together by tight junctions, form a continuous tube. A thin protein–carbohydrate layer, the **basal lamina**, surrounds the endothelium and separates it from the adjacent connective tissues. The endothelial cells are separated by narrow **intercellular clefts** about 4 nm wide. Small solutes such as glucose can pass through these clefts, but most plasma protein, other large molecules, and platelets and blood cells are held back. The continuous capillaries of the brain lack intercellular clefts and have more complete tight junctions that form the blood–brain barrier discussed in chapter 14.

Some continuous capillaries exhibit cells called **pericytes** that lie external to the endothelium.

FIGURE 20.5 Structure of a Continuous Capillary. Cross section.

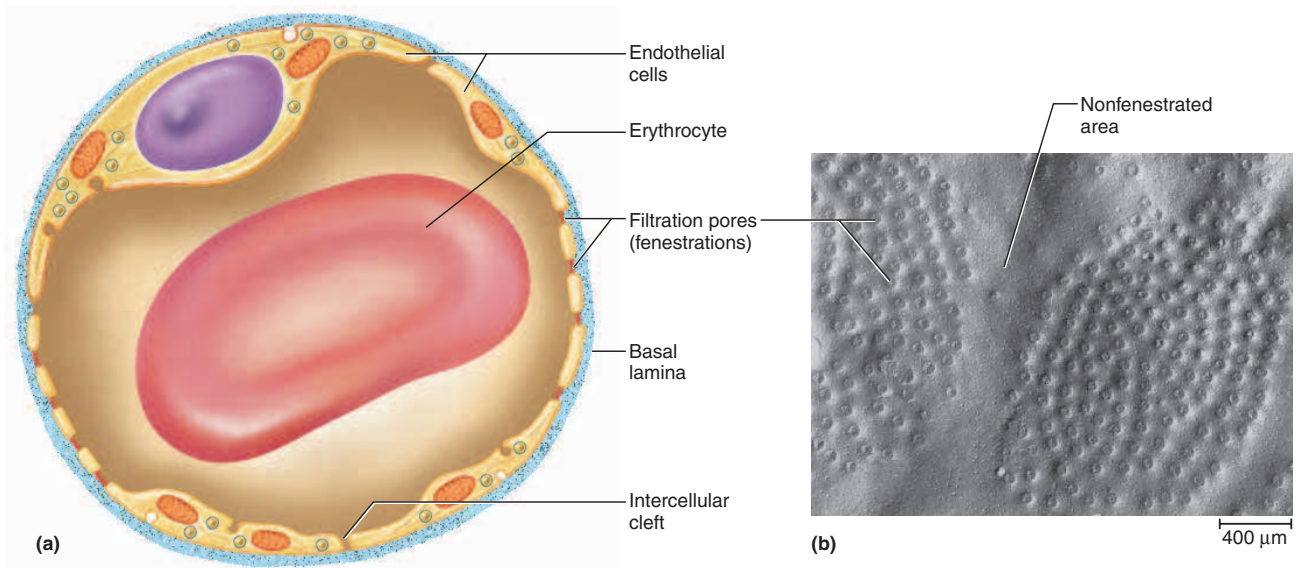

FIGURE 20.6 Structure of a Fenestrated Capillary. (a) Cross section of the capillary wall. (b) Surface view of a fenestrated endothelial cell (SEM). The cell has patches of filtration pores (fenestrations) separated by nonfenestrated areas.

Identify some organs that have this type of capillary rather than continuous capillaries.

Pericytes have elongated tendrils that wrap around the capillary. They contain the same contractile proteins as muscle, and it is thought that they contract and regulate blood flow through the capillaries. They also can differentiate into endothelial and smooth muscle cells and thus contribute to vessel growth and repair.

- Fenestrated capillaries** have endothelial cells riddled with holes called **filtration pores (fenestrations)**⁵ (fig. 20.6). These pores are about 20 to 100 nm in diameter, and are often spanned by a glycoprotein membrane that is much thinner than the cell's plasma membrane. They allow for the rapid passage of small molecules, but still retain most proteins and larger particles in the bloodstream. Fenestrated capillaries are important in organs that engage in rapid absorption or filtration—the kidneys, endocrine glands, small intestine, and choroid plexuses of the brain, for example.
- Sinusoids (discontinuous capillaries)** are irregular blood-filled spaces in the liver, bone marrow, spleen, and some other organs (fig. 20.7). They are twisted, tortuous passageways, typically 30 to 40 μm wide, that conform to the shape of the surrounding tissue. The endothelial cells are separated by wide gaps with no basal lamina, and the cells also frequently have especially large fenestrations through them. Even proteins and blood cells can pass through these pores; this is how albumin, clotting factors, and

FIGURE 20.7 A Sinusoid of the Liver. Large gaps between the endothelial cells allow blood plasma to directly contact the liver cells but retain blood cells in the lumen of the sinusoid.

⁵fenestra = window

other proteins synthesized by the liver enter the blood, and how newly formed blood cells enter the circulation from the bone marrow and lymphatic organs. Some sinusoids contain macrophages or other specialized cells.

Capillary Beds

Capillaries are organized into networks called **capillary beds**—usually 10 to 100 capillaries supplied by a single metarteriole (fig. 20.3; see also photo on p. 755). Beyond the origins of the capillaries, the metarteriole continues as a **thoroughfare channel** leading directly to a venule. Capillaries empty into the distal end of the thoroughfare channel or directly into the venule.

When the precapillary sphincters are open, the capillaries are well perfused with blood and engage in exchanges with the tissue fluid. When the sphincters are closed, blood bypasses the capillaries, flows through the thoroughfare channel to a venule, and engages in relatively little fluid exchange. There is not enough blood in the body to fill the entire vascular system at once; consequently, about three-quarters of the body's capillaries are shut down at any given time. In the skeletal muscles, for example, about 90% of the capillaries have little to no blood flow during periods of rest. During exercise, they receive an abundant blood flow, while capillary beds elsewhere—for example, in the skin and intestines—shut down to compensate for this.

Veins

Veins are regarded as the *capacitance vessels* of the cardiovascular system because they are relatively thin-walled and flaccid, and expand easily to accommodate an increased volume of blood; that is, they have a greater capacity for blood containment than arteries do. At rest, about 54% of the blood is found in the systemic veins as compared with only 11% in the systemic arteries (fig. 20.8). The reason that veins are so thin-walled and accommodating is that, being distant from the ventricles of the heart, they are subjected to relatively low blood pressure. In large arteries, blood pressure averages 90 to 100 mm Hg and surges to 120 mm Hg during systole, whereas in veins it averages about 10 mm Hg. Furthermore, the blood flow in the veins is steady, rather than pulsating with the heart-beat like the flow in the arteries. Veins therefore do not require thick, pressure-resistant walls. They collapse when empty and thus have relatively flattened, irregular shapes in histological sections (see fig. 20.1a).

As we trace blood flow in the arteries, we find it splitting off repeatedly into smaller and smaller *branches* of the arterial system. In the venous system, conversely, we find small veins merging to form larger and larger ones as they approach the heart. We refer to the smaller veins as *tributaries*, by analogy to the streams that converge and act as tributaries to rivers. In examining the types of

FIGURE 20.8 Typical Blood Distribution in a Resting Adult.

What anatomical fact allows the veins to contain so much more blood than the arteries do?

veins, we will follow the direction of blood flow, working up from the smallest to the largest vessels.

- Postcapillary venules** are the smallest of the veins, beginning with diameters of about 15 to 20 μm . They receive blood from capillaries directly or by way of the distal ends of the thoroughfare channels. They have a tunica interna with only a few fibroblasts around it and no muscle. Like capillaries, they are often surrounded by pericytes. Postcapillary venules are even more porous than capillaries; therefore, venules also exchange fluid with the surrounding tissues. Most leukocytes emigrate from the bloodstream through the venule walls.
- Muscular venules** receive blood from the postcapillary venules. They are up to 1 mm in diameter. They have a tunica media of one or two layers of smooth muscle, and a thin tunica externa.
- Medium veins** range up to 10 mm in diameter. Most veins with individual names are in this category, such as the radial and ulnar veins of the forearm and the small and great saphenous veins of the leg. Medium veins have a tunica interna with an endothelium, basement membrane, loose connective tissue, and sometimes a thin internal elastic lamina. The tunica media is much thinner than it is in medium arteries; it exhibits bundles of smooth muscle, but not a continuous muscular layer as seen in arteries. The muscle is interrupted by regions of collagenous, reticular, and elastic tissue. The tunica externa is relatively thick.

Many medium veins, especially in the limbs, exhibit infoldings of the tunica interna that meet in the middle of the lumen, forming **venous valves** directed toward the heart (see fig. 20.19). The pressure

in the veins is not high enough to push all of the blood upward against the pull of gravity in a standing or sitting person. The upward flow of blood in these vessels depends partly on the massaging action of skeletal muscles and the ability of these valves to keep the blood from dropping down again when the muscles relax. When the muscles surrounding a vein contract, they force blood through these valves. The propulsion of venous blood by muscular massaging, aided by the venous valves, is a mechanism of blood flow called the *skeletal muscle pump*. Varicose veins result in part from the failure of the valves (see Insight 20.2). Such valves are absent from very small and large veins, veins of the abdominal and thoracic cavities, and veins of the brain.

- Venous sinuses** are veins with especially thin walls, large lumens, and no smooth muscle. Examples include the coronary sinus of the heart and the dural sinuses of the brain. Unlike other veins, they are not capable of vasomotion.
- Large veins** have diameters greater than 10 mm. They have some smooth muscle in all three tunics. They have a relatively thin tunica media with only a moderate amount of smooth muscle; the tunica externa is the thickest layer and contains longitudinal bundles of smooth muscle. Large veins include the venae cavae, pulmonary veins, internal jugular veins, and renal veins.

Circulatory Routes

The simplest and most common route of blood flow is heart → arteries → capillaries → veins → heart. Blood usually passes through only one network of capillaries from the time it leaves the heart until the time it returns

INSIGHT 20.2 Clinical Application

Varicose Veins

In people who stand for long periods, such as barbers and cashiers, blood tends to pool in the lower limbs and stretch the veins. This is especially true of superficial veins, which are not surrounded by supportive tissue. Stretching pulls the cusps of the venous valves farther apart until the valves become incapable of sealing the vessel and preventing the backflow of blood. As the veins become further distended, their walls grow weak and they develop into *varicose veins* with irregular dilations and twisted pathways. Obesity and pregnancy also promote development of varicose veins by putting pressure on large veins of the pelvic region and obstructing drainage from the limbs. Varicose veins sometimes develop because of hereditary weakness of the valves. With less drainage of blood, tissues of the leg and foot may become edematous and painful. *Hemorrhoids* are varicose veins of the anal canal.

(fig. 20.9a), but there are exceptions, notably portal systems and anastomoses.

In a **portal system** (fig. 20.9b), blood flows through two consecutive capillary networks before returning to the heart. Portal systems occur in the kidneys (chapter 23); connecting the hypothalamus and anterior pituitary (chapter 17); and connecting the intestines to the liver (table 20.9, part III).

An **anastomosis** is a point where two blood vessels merge. In an **arteriovenous anastomosis (shunt)**, blood flows from an artery directly into a vein and bypasses the capillaries (fig. 20.9c). Shunts occur in the fingers, palms, toes, and ears, where they reduce heat loss in cold weather by allowing warm blood to bypass these exposed surfaces. Unfortunately, this makes these poorly perfused areas more susceptible to frostbite. The most common anastomoses are **venous anastomoses**, in which one vein empties directly into another (fig. 20.9d). These provide several alternative routes of drainage from an organ, so blockage of a vein is rarely as life-threatening as blockage of an artery. **Arterial anastomoses**, in which two arteries

FIGURE 20.9 Variations in Circulatory Pathways.

After studying tables 20.3 through 20.13, identify specific sites in the body where one can find arterial anastomoses, venous anastomoses, and portal systems.

merge (fig. 20.9e), provide *collateral* (alternative) routes of blood supply to a tissue. Those of the coronary circulation were mentioned in chapter 19. They are also common around joints where movement may temporarily compress an artery and obstruct one pathway. Several arterial and venous anastomoses are described later in this chapter.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Name the three tunics of a typical blood vessel and explain how they differ from each other.
2. Contrast the tunica media of a conducting artery, arteriole, and venule and explain how the histological differences are related to the functional differences between these vessels.
3. Describe the differences between a continuous capillary, a fenestrated capillary, and a sinusoid.
4. Describe two routes by which substances can escape the bloodstream and pass through a capillary wall into the tissue fluid.
5. Describe the differences between a medium vein and a medium (muscular) artery. State the functional reasons for these differences.
6. Contrast an anastomosis and a portal system with the more typical pathway of blood flow.

20.2 Blood Pressure, Resistance, and Flow

Objectives

When you have completed this section, you should be able to

- explain the relationship between blood pressure, resistance, and flow;
- describe how blood pressure is expressed and how pulse pressure and mean arterial pressure are calculated;
- describe three factors that determine resistance to blood flow;
- explain how vasomotion influences blood pressure and flow; and
- describe some local, neural, and hormonal influences on vasomotion.

To sustain life, the circulatory system must deliver oxygen and nutrients to the tissues, and remove their wastes, at a rate that keeps pace with tissue metabolism. Inadequate circulatory services to a tissue can lead within minutes to

tissue necrosis and possibly death of the individual. Thus, it is crucial for the cardiovascular system to respond promptly to local needs and ensure that the tissues have an adequate blood supply at all times. This section of the chapter explores the mechanisms for achieving this.

The blood supply to a tissue can be expressed in terms of *flow* and *perfusion*. **Flow** is the amount of blood flowing through an organ, tissue, or blood vessel in a given time (such as mL/min). **Perfusion** is the flow per given volume or mass of tissue (such as mL/min/g). Thus, a large organ such as the femur could have a *greater flow* but *less perfusion* than a small organ such as the ovary, because the ovary receives much more blood per gram of tissue.

In a resting individual, *total flow* is quite constant and is equal to cardiac output (typically 5.25 L/min). Flow through individual organs, however, varies from minute to minute as blood is redirected from one organ to another. Digestion, for example, requires abundant flow to the intestines, and the cardiovascular system reduces flow through other organs such as the kidneys in order to make it available to the digestive system. When digestion and nutrient absorption are over, blood flow to the intestines declines and a higher priority is given to the kidneys and other organs. Great variations in regional flow can occur with little or no change in total flow.

Hemodynamics, the physical principles of blood flow, are based mainly on pressure and resistance. These relationships can be concisely summarized by the proportionality $F \propto \Delta P/R$. In other words, the greater the pressure difference (ΔP) between two points, the greater the flow (F); the greater the resistance (R), the less the flow. Therefore, to understand the flow of blood, we must consider the factors that affect pressure and resistance.

Blood Pressure

Blood pressure (BP) is the force that the blood exerts against a vessel wall. It can be measured within a blood vessel or the heart by inserting a catheter or needle connected to an external manometer (pressure-measuring device). For routine clinical purposes, however, the measurement of greatest interest is the systemic arterial BP at a point close to the heart. We customarily measure it with a sphygmomanometer (see p. 739) connected to an inflatable cuff wrapped around the arm. The *brachial artery* passing through this region is sufficiently close to the heart that the BP recorded here approximates the maximum arterial BP found anywhere in the body.

Two pressures are recorded: **systolic pressure** is the peak arterial BP attained during ventricular contraction, and **diastolic pressure** is the minimum arterial BP occurring during the ventricular relaxation between heartbeats. For a healthy person age 20 to 30, these pressures are typically about 120 and 75 mm Hg, respectively. Arterial BP is written as a ratio of systolic over diastolic pressure: 120/75.

The difference between systolic and diastolic pressure is called **pulse pressure** (not to be confused with pulse *rate*). For the preceding BP, pulse pressure would be $120 - 75 = 45$ mm Hg. This is an important measure of the maximum stress exerted on small arteries by the pressure surges generated by the heart. Another measure of stress on the blood vessels is the **mean arterial pressure (MAP)**—the mean pressure you would obtain if you took measurements at several intervals (say every 0.1 sec) throughout the cardiac cycle. It is this *average* blood pressure that most influences the risk level for disorders such as edema, *syncope* (SIN-co-pee) (fainting), atherosclerosis, kidney failure, and aneurysm. MAP is not simply an arithmetic mean of systolic and diastolic pressures, however, because the low-pressure diastole lasts longer than the high-pressure systole. The best estimate of MAP is diastolic pressure plus one-third of the pulse pressure. For a blood pressure of 120/75, $MAP \approx 75 + 45/3 = 90$ mm Hg. This is typical for vessels at the level of the heart, but MAP varies with the influence of gravity. In a standing adult, it is about 62 mm Hg in the major arteries of the head and 180 mm Hg in major arteries of the ankle.

Hypertension (high BP) is commonly considered to be a chronic resting blood pressure higher than 140/90. (*Transient* high BP resulting from emotion or exercise is not hypertension.) Among other effects, hypertension can weaken the small arteries and cause aneurysms, and it promotes the development of atherosclerosis (see Insight 20.5, p. 808). **Hypotension** is chronic low resting BP. It may be a consequence of blood loss, dehydration, anemia, or other factors and is normal in people approaching death.

The importance of preventing excessive blood pressure is clear. One of the body's chief mechanisms for doing so is the ability of the arteries to stretch and recoil during the cardiac cycle. If the arteries were rigid tubes, pressure would rise much higher in systole and drop to nearly zero in diastole. Blood throughout the circulatory system would flow and stop, flow and stop, and put great stress on the small vessels. But healthy conducting arteries expand with each systole and absorb some of the force of the ejected blood. Then, when the heart is in diastole, their elastic recoil exerts pressure on the blood and prevents the BP from dropping to zero. This combination of expansion and recoil maintains a steady flow of blood downstream, in the capillaries, throughout the cardiac cycle. Thus, the elastic arteries smooth out the pressure fluctuations and reduce stress on the smaller arteries.

Nevertheless, blood flow in the arteries is *pulsatile*. In the aorta, blood rushes forward at 120 cm/s during systole and has an average speed of 40 cm/s over the cardiac cycle. When measured farther away from the heart, systolic and diastolic pressures are lower and there is less difference between them (fig. 20.10). In capillaries and veins, the blood flows at a steady speed without pulsation

FIGURE 20.10 Changes in Blood Pressure Relative to Distance from the Heart. Because of arterial elasticity and the effect of friction against the vessel wall, all measures of blood pressure decline with distance—systolic pressure, diastolic pressure, pulse pressure, and mean arterial pressure. There is no pulse pressure beyond the arterioles, but there are slight pressure oscillations in the venae cavae caused by the respiratory pump described later in this chapter.

because the pressure surges have been damped out by the distance traveled and the elasticity of the arteries. This is why an injured vein exhibits relatively slow, steady bleeding, whereas blood jets intermittently from a severed artery. In the inferior vena cava near the heart, however, venous flow fluctuates with the respiratory cycle for reasons explained later, and there is some fluctuation in the jugular veins of the neck.

Think About It

Explain how the histological structure of large arteries relates to their ability to stretch during systole and recoil during diastole.

As we get older, our arteries become less distensible and absorb less systolic force. Blood pressure therefore rises with age (table 20.1). Atherosclerosis also stiffens the arteries and raises the blood pressure.

Blood pressure is physiologically determined by three principal variables:

1. Cardiac output, which was discussed in chapter 19.
2. Blood volume, which is regulated mainly by the kidneys. Perhaps surprisingly, the kidneys have a greater influence than any other organ on blood pressure (assuming the heart is beating). Their role is discussed in chapters 23 and 24.

TABLE 20.1

Normal Arterial Blood Pressure at Various Ages (mm Hg)*

Age (Years)	Male	Female
1	96/66	95/65
5	92/62	92/62
10	103/69	103/70
15	112/75	112/76
20	123/76	116/72
25	125/78	117/74
30	126/79	120/75
40	129/81	127/80
50	135/83	137/84
60	142/85	144/85
70	145/82	159/85
80	145/82	157/83

*Average for healthy individuals

- Resistance to flow, which results from the friction of the blood against the walls of the vessels. Resistance, in turn, hinges on three variables that we will now consider: blood viscosity, vessel length, and vessel radius.

Peripheral Resistance

Peripheral resistance is the opposition to flow that the blood encounters in vessels away from the heart. A moving fluid has no pressure unless it encounters at least some resistance. Thus, pressure and resistance are not independent variables in blood flow—rather, pressure is affected by resistance and flow is affected by both.

Blood Viscosity

Chapter 18 discusses the factors that affect the viscosity (“thickness”) of the blood (p. 687). The most significant of these are the erythrocyte count and albumin concentration. A deficiency of erythrocytes (anemia) or albumin (hypoalbuminemia) reduces viscosity and speeds up blood flow. On the other hand, viscosity increases and flow declines in such conditions as polycythemia and dehydration.

Vessel Length

The farther a liquid travels through a tube, the more cumulative friction it encounters; thus, pressure and flow decline with distance. Partly for this reason, if you were to measure mean arterial pressure in a reclining person, you would obtain a higher value in the arm, for example, than in the ankle. (This would not be true in a standing person because of the influence of gravity, explained earlier.) A strong pulse in the *dorsal pedal artery* of the foot is a good sign of adequate cardiac output. If perfusion is

good at that distance from the heart, it is likely to be good elsewhere in the systemic circulation.

Vessel Radius

In a healthy individual, blood viscosity is quite stable, and of course vessel lengths do not change in the short term. Therefore, the only significant way of controlling peripheral resistance from moment to moment is by vasomotion—adjusting the radius of the blood vessels. This includes **vasoconstriction**, the narrowing of a vessel, and **vasodilation**, the widening of a vessel. Vasoconstriction occurs when the smooth muscle of the tunica media contracts. Vasodilation, however, is brought about not by any muscular effort to widen a vessel, but rather by muscular passivity—relaxation of the smooth muscle, allowing blood pressure to expand the vessel.

The effect of vessel radius on blood flow stems from the friction of the moving blood against the vessel walls. Blood normally exhibits smooth, silent **laminar**⁶ flow. That is, it flows in “layers”—faster near the center of a vessel, where it encounters less friction, and slower near the walls, where it drags against the vessel. You can observe a similar effect from the vantage point of a riverbank. The current may be very swift in the middle of a river but quite sluggish near shore, where the water encounters more friction against the riverbank and bottom. When a blood vessel dilates, a greater portion of the blood is in the middle of the stream and the average flow may be quite swift. When the vessel constricts, more of the blood is close to the wall and the average flow is slower (fig. 20.11).

⁶lamina = layer

FIGURE 20.11 Laminar Flow and the Effect of Vessel Radius. Blood flows more slowly near the vessel wall, as indicated by shorter arrows, than it does near the center of the vessel. (a) When the vessel radius is large, the average velocity of flow is high. (b) When the radius is less, the average velocity is lower because a larger portion of the blood is slowed down by friction against the vessel wall.

Thus, the radius of a vessel markedly affects blood velocity. Indeed, blood flow is proportional not merely to vessel radius but to the *fourth power* of radius—that is, $F \propto r^4$. This makes vessel radius a very potent factor in the control of flow. For the sake of simplicity, consider a hypothetical blood vessel with a 1 mm radius when maximally constricted and a 3 mm radius when completely dilated. At a 1 mm radius, suppose the blood travels 1 mm/sec. By the formula $F \propto r^4$, consider how the velocity would change as radius changed:

$$\begin{array}{lll} r = 1 \text{ mm} & r^4 = 1^4 = 1 & F = 1 \text{ mm/s (given)} \\ r = 2 \text{ mm} & r^4 = 2^4 = 16 & F = 16 \text{ mm/s} \\ r = 3 \text{ mm} & r^4 = 3^4 = 81 & F = 81 \text{ mm/s} \end{array}$$

These actual numbers do not matter; what matters is that a mere 3-fold increase in radius has produced an 81-fold increase in velocity—a demonstration that vessel radius exerts a very powerful influence over flow.

Blood vessels are, indeed, capable of substantial changes in radius. The arteriole in figure 20.12, for example, has constricted to one-third of its relaxed diameter under the influence of a drop of epinephrine. Since blood viscosity and vessel length do not change from moment to moment, vessel radius is the most adjustable of all variables that govern peripheral resistance.

FIGURE 20.12 The Capacity for Vasoconstriction in an Arteriole. (a) A dilated arteriole (cross section, TEM). (b) The same arteriole, at a point just 1 mm from the area photographed in part (a). A single drop of epinephrine applied here has caused the arteriole to constrict to about one-third of its dilated diameter.

Think About It

Suppose a vessel with a radius of 1 mm had a flow of 5 mm/s, and then the vessel dilated to a radius of 5 mm. What would be the new flow rate?

To integrate this information, consider how the velocity of blood flow differs from one part of the systemic circuit to another (table 20.2). Flow is fastest in the aorta because it is a large vessel close to the pressure source, the left ventricle. From aorta to capillaries, velocity diminishes for three reasons: (1) The blood has traveled a greater distance, so friction has slowed it down. (2) The arterioles and capillaries have smaller radii and therefore put up more resistance. (3) Even though the radii of individual vessels become smaller as we progress farther from the heart, the number of vessels and their *total* cross-sectional area become greater and greater. The aorta has a cross-sectional area of 3 to 5 cm², whereas the total cross-sectional area of all the capillaries is about 4,500 to 6,000 cm². Thus, a given volume of aortic blood is distributed over a greater total area in the capillaries, which *collectively* form a wider path in the bloodstream. Just as water slows down when a narrow mountain stream flows into a lake, blood slows down as it enters pathways with a greater total width or volume.

From capillaries to vena cava, velocity rises again. One reason for this is that the veins have larger diameters than the capillaries, so they create less resistance. Furthermore, since many capillaries converge on one venule, and many venules on a larger vein, a large amount of blood is being forced into a progressively smaller channel—like water flowing from a lake into an outlet stream and thus flowing faster again. Note, however, that blood in the veins never regains the velocity it had in the large arteries. This is because the veins are farther from the heart and the pressure is much lower.

The arterioles are the most significant point of control over peripheral resistance and blood flow because (1) they are on the proximal sides of the capillary beds, so they are best positioned to regulate flow into the capillaries; (2) they greatly outnumber any other class of arteries and thus provide the most numerous control points; and

TABLE 20.2		Blood Velocity in the Systemic Circuit
Vessel	Typical Lumen Diameter	Velocity*
Aorta	2.5 cm	1,200 mm/s
Arterioles	20–50 μm	15 mm/s
Capillaries	5–9 μm	0.4 mm/s
Venules	20 μm	5 mm/s
Inferior vena cava	3 cm	80 mm/s

*Peak systolic velocity in the aorta; mean or steady velocity in other vessels

(3) they are more muscular in proportion to their diameters than any other class of blood vessels and are highly capable of vasomotion. Arterioles alone account for about half of the total peripheral resistance of the circulatory system. However, larger arteries and veins are also capable of considerable vasomotion and control of peripheral resistance.

Regulation of Blood Pressure and Flow

Vasomotion, we have seen, is a quick and powerful way of altering blood pressure and flow. There are three ways of controlling vasomotion: local, neural, and hormonal mechanisms. We now consider each of these influences in turn.

Local Control

Autoregulation is the ability of tissues to regulate their own blood supply. According to the *metabolic theory of autoregulation*, if a tissue is inadequately perfused, it becomes hypoxic and its metabolites (waste products) accumulate—CO₂, H⁺, K⁺, lactic acid, and adenosine, for example. These factors stimulate vasodilation, which increases perfusion. As the bloodstream delivers oxygen and carries away the metabolites, the vessels reconstrict. Thus, a homeostatic dynamic equilibrium is established that adjusts perfusion to the tissue's metabolic needs.

In addition, platelets, endothelial cells, and the perivascular tissues secrete a variety of **vasoactive chemicals**—substances that stimulate vasomotion. Histamine, bradykinin, and prostaglandins stimulate vasodilation under such conditions as trauma, inflammation, and exercise. Endothelial cells secrete prostacyclin and nitric oxide, which are vasodilators, and polypeptides called *endothelins*, which are vasoconstrictors.

If a tissue's blood supply is cut off for a time and then restored, it often exhibits **reactive hyperemia**—an increase above the normal level of flow. This may be due to the accumulation of metabolites during the period of ischemia. Reactive hyperemia is seen when the skin flushes after a person comes in from the cold. It also occurs in the forearm if a blood pressure cuff is inflated for too long and then loosened.

Over a longer time, a hypoxic tissue can increase its own perfusion by **angiogenesis**⁷—the growth of new blood vessels. (This term also refers to embryonic development of blood vessels.) Three situations in which this is important are the regrowth of the uterine lining after each menstrual period, the development of a higher density of blood capillaries in the muscles of well-conditioned athletes, and the growth of arterial bypasses around obstructions in the coronary circulation. Several growth factors and inhibitors control angiogenesis, but physiologists are not yet sure how it is regulated. There is great clinical importance in finding out. Malignant tumors secrete growth factors that stimulate a dense network of vessels to grow into them and provide nourishment to the cancer cells. Oncologists are

interested in finding a way to block tumor angiogenesis, which would choke off a tumor's blood supply and perhaps shrink or kill it.

Neural Control

In addition to local control, the blood vessels are under remote control by the central and autonomic nervous systems. The **vasomotor center** of the medulla oblongata exerts sympathetic control over blood vessels throughout the body. (Precapillary sphincters have no innervation, however, and respond only to local and hormonal stimuli.) Sympathetic nerve fibers stimulate most blood vessels to constrict, but they dilate the vessels of skeletal and cardiac muscle in order to meet the metabolic demands of exercise. The role of sympathetic tone and vasomotor tone in controlling vessel diameter is explained in chapter 15 (p. 580).

The vasomotor center is an integrating center for three autonomic reflexes—*baroreflexes*, *chemoreflexes*, and the *medullary ischemic reflex*. A **baroreflex**⁸ is an autonomic, negative feedback response to changes in blood pressure. The changes are detected by the carotid sinuses described earlier (p. 760). Glossopharyngeal nerve fibers from these sinuses transmit signals continually to the brainstem. When the blood pressure rises, their signaling rate rises. This input *inhibits* the sympathetic cardiac and vasomotor neurons and *excites* the vagal fibers to the heart. Thus, it reduces the heart rate and cardiac output, dilates the arteries and veins, and reduces the blood pressure (fig. 20.13). When blood pressure drops below normal,

⁸baro = pressure

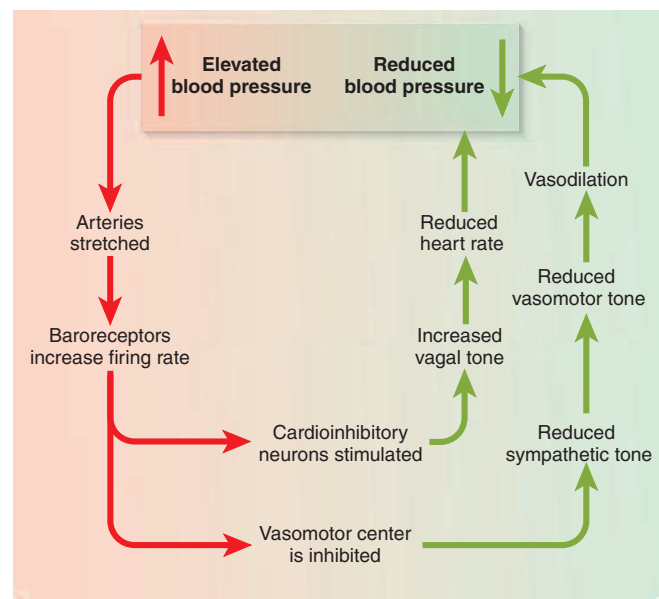

FIGURE 20.13 Negative Feedback Control of Blood Pressure. High blood pressure activates this cycle of reactions that return blood pressure to normal.

⁷angio = vessels + genesis = production of

on the other hand, the opposite reactions occur and BP rises back to normal (see fig. 1.11, p. 18).

Baroreflexes are important chiefly in short-term regulation of BP, for example in adapting to changes in posture. Perhaps you have jumped quickly out of bed and felt a little dizzy for a moment. This occurs because gravity draws the blood into the large veins of the abdomen and lower limbs when you stand, which reduces venous return to the heart and cardiac output to the brain. Normally, the baroreceptors respond quickly to this drop in pressure and restore cerebral perfusion. Baroreflexes are not effective in correcting chronic hypertension, however. Apparently they adjust their set point to the higher BP and maintain dynamic equilibrium at this new level.

A **chemoreflex** is an autonomic response to changes in blood chemistry, especially its pH and concentrations of O₂ and CO₂. It is initiated by the chemoreceptors called aortic bodies and carotid bodies (see p. 760). The primary role of chemoreflexes is to adjust respiration to changes in blood chemistry, but they have a secondary role in stimulating vasomotion. Hypoxemia (blood O₂ deficiency), hypercapnia (CO₂ excess), and acidosis (low blood pH) stimulate the chemoreceptors and act through the vasomotor center to induce widespread vasoconstriction. This increases overall BP, thus increasing perfusion of the lungs and the rate of gas exchange. Chemoreceptors also stimulate breathing, so increased ventilation of the lungs matches their increased perfusion. Increasing one without the other would be of little use.

The **medullary ischemic** (iss-KEE-mic) **reflex** is an autonomic response to a drop in perfusion of the brain; in other words, the medulla oblongata monitors its own blood supply and activates corrective reflexes when it senses a state of ischemia (insufficient perfusion). Within seconds of a drop in perfusion, the cardiac and vasomotor centers of the medulla oblongata send sympathetic signals to the heart and blood vessels that induce (1) an increase in heart rate and contraction force and (2) widespread vasoconstriction. These actions raise the blood pressure and, ideally, restore normal perfusion of the brain. The cardiac and vasomotor centers also receive input from other brain centers. Thus stress, anger, and arousal can raise the blood pressure. The hypothalamus acts through the vasomotor center to redirect blood flow in response to exercise or changes in body temperature.

Hormonal Control

All of the following hormones influence blood pressure, some through their vasoactive effects and some through means such as regulating water balance:

- **Angiotensin II.** This is a potent vasoconstrictor that raises the blood pressure. Its synthesis and action are detailed in chapter 23 (see fig. 23.14, p. 919). One of the enzymes required for its synthesis is *angiotensin converting enzyme (ACE)*. Hypertension is often treated with drugs called *ACE inhibitors*,

which block the action of this enzyme, thus lowering angiotensin II levels and blood pressure.

- **Aldosterone.** This “salt-retaining hormone” primarily promotes Na⁺ retention by the kidneys. Since water follows sodium osmotically, Na⁺ retention promotes water retention, thus promoting a higher blood volume and pressure.
- **Atrial natriuretic peptide.** ANP, secreted by the heart, antagonizes aldosterone. It increases Na⁺ excretion by the kidneys, thus reducing blood volume and pressure. It also has a generalized vasodilator effect that contributes to lowering the blood pressure. Brain natriuretic peptide (BNP) has a similar effect.
- **Antidiuretic hormone.** ADH primarily promotes water retention, but at pathologically high concentrations it is also a vasoconstrictor—hence its alternate name, *vasopressin*. Both of these effects raise blood pressure.
- **Epinephrine and norepinephrine.** These adrenal and sympathetic catecholamines bind to α-adrenergic receptors on the smooth muscle of most blood vessels. This stimulates the muscle to contract, thus producing vasoconstriction and raising the blood pressure. In the coronary blood vessels and blood vessels of the skeletal muscles, however, these chemicals bind to β-adrenergic receptors and cause vasodilation, thus increasing blood flow to the myocardium and muscular system during exercise.

Two Purposes of Vasomotion

Vasomotion can serve either of two physiological purposes: a generalized raising or lowering of blood pressure throughout the body, or selectively modifying the perfusion of a particular organ and rerouting blood from one region of the body to another.

A generalized increase in blood pressure requires centralized control—an action on the part of the medullary vasomotor center or by hormones that circulate throughout the system, such as angiotensin II or epinephrine, and affect blood vessels everywhere. Widespread vasoconstriction raises the overall blood pressure because the whole “container” (the blood vessels) squeezes on a fixed amount of blood. This can be important in supporting cerebral perfusion in situations such as hemorrhaging or dehydration, in which blood volume has significantly fallen. Conversely, generalized vasodilation lowers BP throughout the system.

The rerouting of blood flow and changes in the perfusion of individual organs can be achieved by either central or local control. For example, during periods of exercise, the sympathetic nervous system can selectively reduce blood flow to the kidneys and digestive tract yet increase perfusion of the skeletal muscles; and, as we saw earlier, metabolite accumulation in a tissue can stimulate local vasodilation and increase perfusion of that tissue without affecting circulation elsewhere in the body.

If a specific artery constricts, pressure downstream from the constriction drops and pressure upstream from it rises. If blood can travel by either of two routes and one route puts up more resistance than the other, most blood follows the path of least resistance. This mechanism enables the body to redirect blood from one organ to another.

For example, if you are dozing in an armchair after a big meal (fig. 20.14a), vasoconstriction shuts down blood flow to 90% or more of the capillaries in the muscles of your lower limbs (and muscles elsewhere). This raises the

BP above the limbs, where the aorta gives off a branch, the superior mesenteric artery, supplying the small intestine. High resistance in the circulation of the limbs and low resistance in the superior mesenteric artery route blood to the small intestine, where it is needed to absorb the nutrients you are digesting.

On the other hand, during vigorous exercise, the arteries in your lungs, coronary circulation, and muscles dilate. To increase the circulation in these routes, vasoconstriction must occur elsewhere, such as the kidneys and digestive tract (figs. 20.14b, 20.15). That reduces their

FIGURE 20.14 Redirection of Blood Flow in Response to Changing Metabolic Needs. (a) After a meal, the intestines receive priority and the skeletal muscles receive relatively little flow. (b) During exercise, the muscles receive higher priority. Although vasodilation and vasoconstriction are shown here in major arteries for illustration purposes, most control occurs at a microscopic level in the arterioles.

FIGURE 20.15 Differences in Systemic Blood Flow During Rest and Exercise.

perfusion for the time being, making more blood available to the organs important in sustaining exercise. Thus, local changes in peripheral resistance can shift blood flow from one organ system to another to meet the changing metabolic priorities of the body.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. For a healthy 15-year-old girl at rest, what would be typical readings for systolic pressure, diastolic pressure, pulse pressure, and mean arterial pressure?
8. Explain why arterial blood flow is pulsatile and venous flow is not.
9. What three variables affect peripheral resistance to blood flow? Which of these is most able to change from one minute to the next?
10. What are the three primary mechanisms for controlling vessel radius? Briefly explain each.
11. Explain how the baroreflex serves as an example of homeostasis and negative feedback.
12. Explain how the body can shift the flow of blood from one organ system to another.

20.3 Capillary Exchange

Objectives

When you have completed this section, you should be able to

- describe how materials get from the blood to the surrounding tissues;
- describe and calculate the forces that enable capillaries to give off and reabsorb fluid; and
- describe the causes and effects of edema.

Only 250 to 300 mL (5%) of the blood is in the capillaries at any given time. This is the most important blood in the body, however, for it is mainly across capillary walls that exchanges occur between the blood and surrounding tissues. **Capillary exchange** refers to this two-way movement of fluid.

Chemicals given off by the capillary blood to serve the perivascular tissues include oxygen; glucose, amino acids, lipids, and other organic nutrients; minerals; antibodies; and hormones. Chemicals taken up by the capillaries include carbon dioxide, ammonia, and other wastes, and many of the same substances as they give off: glucose and fatty acids released from storage in the liver and adipose tissue; calcium and other minerals released from bone; antibodies secreted by immune cells; and hormones secreted by the endocrine glands. Thus, many of these chemicals have a two-way traffic between the blood and

connective tissue, leaving the capillaries at one point and entering at another. Along with all these solutes, there is substantial movement of water in and out of the bloodstream across the capillary walls.

The mechanisms of capillary exchange are difficult to study quantitatively because it is hard to measure pressure and flow in such small vessels. For this reason, theories of capillary exchange remain in dispute. Few capillaries of the human body are accessible to direct, noninvasive observation, but those of the fingernail bed and eponychium (cuticle) at the base of the nails can be observed with a stereomicroscope and have been the basis for a number of studies. Their BP has been measured at 32 mm Hg at the arterial end and 15 mm Hg at the venous end, 1 mm away. Capillary BP drops rapidly because of the substantial friction the blood encounters in such narrow vessels. It takes 1 to 2 seconds for an RBC to pass through a nail bed capillary, traveling about 0.7 mm/s.

Chemicals pass through the capillary wall by three routes (fig. 20.16):

1. the endothelial cell cytoplasm;
2. intercellular clefts between the endothelial cells; and
3. filtration pores (fenestrations) of the fenestrated capillaries.

The mechanisms of movement through the capillary wall are *diffusion*, *transcytosis*, *filtration*, and *reabsorption*, which we will examine in that order.

Diffusion

The most important mechanism of exchange is diffusion. Glucose and oxygen, being more concentrated in the systemic blood than in the tissue fluid, diffuse out of the

FIGURE 20.16 Routes of Capillary Fluid Exchange. Materials move through the capillary wall through filtration pores (in fenestrated capillaries only), by transcytosis, by diffusion through the endothelial cells, and through intercellular clefts.

blood. Carbon dioxide and other wastes, being more concentrated in the tissue fluid, diffuse into the blood. (Oxygen and carbon dioxide diffuse in the opposite directions in the pulmonary circuit.) Such diffusion is only possible if the solute can either permeate the plasma membranes of the endothelial cells or find passages large enough to pass through—namely, the filtration pores and intercellular clefts. Such lipid-soluble substances as steroid hormones, O_2 , and CO_2 diffuse easily through the plasma membranes. Substances insoluble in lipids, such as glucose and electrolytes, must pass through membrane channels, filtration pores, or intercellular clefts. Large molecules such as proteins are usually held back.

Transcytosis

Transcytosis is a process in which endothelial cells pick up material on one side of the plasma membrane by pinocytosis or receptor-mediated endocytosis, transport the vesicles across the cell, and discharge the material on the other side by exocytosis (see fig. 3.23, p. 108). This probably accounts for only a small fraction of solute exchange across the capillary wall, but fatty acids, albumin, and some hormones such as insulin move across the

endothelium by this mechanism. Cytologists think that the filtration pores of fenestrated capillaries might be only a chain of pinocytotic vesicles that have temporarily fused to form a continuous channel through the cell, as the suggestive appearance of fig. 20.16 conveys.

Filtration and Reabsorption

The equilibrium between filtration and osmosis discussed in chapter 3 becomes particularly relevant when we consider capillary fluid exchange. Typically, fluid filters out of the arterial end of a capillary and osmotically reenters it at the venous end (fig. 20.17). This fluid delivers materials to the cells and removes their metabolic wastes. It may seem odd that a capillary could give off fluid at one point and reabsorb it at another. This comes about as the result of a shifting balance between hydrostatic and osmotic forces. **Hydrostatic pressure** is the physical force exerted by a liquid against a surface such as a capillary wall. Blood pressure is one example of hydrostatic pressure.

A typical capillary has a blood hydrostatic pressure of about 30 mm Hg at the arterial end. The hydrostatic pressure of the interstitial space has been difficult to measure

FIGURE 20.17 The Forces of Capillary Filtration and Reabsorption. Note the shift from net filtration at the arterial end (left) to net reabsorption at the venous end (right).

and remains a point of controversy, but a typical value accepted by many authorities is -3 mm Hg. The negative value indicates that this is a slight suction, which helps draw fluid out of the capillary. (This force will be represented hereafter as 3_{out} .) In this case, the positive hydrostatic pressure within the capillary and the negative interstitial pressure work in the same direction, creating a total outward force of about 33 mm Hg.

These forces are opposed by **colloid osmotic pressure (COP)**, the portion of the osmotic pressure due to protein. The blood has a COP of about 28 mm Hg, due mainly to albumin. Tissue fluid has less than one-third the protein concentration of blood plasma and has a COP of about 8 mm Hg. The difference between the COP of blood and tissue fluid is called **oncotic pressure**: $28_{\text{in}} - 8_{\text{out}} = 20_{\text{in}}$. Oncotic pressure tends to draw water into the capillary by osmosis, opposing hydrostatic pressure.

These opposing forces produce a **net filtration pressure (NFP)** of 13 mm Hg out, as follows:

Hydrostatic pressure

Blood pressure		30_{out}
Interstitial pressure	+	3_{out}
Net hydrostatic pressure		33_{out}

Colloid osmotic pressure

Blood COP		28_{in}
Tissue fluid COP	-	8_{out}
Oncotic pressure		20_{in}

Net filtration pressure

Net hydrostatic pressure		33_{out}
Oncotic pressure	-	20_{in}
Net filtration pressure		13_{out}

The NFP of 13 mm Hg causes about 0.5% of the blood plasma to leave the capillaries at the arterial end.

At the venous end, however, capillary blood pressure is lower—about 10 mm Hg. All the other pressures are essentially unchanged. Thus, we get:

Hydrostatic pressure

Blood pressure		10_{out}
Interstitial pressure	+	3_{out}
Net hydrostatic pressure		13_{out}

Net reabsorption pressure

Oncotic pressure		20_{in}
Net hydrostatic pressure	-	13_{out}
Net reabsorption pressure		7_{in}

The prevailing force is inward at the venous end because osmotic pressure overrides filtration pressure. The **net reabsorption pressure** of 7 mm Hg inward causes the capillary to reabsorb fluid at this end.

Now you can see why a capillary gives off fluid at one end and reabsorbs it at the other. The only pressure that changes significantly from the arterial end to the venous end is the capillary blood pressure, and this change is responsible for the shift from filtration to reabsorption. With a reabsorption pressure of 7 mm Hg and a net filtration pressure of 13 mm Hg, it might appear that far more fluid would leave the capillaries than reenter them. However, since capillaries branch along their length, there are more of them at the venous end than at the arterial end, which partially compensates for the difference between filtration and reabsorption pressures. They also typically have nearly twice the diameter at the venous end that they have at the arterial end, so there is more capillary surface area available to reabsorb fluid than to give it off. Consequently, capillaries reabsorb about 85% of the fluid they filter. The other 15% is absorbed and returned to the blood by way of the lymphatic system, as described in chapter 21.

Of course, water is not the only substance that crosses the capillary wall by filtration and reabsorption. Chemicals dissolved in the water are “dragged” along with it and pass through the capillary wall if they are not too large. This process, called **solvent drag**, will be important in our discussions of kidney and intestinal function in later chapters.

Variations in Capillary Filtration and Reabsorption

The figures used in the preceding discussion serve only as examples; circumstances differ from place to place in the body and from time to time in the same capillaries. Capillaries usually reabsorb most of the fluid they filter, but this is not always the case. The kidneys have capillary networks called *glomeruli* in which there is little or no reabsorption; they are entirely devoted to filtration. Alveolar capillaries of the lungs, by contrast, are almost entirely dedicated to absorption so fluid does not fill the air spaces.

Capillary activity also varies from moment to moment. In a resting tissue, most precapillary sphincters are constricted and the capillaries are collapsed. Capillary BP is very low (if there is any flow at all), and reabsorption predominates. When a tissue becomes metabolically active, its capillary flow increases. In active muscles, capillary pressure rises to the point that filtration overrides reabsorption along the entire length of the capillary. Fluid accumulates in the muscle and increases muscular bulk by as much as 25%. Capillary permeability is also subject to chemical influences. Traumatized tissue releases such chemicals as substance P, bradykinin, and histamine, which increase permeability and filtration.

Edema

Edema is the accumulation of excess fluid in a tissue. It often shows as swelling of the face, fingers, abdomen, or ankles, but also occurs in internal organs where its effects are hidden from view. Edema occurs when fluid filters into a tissue faster than it is reabsorbed. It has three fundamental causes:

1. **Increased capillary filtration.** Numerous conditions can increase the rate of capillary filtration and accumulation of fluid in the tissues. Kidney failure, for example, leads to water retention and hypertension, thus raising capillary blood pressure and filtration rate. Histamine dilates arterioles and raises capillary pressure and also makes the capillary wall more permeable. Capillaries generally become more permeable in old age as well, putting elderly people at increased risk for edema. Capillary blood pressure also rises in cases of poor venous return—the flow of blood from the capillaries back to the heart. As we will see in the next section, good venous return depends on muscular activity. Therefore, edema is a common problem among people confined to bed or a wheelchair. Failure of the right ventricle of the heart tends to cause pressure to back up in the systemic veins and capillaries, thus resulting in systemic edema. Failure of the left ventricle causes pressure to back up in the lungs, causing pulmonary edema.
2. **Reduced capillary reabsorption.** Capillary reabsorption depends on oncotic pressure, which is proportional to the concentration of blood albumin. Therefore, a deficiency of albumin (hypoproteinemia) produces edema by reducing the reabsorption of tissue fluid. Since albumin is produced by the liver, liver diseases such as cirrhosis tend to lead to hypoproteinemia and edema. Edema is commonly seen in regions of famine due to dietary protein deficiency (see kwashiorkor, p. 688). Hypoproteinemia and edema also commonly results from severe burns, owing to the loss of protein from body surfaces no longer covered with skin, and from kidney diseases that allow protein to escape in the urine.
3. **Obstructed lymphatic drainage.** The lymphatic system, described in detail in chapter 21, is a network of one-way vessels that collect fluid from the tissues and return it to the bloodstream. Obstruction of these vessels or the surgical removal of lymph nodes can interfere with fluid drainage and lead to the accumulation of tissue fluid distal to the obstruction (see elephantiasis, p. 818).

Edema has multiple pathological consequences. As the tissues become congested with fluid, oxygen delivery and waste removal are impaired and the tissues may begin to die. Pulmonary edema presents a threat of suffocation as fluid replaces air in the lungs, and cerebral edema can

produce headaches, nausea, and sometimes delirium, seizures, and coma. In severe edema, so much fluid may transfer from the blood vessels to the tissue spaces that blood volume and pressure drop low enough to cause circulatory shock (described in the next section).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

13. List the three mechanisms of capillary exchange and relate each one to the structure of capillary walls.
14. What forces favor capillary filtration? What forces favor reabsorption?
15. How can a capillary shift from a predominantly filtering role at one time to a predominantly reabsorbing role at another?
16. State the three fundamental causes of edema and explain why edema can be dangerous.

20.4 Venous Return and Circulatory Shock

Objectives

When you have completed this section, you should be able to

- explain how blood in the veins is returned to the heart;
- discuss the importance of physical activity in venous return;
- discuss several causes of circulatory shock; and
- name and describe the stages of shock.

Hieronymus Fabricius (1537–1619) discovered the valves of the veins and argued that they would allow blood to flow in only one direction, not back and forth as Galen had thought. One of his medical students was William Harvey, who performed simple experiments on the valves that you can easily reproduce. In figure 20.18, by Harvey, the experimenter has pressed on a vein at point H to block flow from the wrist toward the elbow. With another finger, he has milked the blood out of it up to point O, the first valve proximal to H. When he tries to force blood downward, it stops at that valve. It can go no farther, and it causes the vein to swell at that point. Blood can flow from right to left through that valve but not from left to right.

You can easily demonstrate the action of these valves in your own hand. Hold your hand still, below waist level, until veins stand up on the back of it. (Do not apply a tourniquet!) Press on a vein close to your knuckles, and while holding it down, use another finger to milk that

FIGURE 20.18 An Illustration from William Harvey's *De Motu Cordis* (1628). These experiments demonstrate the existence of one-way valves in veins of the arms. See text for explanation.

■ In the space between O and H, what (if anything) would happen if the experimenter lifted his finger from point O? What if he lifted his finger from point H? Why?

vein toward the wrist. It collapses as you force the blood out of it, and if you remove the second finger, it will not refill. The valves prevent blood from flowing back into it from above. When you remove the first finger, however, the vein fills from below.

Mechanisms of Venous Return

The flow of blood back to the heart, called **venous return**, is achieved by five mechanisms:

1. **The pressure gradient.** Pressure generated by the heart is the most important force in venous flow, even though it is substantially weaker in the veins than in the arteries. Pressure in the venules ranges from 12 to 18 mm Hg, and pressure at the point where the venae cavae enter the heart, called **central venous pressure**, averages 4.6 mm Hg. Thus, there is a venous pressure gradient (ΔP) of about 7 to 13 mm Hg favoring the flow of blood toward the heart. The pressure gradient and venous return increase when blood volume increases. Venous return also increases in the event of generalized, widespread vasoconstriction because this reduces the volume of the circulatory system and raises blood pressure and flow.
2. **Gravity.** When you are sitting or standing, blood from your head and neck returns to the heart simply by “flowing downhill” through the large veins above the heart. Thus, the large veins of the neck are normally collapsed or nearly so, and their venous pressure is close to zero. The dural sinuses of the brain, however, have more rigid walls and cannot collapse. Their pressure is as low as -10 mm Hg, creating a risk of *air embolism* if they are punctured (see Insight 20.3).
3. **The skeletal muscle pump.** In the limbs, the veins are surrounded and massaged by the muscles. Contracting muscles squeeze the blood out of the compressed part of a vein, and the valves ensure that this blood can go in only one direction—toward the heart (fig. 20.19).

INSIGHT 20.3 Clinical Application

Air Embolism

Injury to the dural sinuses or jugular veins presents less danger from loss of blood than from air sucked into the circulatory system. The presence of air in the bloodstream is called *air embolism*. This is an important concern to neurosurgeons, who sometimes operate with the patient in a sitting position. If a dural sinus is punctured, air can be sucked into the sinus and accumulate in the heart chambers, which blocks cardiac output and causes sudden death. Smaller air bubbles in the systemic circulation can cut off blood flow to the brain, lungs, myocardium, and other vital tissues.

FIGURE 20.19 The Skeletal Muscle Pump. (a) Muscle contraction squeezes the deep veins and forces blood through the next valve in the direction of the heart. Valves below the point of compression prevent backflow. (b) When the muscles relax, blood flows back downward under the pull of gravity but can flow only as far as the nearest valve.

4. **The thoracic (respiratory) pump.** This mechanism aids the flow of venous blood from the abdominal to the thoracic cavity. When you inhale, your thoracic cavity expands and its internal pressure drops, while downward movement of the diaphragm raises the pressure in your abdominal cavity. The *inferior vena cava (IVC)*, your largest vein, is a flexible tube passing through both of these cavities. If abdominal pressure on the IVC rises while thoracic pressure on it drops, then blood is squeezed upward toward the heart. It is not forced back into the lower limbs because the venous valves there prevent this. Because of the thoracic pump, central venous

pressure fluctuates from 2 mm Hg when you inhale to 6 mm Hg when you exhale, and blood flows faster when you inhale.

5. **Cardiac suction.** During ventricular systole, the tendinous cords pull the AV valve cusps downward, slightly expanding the atrial space. This creates a slight suction that draws blood into the atria from the venae cavae and pulmonary veins.

Venous Return and Physical Activity

Exercise increases venous return for many reasons. The heart beats faster and harder, increasing cardiac output and blood pressure. Blood vessels of the skeletal muscles, lungs, and coronary circulation dilate, increasing flow. The increase in respiratory rate and depth enhances the action of the thoracic pump. Muscle contractions increase venous return by means of the skeletal muscle pump. Increased venous return increases cardiac output, which is important in perfusion of the muscles just when they need it most.

Conversely, when a person is still, blood accumulates in the limbs because venous pressure is not high enough to override the weight of the blood and drive it upward. Such accumulation of blood is called **venous pooling**. To demonstrate this effect, hold one hand below your waist for about a minute and (just for comparison) hold the other hand over your head. Then, quickly bring your two hands together and compare the palms. The hand held over head usually appears pale because its blood has drained out of it; the hand held below the waist appears redder than normal because of venous pooling in its veins and capillaries. Venous pooling is troublesome to people who must stand for prolonged periods. If enough blood accumulates in the limbs, cardiac output may become so low that the brain is inadequately perfused and a person may experience dizziness or syncope. This can usually be prevented by periodically tensing the calf and other muscles to keep the skeletal muscle pump active. Military jet pilots often perform maneuvers that could cause the blood to pool in the abdomen and lower limbs, causing partial loss of vision or loss of consciousness. To prevent this, they wear pressure suits that inflate and tighten on the lower limbs during these maneuvers; in addition, they may tense their abdominal muscles to prevent venous pooling and blackout.

Think About It

Why is venous pooling not a problem when you are sleeping and the skeletal muscle pump is inactive?

Circulatory Shock

Circulatory shock (not to be confused with electrical or spinal shock) is any state in which cardiac output is insufficient to meet the body's metabolic needs. All forms of

circulatory shock fall into two categories: (1) **cardiogenic shock**, caused by inadequate pumping by the heart, usually as a result of myocardial infarction, and (2) **low venous return (LVR) shock**, in which cardiac output is low because too little blood is returning to the heart.

There are three principal forms of LVR shock:

1. **Hypovolemic shock**, the most common form, is produced by a loss of blood volume as a result of hemorrhage, trauma, bleeding ulcers, burns, or dehydration. Dehydration is a major cause of death from heat exposure. In hot weather, the body excretes as much as 1.5 L of sweat per hour. Water transfers from the bloodstream to replace tissue fluid lost in the sweat, and blood volume may drop too low to maintain adequate circulation.
2. **Obstructed venous return shock** occurs when any object, such as a growing tumor or aneurysm, compresses a vein and impedes its blood flow.
3. **Venous pooling (vascular) shock** occurs when the body has a normal total blood volume, but too much of it accumulates in the limbs. This can result from long periods of standing or sitting or from widespread vasodilation. **Neurogenic shock** is a form of venous pooling shock that results from a sudden loss of vasomotor tone, allowing the vessels to dilate. This can result from causes as severe as brainstem trauma or as slight as an emotional shock.

Elements of both venous pooling and hypovolemic shock are present in certain cases, such as septic shock and anaphylactic shock, which involve both vasodilation and a loss of fluid through abnormally permeable capillaries. **Septic shock** occurs when bacterial toxins trigger vasodilation and increased capillary permeability. **Anaphylactic shock**, discussed more fully in chapter 21, results from exposure to an antigen to which a person is allergic, such as bee venom. Antigen–antibody complexes trigger the release of histamine, which causes generalized vasodilation and increased capillary permeability.

Responses to Circulatory Shock

In **compensated shock**, several homeostatic mechanisms act to bring about spontaneous recovery. The hypotension resulting from low cardiac output triggers the baroreflex and the production of angiotensin II, both of which counteract shock by stimulating vasoconstriction. Furthermore, if a person faints and falls to a horizontal position, gravity restores blood flow to the brain. Even quicker recovery is achieved if the person's feet are elevated to promote drainage of blood from the legs.

If these mechanisms prove inadequate, **decompensated shock** ensues and several life-threatening positive feedback loops occur. Poor cardiac output results in myocardial ischemia and infarction, which further weakens the heart and reduces output. Slow circulation of the

blood can lead to disseminated intravascular coagulation (DIC) (see p. 714). As the vessels become congested with clotted blood, venous return grows even worse. Ischemia and acidosis of the brainstem depress the vasomotor and cardiac centers, causing loss of vasomotor tone, further vasodilation, and further drop in BP and cardiac output. Before long, damage to the cardiac and brain tissues may be too great to survive. About half of those who go into decompensated shock die from it.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

17. Explain how respiration aids venous return.
18. Explain how muscular activity and venous valves aid venous return.
19. Define circulatory shock. What are some of the causes of low venous return shock?

20.5 Special Circulatory Routes

Objectives

When you have completed this section, you should be able to

- explain how the brain maintains stable perfusion;
- discuss the causes and effects of strokes and transient ischemic attacks;
- explain the mechanisms that increase muscular perfusion during exercise; and
- contrast the blood pressure of the pulmonary circuit with that of the systemic circuit, and explain why the difference is important in pulmonary function.

Certain circulatory pathways have special physiological properties adapted to the functions of their organs. Two of these are described in other chapters: the coronary circulation in chapter 19 and fetal and placental circulation in chapter 29. Here we take a closer look at the circulation to the brain, skeletal muscles, and lungs.

Brain

Total blood flow to the brain fluctuates less than that of any other organ (about 700 mL/min at rest). Such constancy is important because even a few seconds of oxygen deprivation causes loss of consciousness, and 4 or 5 minutes of anoxia is time enough to cause irreversible damage. Although total cerebral perfusion is fairly stable, blood flow can be shifted from one part of the brain to another in a matter of seconds as different parts engage in motor, sensory, or cognitive functions.

The brain regulates its own blood flow in response to changes in BP and chemistry. The cerebral arteries dilate when the systemic BP drops and constrict when it rises, thus minimizing fluctuations in cerebral BP. Cerebral blood flow thus remains quite stable even when mean arterial pressure (MAP) fluctuates from 60 to 140 mm Hg. An MAP below 60 mm Hg produces syncope and an MAP above 160 mm Hg causes cerebral edema.

The main chemical stimulus for cerebral autoregulation is pH. Poor perfusion allows CO₂ to accumulate in the brain tissue. This lowers the pH of the tissue fluid and triggers local vasodilation, which improves perfusion. Extreme hypercapnia, however, depresses neural activity. The opposite condition, hypocapnia, raises the pH and stimulates vasoconstriction, thus reducing perfusion and giving CO₂ a chance to rise to a normal level. Hyperventilation (exhaling CO₂ faster than the body produces it) induces hypocapnia, which leads to cerebral vasoconstriction, ischemia, dizziness, and sometimes syncope.

Brief episodes of cerebral ischemia produce **transient ischemic attacks (TIAs)**, characterized by temporary dizziness, loss of vision or other senses, weakness, paralysis, headache, or aphasia. A TIA may result from spasms of diseased cerebral arteries. It lasts from just a moment to a few hours and is often an early warning of an impending stroke. People with TIAs should receive prompt medical attention to identify the cause using brain imaging and other diagnostic means. Immediate treatment should be initiated to prevent a stroke.

A **stroke**, or **cerebrovascular accident (CVA)**, is the sudden death (infarction) of brain tissue caused by ischemia. Cerebral ischemia can be produced by atherosclerosis, thrombosis, or a ruptured aneurysm. The effects of a CVA range from unnoticeable to fatal, depending on the extent of tissue damage and the function of the affected tissue. Blindness, paralysis, loss of sensation, and loss of speech are common. Recovery depends on the ability of neighboring neurons to take over the lost functions and on the extent of collateral circulation to regions surrounding the cerebral infarction.

Skeletal Muscles

In contrast to the brain, the skeletal muscles receive a highly variable blood flow depending on their state of exertion. At rest, the arterioles are constricted, most of the capillary beds are shut down, and total flow through the muscular system is about 1 L/min. During exercise, the arterioles dilate in response to epinephrine and norepinephrine from the adrenal medulla and sympathetic nerves. Precapillary sphincters, which lack innervation, dilate in response to muscle metabolites such as lactic acid, CO₂, and adenosine. Blood flow through the muscles can increase more than 20-fold during strenuous exercise, which requires that blood be diverted from other organs such as the digestive tract and kidneys to meet the needs of the working muscles.

Muscular contraction compresses the blood vessels and impedes flow. For this reason, isometric contraction causes fatigue more quickly than intermittent isotonic contraction. If you squeeze a rubber ball as hard as you can without relaxing your grip, you feel the muscles fatigue more quickly than if you intermittently squeeze and relax.

Lungs

After birth, the pulmonary circuit is the only route in which the arterial blood contains less oxygen than the venous blood. The pulmonary arteries have thin distensible walls with less elastic tissue than the systemic arteries. Thus, they have a BP of only 25/10. Capillary hydrostatic pressure is about 10 mm Hg in the pulmonary circuit as compared with an average of 17 mm Hg in systemic capillaries. This lower pressure has two implications for pulmonary circulation: (1) blood flows more slowly through the pulmonary capillaries, and therefore it has more time for gas exchange; and (2) oncotic pressure overrides hydrostatic pressure, so these capillaries are engaged almost entirely in absorption. This prevents fluid accumulation in the alveolar walls and lumens, which would compromise gas exchange. In a condition such as mitral valve stenosis, however, blood may back up in the pulmonary circuit, raising the capillary hydrostatic pressure and causing pulmonary edema, congestion, and hypoxemia.

Think About It

What abnormal skin coloration would result from pulmonary edema?

Another unique characteristic of the pulmonary arteries is their response to hypoxia. Systemic arteries dilate in response to local hypoxia and improve tissue perfusion. By contrast, pulmonary arteries constrict. Pulmonary hypoxia indicates that part of the lung is not being ventilated well, perhaps because of mucous congestion of the airway or a degenerative lung disease. Vasoconstriction in poorly ventilated regions of the lung redirects blood flow to better ventilated regions.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- In what conspicuous way does perfusion of the brain differ from perfusion of the skeletal muscles?
- How does a stroke differ from a transient ischemic attack? Which of these bears closer resemblance to a myocardial infarction?
- How does the low hydrostatic blood pressure in the pulmonary circuit affect the fluid dynamics of the capillaries there?
- Contrast the vasomotor response of the lungs with that of skeletal muscles to hypoxia.

20.6 Anatomy of the Pulmonary Circuit

Objective

When you have completed this section, you should be able to

- trace the route of blood through the pulmonary circuit.

The next three sections of this chapter center on the names and pathways of the principal arteries and veins. The pulmonary circuit is described here, and the systemic arteries and veins are described in the two sections that follow.

The pulmonary circuit (fig. 20.20) begins with the **pulmonary trunk**, a large vessel that ascends diagonally from the right ventricle and branches into the right and left **pulmonary arteries**. As it approaches the lung, the right pulmonary artery branches in two, and both branches enter the lung at a medial indentation called the *hilum* (see fig. 22.9, p. 872). The upper branch is the **superior lobar artery**, serving the superior lobe of the lung. The lower branch divides again within the lung to form the **middle lobar** and **inferior lobar arteries**, supplying the lower two lobes of that lung. The left pulmonary artery is much more variable. It gives off several superior lobar arteries to the superior lobe before entering the hilum, then enters the lung and gives off a variable number of inferior lobar arteries to the inferior lobe.

In both lungs, these arteries lead ultimately to small basketlike capillary beds that surround the pulmonary alveoli (air sacs). This is where the blood unloads CO₂ and picks up O₂. After leaving the alveolar capillaries, the pulmonary blood flows into venules and veins, ultimately leading to the main **pulmonary veins** that exit the lung at the hilum. The left atrium of the heart receives two pulmonary veins on each side (see fig. 19.5b, p. 724).

The purpose of the pulmonary circuit is primarily to exchange CO₂ for O₂. The lungs also receive a separate systemic blood supply by way of the *bronchial arteries* (see part I.1 in table 20.6).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Trace the flow of an RBC from right ventricle to left atrium and name the vessels along the way.
- The lungs have two separate arterial supplies. Explain their functions.

FIGURE 20.20 The Pulmonary Circulation. (a) Gross anatomy. (b) Microscopic anatomy of the blood vessels that supply the pulmonary alveoli. All alveoli are surrounded by a basketlike mesh of capillaries, but to show the alveoli, this drawing omits the capillaries from some of them.

20.7 Systemic Vessels of the Axial Region

Objectives

When you have completed this section, you should be able to

- identify the principal systemic arteries and veins of the axial region; and
- trace the flow of blood from the heart to any major organ of the axial region and back to the heart.

The systemic circuit (figs. 20.21 and 20.22) supplies oxygen and nutrients to all organs and removes their metabolic wastes. Part of it, the coronary circulation, was described in chapter 19. This section surveys the remaining arteries and veins of the axial region—the head, neck, and trunk. Tables 20.3 through 20.9 trace the arterial outflow and venous return, region by region. They outline only the most common circulatory pathways; there is

a great deal of anatomical variation in the circulatory system from one person to another.

The names of the blood vessels often describe their location by indicating the body region traversed (as in the *axillary artery* and *brachial veins*), an adjacent bone (as in *temporal artery* and *ulnar vein*), or the organ supplied or drained by the vessel (as in *hepatic artery* and *renal vein*). In many cases, an artery and adjacent vein have similar names (*femoral artery* and *femoral vein*, for example).

As you trace blood flow in these tables, it is important to refer frequently to the illustrations. Verbal descriptions alone are likely to seem obscure if you do not make full use of the accompanying explanatory illustrations. Throughout these tables and illustrations, the abbreviations *a.* and *aa.* mean *artery* and *arteries*, and *v.* and *vv.* mean *vein* and *veins*.

FIGURE 20.21 The Major Systemic Arteries. Different arteries are illustrated on the left than on the right for clarity, but nearly all of those shown occur on both sides.

FIGURE 20.22 The Major Systemic Veins. Different veins are illustrated on the left than on the right for clarity, but nearly all of those shown occur on both sides.

TABLE 20.3 The Aorta and Its Major Branches

All systemic arteries arise from the aorta, which has three principal regions (fig. 20.23):

1. The **ascending aorta** rises for about 5 cm above the left ventricle. Its only branches are the coronary arteries, which arise behind two cusps of the aortic valve. They are the origins of the coronary circulation described in chapter 19.
2. The **aortic arch** curves to the left like an inverted U superior to the heart. It gives off three major arteries in this order: the **brachiocephalic**⁹ (BRAY-kee-oh-seh-FAL-ic) **trunk**, **left common carotid artery** (cah-ROT-id) **artery**, and **left subclavian**¹⁰ (sub-CLAY-vee-un) **artery**. These are further traced in tables 20.4 and 20.10.
3. The **descending aorta** passes downward posterior to the heart, at first to the left of the vertebral column and then anterior to it, through the thoracic and abdominal cavities. It is called the *thoracic aorta* above the diaphragm and the *abdominal aorta* below it. It ends in the lower abdominal cavity by forking into the *right and left common iliac arteries* (see table 20.8, part IV).

**FIGURE 20.23** The Thoracic Aorta. (L. = left; R. = right)**TABLE 20.4** Arteries of the Head and Neck**I. Origins of the Head-Neck Arteries**

The head and neck receive blood from four pairs of arteries (fig. 20.24):

1. The **common carotid arteries**. Shortly after leaving the aortic arch, the brachiocephalic trunk divides into the *right subclavian artery* (further traced in table 20.6) and **right common carotid artery**. A little farther along the aortic arch, the **left common carotid artery** arises independently. The common carotids pass up the anterolateral region of the neck, alongside the trachea (see part II of this table).
2. The **vertebral arteries**. These arise from the right and left subclavian arteries and travel up the neck through the transverse foramina of vertebrae C1 through C6. They enter the cranial cavity through the foramen magnum (see part III of this table).
3. The **thyrocervical**¹¹ **trunks**. These tiny arteries arise from the subclavian arteries lateral to the vertebral arteries; they supply the thyroid gland and some scapular muscles.
4. The **costocervical**¹² **trunks**. These arteries arise from the subclavian arteries a little farther laterally. They supply the deep neck muscles and some of the intercostal muscles of the superior rib cage.

⁹*brachio* = arm + *cephal* = head

¹⁰*sub* = below + *clavi* = clavicle, collarbone

¹¹*thyro* = thyroid gland + *cerv* = neck

¹²*costo* = rib + *cerv* = neck

TABLE 20.4 Arteries of the Head and Neck (*cont.*)

FIGURE 20.24 Superficial (Extracranial) Arteries of the Head and Neck. The upper part of the schematic (b) depicts the cerebral circulation in figure 20.25.

• List the arteries, in order, that an erythrocyte must travel to get from the left ventricle to the skin of the left side of the forehead.

II. Continuation of the Common Carotid Arteries

The common carotid arteries have the most extensive distribution of all the head-neck arteries. Near the laryngeal prominence (“Adam’s apple”), each common carotid branches into an *external* and *internal carotid artery*.

1. The **external carotid artery** ascends the side of the head external to the cranium and supplies most external head structures except the orbits. It gives rise to the following arteries in ascending order:
 - a. the **superior thyroid artery** to the thyroid gland and larynx;
 - b. the **lingual artery** to the tongue;
 - c. the **facial artery** to the skin and muscles of the face;
 - d. the **occipital artery** to the posterior scalp;
 - e. the **maxillary artery** to the teeth, maxilla, oral cavity, and external ear; and
 - f. the **superficial temporal artery** to the chewing muscles, nasal cavity, lateral aspect of the face, most of the scalp, and the dura mater.
2. The **internal carotid artery** passes medial to the angle of the mandible and enters the cranial cavity through the carotid canal of the temporal bone. It supplies the orbits and about 80% of the cerebrum. Compressing the internal carotids near the mandible can therefore cause loss of consciousness. After entering the cranial cavity, each internal carotid gives rise to the following branches:
 - a. the **ophthalmic artery** to the orbit, nose, and forehead;
 - b. the **anterior cerebral artery** to the medial aspect of the cerebral hemisphere (see part IV of this table); and
 - c. the **middle cerebral artery**, which travels in the lateral sulcus of the cerebrum, supplies the insula, and then issues numerous branches to the lateral region of the frontal, temporal, and parietal lobes of the brain.

TABLE 20.4 Arteries of the Head and Neck (*cont.*)**III. Continuation of the Vertebral Arteries**

The vertebral arteries give rise to small branches that supply the spinal cord and its meninges, the cervical vertebrae, and deep muscles of the neck. They then enter the foramen magnum, supply the cranial bones and meninges, and converge to form a single **basilar artery** along the anterior aspect of the brainstem. Branches of the basilar artery supply the cerebellum, pons, and inner ear. At the pons-midbrain junction, the basilar artery divides and flows into the *cerebral arterial circle*, described next.

IV. The Cerebral Arterial Circle

Blood supply to the brain is so critical that it is furnished by several arterial anastomoses, especially an array of arteries called the **cerebral arterial circle (circle of Willis¹³)**, which surrounds the pituitary gland and optic chiasm (fig. 20.25). The circle receives blood from the internal carotid and basilar arteries. Most people lack one or more of its components; only 20% have a complete arterial circle. Knowledge of the distribution of the arteries arising from the circle is crucial for understanding the effects of blood clots, aneurysms, and strokes on brain function. The anterior and posterior cerebral arteries described here and the middle cerebral artery described in part II provide the most significant blood supplies to the cerebrum. Refer to chapter 14 for reminders of the relevant brain anatomy.

1. Two **posterior cerebral arteries** arise from the basilar artery and sweep posteriorly to the rear of the brain, serving the inferior and medial regions of the temporal and occipital lobes as well as the midbrain and thalamus.
2. Two **anterior cerebral arteries** arise from the internal carotids, travel anteriorly, and then arch posteriorly over the corpus callosum as far as the posterior limit of the parietal lobe. They give off extensive branches to the frontal and parietal lobes.
3. The **single anterior communicating artery** is a short anastomosis between the right and left anterior cerebral arteries.
4. The two **posterior communicating arteries** are small anastomoses between the posterior cerebral and internal carotid arteries.

FIGURE 20.25 The Cerebral Blood Supply. (a) Inferior view of the brain showing the blood supply to the brainstem, cerebellum, and cerebral arterial circle. (b) Medial section of the brain showing the more distal branches of the anterior and posterior cerebral arteries. Branches of the middle cerebral artery are distributed over the lateral surface of the cerebrum (not illustrated).

¹³Thomas Willis (1621–75), English anatomist

TABLE 20.5 Veins of the Head and Neck

The head and neck are drained mainly by three pairs of veins—the *internal jugular*, *external jugular*, and *vertebral veins*. We will trace these from their origins to the *subclavian veins*.

I. Dural Venous Sinuses

After blood circulates through the brain, it collects in large thin-walled veins called **dural venous sinuses**—blood-filled spaces between the layers of the dura mater (fig. 20.26a, b). A reminder of the structure of the dura mater will be helpful in understanding these sinuses. This tough membrane between the brain and cranial bone has a periosteal layer against the bone and a meningeal layer against the brain. In a few places, a space exists between these layers to accommodate a blood-collecting sinus. Between the two cerebral hemispheres is a vertical, sickle-shaped wall of dura called the *falx cerebri*, which contains two of the sinuses. There are about 13 dural venous sinuses in all; we survey only the few most prominent ones here.

1. The **superior sagittal sinus** is contained in the superior margin of the falx cerebri and overlies the longitudinal fissure of the brain (fig. 20.26a; see also figs. 14.5 and 14.7, pp. 520 and 523). It begins anteriorly near the crista galli of the skull and extends posteriorly to the very rear of the head, ending at the level of the posterior occipital protuberance of the skull. Here it bends, usually to the right, and drains into a *transverse sinus*.
2. The **inferior sagittal sinus** is contained in the inferior margin of the falx cerebri and arches over the corpus callosum, deep in the longitudinal fissure. Posteriorly, it joins the *great cerebral vein*, and their union forms the **straight sinus**, which continues to the rear of the head (see fig. 14.7). There, the superior sagittal and straight sinuses meet in a space called the **confluence of the sinuses**.
3. Right and left **transverse sinuses** lead away from the confluence and encircle the inside of the occipital bone, leading toward the ears (fig. 20.26b); their path is marked by grooves on the inner surface of the occipital bone (see fig. 8.5b, p. 247). The right transverse sinus receives blood mainly from the superior sagittal sinus, and the left one drains mainly the straight sinus. Laterally, each transverse sinus makes an S-shaped bend, the **sigmoid sinus**, then exits the cranium through the jugular foramen. From here, the blood flows down the internal jugular vein (see part II.1 of this table).
4. The **cavernous sinuses** are honeycombs of blood-filled spaces on each side of the body of the sphenoid bone (fig. 20.26b). They receive blood from the *superior ophthalmic vein* of the orbit and the *superficial middle cerebral vein* of the brain, among other sources. They drain through several outlets including the transverse sinus, internal jugular vein, and facial vein. They are clinically important because infections can pass from the face and other superficial sites into the cranial cavity by this route. Also, inflammation of a cavernous sinus can injure important structures that pass through it, including the internal carotid artery and cranial nerves III to VI.

II. Major Veins of the Neck

Blood flows down the neck mainly through three veins on each side, all of which empty into the subclavian vein (fig. 20.26c).

1. The **internal jugular¹⁴ (JUG-you-lur) vein** courses down the neck deep to the sternocleidomastoid muscle. It receives most of the blood from the brain; picks up blood from the **facial vein**, **superficial temporal vein**, and **superior thyroid vein** along the way; passes behind the clavicle; and joins the subclavian vein (which is further traced in table 20.7).
2. The **external jugular vein** courses down the side of the neck superficial to the sternocleidomastoid muscle and empties into the subclavian vein. It drains tributaries from the parotid gland, facial muscles, scalp, and other superficial structures. Some of this blood also follows venous anastomoses to the internal jugular vein.
3. The **vertebral vein** travels with the vertebral artery in the transverse foramina of the cervical vertebrae. Although the companion artery leads to the brain, the vertebral vein does not come from there. It drains the cervical vertebrae, spinal cord, and some of the small deep muscles of the neck, and empties into the subclavian vein.

Table 20.7 traces this blood flow the rest of the way to the heart.

¹⁴jugul = neck, throat

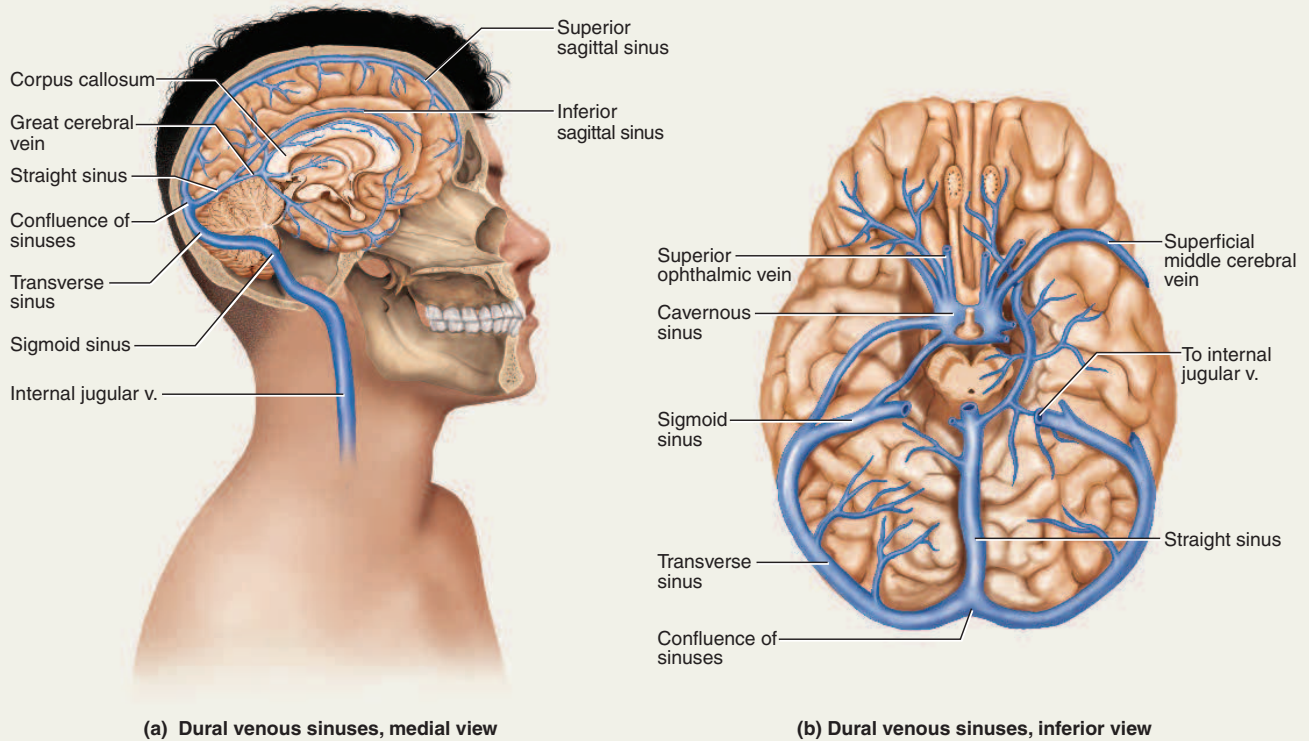

TABLE 20.5 Veins of the Head and Neck (*cont.*)

FIGURE 20.26 Veins of the Head and Neck. (a) Dural venous sinuses seen in a median section of the cerebrum. (b) Dural venous sinuses seen in an inferior view of the cerebrum. (c) Superficial (extracranial) veins of the head and neck.

TABLE 20.6 Arteries of the Thorax

The thorax is supplied by several arteries arising directly from the aorta (parts I and II of this table) and from the subclavian and axillary arteries (part III). The thoracic aorta begins distal to the aortic arch and ends at the **aortic hiatus** (hy-AY-tus), a passage through the diaphragm. Along the way, it sends off numerous small branches to the thoracic viscera and the body wall (fig. 20.27).

I. Visceral Branches of the Thoracic Aorta

These supply the viscera of the thoracic cavity:

1. **Bronchial arteries.** Although variable in number and arrangement, there are usually two of these on the left and one on the right. The right bronchial artery usually arises from one of the left bronchial arteries or from a *posterior intercostal artery* (see part II.1). The bronchial arteries supply the bronchi, bronchioles, and larger blood vessels of the lungs, the visceral pleura, the pericardium, and the esophagus.
2. **Esophageal arteries.** Four or five unpaired esophageal arteries arise from the anterior surface of the aorta and supply the esophagus.
3. **Mediastinal arteries.** Many small mediastinal arteries (not illustrated) supply structures of the posterior mediastinum.

II. Parietal Branches of the Thoracic Aorta

The following branches supply chiefly the muscles, bones, and skin of the chest wall; only the first are illustrated:

1. **Posterior intercostal arteries.** Nine pairs of these arise from the posterior surface of the aorta and course around the posterior side of the rib cage between ribs 3 through 12, then anastomose with the *anterior intercostal arteries* (see part III.1 in this table). They supply the intercostal, pectoralis, serratus anterior, and some abdominal muscles, as well as the vertebrae, spinal cord, meninges, breasts, skin, and subcutaneous tissue. They are enlarged in lactating women.
2. **Subcostal arteries.** A pair of these arise from the aorta inferior to the twelfth rib. They supply the posterior intercostal tissues, vertebrae, spinal cord, and deep muscles of the back.
3. **Superior phrenic¹⁵ (FREN-ic) arteries.** These arteries, variable in number, arise at the aortic hiatus and supply the superior and posterior regions of the diaphragm.

¹⁵phren = diaphragm

TABLE 20.6 Arteries of the Thorax (*cont.*)**III. Branches of the Subclavian and Axillary Arteries**

The thoracic wall is also supplied by the following arteries, which arise in the shoulder region—the first one from the subclavian artery and the other three from its continuation, the axillary artery:

- The **internal thoracic (mammary) artery** supplies the breast and anterior thoracic wall and issues the following branches:
 - The **pericardiophrenic artery** supplies the pericardium and diaphragm.
 - The **anterior intercostal arteries** arise from the thoracic artery as it descends alongside the sternum. They travel between the ribs, supply the ribs and intercostal muscles, and anastomose with the posterior intercostal arteries. Each of these sends one branch along the lower margin of the rib above and another branch along the upper margin of the rib below.
- The **thoracoacromial¹⁶** (THOR-uh-co-uh-CRO-me-ul) **trunk** provides branches to the superior shoulder and pectoral regions.
- The **lateral thoracic artery** supplies the pectoral, serratus anterior, and subscapularis muscles. It also issues branches to the breast and is larger in females than in males.
- The **subscapular artery** is the largest branch of the axillary artery. It supplies the scapula and the latissimus dorsi, serratus anterior, teres major, deltoid, triceps brachii, and intercostal muscles.

**(a) Major arteries****(b) Blood-flow schematic****FIGURE 20.27** Arteries of the Thorax.¹⁶thoraco = chest + acr = tip + om = shoulder

TABLE 20.7 Veins of the Thorax**I. Tributaries of the Superior Vena Cava**

The most prominent veins of the upper thorax are as follows. They carry blood from the shoulder region to the heart (fig. 20.28).

1. The **subclavian vein** drains the upper limb (see table 20.11). It begins at the lateral margin of the first rib and travels posterior to the clavicle. It receives the external jugular and vertebral veins, then ends (changes name) where it receives the internal jugular vein.
2. The **brachiocephalic vein** is formed by union of the subclavian and internal jugular veins. The right brachiocephalic is very short, about 2.5 cm, and the left is about 6 cm long. They receive tributaries from the vertebrae, thyroid gland, and upper thoracic wall and breast, then converge to form the next vein.
3. The **superior vena cava** is formed by the union of the right and left brachiocephalic veins. It travels inferiorly for about 7 cm and empties into the right atrium of the heart. Its main tributary is the *azygos vein*. It drains all structures superior to the diaphragm except the pulmonary circuit and coronary circulation. It also receives drainage from the abdominal cavity by way of the azygos system, described next.

II. The Azygos System

The principal venous drainage of the thoracic organs is by way of the *azygos* (AZ-ih-goss) *system* (fig. 20.28). The most prominent vein of this system is the **azygos¹⁷ vein**, which ascends the right side of the posterior thoracic wall and is named for the lack of a mate on the left. It receives the following tributaries, then empties into the superior vena cava at the level of vertebra T4.

1. The right **ascending lumbar vein** drains the right abdominal wall, then penetrates the diaphragm and enters the thoracic cavity. The azygos vein begins where the ascending lumbar vein meets the right **subcostal vein** beneath rib 12.
2. The right **posterior intercostal veins** drain the intercostal spaces. The first (superior) one empties into the right brachiocephalic vein; intercostals 2 and 3 join to form a *right superior intercostal vein* before emptying into the azygos; and intercostals 4 through 11 each enter the azygos vein separately.
3. The right **esophageal, mediastinal, pericardial, and bronchial veins** (not illustrated) drain their respective organs into the azygos.
4. The **hemiazzygos¹⁸ vein** ascends the posterior thoracic wall on the left. It begins where the left ascending lumbar vein, having just penetrated the diaphragm, joins the subcostal vein below rib 12. The hemiazzygos then receives the lower three posterior intercostal veins, esophageal veins, and mediastinal veins. At the level of vertebra T9, it crosses to the right and empties into the azygos.
5. The **accessory hemiazzygos vein** descends the posterior thoracic wall on the left. It receives drainage from posterior intercostal veins 4 through 8 and sometimes the left bronchial veins. It crosses to the right at the level of vertebra T8 and empties into the azygos vein.

The left posterior intercostal veins 1 to 3 are the only ones on this side that do not ultimately drain into the azygos vein. They unite to form the *left superior intercostal vein*, which empties into the left brachiocephalic vein.

¹⁷unpaired; from *a* = without + *zygo* = union, mate

¹⁸*hemi* = half

TABLE 20.7 Veins of the Thorax (*cont.*)

(a)

(b)

FIGURE 20.28 Venous Drainage of the Posterior Wall of the Thorax and Abdomen. (a) The azygos system of the thoracic wall. This system provides venous drainage from the wall and viscera of the thorax, but the visceral tributaries are not illustrated. (b) Blood-flow schematic of the thoracic and abdominal drainage. The components above the diaphragm constitute the azygos system. There is a great deal of individual variation in this anatomy.

TABLE 20.8 Arteries of the Abdomen and Pelvic Region

After passing through the aortic hiatus, the aorta descends through the abdominal cavity and ends at the level of vertebra L4, where it branches into right and left *common iliac arteries*. The abdominal aorta is retroperitoneal.

I. Major Branches of the Abdominal Aorta

The abdominal aorta gives off arteries in the order listed here (fig. 20.29). Those indicated in the plural are paired right and left, and those indicated in the singular are solitary median arteries.

1. The **inferior phrenic arteries** supply the inferior surface of the diaphragm. They may arise from the aorta, celiac trunk, or renal artery. Each issues two or three small **superior suprarenal arteries** to the ipsilateral adrenal (suprarenal) gland.
2. The **celiac**¹⁹ (SEE-lee-ac) **trunk** supplies the upper abdominal viscera (see part II of this table).
3. The **superior mesenteric artery** supplies the intestines (see part III).
4. The **middle suprarenal arteries** arise laterally from the aorta, usually at the same level as the superior mesenteric artery; they supply the adrenal glands.
5. The **renal arteries** supply the kidneys and issue a small **inferior suprarenal artery** to each adrenal gland.
6. The gonadal arteries (**ovarian arteries** in the female and **testicular arteries** in the male) are long, slender arteries that arise from the midabdominal aorta and descend along the posterior body wall to the female pelvic cavity or male scrotum. The gonads begin their embryonic development near the kidneys, and the gonadal arteries are then quite short. As the gonads descend to the pelvic cavity, these arteries grow and acquire their peculiar length and course.
7. The **inferior mesenteric artery** supplies the distal end of the large intestine (see part III).
8. The **lumbar arteries** arise from the lower aorta in four pairs. They supply the posterior abdominal wall (muscles, joints, and skin) and the spinal cord and other tissues in the vertebral canal.
9. The **median sacral artery**, a tiny medial artery at the inferior end of the aorta, supplies the sacrum and coccyx.
10. The **common iliac arteries** arise as the aorta forks at its inferior end. They are further traced in part IV of this table.

FIGURE 20.29 The Abdominal Aorta and Its Major Branches.

II. Branches of the Celiac Trunk

The celiac circulation to the upper abdominal viscera is perhaps the most complex route off the abdominal aorta. Because it has numerous anastomoses, the bloodstream does not follow a simple linear path but divides and rejoins itself at several points (fig. 20.30). As you study the following description, locate these branches in the figure and identify the points of anastomosis.

The short, stubby celiac trunk, barely more than 1 cm long, is a median branch of the aorta just below the diaphragm. It immediately gives rise to three branches—the *common hepatic*, *left gastric*, and *splenic arteries*.

1. The **common hepatic artery** passes to the right and issues two main branches—the gastroduodenal artery and the hepatic artery proper.
 - a. The **gastroduodenal artery** gives off the **right gastro-omental (gastroepiploic)²⁰ artery** to the stomach. It then continues as the **superior pancreaticoduodenal (PAN-cree-AT-ih-co-dew-ODD-eh-nul) artery**, which splits into two branches that pass around the anterior and posterior sides of the head of the pancreas. These anastomose with the two branches of the *inferior pancreaticoduodenal artery*, discussed in part III.1.
 - b. The **hepatic artery proper** ascends toward the liver. It gives off the **right gastric artery**, then branches into **right and left hepatic arteries**. The right hepatic artery issues a **cyctic artery** to the gallbladder, then the two hepatic arteries enter the liver from below.
2. The **left gastric artery** supplies the stomach and lower esophagus, arcs around the *lesser curvature* (superomedial margin) of the stomach, and anastomoses with the right gastric artery (fig. 20.30b). Thus, the right and left gastric arteries approach from opposite directions and supply this margin of the stomach. The left gastric also has branches to the lower esophagus, and the right gastric also supplies the duodenum.
3. The **splenic artery** supplies blood to the spleen, but gives off the following branches on the way there:
 - a. Several small **pancreatic arteries** supply the pancreas.
 - b. The **left gastro-omental (gastroepiploic) artery** arcs around the *greater curvature* (inferolateral margin) of the stomach and anastomoses with the right gastro-omental artery. These two arteries stand off about 1 cm from the stomach itself and travel through the superior margin of the *greater omentum*, a fatty membrane suspended from the greater curvature (see figs. A.13, p. 41, and 25.3, p. 969). They furnish blood to both the stomach and omentum.
 - c. The **short gastric arteries** supply the upper portion (fundus) of the stomach.

¹⁹*celi* = belly, abdomen

²⁰*gastro* = stomach + *epi* = upon, above + *ploic* = pertaining to the greater omentum

TABLE 20.8 Arteries of the Abdomen and Pelvic Region (*cont.*)

TABLE 20.8 Arteries of the Abdomen and Pelvic Region (*cont.*)

III. Mesenteric Circulation

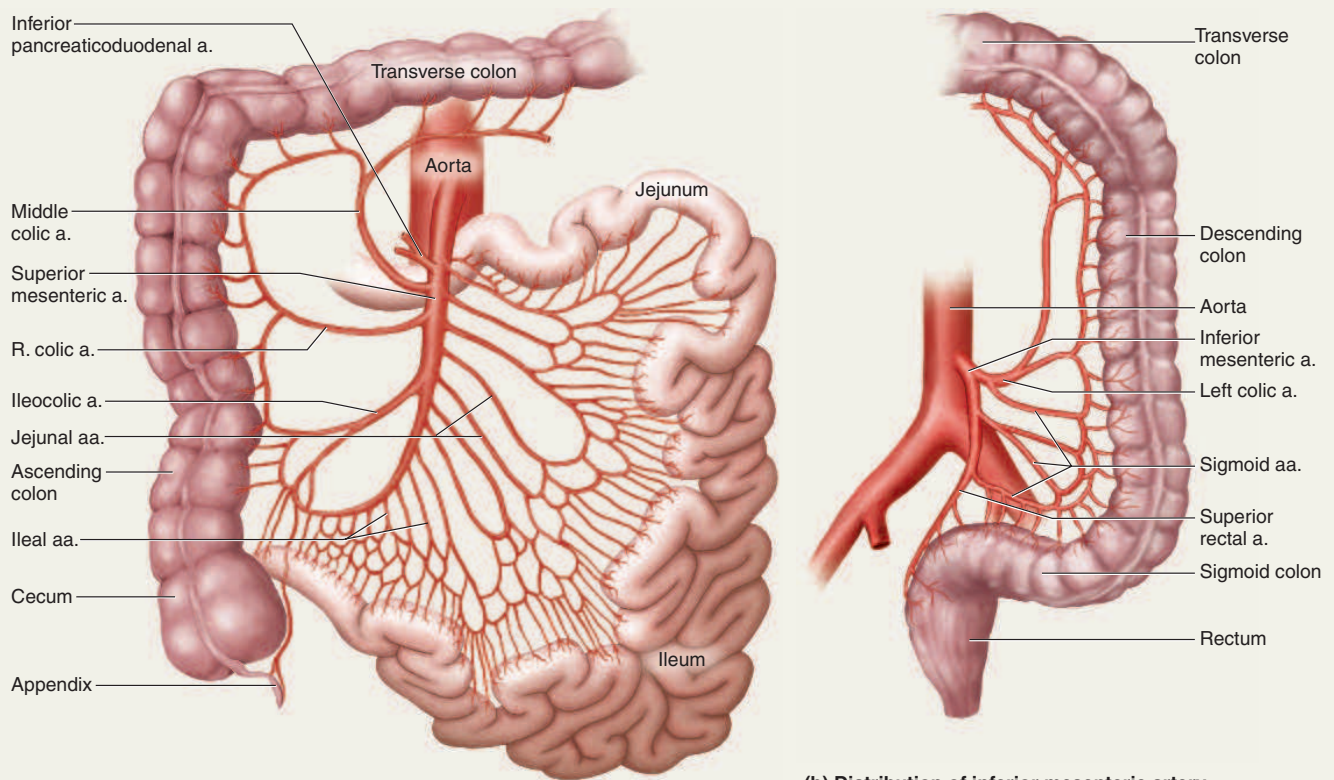

The mesentery is a translucent sheet that suspends the intestines and other abdominal viscera from the posterior body wall (see figs. A.10, p. 37, and 25.3, p. 969). It contains numerous arteries, veins, and lymphatic vessels that supply and drain the intestines. The arterial supply arises from the *superior* and *inferior mesenteric arteries*; numerous anastomoses between these ensure adequate collateral circulation to the intestines even if one route is temporarily obstructed.

The **superior mesenteric artery** (fig. 20.31a) is the most significant intestinal blood supply, serving nearly all of the small intestine and the proximal half of the large intestine. It arises medially from the upper abdominal aorta and gives off the following branches:

1. The **inferior pancreaticoduodenal artery**, already mentioned, branches to pass around the anterior and superior sides of the pancreas and anastomose with the two branches of the superior pancreaticoduodenal artery.
2. Twelve to 15 **jejunal and ileal arteries** form a fanlike array that supplies nearly all of the small intestine (portions called the jejunum and ileum).
3. The **ileocolic (ILL-ee-oh-CO-lic) artery** supplies the ileum, appendix, and parts of the large intestine (cecum and ascending colon).
4. The **right colic artery** also supplies the ascending colon.
5. The **middle colic artery** supplies most of the transverse colon.

The **inferior mesenteric artery** arises from the lower abdominal aorta and serves the distal part of the large intestine (fig. 20.31b):

1. The **left colic artery** supplies the transverse and descending colon.
2. The **sigmoid arteries** supply the descending and sigmoid colon.
3. The **superior rectal artery** supplies the rectum.

(a) Distribution of superior mesenteric artery

(b) Distribution of inferior mesenteric artery

FIGURE 20.31 The Mesenteric Arteries.

TABLE 20.8 Arteries of the Abdomen and Pelvic Region (*cont.*)**IV. Arteries of the Pelvic Region**

The two common iliac arteries arise by branching of the aorta, descend for another 5 cm, and then, at the level of the sacroiliac joint, each divides into an external and internal iliac artery. The external iliac supplies mainly the lower limb (see table 20.12). The **internal iliac artery** supplies mainly the pelvic wall and viscera. Its branches are shown only in schematic form in figure 20.37.

Shortly after its origin, the internal iliac divides into anterior and posterior trunks. The anterior trunk produces the following branches:

1. The **superior vesical**²¹ **artery** supplies the urinary bladder and distal end of the ureter. It arises indirectly from the anterior trunk by way of a short *umbilical artery*, a remnant of the artery that supplies the fetal umbilical cord. The rest of the umbilical artery becomes a closed fibrous cord after birth.
2. In men, the **inferior vesical artery** supplies the bladder, ureter, prostate gland, and seminal vesicle. In women, the corresponding vessel is the **vaginal artery**, which supplies the vagina and part of the bladder and rectum.
3. The **middle rectal artery** supplies the rectum.
4. The **obturator artery** exits the pelvic cavity through the obturator foramen and supplies the adductor muscles of the medial thigh.
5. The **internal pudenda**²² (*pyu-DEN-dul*) **artery** serves the perineum and erectile tissues of the penis and clitoris; it supplies the blood for vascular engorgement during sexual arousal.
6. In women, the **uterine artery** is the main blood supply to the uterus and supplies some blood to the vagina. It enlarges substantially in pregnancy. It passes up the uterine margin, then turns laterally at the uterine tube and anastomoses with the *ovarian artery*, thus supplying blood to the ovary as well (see part I.6 of table 20.8, and fig. 28.7, p. 1083).
7. The **inferior gluteal artery** supplies the gluteal muscles and hip joint.

The posterior trunk produces the following branches:

1. The **iliolumbar artery** supplies the lumbar body wall and pelvic bones.
2. The **lateral sacral arteries** lead to tissues of the sacral canal, skin, and muscles posterior to the sacrum. There are usually two of these, superior and inferior.
3. The **superior gluteal artery** supplies the skin and muscles of the gluteal region and the muscle and bone tissues of the pelvic wall.

²¹*vesic* = bladder

²²*pudend* = literally “shameful parts”; the external genitals

TABLE 20.9 Veins of the Abdomen and Pelvic Region

I. Tributaries of the Inferior Vena Cava

The **inferior vena cava (IVC)** is the body's largest blood vessel, having a diameter of about 3.5 cm. It forms by the union of the right and left common iliac veins at the level of vertebra L5 and drains many of the abdominal viscera as it ascends the posterior body wall. It is retroperitoneal and lies immediately to the right of the aorta. The IVC picks up blood from numerous tributaries in the following ascending order (fig. 20.32):

1. The **internal iliac veins** drain the gluteal muscles; the medial aspect of the thigh, the urinary bladder, rectum, prostate, and ductus deferens of the male; and the uterus and vagina of the female. They unite with the **external iliac veins**, which drain the lower limb and are described in table 20.13. Their union forms the **common iliac veins**, which then converge to form the IVC.
2. Four pairs of **lumbar veins** empty into the IVC, as well as into the ascending lumbar veins described in part II.
3. The gonadal veins (**ovarian veins** in the female and **testicular veins** in the male) drain the gonads. Like the gonadal arteries, and for the same reason (table 20.8, part I.6), these are long slender vessels that end far from their origins. The left gonadal vein empties into the left renal vein, whereas the right gonadal vein empties directly into the IVC.
4. The **renal veins** drain the kidneys into the IVC. The left renal vein also receives blood from the left gonadal and left suprarenal veins. It is up to three times as long as the right renal vein, since the IVC lies to the right of the median plane of the body.
5. The **suprarenal veins** drain the adrenal (suprarenal) glands. The right suprarenal empties directly into the IVC, and the left suprarenal empties into the left renal vein.
6. The **inferior phrenic veins** drain the inferior aspect of the diaphragm.
7. The **hepatic veins** drain the liver, extending a short distance from its superior surface to the IVC.

After receiving these inputs, the IVC penetrates the diaphragm and enters the right atrium of the heart from below. It does not receive any thoracic drainage.

FIGURE 20.32 The Inferior Vena Cava and Its Tributaries. Compare the blood-flow schematic in figure 20.28b.

• Why do the veins that drain the ovaries and testes terminate so far away from the gonads?

TABLE 20.9 Veins of the Abdomen and Pelvic Region (*cont.*)**II. Veins of the Abdominal Wall**

A pair of **ascending lumbar veins** receives blood from the common iliac veins below and from the aforementioned lumbar veins of the posterior body wall (see fig. 20.28b). The ascending lumbar veins give off anastomoses with the inferior vena cava beside them as they ascend to the diaphragm. The left ascending lumbar vein passes through the diaphragm via the aortic hiatus and continues as the hemiazygos vein above. The right ascending lumbar vein passes through the diaphragm to the right of the vertebral column and continues as the azygos vein. The further paths of the azygos and hemiazygos veins are described in table 20.7.

III. The Hepatic Portal System

The **hepatic portal system** receives all of the blood draining from the abdominal digestive tract, as well as from the pancreas, gallbladder, and spleen (fig. 20.33). It is called a portal system because it connects capillaries of the intestines and other digestive organs to modified capillaries (*hepatic sinusoids*) of the liver; thus, the blood passes through two capillary beds in series before it returns to the heart. Intestinal blood is richly laden with nutrients for a few hours following a meal. The hepatic portal system gives the liver first claim to these nutrients before the blood is distributed to the rest of the body. It also allows the blood to be cleansed of bacteria and toxins picked up from the intestines, an important function of the liver. Its principal veins are as follows:

1. The **inferior mesenteric vein** receives blood from the rectum and distal part of the colon. It converges in a fanlike array in the mesentery and empties into the splenic vein.
2. The **superior mesenteric vein** receives blood from the entire small intestine, ascending colon, transverse colon, and stomach. It, too, exhibits a fanlike arrangement in the mesentery and then joins the splenic vein to form the hepatic portal vein.
3. The **splenic vein** drains the spleen and travels across the abdominal cavity toward the liver. Along the way, it picks up **pancreatic veins** from the pancreas, then the inferior mesenteric vein, then ends where it meets the superior mesenteric vein.
4. The **hepatic portal vein** is the continuation beyond the convergence of the splenic and superior mesenteric veins. It travels about 8 cm upward and to the right, receives the **cystic vein** from the gallbladder, then enters the inferior surface of the liver. In the liver, it ultimately leads to the innumerable microscopic hepatic sinusoids. Blood from the sinusoids empties into the hepatic veins described earlier, and they empty into the IVC. Circulation within the liver is described in more detail in chapter 25 (p. 987).
5. The left and right **gastric veins** form an arch along the lesser curvature of the stomach and empty into the hepatic portal vein.

FIGURE 20.33 The Hepatic Portal System and Its Tributaries.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

26. Concisely contrast the destinations of the external and internal carotid arteries.
27. Briefly state the organs or parts of organs that are supplied with blood by (a) the cerebral arterial circle, (b) the celiac trunk, (c) the superior mesenteric artery, and (d) the internal iliac artery.
28. If you were dissecting a cadaver, where would you look for the internal and external jugular veins? What muscle would help you distinguish one from the other?
29. Trace a blood cell from the left lumbar body wall to the superior vena cava, naming the vessels through which it would travel.

The principal vessels of the appendicular region are detailed in tables 20.10 through 20.13. Although the appendicular arteries are usually deep and well protected, the veins occur in both deep and superficial groups; you may be able to see several of the superficial ones in your forearms and hands. Deep veins run parallel to the arteries and often have similar names (*femoral artery* and *femoral vein*, for example). In several cases, the deep veins occur in pairs flanking the corresponding artery (such as the two *radial veins* traveling alongside the *radial artery*).

These blood vessels will be described in an order corresponding to the direction of blood flow. Thus, we will begin with the arteries in the shoulder and pelvic regions and progress to the hands and feet, whereas we will trace the veins beginning in the hands and feet and progressing toward the heart.

Venous pathways have more anastomoses than arterial pathways, so the route of flow is often not as clear. If all the anastomoses were illustrated, many of these venous pathways would look more like confusing networks than a clear route back to the heart. Therefore, most anastomoses—especially the highly variable and unnamed ones—are omitted from the figures to allow you to focus on the more general course of blood flow. The blood-flow schematics in several figures will also help to clarify these routes.

20.8 Systemic Vessels of the Appendicular Region

Objectives

When you have completed this section, you should be able to

- identify the principal systemic arteries and veins of the limbs; and
- trace the flow of blood from the heart to any region of the upper or lower limb and back to the heart.

TABLE 20.10 Arteries of the Upper Limb

The upper limb is supplied by a prominent artery that changes name along its course from *subclavian* to *axillary* to *brachial*, then issues branches to the arm, forearm, and hand (fig. 20.34).

I. The Shoulder and Arm (Brachium)

1. The brachiocephalic trunk arises from the aortic arch and branches into the right common carotid artery and **left subclavian artery**; the **right subclavian artery** arises directly from the aortic arch. Each subclavian arches over the respective lung, rising as high as the base of the neck slightly superior to the clavicle. It then passes posterior to the clavicle, downward over the first rib, and ends in name only at the rib's lateral margin. In the shoulder, it gives off several small branches to the thoracic wall and viscera, described in table 20.6.
2. As the artery continues past the first rib, it is named the **axillary artery**. It continues through the axillary region, gives off small thoracic branches (see table 20.6), and ends, again in name only, at the neck of the humerus. Here, it gives off a pair of **circumflex humeral arteries**, which encircle the humerus, anastomose with each other laterally, and supply blood to the shoulder joint and deltoid muscle. Beyond this loop, the vessel is called the brachial artery.
3. The **brachial** (BRAY-kee-ul) **artery** continues down the medial and anterior sides of the humerus and ends just distal to the elbow, supplying the anterior flexor muscles of the brachium along the way. This artery is the most common site of blood pressure measurement with the sphygmomanometer.
4. The **deep brachial artery** arises from the proximal end of the brachial and supplies the humerus and triceps brachii muscle. About midway down the arm, it continues as the radial collateral artery.
5. The **radial collateral artery** descends in the lateral side of the arm and empties into the radial artery slightly distal to the elbow.
6. The **superior ulnar collateral artery** arises about midway along the brachial artery and descends in the medial side of the arm. It empties into the ulnar artery slightly distal to the elbow.

TABLE 20.10 Arteries of the Upper Limb (*cont.*)

FIGURE 20.34 Arteries of the Upper Limb.

Why are arterial anastomoses especially common at joints such as the shoulder and elbow?

II. The Forearm, Wrist, and Hand

Just distal to the elbow, the brachial artery forks into the *radial* and *ulnar arteries*.

1. The **radial artery** descends the forearm laterally, alongside the radius, nourishing the lateral forearm muscles. The most common place to take a pulse is at the radial artery just proximal to the thumb.
2. The **ulnar artery** descends medially through the forearm, alongside the ulna, nourishing the medial forearm muscles.
3. The **interosseous²³ arteries** of the forearm lie between the radius and ulna. They begin with a short **common interosseous artery** branching from the upper end of the ulnar artery. The common interosseous quickly divides into anterior and posterior branches. The **anterior interosseous artery** travels down the anterior side of the interosseous membrane, nourishing the radius, ulna, and deep flexor muscles. It ends distally by passing through the interosseous membrane to join the posterior interosseous artery. The **posterior interosseous artery** descends along the posterior side of the interosseous membrane and nourishes mainly the superficial extensor muscles.
4. Two U-shaped **palmar arches** arise by anastomosis of the radial and ulnar arteries at the wrist. The **deep palmar arch** is fed mainly by the radial artery and the **superficial palmar arch** mainly by the ulnar artery. The arches issue arteries to the palmar region and fingers.

²³*inter* = between + *osse* = bones

TABLE 20.11 Veins of the Upper Limb

Both superficial and deep veins drain the upper limb, ultimately leading to axillary and subclavian veins that parallel the arteries of the same names (fig. 20.35). The superficial veins are often externally visible and are larger in diameter and carry more blood than the deep veins.

I. Superficial Veins

1. The **dorsal venous network** is a plexus of veins often visible through the skin on the back of the hand; it empties into the major superficial veins of the forearm, the cephalic and basilic.
2. The **cephalic²⁴** (sef-AL-ic) **vein** arises from the lateral side of the network, travels up the lateral side of the forearm and arm to the shoulder, and joins the axillary vein there. Intravenous fluids are often administered through the distal end of this vein.
3. The **basilic²⁵** (bah-SIL-ic) **vein** arises from the medial side of the network, travels up the posterior side of the forearm, and continues into the arm. It turns deeper about midway up the arm and joins the brachial vein at the axilla (see part II.4 of this table).
As an aid to remembering which vein is cephalic and which is basilic, visualize your arm held straight away from the torso (abducted) with the thumb up. The cephalic vein runs along the upper side of the arm closer to the head (as suggested by *cephal*, “head”), and the name *basilic* is suggestive of the lower (basal) side of the arm (although not named for that reason).
4. The **median cubital vein** is a short anastomosis between the cephalic and basilic veins that obliquely crosses the cubital fossa (anterior bend of the elbow). It is often clearly visible through the skin and is the most common site for drawing blood.
5. The **median antebrachial vein** drains a network of blood vessels in the hand called the **superficial palmar venous network**. It travels up the medial forearm and terminates at the elbow, emptying variously into the basilic vein, median cubital vein, or cephalic vein.

II. Deep Veins

1. The **deep and superficial venous palmar arches** receive blood from the fingers and palmar region. They are anastomoses that join the radial and ulnar veins.
2. Two **radial veins** arise from the lateral side of the palmar arches and course up the forearm alongside the radius. Slightly distal to the elbow, they converge and give rise to one of the brachial veins described shortly.
3. Two **ulnar veins** arise from the medial side of the palmar arches and course up the forearm alongside the ulna. They unite near the elbow to form the other brachial vein.
4. The two **brachial veins** continue up the brachium, flanking the brachial artery, and converge into a single vein just before the axillary region.
5. The **axillary vein** forms by the union of the brachial and basilic veins. It begins at the lower margin of the teres major muscle and passes through the axillary region, picking up the cephalic vein along the way. At the lateral margin of the first rib, it changes name to the subclavian vein.
6. The **subclavian vein** continues into the shoulder posterior to the clavicle and ends where it meets the internal jugular vein of the neck. There it becomes the brachiocephalic vein. The right and left brachiocephalics converge and form the superior vena cava, which empties into the right atrium of the heart.

²⁴*cephalic* = related to the head

²⁵*basilic* = royal, prominent, important

TABLE 20.11 Veins of the Upper Limb (cont.)

(a) Major veins

(b) Blood-flow schematic

FIGURE 20.35 Veins of the Upper Limb. Variations on this pattern are highly common. Many venous anastomoses are omitted for clarity.

• Name three veins that are often visible through the skin of the upper limb.

TABLE 20.12 Arteries of the Lower Limb

As we have already seen, the aorta forks at its lower end into the right and left common iliac arteries, and each of these soon divides again into an internal and external iliac artery. We traced the internal iliac artery in table 20.8 (part IV), and we now trace the external iliac as it supplies the lower limb (figs. 20.36 and 20.37).

I. Arteries from the Pelvic Region to the Knee

1. The **external iliac artery** sends small branches to the skin and muscles of the abdominal wall and pelvis, then passes behind the inguinal ligament and becomes the femoral artery.
2. The **femoral artery** passes through the *femoral triangle* of the upper medial thigh, where its pulse can be palpated (see Insight 20.4). In the triangle, it gives off several small arteries to the skin and then produces the following branches before descending the rest of the way to the knee.
 - a. The **deep femoral artery** arises from the lateral side of the femoral, within the triangle. It is the largest branch and is the major arterial supply to the thigh muscles.
 - b. Two **circumflex femoral arteries** arise from the deep femoral, encircle the head of the femur, and anastomose laterally. They supply mainly the femur, hip joint, and hamstring muscles.

FIGURE 20.36 Arteries of the Lower Limb. The foot is strongly plantar flexed with the dorsal surface facing the viewer in part (a) and the sole (plantar surface) facing the viewer in part (b).

TABLE 20.12 Arteries of the Lower Limb (cont.)

3. The **popliteal artery** is a continuation of the femoral artery in the popliteal fossa at the rear of the knee. It begins where the femoral artery emerges from an opening (*adductor hiatus*) in the tendon of the adductor magnus muscle and ends where it splits into the *anterior* and *posterior tibial arteries*. As it passes through the popliteal fossa, it gives off anastomoses called **genicular²⁶ arteries** that supply the knee joint.

II. Arteries of the Leg and Foot

In the leg proper, the three most significant arteries are the anterior tibial, posterior tibial, and fibular arteries.

1. The **anterior tibial artery** arises from the popliteal artery and immediately penetrates through the interosseous membrane of the leg to the anterior compartment. There, it travels lateral to the tibia and supplies the extensor muscles. Upon reaching the ankle, it gives rise to the following dorsal arteries of the foot.
 - a. The **dorsal pedal artery** traverses the ankle and upper medial surface of the foot and gives rise to the arcuate artery.
 - b. The **arcuate artery** sweeps across the foot from medial to lateral and gives rise to vessels that supply the toes.
2. The **posterior tibial artery** is a continuation of the popliteal artery that passes down the leg, deep in the posterior compartment, supplying flexor muscles along the way. Inferiorly, it passes behind the medial malleolus of the ankle and into the plantar region of the foot. It gives rise to the following:
 - a. The **medial and lateral plantar arteries** originate by branching of the posterior tibial artery at the ankle. The medial plantar artery supplies mainly the great toe. The lateral plantar artery sweeps across the sole of the foot and becomes the deep plantar arch.
 - b. The **deep plantar arch** gives off another set of arteries to the toes.
3. The **fibular (peroneal) artery** arises from the proximal end of the posterior tibial artery near the knee. It descends through the lateral side of the posterior compartment, supplying lateral muscles of the leg along the way, and ends in a network of arteries in the heel.

FIGURE 20.37 Arterial Schematic of the Pelvic Region and Lower Limb. Anterior view. The pelvic schematic on the right is stretched for clarity. These arteries are not located as far inferiorly as the arteries depicted adjacent to them on the left.

²⁶genic = knee

TABLE 20.13 Veins of the Lower Limb

We will follow drainage of the lower limb from the toes to the inferior vena cava (figs. 20.38 and 20.39). As in the upper limb, there are deep and superficial veins with anastomoses between them. Most of the anastomoses are omitted from the illustrations.

I. Superficial Veins

1. The **dorsal venous arch** (fig. 20.38a) is often visible through the skin on the dorsum of the foot. It collects blood from the toes and more proximal part of the foot, and has numerous anastomoses similar to the dorsal venous network of the hand. It gives rise to the following two veins.
2. The **small (short) saphenous**²⁷ (sah-FEE-nus) **vein** arises from the lateral side of the arch and passes up that side of the leg as far as the knee. There, it drains into the popliteal vein.
3. The **great (long) saphenous vein**, the longest vein in the body, arises from the medial side of the arch and travels all the way up the leg and thigh to the inguinal region. It empties into the femoral vein slightly inferior to the inguinal ligament. It is commonly used as a site for the long-term administration of intravenous fluids; it is a relatively accessible vein in infants and in patients in shock whose veins have collapsed. Portions of this vein are commonly used as grafts in coronary bypass surgery. The great and small saphenous veins are among the most common sites of varicose veins.

FIGURE 20.38 Veins of the Lower Limb. The foot is strongly plantar flexed with the dorsal surface facing the viewer in part (a) and the sole (plantar surface) facing the viewer in part (b).

²⁷saphen = standing

TABLE 20.13 Veins of the Lower Limb

II. Deep Veins

1. The **deep plantar venous arch** (fig. 20.38b) receives blood from the toes and gives rise to **lateral** and **medial plantar veins** on the respective sides. The lateral plantar vein gives off the *fibular veins*, then crosses over to the medial side and approaches the medial plantar vein. The two plantar veins pass behind the medial malleolus of the ankle and continue as a pair of *posterior tibial veins*.
2. The two **posterior tibial veins** pass up the leg embedded deep in the calf muscles. They converge like an inverted Y into a single vein about two-thirds of the way up the tibia.
3. The two **fibular (peroneal) veins** ascend the back of the leg and similarly converge like a Y.
4. The **popliteal vein** begins near the knee by convergence of these two inverted Ys. It passes through the popliteal fossa at the back of the knee.
5. The two **anterior tibial veins** travel up the anterior compartment of the leg between the tibia and fibula (fig. 20.38a). They arise from the medial side of the dorsal venous arch, converge just distal to the knee, and then flow into the popliteal vein.
6. The **femoral vein** is a continuation of the popliteal vein into the thigh. It drains blood from the deep thigh muscles and femur.
7. The **deep femoral vein** drains the femur and muscles of the thigh supplied by the deep femoral artery. It receives four principal tributaries along the shaft of the femur and then a pair of **circumflex femoral veins** that encircle the upper femur. It finally drains into the upper femoral vein.
8. The **external iliac vein** is formed by the union of the femoral and great saphenous veins near the inguinal ligament.
9. The **internal iliac vein** follows the course of the internal iliac artery and its distribution. Its tributaries drain the gluteal muscles; the medial aspect of the thigh; the urinary bladder, rectum, prostate, and ductus deferens in the male; and the uterus and vagina in the female.
10. The **common iliac vein** is formed by the union of the external and internal iliac veins. The right and left common iliacs then unite to form the inferior vena cava.

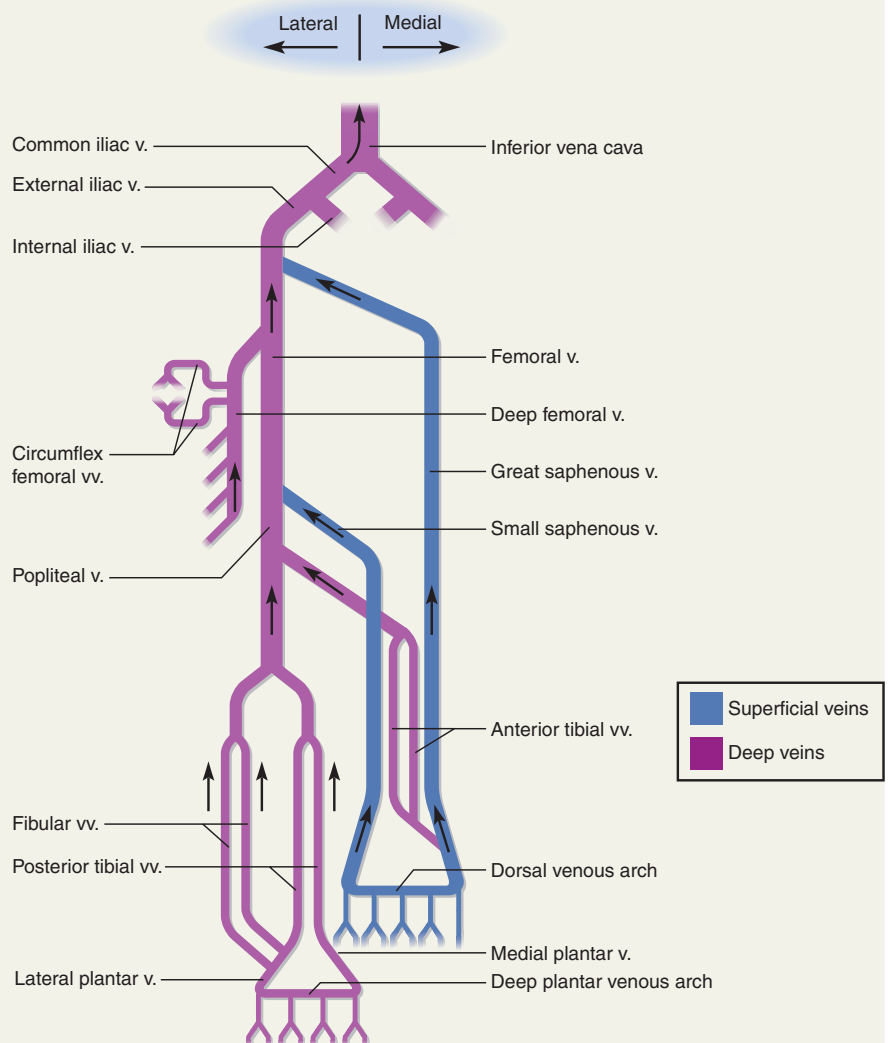

FIGURE 20.39 Venous Schematic of the Lower Limb. Anterior view.

Think About It

There are certain similarities between the arteries of the hand and foot. What arteries of the wrist and hand are most comparable in arrangement and function to the arcuate artery and deep plantar arch of the foot?

Insight 20.4 exemplifies the relevance of vascular anatomy to emergency first aid. The most common cardiovascular diseases are atherosclerosis (discussed in Insight 19.5, p. 750) and hypertension (Insight 20.5). A few additional vascular disorders are briefly described in table 20.14.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

30. *Trace one possible path of a red blood cell from the left ventricle to the toes.*
31. *Trace one possible path of a red blood cell from the fingers to the right atrium.*
32. *The subclavian, axillary, and brachial artery are really one continuous artery. What is the reason for giving it three different names along its course?*
33. *State two ways in which the great saphenous vein has special clinical significance. Where is this vein located?*

TABLE 20.14 Some Disorders of the Arteries and Veins

Dissecting aneurysm	Splitting of the layers of an arterial wall from each other because of the accumulation of blood between layers. Results from either a tear in the tunica interna or rupture of the vasa vasorum.	
Fat embolism	The presence of fat globules traveling in the bloodstream. Globules originate from bone fractures, fatty degeneration of the liver, and other causes and may block cerebral or pulmonary blood vessels.	
Orthostatic hypotension	A decrease in blood pressure that occurs when one stands, often resulting in blurring of vision, dizziness, and syncope (fainting). Results from sluggish or inactive baroreflexes.

INSIGHT 20.4 Clinical Application

Arterial Pressure Points

In some places, major arteries come close enough to the body surface to be palpated. These places can be used to take a pulse, and they can serve as emergency *pressure points*, where firm pressure can be applied to temporarily reduce arterial bleeding (fig. 20.40). One of these points is the *femoral triangle*

of the upper medial thigh. This is an important landmark for arterial supply, venous drainage, and innervation of the lower limb. Its boundaries are the sartorius muscle laterally, the inguinal ligament superiorly, and the adductor longus muscle medially. The femoral artery, vein, and nerve run close to the surface at this point.

FIGURE 20.40 Arterial Pressure Points. (a) Areas where arteries lie close enough to the surface that a pulse can be palpated or pressure can be applied to reduce arterial bleeding. (b) Structures in the femoral triangle. (c) The three boundaries that define the femoral triangle.

INSIGHT 20.5 Clinical Application**Hypertension—The “Silent Killer”**

Hypertension, the most common cardiovascular disease, affects about 30% of Americans over age 50, and 50% by age 74. It is a “silent killer” that can wreak its destructive effects for 10 to 20 years before they are first noticed. Hypertension is the major cause of heart failure, stroke, and kidney failure. It damages the heart because it increases the afterload, which makes the ventricles work harder to expel blood. The myocardium enlarges up to a point (the *hypertrophic response*), but eventually it becomes excessively stretched and less efficient. Hypertension strains the blood vessels and tears the endothelium, thereby creating lesions that become focal points of atherosclerosis. Atherosclerosis then worsens the hypertension and establishes an insidious positive feedback cycle.

Another positive feedback cycle involves the kidneys. Their arterioles thicken in response to the stress, their lumens become narrower, and renal blood flow declines. In response to the resulting drop in blood pressure, the kidneys release renin, which leads to the formation of the vasoconstrictor angiotensin II and the release of aldosterone, a hormone that promotes salt retention (described in detail in chapter 24). These effects worsen the hypertension that already existed. If diastolic pressure exceeds 120 mm Hg, the kidneys and heart deteriorate rapidly, blood vessels of the eye hemorrhage, blindness may ensue, and death usually follows within 2 years.

Primary hypertension, which accounts for 90% of cases, results from such a complex web of behavioral, hereditary, and other factors that it is difficult to sort out any specific underlying cause. It was once considered such a normal part of the “essence” of aging that it continues to be called by another name, *essential hypertension*. That term suggests a fatalistic resignation to hypertension as a fact of life, but this need not be. Many risk factors have been identified, and most of them are controllable.

One of the chief culprits is obesity. Each pound of extra fat requires miles of additional blood vessels to serve it, and all of this added vessel length increases peripheral resistance and blood pressure. Just carrying around extra weight, of course, also increases the workload on the heart. Even a small weight loss can significantly reduce blood pressure. Sedentary behavior

is another risk factor. Aerobic exercise helps to reduce hypertension by controlling weight, reducing emotional tension, and stimulating vasodilation.

Dietary factors are also significant contributors to hypertension. Diets high in cholesterol and saturated fat contribute to atherosclerosis. Potassium and magnesium reduce blood pressure; thus, diets deficient in these minerals promote hypertension. The relationship of salt intake to hypertension has been a very controversial subject. The kidneys compensate so effectively for excess salt intake that dietary salt has little effect on the blood pressure of most people. Reduced salt intake may, however, help to control hypertension in older people and in people with reduced renal function.

Nicotine makes a particularly devastating contribution to hypertension because it stimulates the myocardium to beat faster and harder, while it stimulates vasoconstriction and increases the afterload against which the myocardium must work. Just when the heart needs extra oxygen, nicotine causes coronary vasoconstriction and promotes myocardial ischemia.

Some risk factors cannot be changed at will—race, heredity, and sex. Hypertension runs in some families. A person whose parents or siblings have hypertension is more likely than average to develop it. The incidence of hypertension is about 30% higher, and the incidence of strokes about twice as high, among blacks as among whites. From ages 18 to 54, hypertension is more common in men, but above age 65, it is more common in women. Even people at risk from these factors, however, can minimize their chances of hypertension by changing risky behaviors.

Treatments for primary hypertension include weight loss, diet, and certain drugs. Diuretics lower blood volume and pressure by promoting urination. ACE inhibitors block the formation of the vasoconstrictor angiotensin II. Beta-blockers such as propranolol block the vasoconstrictive action of the sympathetic nervous system. Calcium channel blockers such as verapamil and nifedipine inhibit the inflow of calcium into cardiac and smooth muscle, thus inhibiting their contraction, promoting vasodilation, and reducing cardiac workload.

Secondary hypertension, which accounts for about 10% of cases, is high blood pressure that is secondary to (results from) other identifiable disorders. These include kidney disease (which may cause renin hypersecretion), atherosclerosis, hyperthyroidism, Cushing syndrome, and polycythemia. Secondary hypertension is corrected by treating the underlying disease.

CONNECTIVE ISSUES

Interactions Between the CIRCULATORY SYSTEM and Other Organ Systems

■ indicates ways in which this system affects other systems ■ indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

Dermal blood flow affects sweat production →

Serves as blood reservoir; helps to regulate blood temperature ←

SKELETAL SYSTEM

Provides minerals for bone deposition; delivers erythropoietin to bone marrow and delivers hormones that regulate skeletal growth →

Skeleton provides protective enclosure for heart and thoracic vessels; serves as reservoir of calcium needed for heart contractions and vasomotion; bone marrow carries out hemopoiesis ←

MUSCULAR SYSTEM

Removes heat generated by exercise →

Helps to regulate blood temperature; respiratory and limb muscles aid venous return; aerobic exercise enhances circulatory efficiency ←

NERVOUS SYSTEM

Endothelial cells of blood vessels maintain blood-brain barrier and help to produce CSF →

Modulates heart rate, strength of contraction, and vasomotion; governs routing of blood flow; monitors blood pressure and composition and activates homeostatic mechanisms to regulate these ←

ENDOCRINE SYSTEM

Transports hormones to their target cells →

Regulates blood volume and pressure; stimulates hemopoiesis ←

ALL SYSTEMS

Circulatory system delivers O₂ and nutrients to all other systems and carries away wastes; carries heat from deeper organs to skin for elimination; distributes hormones to all organ systems

LYMPHATIC/IMMUNE SYSTEM

Produces tissue fluid, which becomes lymph; provides the WBCs and plasma proteins employed in immunity →

Lymphatic and circulatory systems jointly regulate fluid balance; lymphatic system returns fluid to bloodstream; spleen acts as platelet reservoir and disposes of old RBCs; lymphatic tissues produce lymphocytes; immune cells protect circulatory system from pathogens ←

RESPIRATORY SYSTEM

Delivers and carries away respiratory gases; low capillary blood pressure keeps alveoli dry →

Site of exchange for blood gases; helps to regulate blood pH; thoracic pump aids venous return ←

URINARY SYSTEM

Blood pressure maintains kidney function →

Controls blood volume, pressure, and composition; initiates renin-angiotensin-aldosterone mechanism; regulates RBC count by producing erythropoietin ←

DIGESTIVE SYSTEM

Carries away absorbed nutrients; helps to reabsorb and recycle bile salts and minerals from intestines →

Provides nutrients for hemopoiesis; affects blood composition ←

REPRODUCTIVE SYSTEM

Distributes sex hormones; vasodilation causes erection →

Estrogens may slow development of atherosclerosis in women; testosterone stimulates erythropoiesis ←

CHAPTER REVIEW

Review of Key Concepts

20.1 General Anatomy of the Blood Vessels (p. 756)

1. Blood flows away from the heart in *arteries* and back to the heart in *veins*. *Capillaries* connect the smallest arteries to the smallest veins.
2. The wall of a blood vessel has three layers: *tunica interna*, *tunica media*, and *tunica externa*. The *tunica interna* is lined with a simple squamous *endothelium*.
3. Arteries are classified as *conducting*, *distributing*, and *resistance arteries* from largest to smallest. Conducting arteries are subject to the highest blood pressure and have the most elastic tissue; distributing and resistance arteries contain more smooth muscle relative to their size.
4. The smallest of the resistance arteries are *arterioles*. *Metarterioles* link arterioles with capillaries.
5. Certain large arteries above the heart contain baroreceptors called *carotid sinuses* for monitoring blood pressure, and chemoreceptors called *carotid bodies* and *aortic bodies* for monitoring blood CO₂, O₂, and pH.
6. Capillaries are the primary point of fluid exchange with the tissues. Their wall is composed of endothelium and basal lamina only.
7. The three types of capillaries are *continuous capillaries*, which form an uninterrupted tube; *fenestrated capillaries* perforated by patches of filtration pores; and *sinusoids*, which are irregular, highly porous blood spaces in such tissues as liver, spleen, and bone marrow.
8. Capillaries are arranged in networks called *capillary beds*, supplied by a single metarteriole. *Precapillary sphincters* regulate blood flow through a capillary bed.
9. The smallest veins, or *venules*, also exchange fluid with the tissues. They converge to form *medium veins*, and medium veins converge to form *large veins*.
10. *Venous sinuses* are blood spaces with large lumens, thin walls, and no muscle. They occur in such places as the heart and brain.

11. Veins have relatively low blood pressure and therefore have thinner walls and less muscular and elastic tissue than arteries do. Medium veins of the limbs have valves to prevent the backflow of blood.
12. Between the arteries and veins, blood normally flows through one capillary bed. Portal systems and anastomoses are exceptions to this rule.

20.2 Blood Pressure, Resistance, and Flow (p. 764)

1. Blood *flow* (mL/min) and *perfusion* (flow/g of tissue) vary with the metabolic needs of a tissue.
2. Flow (*F*) is directly proportional to the pressure difference between two points (ΔP) and inversely proportional to resistance (*R*): $F \propto \Delta P/R$.
3. Blood pressure (BP) is usually measured with a sphygmomanometer. Arterial pressures are expressed as systolic over diastolic pressure—for example, 120/80 mm Hg.
4. *Pulse pressure* is systolic minus diastolic pressure. *Mean arterial pressure* is the average pressure in a vessel over the course of a cardiac cycle, estimated as diastolic pressure + 1/3 of pulse pressure.
5. Chronic, abnormally high BP is *hypertension* and low BP is *hypotension*.
6. The expansion and contraction of arteries during the cardiac cycle reduce the pulse pressure and ease the strain on smaller arteries, but arterial blood flow is nevertheless pulsatile. In capillaries and veins, flow is steady (without pulsation).
7. *Peripheral resistance* is opposition to blood flow in the blood vessels. Resistance is directly proportional to blood viscosity and vessel length, and inversely proportional to vessel radius to the fourth power (r^4). Changes in vessel radius (*vasomotion*) thus have the greatest influence on flow from moment to moment.
8. Blood flow is fastest in the aorta, is slowest in the capillaries, and speeds up somewhat in the veins.
9. Blood pressure is controlled by local, neural, and hormonal mechanisms.

10. *Autoregulation* is the ability of a tissue to regulate its own blood supply. Over the short term, local vasomotion is stimulated by *vasoactive chemicals* (histamine, nitric oxide, and others). Over the long term, autoregulation can be achieved by *angiogenesis*, the growth of new vessels.
11. Neural control of blood vessels is based in the *vasomotor center* of the medulla oblongata. This center integrates *baroreflexes*, *chemoreflexes*, and the *medullary ischemic reflex*, and issues signals to the blood vessels by way of sympathetic nerve fibers.
12. Blood pressure is regulated in various ways by the hormones angiotensin II, aldosterone, atrial natriuretic peptide, antidiuretic hormone, epinephrine, and norepinephrine.
13. Generalized vasomotion raises or lowers blood pressure throughout the body. Local vasomotion often shifts blood flow from organs with less need of perfusion at a given time to organs with greater need—for example, away from the intestines and to the skeletal muscles during exercise.

20.3 Capillary Exchange (p. 771)

1. *Capillary exchange* is a two-way movement of water and solutes between the blood and tissue fluids across the walls of the capillaries and venules.
2. Materials pass through the vessel wall by diffusion, transcytosis, filtration, and reabsorption, passing through intercellular clefts, filtration pores, and the endothelial cell cytoplasm.
3. Fluid is forced out of the vessels by blood pressure and the negative hydrostatic pressure of the interstitial space. The force drawing fluid back into the capillaries is colloid osmotic pressure. The difference between the outward and inward forces is an outward *net filtration pressure* or an inward *net reabsorption pressure*.
4. Capillaries typically give off fluid at the arterial end, where the relatively high blood pressure overrides reabsorption; they reabsorb about 85% as much fluid at the venous end, where

colloid osmotic pressure overrides the lower blood pressure.

- About 15% of the tissue fluid is reabsorbed by the lymphatic system.
- Fluid exchange dynamics vary from place to place in the body (some capillaries engage solely in filtration and some solely in reabsorption) and from moment to moment (as vasomotion shifts the balance between filtration and reabsorption).
- Accumulation of excess tissue fluid is *edema*. It results from increased capillary filtration, reduced reabsorption, or obstructed lymphatic drainage.

20.4 Venous Return and Circulatory Shock (p. 774)

- Venous return*, the flow of blood back to the heart, is driven by the venous blood pressure gradient, gravity, the skeletal muscle pump (aided by valves in the veins of the limbs), the thoracic pump, and cardiac suction.
- Exercise increases venous return because the vessels dilate, the thoracic pump and skeletal muscle pump work more energetically, and cardiac output is elevated.
- Inactivity allows blood to accumulate in low points in the body by gravity; this is called *venous pooling*. It can result in *syncope* (fainting) if too much blood drains away from the brain.
- Circulatory shock* is any state of inadequate cardiac output. Its two basic categories are *cardiogenic shock* and *low venous return (LVR) shock*.
- The main forms of LVR shock are *hypovolemic*, *obstructed venous return*, and *venous pooling shock*.
- Septic shock* and *anaphylactic shock* combine elements of hypovolemia and venous pooling.
- Compensated shock* is corrected by the body's homeostatic mechanisms. *Decompensated shock* is life-threatening, is incapable of self-correction, and requires clinical intervention.

20.5 Special Circulatory Routes (p. 777)

- The brain receives a relatively stable total blood flow of about 700 mL/min, but flow shifts rapidly from one part of the brain to another during varying cerebral activities.
- The brain regulates its own blood flow in response to changes in BP and pH.
- Transient ischemic attacks* result from brief periods of cerebral

ischemia (poor blood flow). A *cerebral vascular accident* (stroke) results from a permanent loss of perfusion due to arterial blockage or rupture.

- Skeletal muscles receive highly variable flow depending on their state of activity. Most muscle capillary beds are shut down at rest. During exercise, flow increases in response to muscle metabolites and sympathetic vasodilation.
- The pulmonary circuit is the only route in which arteries carry less oxygen than veins do.
- Pulmonary arteries have relatively low BP and slow flow, which allows ample time for gas exchange and promotes capillary reabsorption. The latter prevents fluid from accumulating in the lungs.
- Pulmonary arteries, unlike systemic arteries, constrict in response to hypoxia, so less blood is sent to poorly ventilated areas of the lung.

20.6 Anatomy of the Pulmonary Circuit (p. 778)

- The pulmonary circuit begins with the *pulmonary trunk*, which arises from the right ventricle of the heart and branches into the right and left *pulmonary arteries* to the lungs. These divide into one or more *lobar arteries* for each lobe of the respective lung. Finer branches lead to capillaries around the pulmonary alveoli, where gas exchange occurs.
- Pulmonary blood empties into the left atrium of the heart by way of two pulmonary veins on each side.
- The pulmonary circuit serves mainly for CO₂ unloading and O₂ loading. The lung tissue receives nourishment and waste removal by a separate set of vessels, the *bronchial arteries* of the systemic circuit.

20.7 Systemic Vessels of the Axial Region (p. 779)

- The *ascending aorta* arises from the left ventricle and immediately gives off the two coronary arteries to the heart wall. It continues as the *aortic arch*, which gives off three large arteries to the neck, head, and upper limbs: the *brachiocephalic trunk*, *left common carotid artery*, and *left subclavian artery*. Beyond the arch, the aorta turns downward and continues as the *descending aorta*, divided into thoracic and abdominal regions (table 20.3).

- Four arteries ascend each side of the neck: the *common carotid*, the *vertebral artery*, and branches of the *thyrocervical* and *costocervical trunks* (table 20.4, part I).
- The common carotid arteries ascend beside the trachea and branch into an *external carotid artery*, supplying mainly head tissues external to the cranium, and an *internal carotid artery*, supplying mainly the brain. The external carotid gives off *superior thyroid*, *lingual*, *facial*, *occipital*, *maxillary*, and *superficial temporal* arteries. The internal carotid gives off the *ophthalmic*, *anterior cerebral*, and *middle cerebral arteries* (table 20.4, part II).
- The internal carotid and vertebral arteries converge on the *cerebral arterial circle* at the base of the brain, surrounding the pituitary gland. The arterial circle gives off *anterior* and *posterior cerebral arteries* and often has short anastomoses called *anterior* and *posterior communicating arteries* that complete the circle (table 20.4, parts III–IV).
- Blood from the brain drains into numerous *dural venous sinuses*, including the *superior sagittal*, *inferior sagittal*, *transverse*, and *cavernous sinuses*. The greatest outflow from these sinuses is via the *internal jugular vein*, which courses down the neck to the subclavian vein. The *external jugular* and *vertebral veins* drain more superficial structures of the head and neck and empty into the subclavian vein (table 20.5).
- The thoracic aorta gives off *bronchial*, *esophageal*, and *mediastinal arteries* to the thoracic viscera; *posterior intercostal* and *subcostal arteries* to the skin, thoracic muscles, vertebrae, and other structures; and *superior phrenic arteries* to the diaphragm (table 20.6, parts I, II).
- Continuing through the shoulder, the subclavian artery gives off the *internal thoracic artery*, *thoracoacromial trunk*, and *lateral thoracic artery* to the thoracic wall, then continues as the *axillary artery*, which gives off the *subscapular artery* to the scapula and numerous muscles of the thorax and arm (table 20.6, part III).
- The thorax is drained in part by several small tributaries that flow into the *subclavian* and *brachiocephalic veins*. The right and left brachiocephalics

812 PART FOUR Regulation and Maintenance

join to form the *superior vena cava*, which empties into the right atrium of the heart (table 20.7, part I).

9. The thorax is also drained by the azygos system. The major veins of this system are the azygos vein on the right and the hemiazygos and accessory hemiazygos veins on the left. These veins receive blood from most of the posterior intercostal veins and carry it to the superior vena cava. They also receive blood from the subcostal veins; ascending lumbar veins of the abdomen; and esophageal, mediastinal, pericardial, and bronchial veins (table 20.7, part II).
10. As it descends through the abdominal cavity, the abdominal aorta gives off *inferior phrenic arteries*, the *celiac trunk*, and the *superior mesenteric*, *middle suprarenal*, *renal*, *ovarian* or *testicular*, *inferior mesenteric*, *lumbar*, and *median sacral arteries*. It ends by branching into two *common iliac arteries* (table 20.8, part I).
11. The celiac trunk provides a complex, anastomosing blood supply to the upper digestive and some other organs. Its three primary branches are the *common hepatic*, *left gastric*, and *splenic arteries*. The various subdivisions of these arteries supply the liver, gallbladder, pancreas, spleen, greater omentum, lower esophagus, stomach, and duodenum (table 20.8, part II).
12. The *superior mesenteric artery* gives rise to the *inferior pancreaticoduodenal*, *jejunal*, *ileal*, and *right and middle colic arteries*. It supplies nearly all of the small intestine and the proximal half of the large intestine. The *inferior mesenteric artery* gives off the *left colic*, *sigmoid*, and *superior rectal arteries*, serving the distal half of the large intestine (table 20.8, part III).
13. In the pelvic region, the common iliac artery branches into the *external* and *internal iliac arteries*. The internal iliac divides into *posterior* and *anterior trunks*. Subdivisions of these trunks supply the urinary bladder and ureters, rectum, penis and clitoris, and muscles, bones, and skin of the pelvic and femoral regions and contents of the lower vertebral canal (table 20.8, part IV).
14. Ascending the pelvic region, the *internal* and *external iliac veins* join to form the common iliac vein, and the two common iliacs merge to form the *inferior vena cava (IVC)*. The IVC provides the major venous drainage

of the pelvic region and abdomen. As it continues the ascent in the abdominal cavity, it receives the *lumbar veins*, *ovarian* or *testicular veins*, and the *renal*, *suprarenal*, *hepatic*, and *inferior phrenic veins*. It then enters the thorax and empties into the right atrium of the heart (table 20.9, part I).

15. Right and left *ascending lumbar veins* drain the abdominal wall, anastomose with the IVC, then penetrate the diaphragm and continue as the *azygos* and *hemiazygos veins*, respectively (table 20.9, part II).
16. Blood from the stomach, intestines, pancreas, gallbladder, and spleen flows to the liver by way of the *hepatic portal system*. The *splenic vein* receives the *pancreatic veins*, *inferior mesenteric vein*, and finally the *superior mesenteric vein*. From there it continues as the *hepatic portal vein*, which picks up the *cystic vein* and *gastric veins*, then enters the liver. This blood filters through the *hepatic sinusoids*, then exits the liver via the hepatic veins, which empty into the IVC (table 20.9, part III).

20.8 Systemic Vessels of the Appendicular Region (p. 798)

1. Blood flow to the upper limb follows the *subclavian*, *axillary*, and *brachial arteries* into the arm, in that order. The brachial artery descends through the arm and gives off the *deep brachial* and *superior ulnar collateral arteries*; the deep brachial flows into the *radial collateral artery* (table 20.10, part I).
2. Near the elbow, the brachial artery branches into the *radial* and *ulnar arteries* of the forearm. The ulnar artery gives rise (indirectly) to *anterior* and *posterior interosseous arteries*. The radial and ulnar arteries anastomose in a pair of *palmar arches* at the wrist, and these give off branches to the hand and fingers (table 20.10, part II).
3. Superficial venous drainage of the upper limb includes the *dorsal venous network* of the hand, flowing into the *cephalic* and *basilic veins* of the forearm. The *median antebrachial vein* drains the *superficial palmar venous network* of the hand and empties into the cephalic, basilic, or median cubital vein. The *median cubital vein* is a short anastomosis that joins the cephalic and basilic at the elbow (table 20.11, part I).
4. Deep venous drainage of the upper limb includes a pair of *venous palmar arches*, which drain into a pair of *radial veins* laterally and a pair of *ulnar veins* medially. These lead to two *brachial veins*, one formed by convergence of the radial veins and the other by convergence of the ulnar veins. The brachial veins join the basilic vein. This union forms the *axillary vein*, which continues into the shoulder and becomes the *subclavian vein* (table 20.11, part II).
5. Arterial flow to the lower limb comes from the *external iliac artery*, which supplies some structures of the pelvic region, then continues into the thigh as the *femoral artery*. The femoral artery gives off the *deep femoral* and two *circumflex femoral arteries*, then continues its descent, becoming the *popliteal artery* at the back of the knee and finally branching into the *anterior* and *posterior tibial arteries* just below the knee (table 20.12, part I).
6. The anterior tibial artery descends to the ankle and gives rise to the *dorsal pedal* and *arcuate artery* of the foot. The posterior tibial artery branches at the ankle to produce the *medial* and *lateral plantar arteries*. The lateral plantar leads to the *deep plantar arch*, which in turn gives off arteries to the toes. The *fibular artery* arises from the posterior tibial artery near the knee and ends in a network of small vessels in the heel (table 20.12, part II).
7. Blood from the toes and foot drains partly into a superficial *dorsal venous arch*, which drains on the lateral and medial sides into the *small saphenous* and *great saphenous veins*, respectively. The small saphenous ends at the knee by draining into the popliteal vein, whereas the great saphenous extends to the groin and empties into the femoral vein (table 20.13, part I).
8. The deep *plantar venous arch* of the foot drains the toes and gives rise to *lateral* and *medial plantar veins*. These, in turn, produce two *posterior tibial veins* and two *fibular veins* that ascend the leg and converge into a single posterior tibial and fibular vein higher up. Convergence of those two produces the *popliteal vein* of the knee. A pair of *anterior tibial veins* arise from the dorsal venous arch and empty into the popliteal vein (table 20.13, part II).
9. Above the knee, the popliteal vein continues as the *femoral vein*. The

femoral receives the *deep femoral vein*, which drains the muscles and bone of the thigh, then joins the great

saphenous vein to become the *external iliac vein*. In the pelvic region, the external iliac joins the internal

iliac, and their union forms the *common iliac vein* (table 20.13).

Testing Your Recall

- Blood normally flows into a capillary bed from
 - the distributing arteries.
 - the conducting arteries.
 - a metarteriole.
 - a thoroughfare channel.
 - the venules.
- Plasma solutes enter the tissue fluid most easily from
 - continuous capillaries.
 - fenestrated capillaries.
 - arteriovenous anastomoses.
 - collateral vessels.
 - venous anastomoses.
- A blood vessel adapted to withstand a high pulse pressure would be expected to have
 - an elastic tunica media.
 - a thick tunica interna.
 - one-way valves.
 - a flexible endothelium.
 - a rigid tunica media.
- The substance most likely to cause a rapid drop in blood pressure is
 - epinephrine.
 - norepinephrine.
 - angiotensin II.
 - serotonin.
 - histamine.
- A person with a systolic blood pressure of 130 mm Hg and a diastolic pressure of 85 mm Hg would have a mean arterial pressure of about
 - 85 mm Hg.
 - 100 mm Hg.
 - 108 mm Hg.
 - 115 mm Hg.
 - 130 mm Hg.
- The velocity of blood flow decreases if
 - vessel radius increases.
 - blood pressure increases.
 - viscosity increases.
 - afterload increases.
 - vasomotion decreases.
- Blood flows faster in a venule than in a capillary because venules
 - have one-way valves.
 - exhibit vasomotion.
 - are closer to the heart.
 - have higher blood pressures.
 - have larger diameters.
- In a case where interstitial hydrostatic pressure is negative, the only force causing capillaries to reabsorb fluid is
 - colloid osmotic pressure of the blood.
 - colloid osmotic pressure of the tissue fluid.
 - capillary hydrostatic pressure.
 - interstitial hydrostatic pressure.
 - net filtration pressure.
- Intestinal blood flows to the liver by way of
 - the superior mesenteric artery.
 - the celiac trunk.
 - the inferior vena cava.
 - the azygos system.
 - the hepatic portal system.
- The brain receives blood from all of the following vessels *except* the _____ artery or vein.
 - basilar
 - vertebral
 - internal carotid
 - internal jugular
 - anterior communicating
- The highest arterial blood pressure attained during ventricular contraction is called _____ pressure. The lowest attained during ventricular relaxation is called _____ pressure.
- The capillaries of skeletal muscles are of the structural type called _____.
- _____ shock occurs as a result of exposure to an antigen to which one is hypersensitive.
- The role of breathing in venous return is called the _____.
- The difference between the colloid osmotic pressure of blood and that of the tissue fluid is called _____.
- Movement across the capillary endothelium by the uptake and release of fluid droplets is called _____.
- All efferent fibers of the vasomotor center belong to the _____ division of the autonomic nervous system.
- The pressure sensors in the major arteries near the head are called _____.
- Most of the blood supply to the brain comes from a ring of arterial anastomoses called _____.
- The major superficial veins of the arm are the _____ on the medial side and _____ on the lateral side.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- In some circulatory pathways, blood can get from an artery to a vein without going through capillaries.
- In some cases, a blood cell may pass through two capillary beds in a single trip from left ventricle to right atrium.
- The body's longest blood vessel is the great saphenous vein.
- Arteries have a series of valves that ensure a one-way flow of blood.
- If the radius of a blood vessel doubles and all other factors remain the same, blood flow through that vessel also doubles.
- The femoral triangle is bordered by the inguinal ligament, sartorius muscle, and adductor longus muscle.
- The lungs receive both pulmonary and systemic blood.
- Blood capillaries must reabsorb all the fluid they emit, or else edema will occur.
- An aneurysm is a ruptured blood vessel.
- In the baroreflex, a drop in arterial blood pressure triggers a corrective vasodilation of the systemic blood vessels.

Answers in appendix B

Testing Your Comprehension

- It is a common lay perception that systolic blood pressure should be 100 plus a person's age. Evaluate the validity of this statement.
- Calculate the net filtration or reabsorption pressure at a point in a hypothetical capillary assuming a hydrostatic blood pressure of 28 mm Hg, an interstitial hydrostatic pressure of -2 mm Hg, a blood COP of 25 mm Hg, and an interstitial COP of 4 mm Hg. Give the magnitude (in mm Hg) and direction (in or out) of the net pressure.
- Aldosterone secreted by the adrenal gland must be delivered to the kidney immediately below. Trace the route that an aldosterone molecule must take from the adrenal gland to the kidney, naming all major blood vessels in the order traveled.
- People in shock commonly exhibit paleness, cool skin, tachycardia, and a weak pulse. Explain the physiological basis for each of these signs.
- Discuss why it is advantageous to have baroreceptors in the aortic arch and carotid sinus rather than in some other location such as the common iliac arteries.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Endocytosis and exocytosis (pp. 106-108)
- The general structure of glands: capsule, septa, stroma, and parenchyma (p. 175)
- Leukocyte types (pp. 701-704)
- Mechanisms of venous blood flow (p. 775)

It may come as a surprise to know that the human body harbors about 10,000 times as many bacterial cells as human cells. But it shouldn't be surprising. After all, human homeostasis works wonderfully not only to sustain our lives, but also to provide a predictable, warm, wet, nutritious habitat for our internal guests. It is a wonder that the body is not overrun and consumed by microbes—which indeed quickly happens when one dies and homeostasis ceases.

Many of these guest microbes are beneficial or even necessary to human health, but some have the potential to cause disease if they get out of hand. Furthermore, we are constantly exposed to new invaders through the food and water we consume, the air we breathe, and even the surfaces we touch. We must have a means of keeping such would-be colonists in check.

One of these defenses was discovered in 1882 by a moody, intense, Russian zoologist, Elie Metchnikoff (1845–1916). When studying the tiny transparent larvae of starfish, he observed mobile cells wandering throughout their bodies. He thought at first that they must be digestive cells, but when he saw similar cells in sea anemones ingest nonnutritive dye particles, he thought they must play a defensive role. Metchnikoff knew that mobile cells exist in human blood and pus and quickly surround a splinter introduced through the skin, so he decided to experiment to see if the starfish cells would do the same. He impaled a starfish larva on a rose thorn, and the next morning he found the thorn crawling with cells that seemed to be trying to devour it. He later saw similar cells devouring and digesting infectious yeast in tiny transparent crustaceans called water fleas. He coined the word *phagocytosis* for this reaction and termed the wandering cells *phagocytes*—terms we still use today.

Metchnikoff showed that animals from simple sea anemones and starfish to humans actively defend themselves against disease agents. His observations marked the founding of cellular and comparative immunology, and won him the scientific respect he had so long coveted. Indeed, he shared the 1908 Nobel Prize for Physiology or Medicine with Paul Ehrlich, who had developed the theory of humoral immunity, a process also discussed in this chapter.

This chapter focuses largely on the *immune system*, which is not an organ system but rather a population of cells that inhabit all of our organs and defend the body from agents of disease. But immune cells are especially concentrated in a true organ system, the *lymphatic system*. This is a network of organs and veinlike vessels that recover tissue fluid, inspect it for disease agents, activate immune responses, and return the fluid to the bloodstream. It is with the lymphatic system that we will begin this chapter's exploration.

21.1 The Lymphatic System

Objectives

When you have completed this section, you should be able to

- list the functions of the lymphatic system;
- explain how lymph is formed and returned to the bloodstream;
- name the major types of cells in the lymphatic system and state their functions;
- name and describe the types of lymphatic tissue; and
- describe the form and function of red bone marrow, thymus, lymph nodes, tonsils, and spleen.

The **lymphatic system** (fig. 21.1) is composed of a network of vessels that penetrate nearly every tissue of the body, and a collection of tissues and organs that produce immune cells. It has three functions:

1. **Fluid recovery.** Fluid continually filters from the blood capillaries into the tissue spaces. The blood capillaries reabsorb about 85% of it, but the 15% that they do not absorb would amount, over the course of a day, to 2 to 4 L of water and one-quarter to one-half of the plasma protein. One would die of circulatory failure within hours if this water and protein were not returned to the bloodstream. One task of the lymphatic system is to reabsorb this excess and return it to the blood. Even partial interference with lymphatic drainage can lead to severe edema and sometimes even more grotesque consequences (fig. 21.2).
2. **Immunity.** As the lymphatic system recovers excess tissue fluid, it also picks up foreign cells and chemicals from the tissues. On its way back to the bloodstream, the fluid passes through lymph nodes, where immune cells stand guard against foreign matter. When they detect anything potentially harmful, they activate a protective immune response.
3. **Lipid absorption.** In the small intestine, special lymphatic vessels called *lacteals* absorb dietary lipids that are not absorbed by the blood capillaries (see p. 993).

The components of the lymphatic system are (1) *lymph*, the recovered fluid; (2) *lymphatic vessels*, which transport the lymph; (3) *lymphatic tissue*, composed of aggregates of lymphocytes and macrophages that populate many organs of the body; and (4) *lymphatic organs*, in which these cells are especially concentrated and which are set off from surrounding organs by connective tissue capsules.

FIGURE 21.1 The Lymphatic System.

FIGURE 21.2 Elephantiasis, a Tropical Disease Caused by Lymphatic Obstruction. Mosquito-borne roundworms infect the lymph nodes and block the flow of lymph and recovery of tissue fluid. The resulting chronic edema leads to fibrosis and elephant-like thickening of the skin. The extremities are typically affected as shown here; the scrotum of men and breasts of women are often similarly affected.

Lymph and the Lymphatic Vessels

Lymph is usually a clear, colorless fluid, similar to blood plasma but low in protein. It originates as tissue fluid that has been taken up by the lymphatic vessels. Its composition varies substantially from place to place. After a meal, for example, lymph draining from the small intestine has a milky appearance because of its lipid content. Lymph leaving the lymph nodes contains a large number of lymphocytes—indeed, this is the main supply of lymphocytes to the bloodstream. Lymph may also contain macrophages, hormones, bacteria, viruses, cellular debris, or even traveling cancer cells.

Lymphatic Vessels

Lymph flows through a system of **lymphatic vessels (lymphatics)** similar to blood vessels. These begin with microscopic **lymphatic capillaries (terminal lymphatics)**, which penetrate nearly every tissue of the body but are absent from the central nervous system, cartilage, cornea, bone, and

(a)

(b)

FIGURE 21.3 Lymphatic Capillaries. (a) Relationship of the lymphatic capillaries to a bed of blood capillaries. (b) Uptake of tissue fluid by a lymphatic capillary.

Why can metastasizing cancer cells get into the lymphatic system more easily than they can enter the bloodstream?

bone marrow. They are closely associated with blood capillaries, but unlike them, they are closed at one end (fig. 21.3). A lymphatic capillary consists of a sac of thin endothelial cells that loosely overlap each other like the shingles of a roof. The cells are tethered to surrounding tissue by protein filaments that prevent the sac from collapsing.

Unlike the endothelial cells of blood capillaries, lymphatic endothelial cells are not joined by tight junctions, nor do they have a continuous basal lamina; indeed, the gaps between them are so large that bacteria, lymphocytes, and other cells and particles can enter along with the tissue

fluid. Thus, the composition of lymph arriving at a lymph node is like a report on the state of the upstream tissues.

The overlapping edges of the endothelial cells act as valvelike flaps that can open and close. When tissue fluid pressure is high, it pushes the flaps inward (open) and fluid flows into the capillary. When pressure is higher in the lymphatic capillary than in the tissue fluid, the flaps are pressed outward (closed).

Think About It

Contrast the structure of a lymphatic capillary with that of a continuous blood capillary. Explain why their structural difference is related to their functional difference.

Lymphatic vessels form in the embryo by budding from the veins, so it is not surprising that the larger ones have a similar histology. They have a *tunica interna* with

an endothelium and valves (fig. 21.4), a *tunica media* with elastic fibers and smooth muscle, and a thin outer *tunica externa*. Their walls are thinner and their valves are closer together than those of the veins.

As the lymphatic vessels converge along their path, they become larger and larger vessels with changing names. The route from the tissue fluid back to the bloodstream is: lymphatic capillaries → collecting vessels → six lymphatic trunks → two collecting ducts → subclavian veins. Thus, there is a continual recycling of fluid from blood to tissue fluid to lymph and back to the blood (fig. 21.5).

The lymphatic capillaries converge to form **collecting vessels**. These often travel alongside veins and arteries and share a common connective tissue sheath with them. At irregular intervals, they empty into lymph nodes. The

FIGURE 21.4 Valves in the Lymphatic Vessels. (a) Photograph of a lymphatic valve. (b) Operation of the valves to ensure a one-way flow of lymph.

❏ What would be the consequence if these valves did not exist?

FIGURE 21.5 Fluid Exchange Between the Circulatory and Lymphatic Systems. Blood capillaries lose fluid to the tissue spaces. The lymphatic system picks up excess tissue fluid and returns it to the bloodstream.

❏ Identify two benefits in having lymphatic capillaries pick up tissue fluid that is not reclaimed by the blood capillaries.

lymph trickles slowly through each node, where bacteria are phagocytized and immune cells monitor the fluid for foreign antigens. It leaves the other side of the node through another collecting vessel, traveling on and often encountering additional lymph nodes before it finally returns to the bloodstream.

Eventually, the collecting vessels converge to form larger **lymphatic trunks**, each of which drains a major portion of the body. There are six lymphatic trunks, whose names indicate their locations and parts of the body they drain: the *jugular*, *subclavian*, *bronchomediastinal*, *intercostal*, *intestinal*, and *lumbar trunks*. The lumbar trunk drains not only the lumbar region but also the lower limbs.

The lymphatic trunks converge to form two **collecting ducts**, the largest of the lymphatic vessels (fig. 21.6):

1. The **right lymphatic duct** is formed by the convergence of the right jugular, subclavian, and bronchomediastinal trunks in the right thoracic cavity. It receives lymphatic drainage from the right arm and right side of the thorax and head and empties into the right subclavian vein.
2. The **thoracic duct**, on the left, is larger and longer. It begins just below the diaphragm anterior to the vertebral column at the level of the second lumbar vertebra. Here, the two lumbar trunks and the intestinal trunk join and form a prominent sac called the **cisterna chyli** (sis-TUR-nuh KY-lye), named for the large amount of *chyle* (fatty intestinal lymph) that it collects after a meal. The thoracic duct then passes through the diaphragm with the aorta and ascends the mediastinum, adjacent to the vertebral column. As it passes through the thorax, it receives additional lymph from the left bronchomediastinal, left subclavian, and left jugular trunks, then empties into the left subclavian vein. Collectively, this duct therefore drains all of the body below the diaphragm, and the left upper limb and left side of the head, neck, and thorax.

Flow of Lymph

Lymph flows under forces similar to those that govern venous return, except that the lymphatic system has no pump like the heart, and lymph flows at even lower pressure and speed than venous blood. The primary mechanism of flow is rhythmic contractions of the lymphatic vessels themselves, which contract when the fluid stretches them. The valves of lymphatic vessels, like those of veins, prevent the fluid from flowing backward. Lymph flow is also produced by skeletal muscles squeezing the lymphatic vessels, like the skeletal muscle pump that moves venous blood. Since lymphatic vessels are often wrapped with an artery in a common connective tissue sheath, arterial pulsation may also rhythmically squeeze the lymphatic vessels and contribute to lymph flow. A thoracic (respiratory) pump

promotes the flow of lymph from the abdominal to the thoracic cavity as one inhales, just as it does in venous return. Finally, at the point where the collecting ducts empty into the subclavian veins, the rapidly flowing bloodstream draws the lymph into it. Considering these mechanisms of lymph flow, it should be apparent that physical exercise significantly increases the rate of lymphatic return.

Think About It

Why does it make more functional sense for the collecting ducts to connect to the subclavian veins than it would for them to connect to the subclavian arteries?

Lymphatic Cells

Another component of the lymphatic system is the lymphatic tissues, which range from the loosely scattered cells in the mucous membranes of the respiratory, digestive, urinary, and reproductive tracts, to compact cell populations encapsulated in lymphatic organs. These tissues are composed of a variety of lymphocytes and other cells with various roles in defense and immunity:

1. **Natural killer (NK) cells** are large lymphocytes that attack and destroy bacteria, transplanted tissue cells, and *host cells* (cells of one's own body) that have either become infected with viruses or turned cancerous. They are responsible for a mode of defense, discussed later, called *immune surveillance*.
2. **T lymphocytes (T cells)** are lymphocytes that mature in the thymus and later depend on thymic hormones; the *T* stands for *thymus-dependent*. There are several subclasses of T cells that will be introduced later.
3. **B lymphocytes (B cells)** are lymphocytes that differentiate into *plasma cells*—connective tissue cells that secrete the antibodies of the immune system. They are named for an organ in chickens (the *bursa of Fabricius*¹) in which they were first discovered. However, you may find it more helpful to think of *B* for *bone marrow*, the site where these cells mature in humans.
4. **Macrophages** are very large, avidly phagocytotic cells of the connective tissues. They develop from monocytes that have emigrated from the bloodstream. They phagocytize tissue debris, dead neutrophils, bacteria, and other foreign matter (fig. 21.7). They also process foreign matter and display antigenic fragments of it to certain T cells, thus alerting the immune system to the presence of an enemy. Macrophages and other cells that do this are collectively called *antigen-presenting cells (APCs)*.

(b) Lymphatic drainage of the right mammary and axillary regions. (c) Regions of the body drained by the right lymphatic duct and thoracic duct.

❖ Why are the axillary lymph nodes often biopsied in cases of suspected breast cancer?

5. **Dendritic cells** are branched, mobile APCs found in the epidermis, mucous membranes, and lymphatic organs. (In the skin, they are often called *Langerhans² cells*.) They play an important role in

alerting the immune system to pathogens that have breached the body surfaces. They engulf foreign matter by receptor-mediated endocytosis rather than phagocytosis, but otherwise function like macrophages and are included in the *macrophage system*.

²Theodor Langerhans (1839–1915), German pathologist

FIGURE 21.7 Macrophages Phagocytizing Bacteria. Filamentous pseudopods of the macrophages snare the rod-shaped bacteria and draw them to the cell surface, where they are phagocytized.

6. **Reticular cells** are branched stationary cells that contribute to the stroma (connective tissue framework) of the lymphatic organs and act as APCs in the thymus (see fig. 21.10). (They should not be confused with reticular *fibers*, which are fine, branched collagen fibers common in lymphatic organs.)

Lymphatic Tissues

Lymphatic (lymphoid) tissues are aggregations of lymphocytes in the connective tissues of mucous membranes and various organs. The simplest form is **diffuse lymphatic tissue**, in which the lymphocytes are scattered rather than densely clustered. It is particularly prevalent in body passages that are open to the exterior—the respiratory, digestive, urinary, and reproductive tracts—where it is called **mucosa-associated lymphatic tissue (MALT)**. (In the respiratory and digestive tracts, it is sometimes called bronchus-associated and gut-associated lymphatic tissue, BALT and GALT, respectively.)

In some places, lymphocytes and macrophages congregate in dense masses called **lymphatic nodules (follicles)** (fig. 21.8), which come and go as pathogens invade the tissues and the immune system answers the challenge. Abundant lymphatic nodules are, however, a relatively constant feature of the lymph nodes (see fig. 21.12), tonsils, and appendix. In the ileum, the distal portion of the small intestine, they form clusters called **Peyer³ patches**.

Lymphatic Organs

In contrast to the diffuse lymphatic tissue, **lymphatic (lymphoid) organs** have well-defined anatomical sites and at least partial connective tissue capsules that separate the

FIGURE 21.8 Lymphatic Nodule in the Mucosa of the Small Intestine. This nodule is part of the mucosa-associated lymphatic tissue (MALT).

lymphatic tissue from neighboring tissues. These organs include the red bone marrow, thymus, lymph nodes, tonsils, and spleen. The red bone marrow and thymus are regarded as *primary lymphatic organs* because they are the sites where B and T lymphocytes, respectively, become *immunocompetent*—that is, able to recognize and respond to antigens. The lymph nodes, tonsils, and spleen are called *secondary lymphatic organs* because they are populated with immunocompetent lymphocytes only after the cells have matured in the primary lymphatic organs.

Red Bone Marrow

As discussed in chapter 7, there are two kinds of bone marrow: red and yellow. Red bone marrow is involved in hemopoiesis (blood formation) and immunity; the fatty yellow bone marrow can be disregarded for our present purposes. In children, red bone marrow occupies the medullary spaces of nearly the entire skeleton. In adults, it is limited to parts of the axial skeleton and the proximal heads of the humerus and femur. Red bone marrow is an important supplier of lymphocytes to the immune system. Its role in the life history of lymphocytes is described later.

Red bone marrow is a soft, loosely organized, highly vascular material, separated from osseous tissue by the endosteum of the bone. It produces all classes of formed elements of the blood; its red color comes from the abundance of erythrocytes. Numerous small arteries enter *nutrient foramina* on the bone surface, penetrate the bone, and empty into large *sinusoids* (45 to 80 μm wide) in the marrow (fig. 21.9). The sinusoids drain into a *central longitudinal vein* that exits the bone via the same route that the arteries entered. The sinusoids are lined by endothelial cells, like other blood vessels, and are surrounded by reticular cells and reticular fibers. The reticular cells secrete colony-stimulating factors that induce the formation of various leukocyte types. In the long bones of the limbs, aging reticular cells accumulate fat and transform into adipose cells, eventually replacing red bone marrow with yellow bone marrow.

³Johann Conrad Peyer (1653–1712), Swiss anatomist

FIGURE 21.9 Histology of the Red Bone Marrow. The formed elements of blood squeeze through the endothelial cells into the sinuses, which converge on a central longitudinal vein at the lower left.

The spaces between the sinusoids are occupied by *islands (cords)* of hemopoietic cells, composed of macrophages and blood cells in all stages of development. The macrophages destroy malformed blood cells and the nuclei discarded by developing erythrocytes. As blood cells mature, they push their way through the reticular and endothelial cells to enter the sinus and flow away in the bloodstream.

Thymus

The **thymus** is a member of the endocrine, lymphatic, and immune systems. It houses developing lymphocytes and secretes hormones that regulate their later activity. It is a bilobed organ located between the sternum and aortic arch in the superior mediastinum. The thymus shows a remarkable degree of degeneration (involution) with age, as described and illustrated earlier (fig. 17.8, p. 650).

The fibrous capsule of the thymus gives off trabeculae (septa) that divide the gland into several angular lobules. Each lobule has a dense, dark-staining *cortex* and a lighter *medulla* populated by T lymphocytes (fig. 21.10). **Reticular epithelial cells** seal off the cortex from the medulla and surround blood vessels and lymphocyte clusters in the

cortex. They thereby form a *blood–thymus barrier* that isolates developing lymphocytes from blood-borne antigens. After developing in the cortex, the T cells migrate to the medulla, where they spend another 3 weeks. There is no blood–thymus barrier in the medulla; mature T cells enter blood or lymphatic vessels here and leave the thymus. In the medulla, the reticular epithelial cells form whorls called *thymic (Hassall⁴) corpuscles*, useful for identifying the thymus histologically.

Besides forming the blood–thymus barrier, reticular epithelial cells produce several signaling molecules that promote the development and action of T cells, including *thymosin*, *thymopoietin*, *thymulin*, *interleukins*, and *interferon*. If the thymus is removed from newborn mammals, they waste away and never develop immunity. Other lymphatic organs also seem to depend on thymosins or T cells and develop poorly in thymectomized animals. The role of the thymus in T cell development is discussed later.

Lymph Nodes

Lymph nodes (fig. 21.11) are the most numerous lymphatic organs, numbering about 450 in a typical young adult. They serve two functions: to cleanse the lymph and to act as a site of T and B cell activation. A lymph node is an elongated or bean-shaped structure, usually less than 3 cm long, often with an indentation called the *hilum* on one side (fig. 21.12). It is enclosed in a fibrous capsule with trabeculae that partially divide the interior of the node into compartments. Between the capsule and parenchyma is a narrow, relatively clear space called the *subcapsular sinus*, which contains reticular fibers, macrophages, and dendritic cells. Deep to this, the gland consists mainly of a stroma of reticular connective tissue (reticular fibers and reticular cells) and a parenchyma of lymphocytes and antigen-presenting cells.

The parenchyma is divided into an outer C-shaped **cortex** that encircles about four-fifths of the organ, and an inner **medulla** that extends to the surface at the hilum. The cortex consists mainly of ovoid to conical lymphatic nodules. When the lymph node is fighting a pathogen, these nodules acquire light-staining **germinal centers** where B cells multiply and differentiate into plasma cells. The medulla consists largely of a branching network of *medullary cords* composed of lymphocytes, plasma cells, macrophages, reticular cells, and reticular fibers. The cortex and medulla also contain lymph-filled sinuses continuous with the subcapsular sinus.

Several **afferent lymphatic vessels** lead into the node along its convex surface. Lymph flows from these vessels into the subcapsular sinus, percolates slowly through the sinuses of the cortex and medulla, and

⁴Arthur H. Hassall (1817–94), British chemist and physician

FIGURE 21.10 The Thymus. (a) Gross anatomy. (b) Histology. (c) Cellular architecture of a lobule. The reticular epithelial cells are interconnected to form a blood-thymus barrier.

leaves the node through one to three **efferent lymphatic vessels** that emerge from the hilum. No other lymphatic organs have afferent lymphatic vessels; lymph nodes are the only organs that filter lymph as it flows along its course. The lymph node is a bottleneck that slows down lymph flow and allows time for cleansing it of foreign matter. The macrophages and reticular cells of the sinuses remove about 99% of the impurities before the lymph leaves the node. On its way to the bloodstream, lymph flows through one lymph node after another and thus becomes quite thoroughly cleansed of most impurities.

Blood vessels also penetrate the hilum of a lymph node. Arteries follow the medullary cords and give rise to capillary beds in the medulla and cortex. In the *deep cortex* near the junction with the medulla, lymphocytes can emigrate from the bloodstream into the parenchyma of the node. Most lymphocytes in the deep cortex are T cells.

Lymph nodes are widespread but especially concentrated in the following locations (see fig. 21.1):

- *Cervical lymph nodes* occur in deep and superficial groups in the neck, and monitor lymph coming from the head and neck.

(a)

(b)

FIGURE 21.11 Some Areas of Lymph Node Concentration. (a) Mesenteric lymph nodes associated with the large intestine. (b) Inguinal lymph nodes in a female cadaver.

- *Axillary lymph nodes* are concentrated in the armpit (axilla) and receive lymph from the upper limb and the female breast (fig. 21.6b).
- *Thoracic lymph nodes* occur in the thoracic cavity, especially embedded in the mediastinum, and receive lymph from the mediastinum, lungs, and airway.
- *Abdominal lymph nodes* occur in the posterior abdominopelvic wall and monitor lymph from the urinary and reproductive systems.

FIGURE 21.12 Anatomy of a Lymph Node. (a) Partially bisected lymph node showing pathway of lymph flow. (b) Detail of the boxed region in part (a). (c) Reticular fiber stroma and immune cells in a medullary sinus (SEM).

- *Intestinal* and *mesenteric lymph nodes* are found in the mesenteries (fig. 21.11a) and adjacent to the appendix and intestines; they monitor lymph from the digestive tract.
- *Inguinal lymph nodes* occur in the groin (fig. 21.11b) and receive lymph from the entire lower limb.
- *Popliteal lymph nodes* occur at the back of the knee and receive lymph from the leg proper.

When a lymph node is under challenge from a foreign antigen, it may become swollen and painful to the touch—a condition called **lymphadenitis**⁵ (lim-FAD-en-EYE-tis). Physicians routinely palpate the accessible lymph nodes of the cervical, axillary, and inguinal regions for swelling. The collective term for all lymph node diseases is **lymphadenopathy**⁶ (lim-FAD-eh-NOP-a-thee). Lymph nodes are common sites of metastatic cancer (see Insight 21.1).

⁵lymph = water + adeno = gland + itis = inflammation
⁶lymph = water + adeno = gland + pathy = disease

INSIGHT 21.1 Clinical Application

Lymph Nodes and Metastatic Cancer

Metastasis is a phenomenon in which cancerous cells break free of the original *primary tumor*, travel to other sites in the body, and establish new tumors. Because of the high permeability of lymphatic capillaries, metastasizing cancer cells easily enter them and travel in the lymph. They tend to lodge in the first lymph node they encounter and multiply there, eventually destroying the node. Cancerous lymph nodes are swollen but relatively firm and usually painless. Cancer of a lymph node is called *lymphoma*.

Once a tumor is well established in one node, cells may emigrate from there and travel to the next. However, if the metastasis is detected early enough, cancer can sometimes be eradicated by removing not only the primary tumor, but also the nearest lymph nodes downstream from that point. For example, breast cancer is often treated with a combination of lumpectomy or mastectomy along with removal of the nearby axillary lymph nodes.

Tonsils

The **tonsils** are patches of lymphatic tissue located at the entrance to the pharynx, where they guard against ingested and inhaled pathogens. Each is covered by an

epithelium and has deep pits called **tonsillar crypts** lined by lymphatic nodules (fig. 21.13). The crypts often contain food debris, dead leukocytes, bacteria, and antigenic chemicals. Below the crypts, the tonsils are partially separated from underlying connective tissue by an incomplete fibrous capsule.

There are three main sets of tonsils: (1) a single median **pharyngeal tonsil (adenoids)** on the wall of the pharynx just behind the nasal cavity; (2) a pair of **palatine tonsils** at the posterior margin of the oral cavity; and (3) numerous **lingual tonsils**, each with a single crypt, concentrated in a patch on each side of the root of the tongue (see fig. 25.5a, p. 971).

The palatine tonsils are the largest and most often infected. *Tonsillitis* is an acute inflammation of the palatine tonsils, usually caused by a *Streptococcus* infection. Their surgical removal, called *tonsillectomy*, used to be one of the most common surgical procedures performed on children, but it is done less often today. Tonsillitis is now usually treated with antibiotics.

Spleen

The **spleen** is the body's largest lymphatic organ, measuring up to 12 cm long and weighing up to 160 g. It is located in the left hypochondriac region, just inferior to the diaphragm and posterolateral to the stomach (fig. 21.14; see also fig. A.15, p. 43). It is protected by ribs 10 through 12.

FIGURE 21.13 The Tonsils. (a) Locations of the tonsils. (b) Histology of the palatine tonsil.

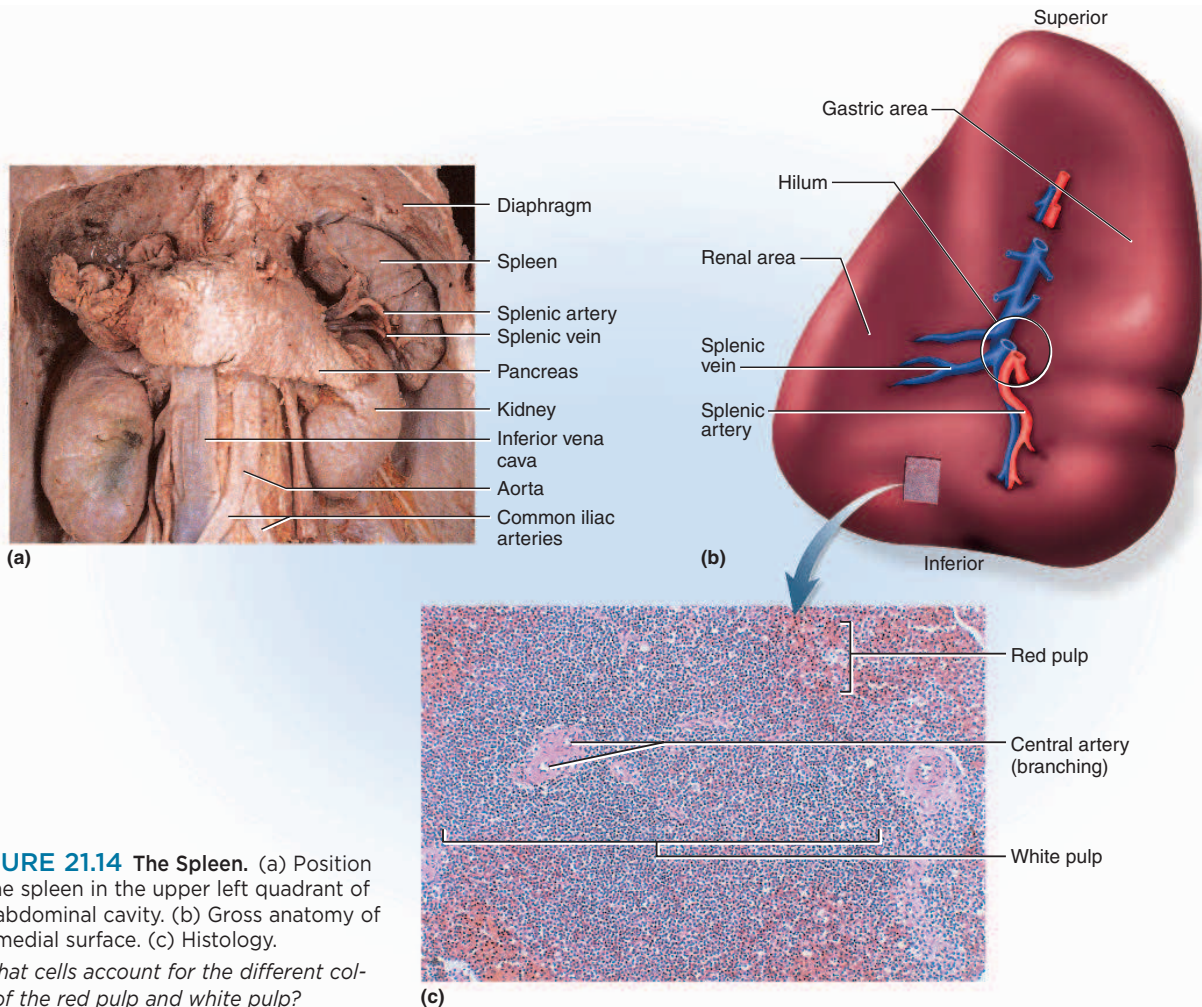

FIGURE 21.14 The Spleen. (a) Position of the spleen in the upper left quadrant of the abdominal cavity. (b) Gross anatomy of the medial surface. (c) Histology.

● What cells account for the different colors of the red pulp and white pulp?

The spleen fits snugly between the diaphragm, stomach, and kidney and has indentations called the *gastric area* and *renal area* where it presses against these adjacent viscera. It has a medial hilum penetrated by the splenic artery, splenic vein, and lymphatic vessels.

The parenchyma exhibits two types of tissue named for their appearance in fresh specimens (not in stained sections): **red pulp**, which consists of sinuses gorged with concentrated erythrocytes; and **white pulp**, which consists of lymphocytes and macrophages aggregated like sleeves along small branches of the splenic artery. In tissue sections, white pulp appears as an ovoid mass of lymphocytes with an arteriole passing through it. However, it is important to bear in mind that the three-dimensional shape is not egglike but cylindrical.

These two tissue types reflect the multiple functions of the spleen. It produces blood cells in the fetus and may resume this role in adults in the event of extreme anemia.

Lymphocytes and macrophages of the white pulp monitor the blood for foreign antigens, much like the lymph nodes do the lymph. The splenic blood capillaries are very permeable; they allow RBCs to leave the bloodstream, accumulate in the sinuses of the red pulp, and reenter the bloodstream later. The spleen is an “erythrocyte graveyard”—old, fragile RBCs rupture as they squeeze through the capillary walls into the sinuses. Macrophages phagocytize their remains, just as they dispose of blood-borne bacteria and other cellular debris. The spleen also helps to stabilize blood volume by transferring excess plasma from the bloodstream into the lymphatic system.

The spleen is highly vascular and vulnerable to trauma and infection. A ruptured spleen can hemorrhage fatally, but is difficult to repair surgically. Therefore a common procedure in such cases is its removal, *splenectomy*. A person can live without a spleen, but is somewhat more vulnerable to infections.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. List the primary functions of the lymphatic system. What do you think would be the most noticeable effect of clamping the right lymphatic duct closed?
2. How does fluid get into the lymphatic system? What prevents it from draining back out?
3. What do NK, T, and B cells have in common? How do their functions differ?
4. List five major cell types of lymphatic tissues and state the function of each.
5. Predict the relative seriousness of removing the following organs from a 2-year-old child: (a) a lymph node, (b) the spleen, (c) the thymus, (d) the palatine tonsils.

21.2 Nonspecific Resistance

Objectives

When you have completed this section, you should be able to

- identify the body's three lines of defense against pathogens;
- contrast nonspecific resistance with immunity;
- describe the defensive functions of each kind of leukocyte;
- describe the role of the complement system in resistance and immunity;
- describe the process of inflammation and explain what accounts for its cardinal signs; and
- describe the body's other nonspecific defenses.

For all living organisms, one of the greatest survival challenges is coping with **pathogens**⁷—environmental agents capable of producing disease. Pathogens include infectious organisms, toxic chemicals, and radiation. The human body has three lines of defense against pathogens:

1. The **first line of defense** consists of external barriers, notably the skin and mucous membranes, which are impenetrable to most of the pathogens that daily assault us.
2. The **second line of defense** consists of several nonspecific defense mechanisms against pathogens that break through the skin or mucous membranes. These

defenses include leukocytes and macrophages, antimicrobial proteins, immune surveillance, inflammation, and fever. They are present from birth, are broadly effective against a wide range of pathogens, and work even against pathogens to which the body has never before been exposed.

3. The **third line of defense** is the immune system, which not only defeats a pathogen but leaves the body with a “memory” of it, enabling us to defeat it so quickly in future encounters that the pathogen causes no illness.

The first two mechanisms are called **nonspecific resistance** because they guard equally against a broad range of pathogens and their effectiveness does not depend on prior exposure. Immunity is called a **specific defense** because it results from prior exposure to a pathogen and usually provides future protection only against that particular one. In this section we study the mechanisms of nonspecific resistance.

External Barriers

Our first line of defense is the skin and mucous membranes, which make it mechanically difficult for microorganisms to enter the body's tissues. When the skin is broken by a scrape or animal bite or destroyed by a burn, one of the most urgent treatment concerns is the prevention of infection. This attests to the importance of intact skin as a barrier. Its surface is composed mainly of keratin, a tough protein that few pathogens can penetrate. Furthermore, the surface is hostile to microbial reproduction. With exceptions such as the axillary and pubic areas, it is too dry and poor in nutrients to support much microbial growth. The skin is also coated with antimicrobial chemicals such as defensins and lactic acid. **Defensins** are peptides that kill microbes by creating holes in their membranes; they are not limited to the epidermis, but are also produced by neutrophils and other cells. The skin is also coated with a thin film of lactic acid (the **acid mantle**) from sweat, which inhibits bacterial growth.

The digestive, respiratory, urinary, and reproductive tracts are open to the exterior, making them vulnerable to invasion, but they are protected by mucous membranes. Mucus physically ensnares microbes. Organisms trapped in the respiratory mucus are moved by cilia to the pharynx, swallowed, and destroyed by stomach acid. Microbes also are flushed from the upper digestive tract by saliva and from the lower urinary tract by urine. Mucus, tears, and saliva also contain **lysozyme**, an enzyme that destroys bacteria by dissolving their cell walls.

Beneath the epithelia of the skin and mucous membranes, there is a layer of areolar tissue. The ground substance of this tissue contains a giant glycosaminoglycan called **hyaluronic acid**, which gives it a viscous consistency.

⁷patho = disease, suffering + gen = producing

It is normally difficult for microbes to migrate through this sticky tissue gel. Some organisms overcome this obstacle, however, by producing an enzyme called *hyaluronidase*, which breaks it down to a thinner consistency that is more easily penetrated. Hyaluronidase occurs in some snake venoms and bacterial toxins and is produced by some parasitic protozoans to facilitate their invasion of the connective tissues.

Leukocytes and Macrophages

If microbes get past the physical barrier of the skin and mucous membranes, they are attacked by **phagocytes** (phagocytic cells) that have a voracious appetite for foreign matter. Leukocytes and macrophages play especially important roles in both nonspecific defense and specific immunity and, therefore, in both the second and third lines of defense.

Leukocytes

The five types of leukocytes are illustrated and described in table 18.7 (pp. 702–703). We will now examine their contributions to resistance and immunity in more detail.

1. **Neutrophils** spend most of their lives wandering in the connective tissues killing bacteria. One of their methods is simple phagocytosis and digestion. The other is a more complex process that produces a cloud of bactericidal chemicals. When a neutrophil detects bacteria in the immediate area, its lysosomes migrate to the cell surface and *degranulate*, or discharge their enzymes into the tissue fluid. Here, the enzymes catalyze a reaction called the **respiratory burst**: The neutrophil rapidly absorbs oxygen and reduces it to *superoxide anions* ($O_2^{\bullet-}$), and superoxide then reacts with H^+ to form hydrogen peroxide (H_2O_2). Another lysosomal enzyme produces hypochlorite ($HClO$), the active ingredient in chlorine bleach, from chloride ions in the tissue fluid. Superoxide, hydrogen peroxide, and hypochlorite are highly toxic; they form a chemical **killing zone** around the neutrophil that destroys far more bacteria than the neutrophil can destroy by phagocytosis alone. Unfortunately for the neutrophil, the killing zone is also deadly to it, and it dies in the course of the attack. These potent oxidizing agents can also damage connective tissues and sometimes contribute to rheumatoid arthritis.
2. **Eosinophils** are found especially in the mucous membranes, standing guard against parasites, allergens (allergy-causing antigens), and other pathogens. They become especially concentrated at sites of allergy, inflammation, or parasitic infection. They help to kill parasites such as tapeworms and roundworms by producing superoxide, hydrogen peroxide, and various toxic proteins including a neurotoxin. They promote the action of basophils and mast cells (see next paragraph). They phagocytize and degrade antigen–antibody complexes. Finally, they secrete enzymes that degrade and limit the action of histamine and other inflammatory chemicals that, unchecked, could cause tissue damage.
3. **Basophils** secrete chemicals that aid the mobility and action of other leukocytes: *leukotrienes* that activate and attract neutrophils and eosinophils; the vasodilator *histamine*, which increases blood flow and speeds the delivery of leukocytes to the area; and the anticoagulant *heparin*, which inhibits the formation of blood clots that would impede leukocyte mobility. These substances are also produced by **mast cells**, a type of connective tissue cell very similar to basophils. Eosinophils promote basophil and mast cell action by stimulating them to release these secretions.
4. **Lymphocytes** all look more or less alike in blood films, but there are several functional types. Three basic categories have already been mentioned: natural killer (NK) cells, T cells, and B cells. In the circulating blood, about 80% of the lymphocytes are T cells, 15% B cells, and 5% NK and stem cells. The roles of these lymphocyte types are too diverse for easy generalizations here, but are described in later sections on immune surveillance and specific immunity.
5. **Monocytes** are leukocytes that emigrate from the blood into the connective tissues and transform into macrophages. All of the body's avidly phagocytotic cells except leukocytes are called the **macrophage system**. Dendritic cells are included in this system even though they come from different stem cells than macrophages and employ receptor-mediated endocytosis instead of phagocytosis to internalize foreign matter. Some phagocytes are wandering cells that actively seek pathogens, whereas reticular cells and others are fixed in place and phagocytize only those pathogens that come to them—although they are strategically positioned for this to occur. Macrophages are widely distributed in the loose connective tissues (where they are sometimes called *histiocytes*), but there are also specialized forms with more specific localities:
 - **microglia** in the central nervous system (see p. 448);
 - **alveolar macrophages** in the lungs (see p. 874); and
 - **hepatic macrophages** in the liver (see p. 987).

Antimicrobial Proteins

Multiple types of proteins inhibit microbial reproduction and provide short-term, nonspecific resistance to pathogenic bacteria and viruses. Two families of antimicrobial proteins are described here—*interferons* and the *complement system*—and others are described in the ensuing discussion of immune surveillance.

Interferons

When certain cells (especially leukocytes) are infected with viruses, they secrete proteins called **interferons**. These are of no benefit to the cell that secretes them, but are like its “dying words” that alert neighboring cells and protect them from becoming infected. Interferons bind to surface receptors on those cells and activate second-messenger systems within. The alerted cell then synthesizes various proteins that defend it from infection by such means as breaking down viral genes or preventing their replication. Interferons also activate NK cells and macrophages, which destroy infected cells before they can liberate a swarm of newly replicated viruses. Interferons confer resistance not only to viruses but also to cancer, as the activated NK cells destroy malignant cells.

Complement System

The **complement system** is a group of 30 or more globulins that make powerful contributions to both nonspecific resistance and specific immunity. Immunology pioneer Paul Ehrlich (1854–1915) named it *complement* because it “completes the action of antibody,” and indeed this is the principal means of pathogen destruction in antibody-mediated immunity. Since Ehrlich’s time, however, the complement system has also been found important in nonspecific defense.

Complement proteins are synthesized mainly by the liver. They circulate in the blood in inactive form and are activated in the presence of pathogens. In their inactive form, the proteins are named with the letter *C* and a number, such as C3. Activation splits them into fragments, which are further identified by lowercase letters (C3a and C3b, for example).

Activated complement brings about four methods of pathogen destruction: inflammation, immune clearance, phagocytosis, and cytolysis. We will examine the pathways of complement activation with a view to understanding how each of these goals is achieved. There are three such routes (fig. 21.15): the classical, alternative, and lectin pathways.

The **classical pathway** requires an antibody molecule to get it started; thus it is part of specific immunity. The antibody binds to an antigen on the surface of a pathogenic organism, forming an antigen–antibody (Ag–Ab)

complex. This changes the antibody’s shape, exposing a pair of *complement-binding sites* (see fig. 21.27a). Binding of the first complement (C1) to these sites sets off a reaction cascade. Like the cascade of blood-clotting reactions, each step generates an enzyme that catalyzes the production of many more molecules at the next step; each step is an amplifying process, so many molecules of product result from a small beginning. In the classical pathway, the cascade is called **complement fixation**, since it results in the attachment of a chain of complement proteins to the antibody.

The alternative and lectin pathways require no antibodies and thus belong to our nonspecific defenses. Complement C3 slowly and spontaneously breaks down in the blood into C3a and C3b. In the **alternative pathway**, C3b binds directly to targets such as human tumor cells, viruses, bacteria, and yeasts. This, too, triggers a reaction cascade—this time with an *autocatalytic effect* in which C3b eventually leads to the accelerated splitting of more C3 and production of even more C3b.

Lectins are plasma proteins that bind to carbohydrates. In the **lectin pathway**, a lectin binds to certain sugars of a microbial cell surface and sets off yet another reaction cascade leading to C3b production.

As we can see (fig. 21.15), the splitting of C3 into C3a and C3b is an intersection where all three pathways converge. These two C3 fragments then produce, directly or indirectly, the end results of the complement system:

1. **Inflammation.** C3a stimulates mast cells and basophils to secrete histamine and other inflammatory chemicals. It also activates and attracts neutrophils and macrophages, the two key cellular agents of pathogen destruction in inflammation. The exact roles of these chemicals and cells are explained in the section on inflammation to follow.
2. **Immune clearance.** C3b binds Ag–Ab complexes to red blood cells. As these RBCs circulate through the liver and spleen, the macrophages of those organs strip off and destroy the Ag–Ab complexes, leaving the RBCs unharmed. This is the principal means of clearing foreign antigens from the bloodstream.
3. **Phagocytosis.** Bacteria, viruses, and other pathogens are phagocytized and digested by neutrophils and macrophages. However, those phagocytes cannot easily internalize “naked” microorganisms. C3b assists them by the process of **opsonization**:⁸ it coats microbial cells and serves as binding sites for phagocyte attachment. The way Elie Metchnikoff described this, opsonization “butters up” the foreign cells to make them more appetizing.

⁸*opson* = to prepare food

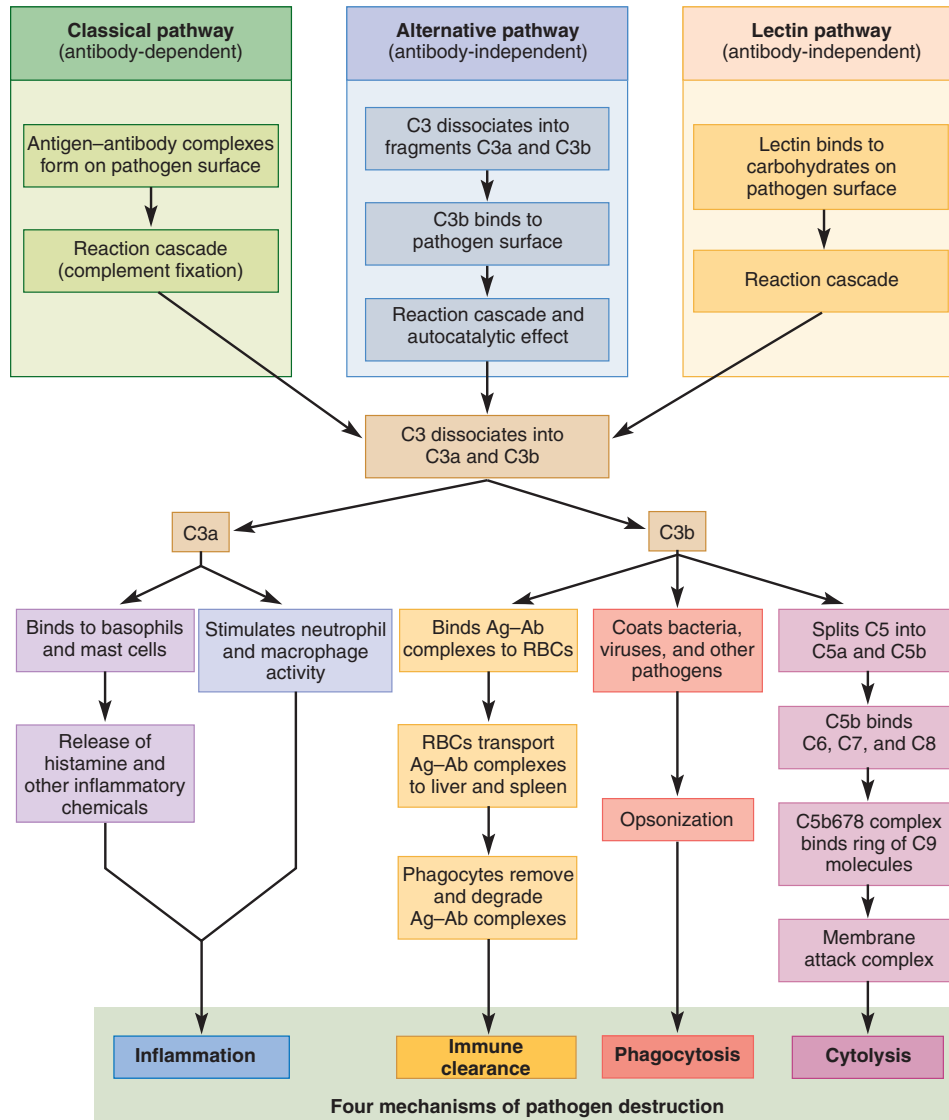

FIGURE 21.15 Complement Activation. The classical, alternative, and lectin pathways all lead to the cleavage of complement C3 into C3a and C3b. Those two fragments activate processes that lead to enhanced inflammation, immune clearance, phagocytosis, and cytolysis.

4. **Cytolysis.**⁹ C3b splits another complement protein, C5, into C5a and C5b. C5a joins C3a in its proinflammatory actions, but C5b plays a more important role in pathogen destruction. It binds to the enemy cell and then attracts complements C6, C7, and C8. This conglomeration of proteins (now called C5b678) goes on to bind up to 17 molecules of complement C9, which form a ring called the *membrane attack complex* (fig. 21.16). The complex forms a hole in

the target cell up to 10 nm wide. The cell can no longer maintain homeostasis; electrolytes leak out, water flows rapidly in, and the cell ruptures.

Immune Surveillance

Immune surveillance is a phenomenon in which natural killer (NK) cells continually patrol the body “on the lookout” for pathogens or diseased host cells. They attack and destroy bacteria, cells of transplanted organs and tissues, cells infected with viruses, and cancer cells.

⁹cyto = cell + lysis = split apart, break down

Upon recognition of an enemy cell, the NK cell binds to it and releases proteins called **perforins**, which polymerize in a ring and create a hole in its plasma membrane (fig. 21.17). The hole allows a rapid flow of water and salts into the enemy cell, which may kill it but is not very effective alone. The NK cell also secretes a group of protein-degrading enzymes called **granzymes**, which enter the pore made by the perforins. Inside the enemy cell, the granzymes destroy cellular enzymes and induce apoptosis (programmed cell death).

FIGURE 21.16 The Membrane Attack Complex. Complement proteins C5b, C6, C7, and C8 form an organizing center around which many C9 molecules create a ring that opens a lethal hole in the enemy cell membrane.

◀ In what way does the action of the membrane attack complex resemble the action of perforin?

Fever

Fever is an abnormal elevation of body temperature. It is also known as **pyrexia**, and the term **febrile** means pertaining to fever (as in a “febrile attack”). Fever results from trauma, infections, drug reactions, brain tumors, and several other causes. Because of variations in human body temperature, there is no exact criterion for what constitutes a fever—a temperature that is febrile for one person may be normal for another.

Fever was long regarded as an undesirable side effect of illness, and efforts were (and still are) made to reduce it for the sake of comfort. It is now recognized, however, as an adaptive defense mechanism that, in moderation, does more good than harm. People with colds, for example, recover more quickly and are less infective to others when they allow a fever to run its course rather than using **antipyretic** (fever-reducing) medications such as aspirin. Fever is beneficial in that it (1) promotes interferon activity, (2) elevates metabolic rate and accelerates tissue repair, and (3) inhibits reproduction of bacteria and viruses.

Fever is typically initiated by **exogenous pyrogens**¹⁰ (fever-producing agents) such as the surface glycolipids of bacteria and viruses. As neutrophils and macrophages attack such pathogens, they secrete a variety of chemicals—interleukins, interferons, and others—that act as **endogenous pyrogens**.¹¹ These chemicals stimulate neurons in the anterior hypothalamus to secrete prostaglandin E₂ (PGE₂). PGE₂, in turn, raises the hypothalamic set point for body temperature—say, to 39°C (102°F) instead

¹⁰exo = from outside + genous = arising + pyro = fire, heat + gen = producing

¹¹endo = from within + genous = arising

FIGURE 21.17 The Action of a Natural Killer Cell.

FIGURE 21.18 The Course of a Fever.

of the usual 37°C (fig. 21.18). Aspirin and ibuprofen reduce fever by inhibiting prostaglandin synthesis, but in some circumstances, using aspirin to control fever can have deadly consequences (see Insight 21.2).

When the set point rises, a person shivers to generate heat and the cutaneous blood vessels constrict to reduce heat loss. In the stage of fever called *onset*, one has chills, feels cold and clammy to the touch, and has a rising temperature. In the next stage, *stadium*, the body temperature oscillates around the new set point for as long as the pathogen is present. The elevated temperature stimulates the liver and spleen to hoard zinc and iron, depriving bacteria of minerals they need to reproduce.

When the infection is defeated, pyrogen secretion ceases and the hypothalamic thermostat is set back to normal. This activates heat-losing mechanisms, especially

cutaneous vasodilation and sweating. The skin is warm and flushed during this phase. The phase of falling temperature is called *defervescence* in general, *crisis (flush)* if the temperature drops abruptly, or *lysis* if it falls slowly.

Even though most fevers are beneficial, excessively high temperature can be dangerous because it speeds up different enzymatic pathways to different degrees, thus causing metabolic discoordination and cellular dysfunction. Fevers above 40.5°C (105°F) can make a person delirious. Convulsions and coma ensue at higher temperatures, and death or irreversible brain damage commonly results from fevers that range from 44° to 46°C (111° to 115°F).

Inflammation

Inflammation is a local defensive response to tissue injury of any kind, including trauma and infection. Its general purposes are (1) to limit the spread of pathogens and ultimately destroy them, (2) to remove the debris of damaged tissue, and (3) to initiate tissue repair. Inflammation is characterized by four **cardinal signs**: redness, swelling, heat, and pain. Some authorities list impaired use as a fifth sign, but this may or may not occur and when it does, it is mostly because of the pain.

Think About It

In spite of the expression, only some of the four “cardinal signs” of inflammation are true signs and the others are symptoms. With the aid of the glossary, identify which are signs and which are symptoms.

Words ending in the suffix *-itis* denote inflammation of specific organs and tissues: *arthritis*, *encephalitis*, *peritonitis*, *gingivitis*, and *dermatitis*, for example. Inflammation can occur anywhere in the body, but it is

INSIGHT 21.2 Clinical Application

Reye Syndrome

In children younger than 15, an acute viral infection such as chickenpox or influenza is sometimes followed by a serious disorder called *Reye¹² syndrome*. First recognized in 1963, this disease is characterized by swelling of brain neurons and fatty infiltration of the liver and other viscera. Neurons die from hypoxia and the pressure of the swelling brain, which results in nausea, vomiting, disorientation, seizures, and coma. About 30% of victims die, and the survivors sometimes suffer mental retardation. Reye syndrome can be triggered by the use of aspirin to control fever; parents are now strictly advised never to give aspirin to children with chickenpox or flulike symptoms.

¹²R. Douglas Reye (1912–77), Australian pathologist

most common and observable in the skin, which is subject to more trauma than any other organ. Examples of cutaneous inflammation include an itchy mosquito bite, sunburn, a poison ivy rash, and the redness and blistering produced by manual labor, tight shoes, or a kitchen burn.

The following discussion of the process of inflammation will account for the four cardinal signs and explain how its three purposes are achieved. These processes are mediated by several types of cells and inflam-

matory chemicals that are summarized in table 21.1. Many of the chemicals that regulate inflammation and immunity are in a class called **cytokines**¹³—small proteins that are secreted mainly by leukocytes and alter the physiology or behavior of the receiving cell. Cytokines usually act at short range, either on neighboring cells or on the same cell that secretes them. These are called

¹³cyto = cell + kin = to set in motion

TABLE 21.1 Agents of Inflammation

TABLE 21.1 Agents of Inflammation	
Cellular agents	
Basophils	Secrete histamine, heparin, leukotrienes, and kinins
Endothelial cells	Produce cell-adhesion molecules to recruit leukocytes; secrete platelet-derived growth factor
Eosinophils*	Produce antiparasitic oxidizing agents and toxic proteins; stimulate basophils and mast cells; limit action of histamine and other inflammatory chemicals
Fibroblasts	Rebuild damaged tissue by secreting collagen, ground substance, and other tissue components
Helper T cells*	Secrete chemotactic factors and colony-stimulating factors
Macrophages*	Clean up tissue damage; phagocytize bacteria, tissue debris, dead and dying leukocytes and pathogens
Mast cells	Same actions as basophils
Monocytes	Emigrate into inflamed tissue and become macrophages
Neutrophils	Phagocytize bacteria; secrete bactericidal oxidizing agents; secrete cytokines that activate more leukocytes
Platelets	Secrete clotting factors and platelet-derived growth factor
Chemical agents	
Bradykinin	A kinin that stimulates vasodilation and capillary permeability, stimulates pain receptors, and is a neutrophil chemotactic factor
Chemotactic factors	Chemicals that provide a trail that neutrophils and other leukocytes can follow to specific sites of infection and tissue injury; include bradykinin, leukotrienes, and some complement proteins
Colony-stimulating factors	Hormones that raise the WBC count by stimulating leukopoiesis
Complement*	Proteins that promote phagocytosis and cytolysis of pathogens, activate and attract neutrophils and macrophages, and stimulate basophils and mast cells to secrete inflammatory chemicals
Cytokines	Small proteins produced mainly by WBCs; have autocrine, paracrine, and endocrine roles in cellular communication; act especially in inflammation and immune responses; include interleukins, interferons, colony-stimulating factors, chemotactic factors, and others
Fibrinogen	A plasma clotting protein that filters into inflamed tissue and forms fibrin, thus coagulating tissue fluid, sequestering pathogens, and forming a temporary scaffold for tissue rebuilding
Heparin	A polysaccharide secreted by basophils and mast cells that inhibits clotting of tissue fluid within the area walled off by fibrin, thus promoting free mobility of leukocytes that attack infectious microorganisms
Histamine	An amino acid derivative produced by basophils and mast cells that stimulates vasodilation and capillary permeability
Kinins	Plasma proteins that are activated by tissue injury and stimulate vasodilation, capillary permeability, pain; include bradykinin
Leukotrienes	Eicosanoids that stimulate vasodilation, capillary permeability, and neutrophil chemotaxis, especially in inflammation and allergy
Prostaglandins	Eicosanoids that stimulate pain, fever, and vasodilation; promote neutrophil diapedesis; and enhance histamine and bradykinin action
Selectins	Cell-adhesion molecules of endothelial cells that adhere to circulating leukocytes, promoting margination and diapedesis

* These agents of inflammation have additional roles in specific immunity described in table 21.4.

*paracrine*¹⁴ and *autocrine*¹⁵ effects, respectively, to distinguish them from the long-distance *endocrine* effects of hormones. Cytokines include interferons, interleukins, tumor necrosis factor, chemotactic factors, and other chemicals you will soon encounter in this discussion.

Inflammation involves three major processes: mobilization of the body's defenses, containment and destruction of pathogens, and tissue cleanup and repair.

Mobilization of Defenses

The most immediate requirement for dealing with tissue injury is to get defensive leukocytes to the site quickly. The way to do this is local **hyperemia**—increasing blood flow beyond its normal rate. This is achieved by local vasodilation.

To bring this about, certain cells secrete *vasoactive* chemicals that dilate the blood vessels. Among these are histamine, leukotrienes, and other cytokines. These are secreted by basophils of the blood; mast cells of the connective tissue; and cells damaged by the trauma, toxins, or organisms that triggered the inflammation. Hyperemia not only results in the more rapid delivery of leukocytes, but also washes toxins and metabolic wastes from the tissue more rapidly.

In addition to dilating local blood vessels, the vasoactive chemicals stimulate endothelial cells of the blood capillaries to separate a little, widening the intercellular clefts between them and increasing capillary permeability. This allows for the easier movement of fluid, leukocytes, and plasma proteins from the bloodstream into the surrounding tissue. Among the helpful proteins filtering from the blood are complement, antibodies, and clotting proteins, all of which aid in combating pathogens.

Endothelial cells of the blood vessels actively aid in the recruitment of leukocytes. In the area of injury, they produce cell-adhesion molecules called **selectins**, which make their membranes sticky and snag leukocytes arriving in the bloodstream. Leukocytes adhere loosely to the selectins and slowly tumble along the endothelium, sometimes coating it so thickly that they obstruct blood flow. This adhesion to the vessel wall is called **margin-ation**. The leukocytes then crawl through the gaps between the endothelial cells—an action called **diapede-sis**¹⁶ or **emigration**—and thus enter the tissue fluid among the cells of the damaged tissue (fig. 21.19). Most diapede-sis occurs across the walls of the postcapillary venules. Cells and chemicals that have left the bloodstream are said to be *extravasated*.¹⁷

In the events that have already transpired, we can see the basis for the four cardinal signs of inflammation: (1) the heat results from the hyperemia; (2) redness is also

FIGURE 21.19 Neutrophil Behavior in Inflammation. Chemical messengers are released by basophils, mast cells, blood plasma, and damaged tissue. These inflammatory chemicals stimulate leukocyte margination (adhesion to the capillary wall), diapede-sis (crawling through the capillary wall), chemotaxis (movement toward the source of the inflammatory chemicals), and phagocy-tosis (engulfing bacteria or other pathogens).

due to hyperemia and in some cases, such as sunburn, to extravasated erythrocytes in the tissue; (3) swelling (edema) is due to the increased fluid filtration from the capillaries; and (4) pain results from direct injury to the nerves, pressure on the nerves from the edema, and stimulation of pain receptors by prostaglandins, some bacterial toxins, and a kinin called **bradykinin**.

Think About It

Review eicosanoid synthesis (p. 670) and explain why aspirin eases the pain of inflammation.

Containment and Destruction of Pathogens

One priority in inflammation is to prevent pathogens from spreading through the body. The fibrinogen that filters into the tissue fluid clots in areas adjacent to the injury, forming a sticky mesh that sequesters (walls off

¹⁴*para* = next to + *crin* = to secrete

¹⁵*auto* = self + *crin* = to secrete

¹⁶*dia* = through + *pedesis* = stepping

¹⁷*extra* = outside + *vas* = vessel

and isolates) bacteria and other microbes. Heparin, the anticoagulant, prevents clotting in the area of the injury itself, so bacteria or other pathogens are essentially trapped in a fluid pocket surrounded by a gelatinous capsule of clotted fluid. They are attacked by antibodies, phagocytes, and other defenses, while the surrounding areas of clotted tissue fluid prevent them from easily escaping this onslaught.

The chief enemies of bacteria are neutrophils, which accumulate in the inflamed tissue within an hour of injury. After emigrating from the bloodstream, they exhibit **chemotaxis**—attraction to chemicals such as bradykinin and leukotrienes that guide them to the site of injury or infection. As they encounter bacteria, neutrophils avidly phagocytize and digest them, and destroy many more by the respiratory burst described earlier. The four major stages of neutrophil action are summarized in figure 21.19.

Neutrophils also recruit macrophages and additional neutrophils by secreting cytokines, like shouting “Over here!” to bring in reinforcements. Activated macrophages and T cells in the inflamed tissue secrete cytokines called *colony-stimulating factors*, which promote the production of more leukocytes (leukopoiesis) by the red bone marrow. Within a few hours of the onset of inflammation, the neutrophil count in the blood can rise from the normal 4,000 or 5,000 cells/ μL to as high as 25,000 cells/ μL , a condition called **neutrophilia**. In the case of an allergy or parasitic infection, an elevated eosinophil count, or **eosinophilia**, may also occur. The task of eosinophils was described earlier.

Tissue Cleanup and Repair

Monocytes are major agents of tissue cleanup and repair. They arrive within 8 to 12 hours of an injury, emigrate from the bloodstream, and turn into macrophages. Macrophages engulf and destroy bacteria, damaged host cells, and dead and dying neutrophils. They also act as antigen-presenting cells, activating specific immune responses described later in the chapter.

Edema also contributes to tissue cleanup. The swelling compresses veins and reduces venous drainage, while it forces open the valves of lymphatic capillaries and promotes lymphatic drainage. The lymphatics can collect and remove bacteria, dead cells, proteins, and tissue debris better than blood capillaries can.

As the battle progresses, all of the neutrophils and most of the macrophages die. These dead cells, other tissue debris, and tissue fluid form a pool of yellowish fluid called **pus**, which accumulates in a tissue cavity called an **abscess**.¹⁸ Pus is usually absorbed, but sometimes it forms a blister between the epidermis and dermis and may be released by its rupture.

Blood platelets and endothelial cells in an area of injury secrete **platelet-derived growth factor**, an agent that stimulates fibroblasts to multiply and synthesize collagen. Hyperemia, at the same time, delivers the oxygen, amino acids, and other necessities of protein synthesis, while the heat of inflamed tissue increases metabolic rate and the speed of mitosis and tissue repair. The fibrin clot in inflamed tissue may provide a scaffold for tissue reconstruction. Pain also contributes importantly to recovery. It is an important alarm signal that calls our attention to the injury and makes us limit the use of a body part so it has a chance to rest and heal.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

6. What are macrophages? Give four examples and state where they are found.
7. How do interferons and the complement system protect against disease?
8. Summarize the benefits of fever and the limits of these benefits.
9. List the cardinal signs of inflammation and state the cause of each.

21.3 General Aspects of Specific Immunity

Objectives

When you have completed this section, you should be able to

- define *specific immunity*;
- contrast cellular and humoral immunity, active and passive immunity, and natural and artificial immunity;
- describe the chemical properties of antigens;
- describe and contrast the development of T and B lymphocytes; and
- describe the general roles played by lymphocytes, antigen-presenting cells, and interleukins in the immune response.

The remainder of this chapter is concerned with the immune system and specific immunity, the third line of defense. The **immune**¹⁹ **system** is composed of a large population of widely distributed cells that recognize foreign substances and act to neutralize or destroy them.

¹⁸*ab* = away + *scens* (from *cedere*) = to go

¹⁹*immuno* = free

Two characteristics distinguish immunity from nonspecific resistance:

1. **Specificity.** Immunity is directed against a particular pathogen. Immunity to one pathogen usually does not confer immunity to others.
2. **Memory.** When reexposed to the same pathogen, the body reacts so quickly that there is no noticeable illness. The reaction time for inflammation and other nonspecific defenses, by contrast, is just as long for later exposures as for the initial one.

These properties of immunity were recognized even in the fifth century BCE, when Thucydides remarked that people who recover from a disease often become immune to that one but remain susceptible to others. A person might be immune to measles but still susceptible to polio, for example.

Forms of Immunity

In the late 1800s, it was discovered that immunity can be transferred from one animal to another by way of the blood serum. In the mid-1900s, however, it was found that serum does not always confer immunity; sometimes only donor lymphocytes do so. Thus, we now recognize two types of immunity, called cellular and humoral immunity, although they interact extensively and often respond to the same pathogen.

Cellular (cell-mediated) immunity employs lymphocytes that directly attack and destroy foreign cells or diseased host cells. It is a means of ridding the body of pathogens that reside inside human cells, where they are inaccessible to antibodies: for example, intracellular viruses, bacteria, yeasts, and protozoans. Cellular immunity also acts against parasitic worms, cancer cells, and cells of transplanted tissues and organs.

Humoral (antibody-mediated) immunity is mediated by antibodies, which do not directly destroy a pathogen, but tag them for destruction by mechanisms described later. It is an indirect attack in which antibodies, not the immune cells, assault the pathogen. The expression *humoral* comes from the fact that many of the antibodies are dissolved in the body fluids, and body fluids were once called “humors.” Humoral immunity is effective against extracellular viruses, bacteria, yeasts, and protozoans, and against molecular (noncellular) pathogens such as toxins, venoms, and allergens. In the unnatural event of a mismatched blood transfusion, it also destroys foreign erythrocytes.

Note that humoral immunity can work only against the *extracellular* stages of infectious microorganisms. When such microorganisms invade host cells, antibodies cannot get at them. However, the *intracellular* stages are still vulnerable to cellular immunity, which destroys

them by killing the cells that harbor them. Thus, humoral and cellular immunity sometimes attack the same microorganism at different points in its life cycle.

You will find cellular and humoral immunity summarized and compared in table 21.5 (p. 850) following discussion of the details of the two processes.

Other ways of classifying immunity are active versus passive and natural versus artificial. In *active immunity*, the body makes its own antibodies or T cells against a pathogen, whereas in *passive immunity*, the body acquires them from another person or an animal that has developed its own immunity to the pathogen. Either type of immunity can occur naturally or, for treatment and prevention purposes, it can be induced artificially. Thus we can recognize four classes of immunity under this scheme:

1. **Natural active immunity.** This is the production of one’s own antibodies or T cells as a result of natural exposure to an antigen.
2. **Artificial active immunity.** This is the production of one’s own antibodies or T cells as a result of **vaccination** against diseases such as smallpox, tetanus, or influenza. A **vaccine** consists of either dead or *attenuated* (weakened) pathogens that can stimulate an immune response but normally cause little or no discomfort or disease. In some cases, periodic *booster shots* are given to restimulate immune memory and maintain a high level of protection. Vaccination has eliminated smallpox worldwide and greatly reduced the incidence of life-threatening childhood diseases, but many people continue to die from influenza and other diseases that could be prevented by vaccination.
3. **Natural passive immunity.** This is a temporary immunity that results from acquiring antibodies produced by another person. The only natural ways for this to happen are for a fetus to acquire antibodies from the mother through the placenta before birth, or for a baby to acquire them during breast-feeding.
4. **Artificial passive immunity.** This is a temporary immunity that results from the injection of an *immune serum* obtained from another person or from animals (such as horses) that produced antibodies against a certain pathogen. Immune serum is used for emergency treatment of snakebites, botulism, tetanus, rabies, and other diseases.

Only the two forms of active immunity involve immune memory and thus provide future protection. Passive immunity typically lasts for only 2 or 3 weeks, until the acquired antibody is degraded. The remaining discussion is based on natural active immunity.

Antigens

An **antigen**²⁰ (Ag) is any molecule that triggers an immune response. Some antigens are free molecules such as venoms and toxins; others are components of plasma membranes and bacterial cell walls. Small universal molecules such as glucose and amino acids are not antigenic; if they were, our immune systems would attack the nutrients and other molecules essential to our very survival. Most antigens have molecular weights over 10,000 amu and are generally complex molecules that are unique to each individual: proteins, polysaccharides, glycoproteins, and glycolipids. Their uniqueness enables the body to distinguish its own (“self”) molecules from those of any other individual or organism (“nonself”). The immune system “learns” to distinguish self- from nonself-antigens prior to birth; thereafter, it normally attacks only nonself-antigens.

Only certain regions of an antigen molecule, called **epitopes (antigenic determinants)**, stimulate immune responses. One antigen molecule typically has several different epitopes, however, that can stimulate the production of different antibodies.

Some molecules, called **haptens**,²¹ are too small to be antigenic in themselves, but they can stimulate an immune response by binding to a host macromolecule and creating a unique complex that the body recognizes as foreign. After the first exposure, a hapten may stimulate an immune response without needing to bind to another molecule. Many people are allergic to haptens in cosmetics, detergents, industrial chemicals, poison ivy, and animal dander. The most common drug allergy is to penicillin and its derivatives. Penicillin is a hapten that binds to host proteins in allergic individuals, creating modified proteins that bind to mast cells and trigger massive release of histamine and other inflammatory chemicals. This can cause death from *anaphylactic shock*.

Lymphocytes

The major cells of the immune system are lymphocytes, macrophages, and dendritic cells, which are especially concentrated at strategic places such as the lymphatic organs, skin, and mucous membranes. Lymphocytes fall into three classes: natural killer (NK) cells, T lymphocytes, and B lymphocytes. We have already discussed NK cells (see immune surveillance). Here, we must take a closer look at T and B lymphocytes.

T Lymphocytes (T Cells)

The life history of a T cell basically involves three stages and three anatomical stations in the body. We can loosely think of these stages as their “birth,” their “training” or

maturation, and finally their “deployment” to locations where they will carry out their immune function.

T cells are “born” in the red bone marrow as descendants of the pluripotent stem cells (PPSCs) described in chapter 18. The bone marrow releases them into the blood as still-undifferentiated stem cells, which colonize the thymus (fig. 21.20). The thymus is the “school” where they mature into fully functional T cells. In the thymic cortex, reticular epithelial (RE) cells secrete thymic hormones that stimulate the T cells to develop surface antigen receptors. With receptors in place, the T cells are now **immunocompetent**, capable of recognizing antigens presented to them by APCs. The RE cells then test these T cells by presenting self-antigens to them. There are two ways to fail the test: inability to recognize the RE cells at all (specifically, their MHC proteins, described later), or reacting to the self-antigens. Failure to recognize MHC antigens would mean the T cell would be incapable of recognizing a foreign attack on the body, but reacting to self-antigens would mean the T cells would attack one’s own tissues. Either way, T cells that fail the test must be eliminated—a process called **negative selection**. There are two forms of negative selection: **clonal deletion**, in which self-reactive T cells die and macrophages phagocytize them, and **anergy**,²² in which they remain alive but unresponsive. Negative selection leaves the body in a state of **self-tolerance** in which the surviving, active T cells respond only to foreign antigens, not to one’s own.

T cells pass the test if they recognize the RE cells but do not react strongly to self-antigens. They now “graduate” to join the immune workforce. Only 2% of the T cells pass their graduation test. They move on to the medulla of the thymus, where they undergo **positive selection**—they multiply and form **clones** of identical T cells programmed to respond to a particular antigen. These cells, which are immunocompetent but have not yet encountered the “enemy” (foreign antigens), constitute the **naive lymphocyte pool**. Naive T cells leave the thymus and colonize lymphatic tissues and organs everywhere in the body (the bone marrow, lymph nodes, tonsils, and so forth); they are now ready to do battle.

Think About It

Is clonal deletion a case of apoptosis or necrosis? Explain your answer. (Review these concepts in chapter 5 if necessary.)

B Lymphocytes (B Cells)

Another group of fetal stem cells remains in the bone marrow to differentiate into B cells. Those that respond to self-antigens undergo either anergy or clonal deletion, much

²⁰acronym from *antibody generating*

²¹from *haptēin* = to fasten

²²*an* = without + *erg* = action, work

FIGURE 21.20 The Life History and Migrations of B and T Cells. Humoral immunity is represented by the violet pathways and cellular immunity by the red. (a) B cells achieve immunocompetence in the red bone marrow (left), and many emigrate to lymphatic tissues and organs, including the lymph nodes, tonsils, and spleen (right). (b) Plasma cells develop in the lymph nodes (among other sites) and emigrate to the bone marrow and other lymphatic organs, where they spend a few days secreting antibodies. (c) T stem cells emigrate from the bone marrow and attain immunocompetence in the thymus. (d) Immunocompetent T cells emigrate from the thymus and recolonize the bone marrow or colonize various lymphatic organs (right).

like self-reactive T cells. Self-tolerant B cells, on the other hand, go on to produce surface receptors for antigens, divide, and produce immunocompetent B cell clones. These cells disperse throughout the body, colonizing the same organs as T cells. They are abundant in the lymph nodes, spleen, bone marrow, and mucous membranes.

Antigen-Presenting Cells

Although the function of T cells is to recognize and attack foreign antigens, they usually cannot recognize such antigens on their own. They require the help of **antigen-presenting cells (APCs)**. In addition to their other roles, dendritic cells, macrophages, reticular cells, and B cells function as APCs.

APC function hinges on a family of genes on chromosome 6 called the **major histocompatibility complex (MHC)**. These genes code for **MHC proteins**—proteins on the APC surface that are shaped a little like hotdog buns, with an elongated groove for holding the “hotdog” of the foreign antigen. MHC proteins are structurally unique to every person except for identical twins. They act as

“identification tags” that label every cell of your body as belonging to you.

When an APC encounters an antigen, it internalizes it by endocytosis, digests it into molecular fragments, and displays the relevant fragments (its epitopes) in the grooves of the MHC proteins (fig. 21.21a). These steps are called **antigen processing**. Wandering T cells regularly inspect APCs for displayed antigens (fig. 21.21b). If an APC displays a self-antigen, the T cells disregard it. If it displays a nonself-antigen, however, the T cells initiate an immune attack. APCs thus alert the immune system to the presence of a foreign antigen. The key to a successful defense is then to quickly mobilize immune cells against the antigen.

With so many cell types involved in immunity, it is not surprising that they require chemical messengers to coordinate their activities. Lymphocytes and APCs talk to each other with cytokines called **interleukins**²³—chemical signals from one leukocyte (or leukocyte derivative) to another.

²³inter = between + leuk = leukocytes

With this introduction to the main actors in immunity, we can now look at the more specific features of cellular and humoral immunity. Since the terminology of immune cells and chemicals is quite complex, you may find it

helpful to refer often to table 21.4 (p. 849) as you read the following discussions.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- How does specific immunity differ from nonspecific defense?
- How does humoral immunity differ from cellular immunity?
- Contrast active and passive immunity. Give a natural and an artificial example of each.
- What structural properties distinguish antigenic molecules from those that are not antigenic?
- What is an immunocompetent lymphocyte? What does a lymphocyte have to produce in order to become immunocompetent?
- What role does the thymus play in the life history of a T cell?
- What role does an antigen-presenting cell play in the activation of a T cell?

21.4 Cellular Immunity

Objectives

When you have completed this section, you should be able to

- list the types of lymphocytes involved in cellular immunity and describe the roles they play;
- describe the process of antigen presentation and T cell activation;
- describe how T cells destroy enemy cells; and
- explain the role of memory cells in cellular immunity.

Cellular (cell-mediated) immunity is a form of specific defense in which T lymphocytes directly attack and destroy diseased or foreign cells, and the immune system then remembers the antigens of those invaders and prevents them from causing disease in the future. Cellular immunity employs four classes of T cells:

- Cytotoxic T (T_C) cells** are the “effectors” of cellular immunity that carry out the attack on enemy cells. They are also called *killer T cells*, but are not the same as *natural killer cells*.
- Helper T (T_H) cells** promote the action of T_C cells as well as playing key roles in humoral immunity and nonspecific resistance. All other T cells are involved in cellular immunity only.
- Regulatory T (T_R) cells**, or **T-regs**, inhibit multiplication and cytokine secretion by other T cells and thus limit immune responses. They are still not well

understood, but seem especially important in preventing autoimmune disease, as discussed later in this chapter.

4. **Memory T (T_M) cells** are descended from the cytotoxic T cells and are responsible for memory in cellular immunity.

(T_C and T_H are widely used abbreviations, whereas T_R and T_M are used only in this book for parallel symbolism.) T_C cells are also known as T_8 , CD_8 , or CD_8+ cells because they have a surface glycoprotein called CD_8 . T_H and T_R cells are also known as T_4 , CD_4 , or CD_4+ cells, after their glycoprotein, CD_4 . (CD stands for *cluster of differentiation*, a classification system for many cell-surface molecules.) These glycoproteins are cell-adhesion molecules that enable T cells to bind to other cells in the events to be described shortly.

Both cellular and humoral immunity occur in three stages that we can think of as recognition, attack, and memory (or “the three *Rs* of immunity”—recognize, react, and remember). In cellular immunity, the events of each stage are as follows.

Recognition

The recognition phase has two aspects: antigen presentation and T cell activation.

Antigen Presentation

When an antigen-presenting cell (APC) encounters and processes an antigen, it typically migrates to the nearest lymph node and displays it to T cells. Cytotoxic and helper T cells patrol the lymph nodes and other tissues as if looking for trouble. When they encounter a cell displaying an antigen on an MHC protein (MHCP), they initiate an immune response. T cells respond to two classes of MHCPs:

1. **MHC-I proteins** occur on every nucleated cell of the body (not erythrocytes). These proteins are constantly produced by the cell and transported to the plasma membrane. Along the way, they pick up small peptides in the cytoplasm and display these once they are installed in the membrane. If the peptides are normal self-antigens, they do not elicit a T cell response. If they are viral proteins or abnormal antigens made by cancer cells, however, they do. In this case, the Ag–MHCP complex is like a tag on the host cell that says, “I’m diseased; kill me.” Infected or malignant cells are then destroyed before they can do further harm to the body.
2. **MHC-II proteins** (also called *human leukocyte antigens, HLAs*) occur only on APCs and display only foreign antigens.

T_C cells respond only to MHC-I proteins, and T_H cells respond only to MHC-II (table 21.2).

TABLE 21.2

Comparison of the Responses of Cytotoxic and Helper T Cells

Characteristic	T_C Cells	T_H Cells
Cells capable of stimulating a response	Any nucleated cell	Antigen-presenting cells
MHC protein	MHC-I	MHC-II

T Cell Activation

T cell activation is shown in figure 21.22. It begins when a T_C or T_H cell binds to an MHCP displaying an epitope that the T cell is programmed to recognize. Before the response can go any further, the T cell must bind to another APC protein, related to interleukins. In a sense, the T cell has to check twice to see if it really has bound to an APC displaying a foreign antigen. This signaling process, called **costimulation**, helps to ensure that the immune system does not launch an attack in the absence of an enemy, which could turn against one’s own body with injurious consequences. Successful costimulation triggers a process called **clonal selection**: the activated T cell undergoes repeated mitosis, giving rise to a clone of identical T cells programmed against the same epitope. Some cells in the clone become effector cells that carry out an immune attack, and some become memory T cells.

Attack

Helper and cytotoxic T cells play different roles in the attack phase. Helper T cells are necessary for most immune responses. They play a central coordinating role in both humoral and cellular immunity (fig. 21.23). When a helper T cell recognizes an Ag–MHCP complex, it secretes interleukins that exert three effects: (1) they attract neutrophils and natural killer cells; (2) they attract macrophages, stimulate their phagocytic activity, and inhibit them from leaving the area; and (3) they stimulate T and B cell mitosis and maturation.

Cytotoxic T (T_C) cells are the only T lymphocytes that directly attack and kill other cells (fig. 21.24). When a T_C cell recognizes a complex of antigen and MHC-I protein on a diseased or foreign cell, it “docks” on that cell, delivers a **lethal hit** of cytotoxic chemicals that will destroy it, and goes off in search of other enemy cells while the chemicals do their work. Among these chemicals are

- perforin and granzymes, which kill the target cell in the same manner as we saw earlier for NK cells (see fig. 21.17);
- interferons, which inhibit viral replication and recruit and activate macrophages, among other effects; and

FIGURE 21.22 T Cell Activation.

- *tumor necrosis factor (TNF)*, which aids in macrophage activation and kills cancer cells.

As more and more cells are recruited by helper T cells, the immune response exerts an overwhelming force against the pathogen. The primary response, seen on first exposure to a particular pathogen, peaks in about a week and then gradually declines.

Think About It

How is a cytotoxic T cell like a natural killer (NK) cell? How are they different?

Memory

The primary response is followed by immune memory. Following clonal selection, some T_C and T_H cells become memory cells. Memory T cells are long-lived and much

FIGURE 21.23 The Role of Helper T Cells in Defense and Immunity.

Why does AIDS reduce the effectiveness of all three defenses listed across the bottom?

more numerous than naive T cells. Aside from their sheer numbers, they also require fewer steps to be activated, and thus respond to antigens more rapidly. Upon reexposure to the same pathogen later in life, memory cells mount a quick attack called the **T cell recall response**. This time-saving response destroys a pathogen so quickly that no noticeable illness occurs—that is, the person is immune to the disease.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Name three types of lymphocytes that are involved in cellular immunity. Which of these is also essential to humoral immunity?
- What are the three phases of an immune response?
- Explain why cytotoxic T cells are activated by a broader range of host cells than are helper T cells.
- Describe some ways in which cytotoxic T cells destroy target cells.

FIGURE 21.24 Destruction of a Cancer Cell by a Cytotoxic T Cell. (a) T cell binding to cancer cell. (b) Death of the cancer cell due to the lethal hit by the T cell.

21.5 Humoral Immunity

Objectives

When you have completed this section, you should be able to

- explain how B cells recognize and respond to an antigen;
- describe the structure, types, and actions of antibodies;
- explain the mechanism of memory in humoral immunity; and
- compare and contrast cellular and humoral immunity.

Humoral immunity is a more indirect method of defense than cellular immunity. Instead of directly attacking enemy cells, the B lymphocytes of humoral immunity produce antibodies that bind to antigens and tag them for destruction by other means. But like cellular immunity, humoral immunity works in three stages: recognition, attack, and memory.

Recognition

An immunocompetent B cell has thousands of surface receptors for one antigen. B cell activation begins when an antigen binds to several of these receptors, links them together, and is taken into the cell by receptor-mediated endocytosis. One reason small molecules are not antigenic is that they are too small to link multiple receptors

together. After endocytosis, the B cell processes (digests) the antigen, links some of the epitopes to its MHC-II proteins, and displays these on the cell surface.

Usually, the B cell response goes no further unless a helper T cell binds to this Ag–MHC-II complex. (Some B cells are directly activated by antigens without the help of a T_H cell.) When a T_H cell does bind to the complex, it secretes interleukins that activate the B cell. This triggers clonal selection—B cell mitosis giving rise to a battalion of identical B cells programmed against the same antigen (fig. 21.25).

Most cells of the clone differentiate into **plasma cells**. These are larger than B cells and contain an abundance of rough endoplasmic reticulum (fig. 21.26). Plasma cells develop mainly in the germinal centers of the lymphatic nodules of the lymph nodes. About 10% of them remain in the lymph nodes, but the rest leave the nodes, take up residence in the bone marrow and elsewhere, and there produce antibodies until they die. A plasma cell secretes antibodies at the remarkable rate of 2,000 molecules per second over a life span of 4 to 5 days. These antibodies travel throughout the body in the blood and other body

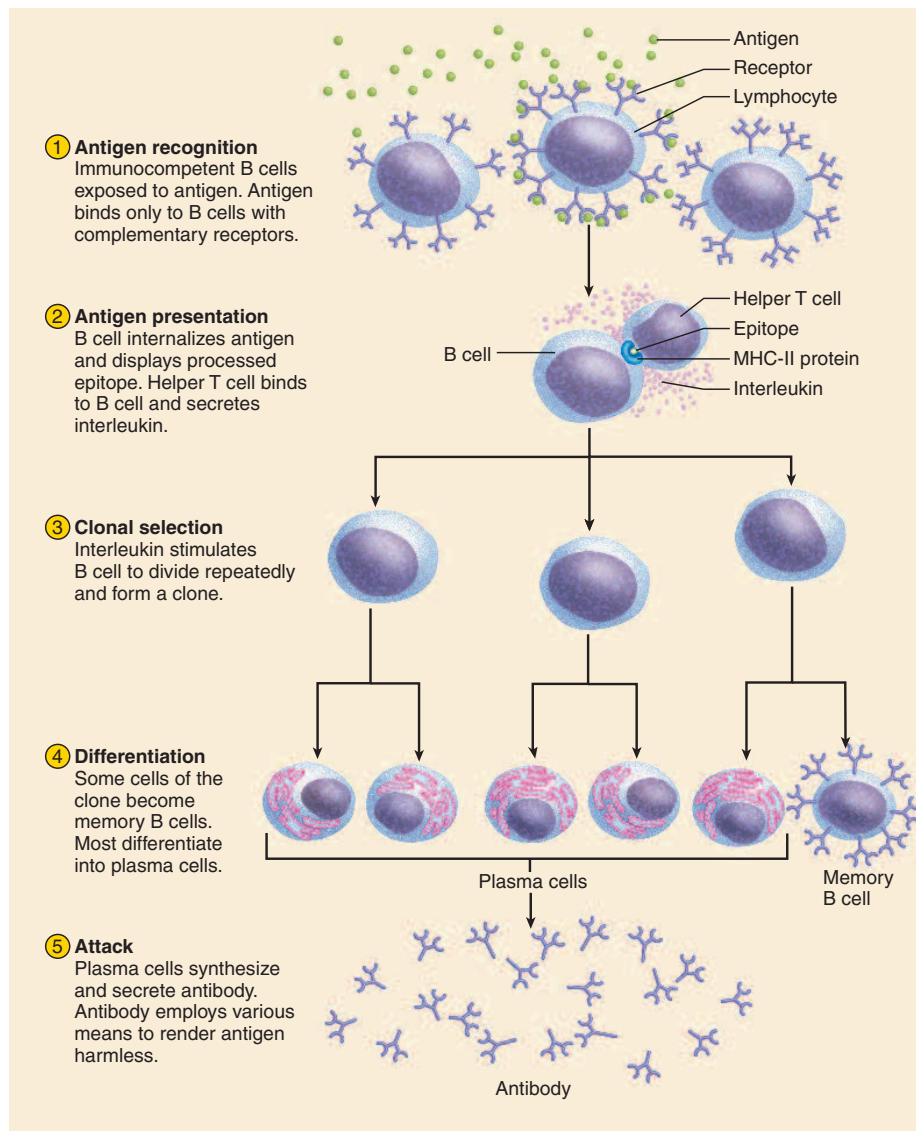

FIGURE 21.25 Clonal Selection and Ensuing Events of the Humoral Immune Response.

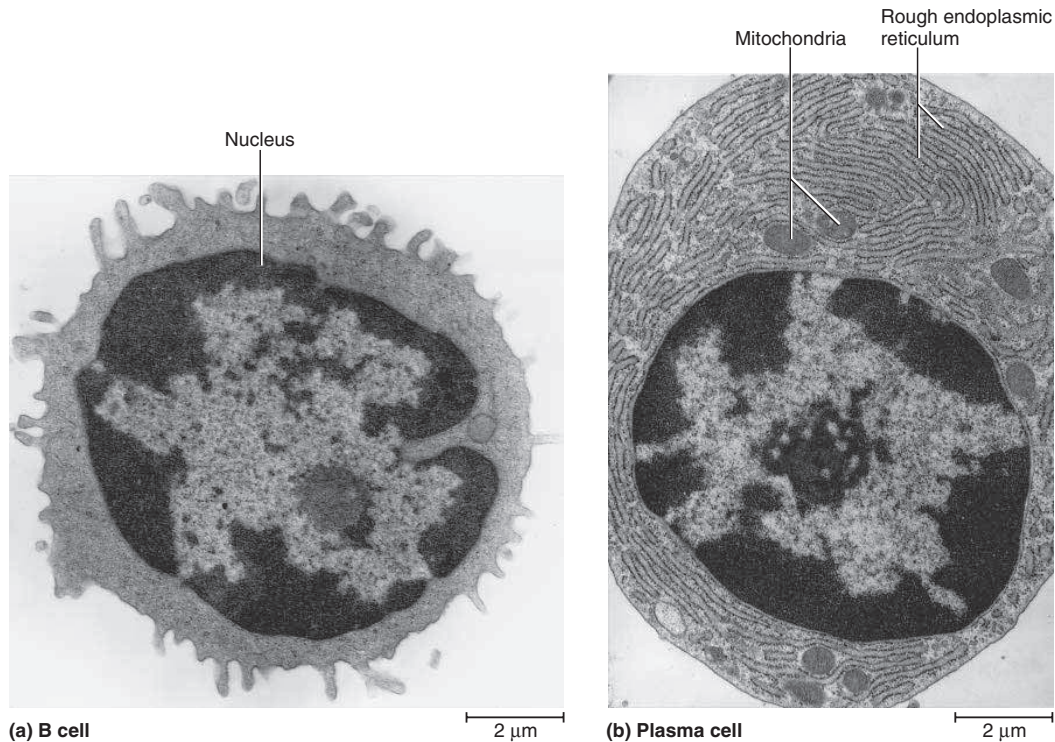

FIGURE 21.26 B Cell and Plasma Cell. (a) B cells have little cytoplasm and scanty organelles. (b) A plasma cell, which differentiates from a B cell, has an abundance of rough endoplasmic reticulum.

• *What does this endoplasmic reticulum do in the plasma cell?*

fluids. The first time you are exposed to a particular antigen, your plasma cells produce mainly an antibody class called IgM. In later exposures to the same antigen, they produce mainly IgG.

Attack

We have said much about antibodies already, and it is now time to take a closer look at what an antibody is and how it works. Also called an **immunoglobulin (Ig)**, an antibody is a defensive gamma globulin found in the blood plasma, tissue fluids, body secretions, and some leukocyte membranes. The basic structural unit of an antibody, an **antibody monomer**, is composed of four polypeptides linked by disulfide (–S–S–) bonds (fig. 21.27). The two larger **heavy chains** are about 400 amino acids long, and the two **light chains** about half that long. Each heavy chain has a hinge region where the antibody is bent, giving the monomer a T or Y shape.

All four chains have a **variable (V) region** that gives an antibody its uniqueness. The V regions of a heavy chain and light chain combine to form an **antigen-binding site** on each arm, which attaches to the epitope of an antigen molecule. The rest of each chain is a **constant (C) region**, which has the same amino acid sequence in all

antibodies of a given class (within one person). The C region determines the mechanism of an antibody's action—for example, whether it can bind complement proteins.

There are five classes of antibodies named **IgA**, **IgD**, **IgE**, **IgG**, and **IgM** (table 21.3), named for the structures of their C regions (*alpha*, *delta*, *epsilon*, *gamma*, and *mu*). IgD, IgE, and IgG are monomers. IgA has a monomeric form as well as a dimer composed of two cojoined monomers. IgM is a pentamer composed of five monomers. The surface antigen receptors synthesized by a developing B cell are IgD and IgM molecules. IgG is particularly important in the immunity of the newborn because it crosses the placenta with relative ease. Thus, it transfers immunity from the mother to her fetus. In addition, an infant acquires some maternal IgA through breast milk and colostrum (the fluid secreted for the first 2 or 3 days of breast-feeding).

The human immune system is believed capable of producing at least 10 billion and perhaps up to 1 trillion different antibodies. Any one individual has a much smaller subset of these possibilities, but such an enormous potential helps to explain why we can deal with the tremendous diversity of antigens that must exist in our environment. Yet such huge numbers are puzzling,

(a)

(b)

FIGURE 21.27 Antibody Structure. (a) A molecule of IgG, a monomer. (b) Computer-generated image of IgG bound to an antigen (lysozyme).

because we are accustomed to thinking of each protein in the body being encoded by one gene, and we have only about 35,000 genes, most of which have functions unrelated to immunity. How can so few genes generate so many antibodies? Obviously there cannot be a different gene for each one. One means of generating diversity is that the genome contains several hundred DNA segments that are shuffled and combined in various ways to produce antibody genes unique to each clone of B cells. This process is called **somatic recombination**, because it forms new combinations of DNA base sequences in somatic (nonreproductive) cells. Another mechanism of generating diversity is that B cells in the germinal centers of lymphatic nodules undergo exceptionally high rates of mutation, a process called **somatic hypermutation**, thereby not just recombining preexisting DNA but creating wholly new DNA sequences. These and other mechanisms explain how we can produce such a tremendous variety of antibodies with a limited number of genes.

TABLE 21.3 The Five Classes of Antibodies

Class	Structure	Location and Function
IgA	<div style="display: flex; justify-content: space-around;"> <div style="text-align: center;"> <p>Monomer</p> </div> <div style="text-align: center;"> <p>Dimer</p> </div> </div>	Found as a monomer in blood plasma and mainly as a dimer in mucus, tears, milk, saliva, and intestinal secretions. Sometimes also forms trimers and tetramers. Prevents pathogens from adhering to epithelia and penetrating underlying tissues. Provides passive immunity to the newborn.
IgD	<div style="text-align: center;"> <p>Monomer</p> </div>	A transmembrane protein of B cells; thought to function in activation of B cells by antigens.
IgE	<div style="text-align: center;"> <p>Monomer</p> </div>	A transmembrane protein of basophils and mast cells. Stimulates them to release histamine and other chemical mediators of inflammation and allergy; important in immediate hypersensitivity reactions and in attracting eosinophils to sites of parasitic infection.
IgG	<div style="text-align: center;"> <p>Monomer</p> </div>	Constitutes about 80% of circulating antibodies in plasma. The predominant antibody secreted in the secondary immune response. IgG and IgM are the only antibodies with significant complement-fixation activity. Crosses placenta and confers temporary immunity on the fetus. Includes the anti-D antibodies of the Rh blood group.
IgM	<div style="display: flex; justify-content: space-around;"> <div style="text-align: center;"> <p>Monomer</p> </div> <div style="text-align: center;"> <p>Pentamer</p> </div> </div>	Constitutes about 10% of circulating antibodies in plasma. Monomer is a transmembrane protein of B cells, where it functions as part of the antigen receptor. Pentamer occurs in blood plasma and lymph. The predominant antibody secreted in the primary immune response; very strong agglutinating and complement-fixation abilities; includes the anti-A and anti-B agglutinins of the ABO blood group.

Once released by a plasma cell, antibodies use four mechanisms to render antigens harmless:

1. **Neutralization.** Only certain regions of an antigen are pathogenic—for example, the parts of a toxin molecule or virus that enable these agents to bind to human cells. Antibodies can neutralize an antigen by masking these active regions.
2. **Complement fixation.** Antibodies IgM and IgG bind to enemy cells and change shape, exposing their complement-binding sites (fig. 21.27a). This initiates the binding of complement to the enemy cell surface and leads to inflammation, phagocytosis, immune clearance, and cytolysis, as described earlier (see fig. 21.15). Complement fixation is the primary mechanism of defense against such foreign cells as bacteria and mismatched erythrocytes.
3. **Agglutination** was described earlier in the discussion of ABO and Rh blood types (see p. 696). It is effective not only in mismatched blood transfusions, but more importantly as a defense against bacteria. An antibody molecule has 2 to 10 binding sites; thus, it can bind to antigen molecules on two or more enemy cells at once and stick them together (fig. 21.28). This immobilizes microbes and antigen molecules and prevents them from spreading through the tissues.

(a)

(b)

FIGURE 21.28 Agglutination by Antibodies.

(a) Agglutination of foreign erythrocytes by IgM, a pentamer.
(b) An antigen-antibody complex involving a free molecular antigen and an antibody monomer such as IgG.

4. **Precipitation** is a similar process in which antibodies link antigen molecules (not whole cells) together. This creates large Ag–Ab complexes that are too large to remain dissolved in solution. These complexes can be removed by immune clearance (see p. 831) or phagocytized by eosinophils in the connective tissues.

You will note that antibodies do not directly destroy an antigen in any of these mechanisms. They render it harmless by masking its pathogenic sites or agglutinating it, and they mark it for destruction by other agents such as complement, macrophages, or eosinophils.

Think About It

Explain why IgM has a stronger power of agglutination than antibodies of any other class.

Memory

When a person is exposed to a particular antigen for the first time, the immune reaction is called the **primary response**. The appearance of protective antibodies is delayed for 3 to 6 days while naive B cells multiply and differentiate into plasma cells. As the plasma cells begin secreting antibody, the **antibody titer** (level in the blood plasma) begins to rise (fig. 21.29). IgM appears first, peaks in about 10 days, and soon declines. IgG levels rise as IgM declines, but even the IgG titer drops to a low level within a month.

FIGURE 21.29 The Primary and Secondary (Anamnestic)

Responses in Humoral Immunity. The individual is exposed to antigen on day 0 in both cases. Note the differences in the speed of response, the height of the antibody titer, and the rate of decline in antibody titer.

The primary response, however, leaves one with an immune memory of the antigen. During clonal selection, some members of the clone become **memory B cells** rather than plasma cells (see fig. 21.25). Memory B cells, found mainly in the germinal centers of the lymph nodes, mount a very quick **secondary**, or **anamnestic**²⁴ (an-am-NESS-tic), **response** if reexposed to the same antigen. Plasma cells form within hours, so the IgG titer rises sharply and peaks

within a few days. The response is so rapid that the antigen has little chance to exert a noticeable effect on the body, and no illness results. A low level of IgM is also secreted and quickly declines, but IgG remains elevated for weeks to years, conferring lasting protection. Memory does not last as long in humoral immunity, however, as it does in cellular immunity.

Table 21.4 summarizes many of the cellular and chemical agents involved in humoral and cellular immunity. Table 21.5 compares the main features of

²⁴ana = back + mnes = remember

TABLE 21.4 Agents of Specific Immunity	
Cellular agents	
B cells	Serve as antigen-presenting cells in humoral immunity; differentiate into antibody-secreting plasma cells
CD4 (T _H) cells*	T lymphocytes with CD4 surface glycoproteins; helper and regulatory T cells
CD8 (T _C) cells	T lymphocytes with CD8 surface glycoproteins, cytotoxic T cells
Cytotoxic T (killer T, T _C , or CD8) cells	Effectors of cellular immunity; directly attack and destroy enemy cells; produce perforin, granzymes, interferon, tumor necrosis factor, and other cytokines
Dendritic cells	Branched, mobile APCs of the skin, mucous membranes, and lymphatic tissues; internalize antigen, migrate to lymph nodes, and present it to T _H and T _C cells
Eosinophils*	Phagocytize and degrade Ag-Ab complexes
Helper T (T _H) cells*	Play a central regulatory role in nonspecific defense and humoral and cellular immunity; recognize antigen fragments displayed by APCs with MHC-II proteins; secrete interleukins that activate B, T _C , and NK cells, neutrophils, and macrophages
Macrophages*	Phagocytize pathogens and expended or damaged host cells; act as antigen-presenting cells (APCs)
Memory B cells	Activated B cells that do not immediately differentiate into plasma cells; act as a pool of B cells that can execute a quick secondary response upon reexposure to the same antigen that initially activated them
Memory T cells	Activated T cells that do not immediately differentiate into effector T cells; act as a pool of T cells that can execute a quick T cell recall response upon reexposure to the same antigen that initially activated them
Naive lymphocytes	Immunocompetent lymphocytes that are capable of responding to an antigen but have not yet encountered one
Plasma cells	Develop from B cells that have been activated by helper T cells; synthesize and secrete antibodies
Regulatory T (T _R) cells	T cells that inhibit other T cells from multiplying or secreting cytokines; important especially in preventing autoimmune diseases but may also play defensive roles against infection and cancer and protect the fetus from maternal immune responses
Reticular cells	Fixed cells in the stroma of the lymph nodes and other lymphatic organs; act as APCs in the thymus, with a role in maturation of T cells
Chemical agents	
Antibody (Ab)	A gamma globulin produced by plasma cells in response to an antigen; counteracts antigen by means of complement fixation, neutralization of toxins, agglutination, or precipitation
Antigen (Ag)	Molecule capable of triggering an immune response; usually a protein, polysaccharide, glycolipid, or glycoprotein
Complement*	Group of plasma proteins that help to destroy pathogens by cytolysis, phagocytosis, immune clearance, or nonspecific defense (inflammation)
Granzyme	Proteolytic enzyme produced by NK and T _C cells; enters the pore made by perforins, degrades enzymes of the enemy cell, and induces apoptosis
Hapten	Small molecule unable to trigger an immune response by itself but able to bind to host molecules and produce a complex that is antigenic
Interleukin	Cytokine produced by leukocytes and macrophages to stimulate other leukocytes
Perforin	A protein produced by NK and T _C cells that binds to target cells, produces a hole, and admits granzymes into the cell
Tumor necrosis factor (TNF)	Cytokine secreted by T _C cells that activates macrophages and kills cancer cells

* These agents have additional roles in inflammation described in table 21.1.

TABLE 21.5 Some Comparisons Between Humoral and Cellular Immunity

Characteristic	Cellular Immunity	Humoral Immunity
Pathogens	Intracellular viruses, bacteria, yeasts, and protozoans; parasitic worms; cancer cells; transplanted tissues and organs	Extracellular viruses, bacteria, yeasts, and protozoans; toxins, venoms, and allergens; mismatched RBCs
Effector cells	Cytotoxic T cells	Plasma cells (develop from B cells)
Other cells involved in attack	Helper T cells	Helper T cells
Antigen-presenting cells	B cells, macrophages, dendritic cells, nearly all cells	B cells
MHC proteins	MHC-I and MHC-II	MHC-II only
Chemical agents of attack	Perforins, granzymes, interferons, tumor necrosis factor	Antibodies, complement
Mechanisms of counteracting or destroying pathogens	Cytolysis, phagocytosis, apoptosis	Cytolysis, phagocytosis, immune clearance, inflammation, neutralization, agglutination, precipitation
Memory	T cell recall response	Secondary (anamnesic) response

humoral and cellular immunity. Remember that these two processes often occur simultaneously, and in conjunction with inflammation as a three-pronged attack on the same pathogen.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What is the difference between a B cell and a plasma cell?
2. Describe four ways in which an antibody acts against an antigen.
3. Why does the secondary immune response prevent a pathogen from causing disease, while the primary immune response does not?

21.6 Immune System Disorders

Objectives

When you have completed this section, you should be able to

- distinguish between the four classes of immune hypersensitivity and give an example of each;
- explain the cause of anaphylaxis and distinguish local anaphylaxis from anaphylactic shock;
- state some reasons immune self-tolerance may fail, and give examples of the resulting diseases; and
- describe the pathology of immunodeficiency diseases, especially AIDS.

Because the immune system involves complex cellular interactions controlled by numerous chemical messengers, there are many points at which things can go wrong. The immune response may be too vigorous, too weak, or misdirected against the wrong targets. A few disorders are summarized here to illustrate the consequences.

Hypersensitivity

Hypersensitivity is an excessive, harmful immune reaction to antigens that most people tolerate. It includes reactions to tissues transplanted from another person (*alloimmunity*), abnormal reactions to one's own tissues (*autoimmunity*), and **allergies**,²⁵ which are reactions to environmental antigens. Such antigens, called **allergens**, occur in mold, dust, pollen, vaccines, bee and wasp venoms, animal dander, toxins from poison ivy and other plants, and foods such as nuts, milk, eggs, and shellfish. Drugs such as penicillin, tetracycline, and insulin are allergenic to some people.

One classification system recognizes four kinds of hypersensitivity, distinguished by the types of immune agents (antibodies or T cells) involved and their methods of attack on the antigen. In this system, type I is also characterized as *acute (immediate) hypersensitivity* because the response is very rapid, whereas types II and III are characterized as *subacute* because they exhibit a slower onset (1–3 hours after exposure) and last longer (10–15 hours). Type IV is a delayed cell-mediated response, whereas the other three are quicker antibody-mediated responses.

²⁵*allo* = altered + *erg* = action, reaction

- **Type I (acute) hypersensitivity** includes the most common allergies. Some authorities use the word *allergy* for type I reactions only, and others use it for all four types. Type I is an IgE-mediated reaction that begins within seconds of exposure and usually subsides within 30 minutes, although it can be severe and even fatal. Allergens bind to IgE on the membranes of basophils and mast cells and stimulate them to secrete histamine and other inflammatory and vasoactive chemicals. These chemicals trigger glandular secretion, vasodilation, increased capillary permeability, smooth muscle spasms, and other effects. The clinical signs include local edema, mucus hypersecretion and congestion, watery eyes, a runny nose, hives (red itchy skin), and sometimes cramps, diarrhea, and vomiting. Some examples of type I hypersensitivity are food allergies and **asthma**,²⁶ a local inflammatory reaction to inhaled allergens (see Insight 21.3).

Anaphylaxis²⁷ (AN-uh-fih-LAC-sis) is an immediate and severe type I reaction. Local anaphylaxis can be relieved with antihistamines. **Anaphylactic shock** is a severe, widespread acute hypersensitivity

that occurs when an allergen such as bee venom or penicillin is introduced to the bloodstream of an allergic individual. It is characterized by bronchoconstriction, dyspnea (labored breathing), widespread vasodilation, circulatory shock, and sometimes sudden death. Antihistamines are inadequate by themselves to counter anaphylactic shock, but epinephrine relieves the symptoms by dilating the bronchioles, increasing cardiac output, and restoring blood pressure. Fluid therapy and respiratory support are sometimes required.

- **Type II (antibody-dependent cytotoxic) hypersensitivity** occurs when IgG or IgM attacks antigens bound to cell surfaces. The reaction leads to complement activation and either lysis or opsonization of the target cell. Macrophages phagocytize and destroy opsonized platelets, erythrocytes, or other cells. Examples of cell destruction by type II reactions are blood transfusion reactions, pemphigus vulgaris (p. 173), and some drug reactions. In some other type II responses, an antibody binds to cell surface receptors and either interferes with their function (as in myasthenia gravis, p. 435) or overstimulates the cell (as in toxic goiter, p. 672).
- **Type III (immune complex) hypersensitivity** occurs when IgG or IgM forms antigen–antibody complexes

²⁶asthma = panting

²⁷ana = against + phylax = prevention

INSIGHT 21.3 Clinical Application

Asthma

Asthma is the most common chronic illness of children, especially boys. It is the leading cause of school absenteeism and childhood hospitalization in the United States. About half of all cases develop before age 10 and only 15% after age 40. In the United States, it affects about 5% of adults and up to 10% of children, and takes about 5,000 lives per year. Moreover, asthma is on the rise; there are many more cases and deaths now than there were a few decades ago.

In *allergic (extrinsic) asthma*, the most common form, a respiratory crisis is triggered by allergens in pollen, mold, animal dander, food, dust mites, or cockroaches. The allergens stimulate plasma cells to secrete IgE, which binds to mast cells of the respiratory mucosa. Reexposure to the allergen causes the mast cells to release a complex mixture of inflammatory chemicals, which trigger intense airway inflammation. *Nonallergic (intrinsic) asthma* is not caused by allergens but can be triggered by infections, drugs, air pollutants, cold dry air, exercise, or emotions. This form is more common in adults than in children, but the effects are much the same.

Within minutes, the bronchioles constrict spasmodically (*bronchospasm*), causing severe coughing, wheezing, and sometimes fatal suffocation. A second respiratory crisis often occurs 6 to 8 hours later. Interleukins attract eosinophils to

the bronchial tissue, where they secrete proteins that paralyze the respiratory cilia, severely damage the epithelium, and lead to scarring and extensive long-term damage to the lungs. The bronchioles also become edematous and plugged with thick, sticky mucus. People who die of asthmatic suffocation typically show airways so plugged with gelatinous mucus that they could not exhale. The lungs remain hyperinflated even at autopsy.

Asthma is treated with epinephrine and other β -adrenergic stimulants to dilate the airway and restore breathing, and with inhaled corticosteroids or nonsteroidal anti-inflammatory drugs to minimize airway inflammation and long-term damage. The treatment regimen can be very complicated, often requiring more than eight different medications daily, and compliance is therefore difficult for children and patients with low income or educational attainment.

Asthma runs in families and seems to result from a combination of heredity and environmental irritants. In the United States, asthma is most common, paradoxically, in two groups: (1) inner-city children who are exposed to crowding, poor sanitation and ventilation, and who do not often go outside or get enough exercise; and (2) children from extremely clean homes, perhaps because they have had too little opportunity to develop normal immunities. Asthma is also more common in countries where vaccines and antibiotics are widely used. It is less common in developing countries and in farm children of the United States.

that precipitate beneath the endothelium of the blood vessels or in other tissues. At the sites of deposition, these complexes activate complement and trigger intense inflammation, causing tissue destruction. Two examples of type III hypersensitivity are the autoimmune diseases acute glomerulonephritis (p. 935) and systemic lupus erythematosus, a widespread inflammation of the connective tissues (see table 21.6).

- **Type IV (delayed) hypersensitivity** is a cell-mediated reaction in which the signs appear about 12 to 72 hours after exposure. It begins when APCs in the lymph nodes display antigens to helper T cells, and these T cells secrete interferon and other cytokines that activate cytotoxic T cells and macrophages. The result is a mixture of nonspecific and immune responses. Type IV reactions include allergies to haptens in cosmetics and poison ivy; graft rejection; the tuberculosis skin test; and the beta cell destruction that causes type 1 diabetes mellitus.

Autoimmune Diseases

Autoimmune diseases are failures of self-tolerance—the immune system fails to distinguish self-antigens from foreign ones and produces **autoantibodies** that attack the body's own tissues. There are at least three reasons why self-tolerance may fail:

1. **Cross-reactivity.** Some antibodies against foreign antigens react to similar self-antigens. In rheumatic fever, for example, a streptococcus infection stimulates production of antibodies that react not only against the bacteria but also against antigens of the heart tissue. It often results in scarring and stenosis (narrowing) of the mitral and aortic valves.
2. **Abnormal exposure of self-antigens to the blood.** Some of our native antigens are normally not exposed to the blood. For example, a blood–testis barrier (BTB) normally isolates sperm cells from the blood. Breakdown of the BTB can cause sterility when sperm first form in adolescence and activate the production of autoantibodies.
3. **Change in the structure of self-antigens.** Viruses and drugs may change the structure of self-antigens and cause the immune system to perceive them as foreign. One theory of type 1 diabetes mellitus is that a viral infection alters the antigens of the insulin-producing beta cells of the pancreatic islets, which leads to an autoimmune attack on the cells.

Evidence is emerging that not all self-reactive T cells are eliminated by clonal deletion in the thymus. We all apparently have at least some T cells poised to attack our own tissues, but *regulatory T* (T_R) cells keep

these others in check and thus normally prevent autoimmune diseases. The existence of T_R cells was confirmed only as recently as 1995 and immunologists are still trying to determine how they work and what range of roles they play.

Immunodeficiency Diseases

In the foregoing diseases, the immune system reacts too vigorously or directs its attack against the wrong targets. In immunodeficiency diseases, by contrast, the immune system fails to respond vigorously enough.

Severe Combined Immunodeficiency Disease

Severe combined immunodeficiency disease (SCID) is a group of disorders caused by recessive alleles that result in a scarcity or absence of both T and B cells. Children with SCID are highly vulnerable to opportunistic infections and must live in protective enclosures. The most publicized case was David Vetter, who spent his life in sterile plastic chambers and suits (fig. 21.30), finally succumbing at age 12 to cancer triggered by a viral infection. Children with SCID are sometimes helped by transplants of bone marrow or fetal thymus, but in some cases the transplanted cells fail to survive and multiply, or transplanted T cells attack

FIGURE 21.30 Boy with Severe Combined Immunodeficiency Disease. David Vetter lived with SCID from birth (1971) to 1984. At the age of 6, he received a portable sterile suit designed by NASA that allowed him to leave the hospital for the first time.

the patient's tissues (the *graft-versus-host response*). David contracted the fatal virus from his sister through a bone marrow transplant.

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency diseases are nonhereditary diseases contracted after birth. The best-known example is **acquired immunodeficiency syndrome (AIDS)**, a group of conditions that involve a severely depressed immune response caused by infection with the **human immunodeficiency virus (HIV)**.

The structure of HIV is shown in figure 21.31a. Its inner core consists of a protein *capsid* enclosing two molecules of RNA, two molecules of an enzyme called *reverse transcriptase*, and a few other enzyme molecules. The capsid is enclosed in another layer of viral protein, the *matrix*. External to this is a *viral envelope* composed of phospholipids and glycoproteins derived from the host cell. Like other viruses, HIV can be replicated only by a living host cell. It invades helper T (CD4) cells, dendritic cells, and macrophages. HIV adheres to a target cell by means of one of its envelope glycoproteins and “tricks” the target cell into internalizing it by receptor-mediated endocytosis. Within the host cell, reverse transcriptase uses the viral RNA as a template to synthesize DNA—the opposite of the usual process of genetic transcription. Viruses that carry out this RNA → DNA reverse transcription are called *retroviruses*.²⁸ The new DNA is inserted into the host cell's DNA, where it may lie dormant for months to years. When activated, however, it induces the

host cell to produce new viral RNA, capsid proteins, and matrix proteins. As the new viruses emerge from the host cell (fig. 21.31b), they are coated with bits of the cell's plasma membrane, forming the new viral envelope. The new viruses then adhere to more host cells and repeat the process.

By destroying T_H cells, HIV strikes at a central coordinating agent of nonspecific defense, humoral immunity, and cellular immunity (see figure 21.23). After an incubation period ranging from a few months to 12 years, the patient begins to experience flulike episodes of chills and fever as HIV attacks T_H cells. At first, antibodies against HIV are produced and the T_H count returns nearly to normal. As the virus destroys more and more cells, however, the signs and symptoms become more pronounced: night sweats, fatigue, headache, extreme weight loss, and lymphadenitis.

A normal T_H count is 600 to 1,200 cells/μL, but a criterion of AIDS is a count less than 200/μL. With such severe depletion of T_H cells, a person succumbs to opportunistic infections with such pathogens as *Toxoplasma* (a protozoan previously known mainly for causing birth defects), *Pneumocystis* (a group of respiratory fungi), herpes simplex virus, cytomegalovirus (which can cause blindness), or tuberculosis bacteria. White patches may appear in the mouth, caused by *Candida* (thrush) or Epstein-Barr²⁹ virus (leukoplakia). A cancer called Kaposi³⁰ sarcoma, common in AIDS patients, originates in the endothelial cells of the blood vessels and causes bruise-like purple lesions visible in the skin (fig. 21.32).

FIGURE 21.31 The Human Immunodeficiency Virus (HIV). (a) Structure of the virus. (b) Viruses emerging from a dying helper T cell. Each virus can now invade a new helper T cell and produce a similar number of descendants.

Which of the molecules in part (a) is the target of the drug azidothymidine (AZT)? How does AZT inhibit the spread of HIV?

FIGURE 21.32 Kaposi Sarcoma. Typical lesions on the face and neck of a person with AIDS.

Patients with full-blown AIDS show no response to standard skin tests for delayed hypersensitivity. Slurred speech, loss of motor and cognitive functions, and dementia may occur as HIV invades the brain by way of infected phagocytes (microglia) and induces them to release toxins that destroy neurons and astrocytes. Death from cancer or infection is inevitable, usually within a few months but sometimes as long as 8 years after diagnosis. Some people, however, have been diagnosed as HIV-positive and yet have survived for 10 years or longer without developing AIDS.

HIV is transmitted through blood, semen, vaginal secretions, and breast milk. It can be transmitted from mother to fetus through the placenta or from mother to infant during childbirth or nursing. HIV occurs in saliva and tears, but is apparently not transmitted by those fluids. The most common means of transmission are sexual intercourse (vaginal, anal, or oral), contaminated blood products, and drug injections with contaminated needles. Worldwide, about 75% of HIV infections are acquired through heterosexual, predominantly vaginal intercourse. In the United States, most cases occur in men who have sex with other men, but adolescents are the fastest rising group of AIDS patients because of the exchange of unprotected sexual intercourse for drugs. The sharing of needles for drug use remains the chief means of transmission in urban ghettos. Since 1984, all blood donated for transfusion has been tested for HIV, and the risk of infection from transfusions is now less than 1%. HIV cannot be contracted by

donating blood, but irrational fear has resulted in an alarming drop in blood donors.

AIDS is not known to be transmitted through casual contact—for example, to family members, friends, coworkers, classmates, or medical personnel in charge of AIDS patients. It is not transmitted by kissing or by mosquitoes or other blood-sucking arthropods.

HIV survives poorly outside the human body. It is destroyed by laundering; dishwashing; exposure to heat (50°C [135°F] for at least 10 minutes); chlorination of swimming pools and hot tubs; and disinfectants such as bleach, Lysol, hydrogen peroxide, rubbing alcohol, and germicidal skin cleansers such as Betadine and Hibiclens. A properly used, undamaged latex condom is an effective barrier to HIV, but animal membrane condoms have gaps too large to block HIV transmission.

The AIDS epidemic has triggered an effort of unprecedented intensity to find a vaccine or cure. The strategies against HIV include efforts to prevent its binding to T_H cells, disrupting the action of reverse transcriptase, or inhibiting the assembly of new viruses or their release from host cells. HIV is a difficult pathogen to attack. Since it hides within host cells, it usually escapes recognition by the immune system. In the brain, it is protected by the blood–brain barrier.

About 1% of HIV's genes mutate every year. Such rapid mutation is a barrier to both natural immunity and development of a vaccine. Even when immune cells do become sensitized to HIV, the virus soon evolves new surface antigens that escape recognition. The high mutation rate also would quickly make today's vaccine ineffective against tomorrow's strain of the virus. Another obstacle to treatment and prevention is the lack of animal models for vaccine and drug research and development. Most animals are not susceptible to HIV. The chimpanzee is an exception, but chimpanzees are difficult to maintain, and there are economic barriers and ethical controversies surrounding their use.

The first anti-HIV drug approved by the Food and Drug Administration (FDA) was azidothymidine (AZT, or Retrovir), which inhibited reverse transcriptase and prolonged the lives of some HIV-positive individuals. In 1996, a family of drugs called protease inhibitors became available, typically used in a “triple cocktail” combining these with two reverse transcriptase inhibitors. But by 1997, HIV had evolved resistance even to those drugs and they were failing in more than half of all patients. Today, at least 24 anti-HIV drugs are on the market, typically used in combinations of three or more. Such drug combinations have substantially reduced AIDS morbidity and mortality (disease and death) and reduced the hospital and hospice census, but none of them totally eliminate HIV from the body, and all of them have serious side effects that contraindicate their long-term use. The major unresolved questions in AIDS therapy today are when to start drug treatment, which drugs to use, when to switch drugs, how to improve patient compliance, and how to

make therapy available in impoverished nations where AIDS is especially rampant.

There also remain a number of unanswered questions about the basic biology of HIV. It is still unknown, for example, why there are such strikingly different patterns of heterosexual versus homosexual transmission in different countries, and why some people succumb so rapidly to infection, but others can be HIV-positive for years without developing AIDS. AIDS remains a stubborn problem sure to challenge virologists and epidemiologists for many years to come.

We have surveyed the major classes of immune system disorders and a few particularly notorious immune diseases. A few additional lymphatic and immune system disorders are described in table 21.6. The effects of aging on the lymphatic and immune systems are described on page 1143.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

24. How does subacute hypersensitivity differ from acute hypersensitivity? Give an example of each.
25. Aside from the time required for a reaction to appear, how does delayed hypersensitivity differ from the acute and subacute types?
26. State some reasons why antibodies may begin attacking self-antigens that they did not previously respond to. What are these self-reactive antibodies called?
27. What is the distinction between a person who has an HIV infection and a person who has AIDS?
28. How does a reverse transcriptase inhibitor such as AZT slow the progress of AIDS?

TABLE 21.6 Some Disorders of the Lymphatic and Immune Systems

Contact dermatitis	A form of delayed hypersensitivity that produces skin lesions limited to the site of contact with an allergen or hapten; includes responses to poison ivy, cosmetics, latex, detergents, industrial chemicals, and some topical medicines.	
Hives (urticaria ³¹)	An allergic skin reaction characterized by a “wheal and flare” reaction—white blisters (wheals) surrounded by reddened areas (flares), usually with itching. Caused by local histamine release in response to allergens. Can be triggered by food or drugs, but sometimes by nonimmunological factors such as cold, friction, or emotional stress.	
Hodgkin ³² disease	A lymph node malignancy, with early symptoms including enlarged painful nodes, especially in the neck, and fever; often progresses to neighboring lymph nodes. Radiation and chemotherapy cure about 75% of patients.	
Splenomegaly ³³	Enlargement of the spleen, sometimes without underlying disease but often indicating infections, autoimmune diseases, heart failure, cirrhosis, Hodgkin disease, and other cancers. The enlarged spleen may “hoard” erythrocytes, causing anemia, and may become fragile and subject to rupture.	
Systemic lupus erythematosus ³⁴	Formation of autoantibodies against DNA and other nuclear antigens, resulting in accumulation of antigen-antibody complexes in blood vessels and other organs, where they trigger widespread connective tissue inflammation. Named for skin lesions once likened to a wolf bite. Causes fever, fatigue, joint pain, weight loss, intolerance of bright light, and a “butterfly rash” across the nose and cheeks. Death may result from renal failure.

INSIGHT 21.4 Clinical Application**Neuroimmunology—The Mind-Body Connection**

Neuroimmunology is a relatively new branch of medicine concerned with the relationship between mind and body in health and disease. It is attempting especially to understand how a person's state of mind influences health and illness through a three-way communication between the nervous, endocrine, and immune systems.

The sympathetic nervous system issues nerve fibers to the spleen, thymus, lymph nodes, and Peyer patches, where nerve fibers contact thymocytes, B cells, and macrophages. These immune cells have adrenergic receptors for norepinephrine and many other neurotransmitters such as neuropeptide Y, substance P, and vasoactive intestinal peptide (VIP). These neurotransmitters have been shown to influence immune cell activity in various ways. Epinephrine, for example, reduces the lymphocyte count and inhibits NK cell activity, thus suppressing immune surveillance and specific immunity. Cortisol, another stress hormone, inhibits T cell and macrophage activity, antibody production, and the secretion of inflammatory chemicals. It also induces atrophy of the thymus, spleen, and lymph nodes and reduces the number of circulating lymphocytes, macrophages, and eosinophils. Thus, it is not surprising that prolonged stress increases susceptibility to illnesses such as infections and cancer.

The immune system also sends messages to the nervous and endocrine systems. Immune cells synthesize numerous hormones and neurotransmitters that we normally associate with endocrine and nerve cells. B lymphocytes produce adrenocorticotropic hormone (ACTH) and enkephalins; T lymphocytes

produce growth hormone, thyroid-stimulating hormone, luteinizing hormone, and follicle-stimulating hormone; and monocytes secrete prolactin, VIP, and somatostatin. The interleukins and tumor necrosis factor (TNF) secreted by immune cells produce feelings of fatigue and lethargy when we are sick, and stimulate the hypothalamus to secrete corticotropin-releasing hormone, thus leading to ACTH and cortisol secretion. It remains uncertain and controversial whether the quantities of some of these substances produced by immune cells are enough to have far-reaching effects on the body, but it seems increasingly possible that immune cells may have wide-ranging effects on nervous and endocrine functions that affect recovery from illness.

Although neuroimmunology has met with some skepticism among physicians, there is less and less room for doubt about the importance of a person's state of mind to immune function. People under stress, such as medical students during examination periods and people caring for relatives with Alzheimer disease, show more respiratory infections than other people and respond less effectively to hepatitis and flu vaccines. The attitudes, coping abilities, and social support systems of patients significantly influence survival time even in such serious diseases as AIDS and breast cancer. Women with breast cancer die at markedly higher rates if their husbands cope poorly with stress. Attitudes such as optimism, cheer, depression, resignation, or despair in the face of disease significantly affect immune function. Religious beliefs can also influence the prospect of recovery. Indeed, ardent believers in voodoo sometimes die just from the belief that someone has cast a spell on them. The stress of hospitalization can counteract the treatment one gives to a patient, and neuroimmunology has obvious implications for treating patients in ways that minimize their stress and thereby promote recovery.

Interactions Between the LYMPHATIC AND IMMUNE SYSTEMS and Other Organ Systems

■ indicates ways in which this system affects other systems ■ indicates ways in which other systems affect this system

CHAPTER REVIEW

Review of Key Concepts

21.1 The Lymphatic System (p. 816)

- The lymphatic system serves to recover tissue fluid and maintain fluid balance; provides immune cells and monitors the body fluids for foreign matter; and transports dietary lipids from the small intestine to the blood.
- The lymphatic system consists of *lymph*, *lymphatic vessels*, *lymphatic tissues*, and *lymphatic organs*.
- Lymph is usually a colorless liquid similar to blood plasma, but is milky when absorbing digested lipids. It contains lymphocytes, macrophages, and hormones, and may contain metastasizing cancer cells, cellular debris, bacteria, and viruses.
- Lymph originates in blind *lymphatic capillaries* that pick up tissue fluid. The endothelial cells of lymphatic capillaries have large gaps between them that permit cells and other large particles to enter the lymph stream.
- Lymphatic capillaries converge to form larger *collecting vessels* with a histology similar to that of veins. Lymph nodes lie at irregular intervals along the collecting vessels and filter the lymph on its way back to the blood.
- Collecting vessels converge to form six *lymphatic trunks* that drain specific regions of the body. The lymphatic trunks then converge to form two *collecting ducts*—the *right lymphatic duct* and *thoracic duct*—which empty lymph into the subclavian veins.
- There is no heartlike pump to move the lymph; lymph flows under forces similar to those that drive venous return, and like some veins, lymphatic vessels have valves that ensure a one-way flow.
- The cells of lymphatic tissue are *natural killer (NK) cells*, *T lymphocytes*, *B lymphocytes*, *macrophages*, *dendritic cells*, and *reticular cells*.
- Diffuse lymphatic tissue* is an aggregation of lymphatic cells in the walls of other organs, especially in the mucous membranes of the respiratory, digestive, urinary, and reproductive tracts—where it is called *mucosa-associated lymphatic tissue (MALT)*. In some places, lymphocytes and macrophages form dense masses called *lymphatic nodules*, such as the *Peyer patches* of the ileum.
- Lymphatic organs have well-defined anatomical locations and have a fibrous capsule that at least partially separates them from adjacent organs and tissues. Two of these, the red bone marrow and thymus, are called *primary lymphatic organs* because lymphocytes mature here before colonizing the other sites. The other sites, called *secondary lymphatic organs*, are the lymph nodes, tonsils, and spleen.
- Red bone marrow* is a hemopoietic organ and the point of origin of all immune cells of the lymphatic system. It consists of *islands* of hemopoietic tissue composed of macrophages and developing blood cells, separated by *sinusoids* that converge on a *central longitudinal vein*. Lymphocytes and other formed elements pass from the islands into the sinusoids and enter the bloodstream.
- The *thymus* is located in the mediastinum above the heart. It is a site of T lymphocyte development and a source of cytokines that regulate lymphocyte activity. It is divided into numerous polygonal *lobules*, each with a dense *cortex* and lighter *medulla*. Reticular epithelial cells separate the cortex from the medulla and surround the blood vessels, forming a *blood–thymus barrier* that isolates developing lymphocytes from blood-borne antigens.
- Lymph nodes* are numerous small, bean-shaped organs that receive lymph through *afferent lymphatic vessels*, filter it, and pass it along via *efferent lymphatic vessels* that exit the hilum. They monitor the lymph for foreign antigens, remove impurities before it returns to the bloodstream, contribute lymphocytes to the lymph and blood, and mount immune responses to foreign antigens.
- The parenchyma of a lymph node exhibits an outer *cortex* composed mainly of lymphatic nodules, and a deeper *medulla* with a network of *medullary cords*. B cells multiply and differentiate into plasma cells in the germinal centers of the nodules. T cells are very concentrated in the *deep cortex* next to the medulla.
- Lymph nodes are widespread but especially concentrated in cervical, axillary, thoracic, abdominal, intestinal, mesenteric, inguinal, and popliteal groups.
- The *tonsils* encircle the pharynx and guard against inhaled and ingested pathogens. They include a medial *pharyngeal tonsil* in the nasopharynx, a pair of *palatine tonsils* at the rear of the oral cavity, and numerous *lingual tonsils* clustered in the root of the tongue. Their superficial surface is covered with epithelium and their deep surface with a fibrous partial capsule. They have deep pits called *tonsillar crypts* bordered by rows of lymphatic nodules.
- The *spleen* lies in the left hypochondriac region between the diaphragm, stomach, and kidney. It monitors the blood for foreign antigens, activates immune responses to them, disposes of old RBCs, and helps to regulate blood volume. Its parenchyma is composed of *red pulp* containing concentrated RBCs and *white pulp* composed of lymphocytes and macrophages.

21.2 Nonspecific Resistance (p. 829)

- The body has three lines of defense against pathogens: (1) external physical barriers, (2) nonspecific defenses, and (3) the immune system. The first two mechanisms are called *nonspecific resistance* because they guard equally against a broad range of pathogens and do not require prior exposure. Immunity is a *specific defense* limited to one pathogen or a few closely related ones.

- The skin acts as a barrier to pathogens because of its tough keratinized surface, its relative dryness, and antimicrobial chemicals such as lactic acid and *defensins*.
- Mucous membranes prevent most pathogens from entering the body because of the stickiness of the mucus, the antimicrobial action of *lysozyme*, and the viscosity of *hyaluronic acid*.
- Neutrophils*, the most abundant leukocytes, destroy bacteria by phagocytizing and digesting them and by a *respiratory burst* that produces a chemical *killing zone* of oxidizing agents.
- Eosinophils* produce antiparasitic agents, promote basophil and mast cell action, and control the action of inflammatory chemicals.
- Basophils* aid in defense by secreting *leukotrienes*, *histamine*, and *heparin*, as do their counterparts in the connective tissues, *mast cells*. These chemicals promote blood flow and leukocyte mobility.
- Lymphocytes* are of several kinds. Only one type, the natural killer (NK) cells, are involved solely in nonspecific defense. They are the agents of a defense mechanism called *immune surveillance*.
- Monocytes develop into macrophages, which have voracious phagocytic activity and act as antigen-presenting cells (APCs). Some organs have specific types of macrophages called *microglia*, and *alveolar* and *hepatic macrophages*. Dendritic cells are also important APCs.
- Interferons* are polypeptides secreted by cells in response to viral infection. They alert neighboring cells to synthesize antiviral proteins before they become infected, and they activate NK cells and macrophages.
- The *complement system* is a group of 30 or more globulins that are activated by pathogens and combat them by enhancing inflammation, *opsonizing* bacteria, and causing *immune clearance* of antigens and *cytolysis* of foreign cells.
- Immune surveillance* is a process in which NK cells nonspecifically detect and destroy foreign cells and diseased host cells. They employ *perforins* to create a hole in the enemy cell surface and *granzymes* to destroy its

intracellular enzymes and induce cell death.

- Fever (pyrexia)* is induced by chemical *pyrogens* introduced by bacteria and viruses and secreted by neutrophils and macrophages. Pyrogens raise the hypothalamic set point for body temperature. The elevated body temperature inhibits the reproduction of pathogens and the spread of infection.
- Inflammation* is a defensive response to infection and trauma, characterized by redness, swelling, heat, and pain (the four *cardinal signs*).
- Inflammation begins with a mobilization of defenses by vasoactive inflammatory chemicals such as histamine, leukotrienes, and other cytokines. These chemicals dilate blood vessels, increase blood flow, and make capillary walls more permeable, thus hastening the delivery of defensive cells and chemicals to the site of injury.
- Leukocytes adhere to the vessel wall (*margination*), crawl between the endothelial cells into the connective tissues (*diapedesis*), and migrate toward sources of inflammatory chemicals (*chemotaxis*).
- Inflammation continues with containment and destruction of the pathogens. This is achieved by clotting of the tissue fluid and attack by macrophages, leukocytes, and antibodies.
- Inflammation concludes with tissue cleanup and repair, including phagocytosis of tissue debris and pathogens by macrophages; edema and lymphatic drainage of the inflamed tissue; and tissue repair stimulated by platelet-derived growth factor.

21.3 General Aspects of Specific Immunity (p. 837)

- The *immune system* is a group of widely distributed cells that populate most body tissues and help to destroy pathogens.
- Immunity is characterized by its *specificity* and *memory*.
- The two basic forms of immunity are *cellular (cell-mediated)* and *humoral (antibody-mediated)*.
- Immunity can also be characterized as *active* (production of the body's own antibodies or immune cells) or *passive* (conferred by antibodies or lymphocytes donated by another individual), and as *natural* (caused by natural exposure to a pathogen) or

artificial (induced by vaccination or injection of immune serum). Only active immunity results in immune memory and lasting protection.

- Antigens* are any molecules that induce immune responses. They are relatively large, complex, genetically unique molecules (proteins, polysaccharides, glycoproteins, and glycolipids).
- The antigenicity of a molecule is due to specific regions of it called *epitopes*.
- Haptens* are small molecules that become antigenic by binding to larger host molecules.
- T cells* are lymphocytes that mature in the thymus, survive the process of *negative selection* (which eliminates most unreactive and self-reactive T cells), and go on to populate other lymphatic tissues and organs.
- B cells* are lymphocytes that mature in the bone marrow, survive negative selection, and then populate the same organs as T cells.
- Antigen-presenting cells (APCs)* are dendritic cells, macrophages, reticular cells, and B cells that process antigens, display the epitopes on their surface MHC proteins, and alert the immune system to the presence of a pathogen.
- Interleukins* are chemical signals by which immune cells communicate with each other.

21.4 Cellular Immunity (p. 841)

- Cellular immunity employs four classes of T lymphocytes: *cytotoxic (T_C)*, *helper (T_H)*, *regulatory (T_R)*, and *memory (T_M) T cells*.
- Cellular immunity takes place in three stages: recognition, attack, and memory.
- Recognition*: APCs that detect foreign antigens typically migrate to the lymph nodes and display the epitopes there. T_H and T_C cells respond only to epitopes attached to MHC proteins (MHCs).
- MHC-I proteins occur on every nucleated cell of the body and display viral and cancer-related proteins from the host cell. T_C cells respond only to antigens bound to MHC-I proteins.
- MHC-II proteins occur only on APCs and display only foreign antigens. T_H cells respond only to antigens bound to MHC-II proteins.

6. When a T_C or T_H cell recognizes an antigen–MHCP complex, it binds to a second site on the target cell. *Costimulation* by this site triggers *clonal selection*, multiplication of the T cell. Some daughter T cells carry out the attack on the invader and some become T_M cells.
7. *Attack*: Activated T_H cells secrete interleukins that attract neutrophils, NK cells, and macrophages, and stimulate T and B cell mitosis and maturation. Activated T_C cells directly attack and destroy target cells, especially infected host cells, transplanted cells, and cancer cells. They employ a “lethal hit” of cytotoxic chemicals including *perforin*, *granzymes*, *interferons*, and *tumor necrosis factor*.
8. *Memory*: The primary response to the first exposure to a pathogen is followed by immune memory. Upon later reexposure, T_M cells respond so quickly (the *T cell recall response*) that no noticeable illness occurs.

21.5 Humoral Immunity (p. 844)

1. Humoral immunity is based on the production of antibodies rather than on lymphocytes directly contacting and attacking enemy cells. It also occurs in recognition, attack, and memory stages.
2. *Recognition*: An immunocompetent B cell binds and internalizes an antigen, processes it, and displays epitopes on its surface MHC-II proteins. A T_H cell binds to the antigen–MHCP complex and secretes interleukins that activate the B cell.
3. The B cell divides repeatedly. Some daughter cells become memory B cells while others become antibody-synthesizing *plasma cells*.

4. *Attack*: Attack is carried out by antibodies (immunoglobulins). The basic *antibody monomer* is a T- or Y-shaped complex of four polypeptide chains (two heavy and two light chains). Each has a *constant (C) region* that is identical in all antibodies of a given class, and a *variable (V) region* that gives each antibody its uniqueness. Each has an *antigen-binding site* at the tip of each V region and can therefore bind two antigen molecules.
5. There are five classes of antibodies—IgA, IgD, IgE, IgG, and IgM—that differ in the number of antibody monomers (from one to five), the structure of the C region, and their immune functions (table 21.3).
6. Antibodies inactivate antigens by *neutralization*, *complement fixation*, *agglutination*, and *precipitation*.
7. *Memory*: Upon reexposure to the same antigen, memory B cells mount a *secondary (anamnestic) response* so quickly that no illness results.

21.6 Immune System Disorders (p. 850)

1. There are three principal dysfunctions of the immune system: too vigorous or too weak a response, or a response that is misdirected against the wrong target.
2. *Hypersensitivity* is an excessive reaction against antigens that most people tolerate. *Allergy* is the most common form of hypersensitivity.
3. *Type I (acute) hypersensitivity* is an IgE-mediated response that begins within seconds of exposure and subsides within about 30 minutes. Examples include asthma, anaphylaxis, and anaphylactic shock.
4. *Type II (antibody-dependent cytotoxic) hypersensitivity* occurs when IgG or IgM attacks antigens bound to a target cell membrane, as in a transfusion reaction.
5. *Type III (immune complex) hypersensitivity* results from widespread deposition of antigen–antibody complexes in various tissues, triggering intense inflammation, as in acute glomerulonephritis and systemic lupus erythematosus.
6. *Type IV (delayed) hypersensitivity* is a cell-mediated reaction (types I–III are antibody-mediated) that appears 12 to 72 h after exposure, as in the reaction to poison ivy and the TB skin test.
7. *Autoimmune diseases* are disorders in which the immune system fails to distinguish self-antigens from foreign antigens and attacks the body’s own tissues. They are usually prevented by regulatory T cells, but can occur because of cross-reactivity of antibodies, as in rheumatic fever; abnormal exposure of some self-antigens to the blood, as in one form of sterility resulting from sperm destruction; or changes in self-antigen structure, as in type 1 diabetes mellitus.
8. *Immunodeficiency diseases* are failures of the immune system to respond strongly enough to defend the body from pathogens. These include *severe combined immunodeficiency disease (SCID)*, present at birth, and *acquired immunodeficiency disease (AIDS)*, resulting from HIV infection.
9. HIV is a retrovirus that destroys T_H cells. Since T_H cells play a central coordinating role in cellular and humoral immunity and nonspecific defense, HIV knocks out the central control over multiple forms of defense and leaves a person vulnerable to *opportunistic infections* and certain forms of cancer.

Testing Your Recall

- The only lymphatic organ with both afferent and efferent lymphatic vessels is
 - the spleen.
 - a lymph node.
 - a tonsil.
 - a Peyer patch.
 - the thymus.
- Which of the following cells are involved in nonspecific resistance but not in specific defense?
 - helper T cells
 - cytotoxic T cells
 - natural killer cells
 - B cells
 - plasma cells
- The respiratory burst is used by _____ to kill bacteria.
 - neutrophils
 - basophils
 - mast cells
 - NK cells
 - cytotoxic T cells
- Which of these is a macrophage?
 - a microglial cell
 - a plasma cell
 - a reticular cell
 - a helper T cell
 - a mast cell
- The cytolytic action of the complement system is most similar to the action of
 - interleukin-1.
 - platelet-derived growth factor.
 - granzymes.
 - perforin.
 - IgE.
- _____ become antigenic by binding to larger host molecules.
 - Epitopes
 - Haptens
 - Interleukins
 - Pyrogens
 - Cell-adhesion molecules
- Which of the following correctly states the order of events in humoral immunity? Let 1 = antigen display, 2 = antibody secretion, 3 = secretion of interleukin, 4 = clonal selection, and 5 = endocytosis of an antigen.
 - 3-4-1-5-2
 - 5-3-1-2-4
 - 3-5-1-4-2
 - 5-3-1-4-2
 - 5-1-3-4-2
- The cardinal signs of inflammation include all of the following *except*
 - redness.
 - swelling.
 - heat.
 - fever.
 - pain.
- A helper T cell can bind only to another cell that has
 - MHC-II proteins.
 - an epitope.
 - an antigen-binding site.
 - a complement-binding site.
 - a CD4 protein.
- Which of the following results from a lack of self-tolerance?
 - SCID
 - AIDS
 - systemic lupus erythematosus
 - anaphylaxis
 - asthma
- Any organism or substance capable of causing disease is called a/an _____.
 - antibacterial enzyme
 - antigen
 - antibody
 - antigenic determinant
 - antigenic epitope
- Mucous membranes contain an antibacterial enzyme called _____.
 - lysozyme
 - perforin
 - interleukin-1
 - interferon
 - granzyme
- _____ is a condition in which one or more lymph nodes are swollen and painful to the touch.
 - lymphadenitis
 - lymphadenopathy
 - lymphadenoma
 - lymphadenitis
 - lymphadenitis
- The movement of leukocytes through a capillary or venule wall is called _____.
 - chemotaxis
 - diapedesis
 - phagocytosis
 - phagocytosis
 - phagocytosis
- In the process of _____, complement proteins coat bacteria and serve as binding sites for phagocytes.
 - opsonization
 - chemotaxis
 - phagocytosis
 - phagocytosis
 - phagocytosis
- Any substance that triggers a fever is called a/an _____.
 - antigen
 - antibody
 - antigenic determinant
 - antigenic epitope
 - antigenic epitope
- The chemical signals produced by leukocytes to stimulate other leukocytes are called _____.
 - chemokines
 - chemotaxis
 - chemotaxis
 - chemotaxis
 - chemotaxis
- Part of an antibody called the _____ binds to part of an antigen called the _____.
 - variable region; constant region
 - constant region; variable region
 - variable region; variable region
 - constant region; constant region
 - variable region; constant region
- Self-tolerance results from a process called _____, in which lymphocytes programmed to react against self-antigens die.
 - apoptosis
 - chemotaxis
 - chemotaxis
 - chemotaxis
 - chemotaxis
- Any disease in which antibodies attack one's own tissues is called a/an _____ disease.
 - autoimmune
 - autoimmune
 - autoimmune
 - autoimmune
 - autoimmune

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Some bacteria employ lysozyme to liquefy the tissue gel and make it easier for them to get around.
- T lymphocytes undergo clonal deletion and anergy in the thymus.
- Interferons help to reduce inflammation.
- T lymphocytes are involved only in cell-mediated immunity.
- The white pulp of the spleen gets its color mainly from lymphocytes and macrophages.
- Perforins are employed in both nonspecific resistance and cellular immunity.
- Histamine and heparin are secreted by basophils and mast cells.
- A person who is HIV-positive and has a T_H (CD4) count of 1,000 cells/ μ L does not have AIDS.
- Anergy is often a cause of autoimmune diseases.
- Interferons kill pathogenic bacteria by making holes in their cell walls.

Answers in appendix B

Testing Your Comprehension

1. Anti-D antibodies of an Rh⁻ woman sometimes cross the placenta and hemolyze the RBCs of an Rh⁺ fetus (see p. 699). Yet the anti-B antibodies of a type A mother seldom affect the RBCs of a type B fetus. Explain this difference based on your knowledge of the five immunoglobulin classes.
2. In treating a woman for malignancy in the right breast, the surgeon removes some of her axillary lymph nodes. Following surgery, the patient experiences edema of her right arm. Explain why.
3. A girl with a defective heart receives a new heart transplanted from another child who was killed in an accident. The patient is given an antilymphocyte serum containing antibodies against her lymphocytes. The transplanted heart is not rejected, but the patient dies of an overwhelming bacterial infection. Explain why the antilymphocyte serum was given and why the patient was so vulnerable to infection.
4. A burn research center uses mice for studies of skin grafting. To prevent graft rejection, the mice are thymectomized at birth. Even though B cells do not develop in the thymus, these mice show no humoral immune response and are very susceptible to infection. Explain why the removal of the thymus would improve the success of skin grafts but adversely affect humoral immunity.
5. Contrast the structure of a B cell with that of a plasma cell, and explain how their structural difference relates to their functional difference.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Factors that affect simple diffusion (p. 101)
- Serous and mucous membranes (p. 177)
- Bones of the nasal region (p. 256)
- The muscles of respiration (p. 339)
- Basic brainstem anatomy (p. 518)
- Divisions of the autonomic nervous system (p. 567)
- The structure of hemoglobin (p. 690)
- Principles of fluid pressure and flow (p. 739)
- Pulmonary blood circulation (p. 778)

Breath represents life. The first breath of a baby and the last gasp of a dying person are two of the most dramatic moments of human experience. But why do we breathe? It comes down to the fact that most of our metabolism directly or indirectly requires ATP. Most ATP synthesis requires oxygen and generates carbon dioxide—thus driving the need to breathe in order to supply the former and eliminate the latter. The respiratory system consists essentially of tubes that deliver air to the lungs, where oxygen diffuses into the blood and carbon dioxide diffuses out.

The respiratory and cardiovascular systems collaborate to deliver oxygen to tissues throughout the body and to transport carbon dioxide to the lungs for elimination. Not only do these two systems have a close spatial relationship in the thoracic cavity, they also have such a close functional relationship that they are often considered jointly as the *cardiopulmonary system*. A disorder that affects the lungs has direct and pronounced effects on the heart, and vice versa. As discussed in the next two chapters, the respiratory system also collaborates closely with the urinary system to regulate the body's acid-base balance—which is reason to consider these systems consecutively in this group of chapters.

22.1 Anatomy of the Respiratory System

Objectives

When you have completed this section, you should be able to

- state the functions of the respiratory system;
- name and describe the organs of this system;
- trace the flow of air from the nose to the pulmonary alveoli; and
- relate the function of any portion of the respiratory tract to its gross and microscopic anatomy.

The term **respiration** has three meanings: (1) ventilation of the lungs (breathing), (2) the exchange of gases between air and blood and between blood and tissue fluid, and (3) the use of oxygen in cellular metabolism. In this chapter, we are concerned with the first two processes. Cellular respiration was introduced in chapter 2 and is considered more fully in chapter 26.

The **respiratory system** is an organ system that rhythmically takes in air and expels it from the body, thereby supplying the body with oxygen and expelling the carbon dioxide that it generates. However, it has a broader range of functions than is commonly supposed:

1. It provides for oxygen and carbon dioxide exchange between the blood and air.
2. It serves for speech and other vocalizations (laughing, crying).
3. It provides the sense of smell, which is important in social interactions, food selection, and avoiding danger (such as a gas leak or spoiled food).
4. By eliminating CO₂, it helps to control the pH of the body fluids. Excess CO₂ reacts with water and releases hydrogen ions (CO₂ + H₂O → H₂CO₃ → HCO₃⁻ + H⁺); therefore, if the respiratory system does not keep pace with the rate of CO₂ production, H⁺ accumulates and the body fluids have an abnormally low pH (*acidosis*).
5. The lungs carry out a step in the synthesis of a vasoconstrictor called *angiotensin II*, which helps to regulate blood pressure.
6. Breathing creates pressure gradients between the thorax and abdomen that promote the flow of lymph and venous blood.
7. Breath-holding helps to expel abdominal contents during urination, defecation, and childbirth (the *Valsalva maneuver* described later).

The principal organs of the respiratory system are the nose, pharynx, larynx, trachea, bronchi, and lungs (fig. 22.1). Within the lungs, air flows along a dead-end pathway consisting essentially of bronchi → bronchioles → alveoli (with some refinements to be introduced later). Incoming air stops in the *alveoli* (millions of thin-walled, microscopic air sacs), exchanges gases with the bloodstream through the alveolar wall, and then flows back out.

The **conducting division** of the respiratory system consists of those passages that serve only for airflow, essentially from the nostrils through the major bronchioles. The **respiratory division** consists of the alveoli and other distal gas-exchange regions. The airway from the nose through the larynx is often called the **upper respiratory tract** (that is, the respiratory organs in the head and neck), and the regions from the trachea through the lungs compose the **lower respiratory tract** (the respiratory organs of the thorax). However, these are inexact terms and various authorities place the dividing line between the upper and lower tracts at different points.

The Nose

The **nose** has several functions: it warms, cleanses, and humidifies inhaled air; it detects odors in the airstream; and it serves as a resonating chamber that amplifies the voice. It extends from a pair of anterior openings called

FIGURE 22.1 The Respiratory System.

the **nostrils**, or **nares** (NAIR-eze) (singular, *naris*), to a pair of posterior openings called the **posterior nasal apertures**, or **choanae**¹ (co-AH-nee).

The facial part of the nose is shaped by bone and hyaline cartilage. Its superior half is supported by a pair of small nasal bones medially and the maxillae laterally. The inferior half is supported by the **lateral** and **alar cartilages** (fig. 22.2). By palpating your own nose, you can easily find the boundary between the bone and cartilage. The flared portion at the lower end of the nose, called the **ala nasi**² (AIL-ah NAZE-eye), is shaped by the alar cartilages and dense connective tissue.

The internal chamber of the nose, called the **nasal cavity**, is divided into right and left halves called **nasal fossae** (FAW-see). The dividing wall is a vertical plate, the **nasal septum**, composed of bone and hyaline cartilage. The vomer forms the inferior part of the septum, the perpendicular plate of the ethmoid bone forms its superior part, and the *septal cartilage* forms its anterior part (fig. 22.3c). The ethmoid and sphenoid bones compose the roof of the nasal cavity, and the hard palate forms its

(a)

(b)

FIGURE 22.2 Anatomy of the Nasal Region. (a) External anatomy. (b) Connective tissues that shape the nose.

floor. The palate separates the nasal cavity from the oral cavity and allows you to breathe while chewing food. The paranasal sinuses (see p. 248) and the nasolacrimal ducts of the orbits drain into the nasal cavity.

The nasal cavity begins with a small dilated chamber called the **vestibule** just inside the nostril, bordered by the ala nasi. This space is lined with stratified squamous epithelium like the facial skin, and has stiff **guard hairs**, or **vibrissae** (vy-BRISS-ee), that block insects and debris from entering the nose. Posterior to the vestibule, the nasal cavity expands into a much larger chamber, but it does not have much open space. Most of it is occupied by three folds of tissue—the **superior**, **middle**, and **inferior**

¹choana = funnel

²ala = wing + nasi = of the nose

● Draw a line across part (b) of this figure to indicate the boundary between the upper and lower respiratory tract.

nasal conchae³ (CON-kee), or **turbinates**—that project from the lateral walls toward the septum (fig. 22.3). Beneath each concha is a narrow air passage called a **meatus** (me-AY-tus). The narrowness of these passages and the turbulence caused by the conchae ensure that most air contacts the mucous membrane on its way through. As it does, most dust in the air sticks to the mucus, and the air picks up moisture and heat from the mucosa. The conchae thus enable the nose to cleanse, warm, and humidify the air more effectively than if the air had an unobstructed flow through a cavernous space.

Odors are detected by sensory cells in the **olfactory epithelium**, which covers a small area of the roof of the nasal fossa and adjacent parts of the septum and superior concha (see fig. 16.7, p. 598). The rest of the nasal cavity, except for the vestibule, is lined with **respiratory epithelium**. Both of these are ciliated pseudostratified columnar epithelia. However, in the olfactory epithelium, the cilia are immobile and serve to bind odor molecules. In the respiratory epithelium, they are mobile. The respiratory epithelium is similar to the one seen in figure 5.7 (p. 157). Its wineglass-shaped *goblet cells* secrete mucus, and its ciliated cells propel the mucus posteriorly toward the pharynx. The nasal mucosa also contains mucous glands, located in the lamina propria (the connective tissue layer beneath the epithelium). They supplement the mucus produced by the goblet cells. Inhaled dust, pollen, bacteria, and other foreign matter stick to the mucus and are swallowed; they are either digested or pass through the digestive tract rather than contaminating the lungs. The lamina propria is also well populated by lymphocytes and plasma cells that mount immune defenses against inhaled pathogens.

The lamina propria contains large blood vessels that help to warm the air. The inferior concha has an especially extensive venous plexus called the **erectile tissue (swell body)**. Every 30 to 60 minutes, the erectile tissue on one side swells with blood and restricts airflow through that fossa. Most air is then directed through the other nostril and fossa, allowing the engorged side time to recover from drying. Thus, the preponderant flow of air shifts between the right and left nostrils once or twice each hour.

The Pharynx

The **pharynx** (FAIR-inks, FAR-inks) is a muscular funnel extending about 13 cm (5 in.) from the choanae to the larynx. It has three regions: the *nasopharynx*, *oropharynx*, and *laryngopharynx* (fig. 22.3c).

The **nasopharynx** lies posterior to the choanae and above the soft palate. It receives the auditory (eustachian) tubes from the middle ears and houses the pharyngeal tonsil. Inhaled air turns 90° downward as it passes through the nasopharynx. Relatively large particles

(>10 μm) generally cannot make the turn because of their inertia. They collide with the posterior wall of the nasopharynx and stick to the mucosa near the tonsil, which is well positioned to respond to airborne pathogens.

The **oropharynx** is a space between the inferior margin of the soft palate and the epiglottis. It contains the palatine tonsils.

The **laryngopharynx** (la-RIN-go-FAIR-inks) lies mostly posterior to the larynx, extending from the superior margin of the epiglottis to the inferior margin of the cricoid cartilage. The esophagus begins at that point. The nasopharynx passes only air and is lined by pseudostratified columnar epithelium, whereas the oropharynx and laryngopharynx pass air, food, and drink and are lined by stratified squamous epithelium.

The Larynx

The **larynx** (LAIR-inks), or voice box, is a cartilaginous chamber about 4 cm (1.5 in.) long (fig. 22.4). Its primary function is to keep food and drink out of the airway, but it evolved the additional role of sound production (*phonation*) in many animals and achieved its highest vocal sophistication in humans.

The superior opening of the larynx is guarded by a flap of tissue called the **epiglottis**.⁴ At rest, the epiglottis stands almost vertically. During swallowing, however, *extrinsic muscles* of the larynx pull the larynx upward toward the epiglottis, the tongue pushes the epiglottis downward to meet it, and the epiglottis closes the airway and directs food and drink into the esophagus behind it. The *vestibular folds* of the larynx, discussed shortly, play a greater role in keeping food and drink out of the airway, however.

In infants, the larynx is relatively high in the throat and the epiglottis touches the soft palate. This creates a more or less continuous airway from the nasal cavity to the larynx and allows an infant to breathe continually while swallowing. The epiglottis deflects milk away from the airstream, like rain running off a tent while it remains dry inside. By age 2, the root of the tongue becomes more muscular and forces the larynx to descend to a lower position. It then becomes impossible to breathe and swallow at the same time without choking.

The framework of the larynx consists of nine cartilages. The first three are solitary and relatively large. The most superior one, the **epiglottic cartilage**, is a spoon-shaped supportive plate in the epiglottis. The largest, the **thyroid**⁵ **cartilage**, is named for its shieldlike shape. It broadly covers the anterior and lateral aspects of the larynx. The “Adam’s apple” is an anterior peak of the thyroid cartilage called the *laryngeal prominence*. Testosterone stimulates the growth of this prominence, which is

³concha = seashell

⁴epi = above, upon + glottis = back of the tongue

⁵thyr = shield + oid = resembling

FIGURE 22.4 Anatomy of the Larynx. Most muscles are removed in order to show the cartilages.

Which three cartilages in this figure are more mobile than any of the others?

therefore larger in males than in females. Inferior to the thyroid cartilage is a ringlike **cricoid**⁶ (CRY-coyd) **cartilage**, which connects the larynx to the trachea. The thyroid and cricoid cartilages essentially constitute the “box” of the voice box.

The remaining cartilages are smaller and occur in three pairs. Posterior to the thyroid cartilage are the two **arytenoid**⁷ (AR-ih-TEE-noyd) **cartilages**, and attached to their upper ends is a pair of little horns, the **corniculate**⁸ (cornick-you-late) **cartilages**. The arytenoid and corniculate cartilages function in speech, as explained shortly. A pair of **cuneiform**⁹ (cue-NEE-ih-form) **cartilages** supports the soft tissues between the arytenoids and the epiglottis.

A group of fibrous ligaments binds the cartilages of the larynx together and to adjacent structures in the neck. Superiorly, a broad sheet called the **thyrohyoid ligament** joins the thyroid cartilage to the hyoid bone, and inferiorly, the **cricotracheal ligament** joins the cricoid cartilage to the trachea. These are collectively called the *extrinsic ligaments* because they link the larynx to other organs. The *intrinsic ligaments* are contained entirely within the larynx and link its nine cartilages to each other. Two pairs of intrinsic ligaments, the **vestibular** and **vocal ligaments**,

extend from the thyroid cartilage anteriorly to the arytenoid cartilages posteriorly, and support the vestibular folds and vocal cords, described shortly.

The walls of the larynx are quite muscular. The deep *intrinsic muscles* operate the vocal cords, and the superficial *extrinsic muscles* connect the larynx to the hyoid bone and elevate the larynx during swallowing. The extrinsic muscles, also called the *infrahyoid group*, are named and described in chapter 10 (table 10.2, p. 335).

The interior wall of the larynx has two folds on each side that stretch from the thyroid cartilage in front to the arytenoid cartilages in back. The superior **vestibular folds** (fig. 22.4c) play no role in speech but close the larynx during swallowing. They are supported by the aforementioned vestibular ligaments. The inferior **vocal cords (vocal folds)** produce sound when air passes between them. They contain the vocal ligaments and are covered with stratified squamous epithelium, best suited to endure vibration and contact between the cords. The vocal cords and the opening between them are collectively called the **glottis** (fig. 22.5a).

The intrinsic muscles control the vocal cords by pulling on the corniculate and arytenoid cartilages, causing the cartilages to pivot. Depending on their direction of rotation, the arytenoid cartilages abduct or adduct the vocal cords (fig. 22.6). Air forced between the adducted vocal cords vibrates them, producing a high-pitched sound when the cords are relatively taut and

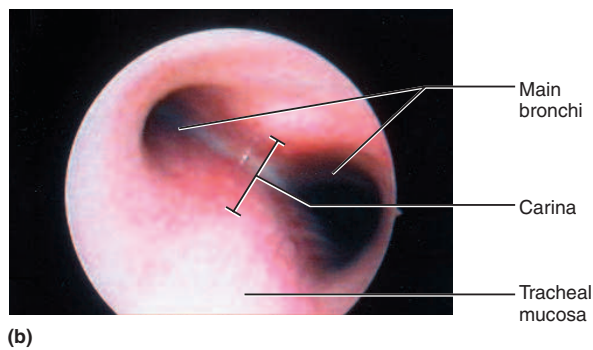

FIGURE 22.5 Endoscopic Views of the Respiratory Tract. (a) Superior view of the larynx, seen with a laryngoscope. (b) Lower end of the trachea, where it forks into the two primary bronchi, seen with a bronchoscope.

a lower-pitched sound when they are more slack. In adult males, the vocal cords are usually longer and thicker, vibrate more slowly, and produce lower-pitched sounds than in females. Loudness is determined by the force of the air passing between the vocal cords. Although the vocal cords alone produce sound, they do not produce intelligible speech; some anatomists have likened their sound to a hunter's duck call. The crude sounds from the larynx are formed into words by actions of the pharynx, oral cavity, tongue, and lips.

The Trachea

The **trachea** (TRAY-kee-uh), or “windpipe,” is a rigid tube about 12 cm (4.5 in.) long and 2.5 cm (1 in.) in diameter, anterior to the esophagus (fig. 22.7a). It is supported by 16 to 20 C-shaped rings of hyaline cartilage, some of which you can palpate between your larynx and sternum. Like the wire spiral in a vacuum cleaner hose, the cartilage rings reinforce the trachea and keep it from collapsing when you inhale. The open part of the C faces posteriorly, where it is spanned by a smooth muscle, the **trachealis** (fig. 22.7c). The gap in the C allows room for the esophagus to expand as swallowed food passes by. The trachealis muscles contract or relax to adjust airflow.

FIGURE 22.6 Action of Some of the Intrinsic Laryngeal Muscles on the Vocal Cords. (a) Adduction of the vocal cords by the lateral cricoarytenoid muscles. (b) Adducted vocal cords seen with the laryngoscope. (c) Abduction of the vocal cords by the posterior cricoarytenoid muscles. (d) Abducted vocal cords seen with the laryngoscope.

FIGURE 22.7 Anatomy of the Lower Respiratory Tract. (a) Anterior view. (b) Longitudinal section of the trachea showing the action of the mucociliary escalator. (c) Cross section of the trachea showing the C-shaped tracheal cartilage.

Why do inhaled objects more often go into the right main bronchus than into the left?

The inner lining of the trachea is a pseudostratified columnar epithelium composed mainly of mucus-secreting goblet cells, ciliated cells, and short basal stem cells (figs. 22.7b and 22.8). The mucus traps inhaled particles, and the upward beating of the cilia drives the debris-laden mucus toward the pharynx, where it is swallowed. This mechanism of debris removal is called the **mucociliary escalator**.

The connective tissue beneath the tracheal epithelium contains lymphatic nodules, mucous and serous glands, and the tracheal cartilages. The outermost layer of the trachea, called the **adventitia**, is fibrous connective tissue that blends into the adventitia of other organs of the mediastinum.

At the level of the sternal angle, the trachea forks into the right and left *main bronchi*. The lowermost tracheal cartilage has an internal median ridge called the **carina**¹⁰ (ca-RY-na) that directs the airflow to the right and left (see fig. 22.5b). The bronchi are further traced in the discussion of the *bronchial tree* of the lungs.

INSIGHT 22.1 Clinical Application

Tracheostomy

The functional importance of the nasal cavity becomes especially obvious when it is bypassed. If the upper airway is obstructed, it may be necessary to make a temporary opening in the trachea inferior to the larynx and insert a tube to allow airflow—a procedure called *tracheostomy*. This prevents asphyxiation, but the inhaled air bypasses the nasal cavity and thus is not humidified. If the opening is left for long, the mucous membranes of the respiratory tract dry out and become encrusted, interfering with the clearance of mucus from the tract and promoting infection. When a patient is on a ventilator and air is introduced directly into the trachea, the air must be filtered and humidified by the apparatus to prevent respiratory tract damage.

¹⁰carina = keel

FIGURE 22.8 The Tracheal Epithelium Showing Ciliated Cells and Nonciliated Goblet Cells (SEM). The small bumps on the goblet cells are microvilli.

❏ What is the function of the goblet cells?

The Lungs and Bronchial Tree

Each **lung** is a somewhat conical organ with a broad, concave **base** resting on the diaphragm and a blunt peak called the **apex** projecting slightly above the clavicle (fig. 22.9). The broad **costal surface** is pressed against the rib cage, and the smaller concave **mediastinal surface** faces medially. The mediastinal surface exhibits a slit called the **hilum** through which the lung receives the main bronchus, blood vessels, lymphatics, and nerves. These structures constitute the **root** of the lung.

The lungs are crowded by adjacent organs (fig. 22.10) and neither fill the entire rib cage, nor are they symmetrical. Inferior to the lungs and diaphragm, much of the space within the rib cage is occupied by the liver, spleen, and stomach (see fig. A.14, p. 43). The right lung is shorter than the left because the liver rises higher on the right. The left lung, although taller, is narrower than the right because the heart tilts toward the left and occupies more space on this side of the mediastinum. On the medial surface, the left lung has an indentation called the **cardiac impression** where the heart presses against it. The right lung has three lobes—**superior**, **middle**, and **inferior**. A deep groove called the **horizontal fissure**

separates the superior and middle lobes, and a similar **oblique fissure** separates the middle and inferior lobes. The left lung has only a **superior** and **inferior lobe** and a single oblique fissure.

The Bronchial Tree

Each lung has a branching system of air tubes called the **bronchial tree**, extending from the main bronchus to about 65,000 *terminal bronchioles*. Arising from the fork in the trachea, the **right main (primary) bronchus** (BRON-cus) is about 2 to 3 cm long. It is slightly wider and more vertical than the left one; consequently, *aspirated* (inhaled) foreign objects lodge in the right bronchus more often than in the left. The main bronchus gives off three branches—the **superior**, **middle**, and **inferior lobar (secondary) bronchi**—one to each lobe of the right lung. The **left main bronchus** is about 5 cm long and slightly narrower and more horizontal than the right. It gives off superior and inferior lobar bronchi to the two lobes of the left lung.

In both lungs, the lobar bronchi branch into **segmental (tertiary) bronchi**. There are 10 of these in the right lung and 8 in the left. Each one ventilates a functionally independent unit of lung tissue called a **bronchopulmonary segment**. Page 863 shows a cast of the bronchial trees made by injecting the airway with colored resins and then dissolving away the tissue. Each bronchopulmonary segment is identified by a different color of resin.

The main bronchi are supported, like the trachea, by C-shaped rings of hyaline cartilage, whereas the lobar and segmental bronchi are supported by overlapping crescent-shaped cartilaginous plates. All of the bronchi are lined with ciliated pseudostratified columnar epithelium, but the cells grow shorter and the epithelium thinner as we progress distally. The lamina propria has an abundance of mucous glands and lymphocyte nodules (*bronchus-associated lymphatic tissue, BALT*), favorably positioned to intercept inhaled pathogens. All divisions of the bronchial tree have a substantial amount of elastic connective tissue, which contributes to the recoil that expels air from the lungs in each respiratory cycle. The mucosa also has a well-developed layer of smooth muscle, the *muscularis mucosae*, which contracts or relaxes to constrict or dilate the airway, thus regulating airflow.

Branches of the *pulmonary artery* closely follow the bronchial tree on their way to the alveoli. The bronchial tree itself is serviced by the *bronchial artery*, which arises from the aorta and carries systemic blood.

Bronchioles are continuations of the airway that lack supportive cartilage and are 1 mm or less in diameter. The portion of the lung ventilated by one bronchiole is called a **pulmonary lobule**. Bronchioles have a ciliated cuboidal epithelium and a well-developed layer of smooth muscle in their walls. Spasmodic contractions of this muscle at death cause the bronchioles to exhibit a wavy lumen in most histological sections.

FIGURE 22.9 Gross Anatomy of the Lungs.

Each bronchiole divides into 50 to 80 **terminal bronchioles**, the final branches of the conducting division. These measure 0.5 mm or less in diameter and have no mucous glands or goblet cells. They do have cilia, however, so that mucus draining into them from the higher passages can be driven back by the mucociliary escalator,

thus preventing congestion of the terminal bronchioles and alveoli.

Each terminal bronchiole gives off two or more smaller **respiratory bronchioles**, which have alveoli budding from their walls. They are considered the beginning of the respiratory division because their alveoli participate in

FIGURE 22.10 Cross Section Through the Thoracic Cavity. This photograph is oriented the same way as the reader's body. The pleural cavity is especially evident where the left lung has shrunk away from the thoracic wall, but in a living person the lung fully fills this space, the parietal and visceral pleurae are pressed together, and the pleural cavity is only a potential space between the membranes, as on the right side of this photograph.

gas exchange. Their walls have scanty smooth muscle, and the smallest of them are nonciliated. Each respiratory bronchiole divides into 2 to 10 elongated, thin-walled passages called **alveolar ducts**, which also have alveoli along their walls (fig. 22.11). The alveolar ducts and smaller divisions have nonciliated simple squamous epithelia. The ducts end in **alveolar sacs**, which are grape-like clusters of alveoli arrayed around a central space

called the **atrium**. The distinction between an alveolar duct and atrium is their shape—an elongated duct, or an atrium with about equal length and width. It is sometimes a subjective judgment whether to regard a space as an alveolar duct or atrium.

In summary, the path of airflow is as follows. The first several passages belong to the conducting division, where the tissue walls are too thick for any significant exchange of oxygen or carbon dioxide with the blood: nasal cavity → pharynx → trachea → main bronchus → lobar bronchus → segmental bronchus → bronchiole → terminal bronchiole. Then begins the respiratory division; all of the following passages have alveoli along their walls (or are themselves

FIGURE 22.11 Histology of the Lung. (a) Light micrograph. (b) Scanning electron micrograph. Note the spongy texture of the lung.

● Histologically, how can we tell that the passage at the top of part (a) is a bronchiole and not a bronchus?

alveoli) and thus engage in gas exchange: respiratory bronchiole → alveolar duct → atrium → alveolus.

Alveoli

The functional importance of human lung structure is best appreciated by comparison to the lungs of a few other animals. In frogs and other amphibians, the lung is a simple sac lined with blood vessels. This is sufficient to meet the oxygen needs of animals with relatively low metabolic rates. Mammals, with their high metabolic rates, could never have evolved with such a simple lung. Rather than consisting of one large sac, each human lung is a spongy mass composed of 150 million little sacs, the alveoli, which provide about 70 m² of surface for gas exchange.

An **alveolus** (AL-vee-OH-lus) is a pouch about 0.2 to 0.5 mm in diameter (fig. 22.12). Thin, broad cells called **squamous (type I) alveolar cells** cover about 95% of the alveolar surface area. Their thinness allows for rapid gas diffusion between the alveolus and bloodstream. The other 5% is covered by round to cuboidal **great (type II) alveolar cells**. Even though they cover less surface area, these considerably outnumber the squamous alveolar

cells. They have two functions: (1) they repair the alveolar epithelium when the squamous alveolar cells are damaged, and (2) they secrete *pulmonary surfactant*, a mixture of phospholipids and protein that coats the alveoli and smallest bronchioles and prevents them from collapsing when one exhales. Without surfactant, the walls of a deflating alveolus would tend to cling together like sheets of wet paper, and it would be very difficult to reinflate them on the next inhalation.

The most numerous of all cells in the lung are **alveolar macrophages (dust cells)**, which wander the lumens of the alveoli and the connective tissue between them. These cells keep the alveoli free of debris by phagocytizing dust particles that escape entrapment by mucus in the higher parts of the respiratory tract. In lungs that are infected or bleeding, the macrophages also phagocytize bacteria and loose blood cells. As many as 100 million alveolar macrophages perish each day as they ride up the mucociliary escalator to be swallowed and digested, thus ridding the lungs of their load of debris.

Each alveolus is surrounded by a basket of blood capillaries supplied by the pulmonary artery. The barrier between the alveolar air and blood, called the **respiratory**

FIGURE 22.12 Pulmonary Alveoli. (a) Clusters of alveoli and their blood supply. (b) Structure of an alveolus. (c) Structure of the respiratory membrane.

membrane, consists only of the squamous alveolar cell, the squamous endothelial cell of the capillary, and their shared basement membrane. These have a total thickness of only 0.5 μm , in contrast to the 7.5 μm diameter of the erythrocytes passing through the capillaries.

It is very important to prevent fluid from accumulating in the alveoli, because gases diffuse too slowly through liquid to sufficiently aerate the blood. Except for a thin film of moisture on the alveolar wall, the alveoli are kept dry by the absorption of excess liquid by the blood capillaries. Their mean blood pressure is only 10 mm Hg and the oncotic pressure is 28 mm Hg (compare p. 773), so the osmotic uptake of water overrides filtration and keeps the alveoli free of fluid. The lungs also have a more extensive lymphatic drainage than any other organ in the body. The low capillary blood pressure also prevents the rupture of the delicate respiratory membrane.

The Pleurae

The surface of the lung is covered by a serous membrane, the **visceral pleura** (PLOOR-uh), which extends into the fissures. At the hilum, the visceral pleura turns back on itself and forms the **parietal pleura**, which adheres to the mediastinum, inner surface of the rib cage, and superior surface of the diaphragm (see fig. 22.10). An extension of the parietal pleura, the *pulmonary ligament*, connects it to the diaphragm.

The space between the parietal and visceral pleurae is called the **pleural cavity**. The pleural cavity does not *contain* a lung, but rather, wraps around it, somewhat like wrapping a pillowcase (representing the two pleural membranes) around a watermelon, not putting the melon inside the pillowcase. The pleural cavity contains nothing but a film of slippery **pleural fluid**; the cavity is only a *potential space*, meaning there is normally no room between the membranes. However, under pathological conditions, the space can fill with air or liquid (see *pneumothorax*, p. 883).

The pleurae and pleural fluid have three functions:

1. **Reduction of friction.** Pleural fluid acts as a lubricant that enables the lungs to expand and contract with minimal friction.
2. **Creation of pressure gradient.** Pressure in the pleural cavity is lower than atmospheric pressure; as explained later, this assists in inflation of the lungs.
3. **Compartmentalization.** The pleurae, mediastinum, and pericardium compartmentalize the thoracic organs and prevent infections of one organ from spreading easily to neighboring organs.

Think About It

In what ways do the structure and function of the pleurae resemble the structure and function of the pericardium?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. A dust particle is inhaled and gets into an alveolus without being trapped along the way. Describe the path it takes, naming all air passages from external nares to alveolus. What would happen to it after arrival in the alveolus?
2. Describe the histology of the epithelium and lamina propria of the nasal cavity and the functions of the cell types present.
3. Palpate two of your laryngeal cartilages and name them. Name the ones that cannot be palpated on a living person.
4. Describe the roles of the intrinsic muscles, corniculate cartilages, and arytenoid cartilages in speech.
5. Contrast the epithelium of the bronchioles with that of the alveoli and explain how the structural difference is related to their functional difference.

22.2 Pulmonary Ventilation

Objectives

When you have completed this section, you should be able to

- name the muscles of respiration and describe their roles in breathing;
- describe the brainstem centers that control breathing and the inputs they receive from other levels of the nervous system;
- explain how pressure gradients account for the flow of air in and out of the lungs, and how those gradients are produced;
- identify the sources of resistance to airflow and discuss their relevance to respiration;
- explain the significance of anatomical dead space to alveolar ventilation;
- define the clinical measurements of pulmonary volume and capacity; and
- define terms for various deviations from the normal pattern of breathing.

With the foregoing anatomical background, our next objective is to reach an understanding of how the lungs are ventilated. Breathing, or pulmonary ventilation, consists of a repetitive cycle of **inspiration** (inhaling) and **expiration** (exhaling). One complete inspiration and expiration is called a **respiratory cycle**.

Remember from chapter 19 that fluids (including air) flow down a pressure gradient from a point of higher pressure to one of lower pressure. If we have air in an enclosed space and then increase the volume of the space, we create a drop in pressure. If the pressure within the space is now lower than the pressure outside, and there is an inlet, air will flow in. This was earlier illustrated with an analogy to pulling out the plunger of a syringe to suck in air (see fig. 19.18, p. 740). Conversely, if we push the plunger in, the space becomes smaller, its pressure rises, and air flows out. Breathing is like this—the enclosed space is the lung, and its volume rises and falls through the actions of the respiratory muscles. We will examine these muscular actions, how the nervous system controls them, and then how the variables of pressure and resistance affect airflow and pulmonary ventilation.

We will need to distinguish at times between quiet and forced respiration. *Quiet respiration* refers to the way one breathes at rest, without conscious effort. It is relaxed,

unconscious, automatic breathing, the way one would breathe when reading a book or listening to a class lecture and not thinking about breathing. *Forced respiration* is unusually deep or rapid breathing, as in a state of exercise or when singing, playing a wind instrument, blowing up a balloon, coughing, or sneezing.

The Respiratory Muscles

The lungs do not ventilate themselves. The only muscle they contain is smooth muscle in the walls of the bronchi and bronchioles. This muscle adjusts the diameter of the airway and affects the speed of airflow, but it does not expand or shrink the lungs or create the airflow. That job belongs to the skeletal muscles of the trunk, especially the diaphragm and intercostal muscles (fig. 22.13).

The prime mover of pulmonary ventilation is the diaphragm (see table 10.4, p. 339). When relaxed, it bulges upward to its farthest extent, pressing against the base of

FIGURE 22.13 The Respiratory Muscles. Boldface indicates the principal respiratory muscles; the others are accessory. Arrows indicate the direction of muscle action. Muscles listed on the left are active during inspiration and those on the right are active during forced expiration. Note that the diaphragm is active in both phases, and different parts of the internal intercostal muscles serve for inspiration and expiration. Some other accessory muscles not shown here are discussed in the text.

the lungs. The lungs are at their minimum volume. When the diaphragm contracts, it tenses and flattens somewhat, dropping about 1.5 cm in relaxed inspiration and as much as 7 cm in deep breathing. This enlarges the thoracic cavity and lungs, creating an inflow of air. When the diaphragm relaxes, it bulges upward again, compresses the lungs, and expels air. The diaphragm alone accounts for about two-thirds of the pulmonary airflow.

Several other muscles aid the diaphragm as synergists. Chief among these are the internal and external intercostal muscles between the ribs. Their primary function is to stiffen the thoracic cage during respiration and prevent it from caving inward when the diaphragm descends. However, they also contribute to enlargement and contraction of the thoracic cage and add about one-third of the air that ventilates the lungs. During quiet breathing, the scalene muscles of the neck fix (hold stationary) ribs 1 and 2, while the external intercostal muscles pull the other ribs upward. Since most ribs are anchored at both ends—by their attachment to the vertebral column at the proximal end and their attachment through the costal cartilage to the sternum at the distal end—they swing upward like the handles on a bucket and thrust the sternum forward. These actions increase both the transverse (left to right) and anteroposterior (AP) diameters of the chest. In deep breathing, the AP diameter can increase by as much as 20%.

Other muscles of the chest and abdomen also aid in breathing, especially during forced respiration; thus they are considered *accessory muscles* of respiration. Deep inspiration is aided by the erector spinae, which arches the back and increases AP chest diameter, and by several muscles that elevate the upper ribs: the sternocleidomastoids and scalenes of the neck; the pectoralis minor, pectoralis major, and serratus anterior of the chest; and the *intercartilaginous part* of the internal intercostals (the anterior part between the costal cartilages). Although the scalenes merely fix the upper ribs during quiet respiration, they elevate them during forced inspiration.

Normal expiration is an energy-saving passive process achieved by the elasticity of the lungs and thoracic cage. The bronchial tree, the attachments of the ribs to the spine and sternum, and the tendons of the diaphragm and other respiratory muscles spring back when the muscles relax. As these structures recoil, the thoracic cage diminishes in size, the air pressure in the lungs rises above the atmospheric pressure outside, and the air flows out. The only muscular effort involved in normal expiration is a braking action—that is, the muscles relax gradually rather than abruptly, thus preventing the lungs from recoiling too suddenly. This makes the transition from inspiration to expiration smoother.

In forced expiration, the *rectus abdominis* pulls down on the sternum and lower ribs, while the *interosseous part* of the internal intercostals (the lateral part between the ribs proper) pulls the other ribs downward. These actions reduce the chest dimensions and expel air more

rapidly and thoroughly than usual. Other lumbar, abdominal, and even pelvic muscles contribute to forced expiration by raising the pressure in the abdominal cavity and pushing some of the viscera, such as the stomach and liver, up against the diaphragm. This increases the pressure in the thoracic cavity and thus helps to expel air. Abdominal control of airflow is particularly important in singing and public speaking.

Not only does abdominal pressure affect thoracic pressure, but the opposite is also true. Depression of the diaphragm raises abdominal pressure and helps to expel the contents of certain abdominal organs, thus aiding in childbirth, urination, defecation, and vomiting. During such actions, we often consciously or unconsciously employ the **Valsalva**¹¹ **maneuver**. This consists of taking a deep breath, holding it by closing the glottis, and then contracting the abdominal muscles to raise abdominal pressure and push the organ contents out.

Neural Control of Breathing

The heartbeat and breathing are the two most conspicuously rhythmic processes in the body. The heart, we have seen, has an internal pacemaker and continues beating even if all nerves to it are severed, but the lungs do not. No autorhythmic pacemaker cells for respiration have been found that are analogous to those of the heart, and the exact mechanism for setting the rhythm of respiration remains unknown. But we do know that breathing depends on repetitive stimuli from the brain. It ceases if the nerve connections to the thoracic muscles are severed or if the spinal cord is severed high on the neck. There are two reasons for this dependence on the brain: (1) Skeletal muscles, unlike cardiac muscle, cannot contract without nervous stimulation. (2) Breathing involves the well-orchestrated action of multiple muscles and thus requires a central coordinating mechanism.

Breathing is controlled at two levels of the brain. One is cerebral and conscious, enabling us to inhale or exhale at will. Most of the time, however, we breathe without thinking about it—fortunately, for we otherwise could not go to sleep without fear of respiratory arrest (see Insight 22.2).

Brainstem Respiratory Centers

The automatic, unconscious cycle of breathing is controlled by three pairs of respiratory centers in the reticular formation of the medulla oblongata and pons (fig. 22.14). There is one of each on the right and left sides of the brainstem; the two sides communicate with each other so that the respiratory muscles contract symmetrically.

1. The **ventral respiratory group (VRG)** is the primary generator of the respiratory rhythm. It is an elongated nucleus in the medulla with two commingled webs of neurons—**inspiratory (I) neurons** and **expiratory**

¹¹ Antonio Maria Valsalva (1666–1723), Italian anatomist

FIGURE 22.14 Respiratory Control Centers in the Central Nervous System. The ventral respiratory group (VRG) generates the rhythm of breathing. Its output goes to a spinal integrating center that gives rise to the intercostal and phrenic nerves to the intercostal muscles and diaphragm. The dorsal respiratory group (DRG) is an integrating center that processes information from multiple sources and then issues output to the VRG to adjust the respiratory rhythm. The DRG gets input from higher brain centers involved in emotional and voluntary influences on respiration; from the pontine respiratory group (PRG); from the chemosensitive area (central chemoreceptors) of the medulla oblongata; and from peripheral chemoreceptors and stretch receptors by way of the vagus and glossopharyngeal nerves. Additional output from higher brain centers bypasses both the DRG and VRG and goes to spinal integrating centers that control the accessory muscles of respiration, such as the abdominal muscles.

INSIGHT 22.2 Clinical Application**Ondine's Curse**

In German legend, there was a water nymph named Ondine who took a mortal lover. When her lover proved unfaithful, the king of the nymphs put a curse on him that took away his automatic physiological functions. Consequently, he had to remember to take each breath, and he could not go to sleep or he would die of suffocation—which, as exhaustion overtook him, was indeed his fate.

Some people suffer a disorder called *Ondine's curse*, in which the automatic respiratory functions are disabled—usually as a result of brainstem damage from poliomyelitis or as an accident of neurosurgery. Victims of Ondine's curse must remember to take each breath and cannot go to sleep without the aid of a mechanical ventilator.

(E) neurons—each forming a reverberating neural circuit (see p. 472). In quiet breathing (called *eupnea*), the I neuron circuit fires for about 2 seconds at a time, issuing nerve signals to integrating centers in the spinal cord. Output from the spinal centers travels by way of the phrenic nerves to the diaphragm and by way of intercostal nerves to the external intercostal muscles. Contraction of these muscles enlarges the thoracic cage and causes inspiration. As long as the I neurons are firing, they also inhibit the E neurons. Eventually, however, the I neurons stop firing, either because of fatigue or because they are inhibited by signals from an outside source. As their activity wanes, the E neurons begin firing. They further inhibit the I neurons, allowing the inspiratory muscles to relax. Elastic recoil of the thoracic cage expels air from the lungs. Expiration in eupnea typically lasts about 3 seconds. Then the E neuron activity wanes, the I neurons resume firing, and the cycle repeats itself. In eupnea, this oscillating pattern of neural activity, alternating between the I neuron and E neuron circuits, produces a respiratory rhythm of about 12 breaths per minute.

- Obviously, one does not always breathe at that rate. Breathing can be faster or slower, shallower or deeper, because the VRG is subject to influence from external sources. Chief among these is the **dorsal respiratory group (DRG)**, another web of neurons that extends for much of the length of the medulla between the VRG and the central canal of the brainstem. The DRG is apparently an integrating center that receives input from several sources detailed in the coming discussion: a respiratory center in the pons; a chemosensitive center of the anterior medulla oblongata; chemoreceptors in certain major arteries; and stretch and irritant receptors in the airway. The DRG issues

output to the VRG that modifies the respiratory rhythm to adapt to varying conditions.

- Furthermore, each side of the pons has a **pontine respiratory group (PRG)** (formerly called the *pneumotaxic center*) that modifies the rhythm of the VRG. The pontine group receives input from higher brain centers including the hypothalamus, limbic system, and cerebral cortex, and issues output to both the DRG and VRG. By acting on those centers in the medulla, it hastens or delays the transition from inspiration to expiration, making each breath shorter and shallower, or longer and deeper. The PRG adapts breathing to special circumstances such as sleep, exercise, vocalization, and emotional responses (for example, in crying, gasping, or laughing).

Think About It

Some authorities refer to the respiratory rhythm as an autonomic function. Discuss whether you think this is an appropriate word for it. What are the effectors of the autonomic nervous system? (See chapter 15.) What are the effectors that ventilate the lungs? What bearing might this have on the question?

Central and Peripheral Input to the Respiratory Centers

Variations in the respiratory rhythm are possible because the respiratory centers of the medulla and pons receive input from several other levels of the nervous system and therefore respond to the body's varying physiological needs. For example, anxiety can trigger a bout of uncontrollable *hyperventilation* in some people, a state in which breathing is so rapid that it expels CO₂ from the body faster than it is produced. As blood CO₂ levels drop, the pH rises and causes the cerebral arteries to constrict. This reduces cerebral perfusion and may cause dizziness or fainting. Hyperventilation can be brought under control by having a person rebreathe the expired CO₂ from a paper bag.

Multiple sensory receptors also provide information to the respiratory centers:

- Central chemoreceptors** are brainstem neurons that respond especially to changes in the pH of the cerebrospinal fluid. They are concentrated on each side of the medulla oblongata at a point only 0.2 mm beneath its anterior surface. The pH of the CSF reflects the CO₂ level in the blood. By regulating respiration to maintain a stable pH, the respiratory centers also ensure a stable CO₂ level in the blood.
- Peripheral chemoreceptors** are located in the carotid and aortic bodies of the large arteries above the heart (fig. 22.15). They respond to the O₂ and CO₂ content and the pH of the blood. The carotid bodies communicate with the brainstem by way of the glossopharyngeal nerves, and the aortic bodies by way of the

FIGURE 22.15 The Peripheral Chemoreceptors of Respiration. Peripheral chemoreceptors in the aortic arch and carotid bodies monitor blood gas concentrations and blood pH. They send signals about blood chemistry to the dorsal respiratory group of the medulla oblongata through sensory fibers in the vagus and glossopharyngeal nerves.

vagus nerves. Sensory fibers in these nerves enter the medulla and synapse with neurons of the DRG.

- **Stretch receptors** are found in the smooth muscle of the bronchi and bronchioles and in the visceral pleura. They respond to inflation of the lungs and signal the DRG by way of the vagus nerves. Excessive inflation triggers the **inflation (Hering-Breuer)¹² reflex**, a protective somatic reflex that strongly inhibits the I neurons and stops inspiration. In infants, this may be a normal mechanism of transition from inspiration to expiration, but after infancy it is activated only by extreme stretching of the lungs.
- **Irritant receptors** are nerve endings amid the epithelial cells of the airway. They respond to smoke, dust, pollen, chemical fumes, cold air, and excess mucus. They transmit signals by way of the vagus nerves to

the DRG, and the DRG returns signals to the respiratory and bronchial muscles, resulting in such protective reflexes as bronchoconstriction, shallower breathing, breath-holding (*apnea*), or coughing.

Voluntary Control of Breathing

Voluntary control of breathing is important in singing, speaking, breath-holding, and other circumstances. Such control originates in the motor cortex of the frontal lobe of the cerebrum. The output neurons send impulses down the corticospinal tracts to the integrating centers in the spinal cord, bypassing the brainstem centers. There are limits to voluntary control. Temperamental children may threaten to hold their breath until they die, but it is impossible to do so. Holding one's breath raises the CO₂ level of the blood until a *breaking point* is reached when automatic controls override one's will. This forces a person to resume breathing even if he or she has lost consciousness.

Pressure, Resistance, and Airflow

Now that we know the neuromuscular aspects of breathing, we'll explore how the expansion and contraction of the thoracic cage produce airflow into and out of the lungs.

Understanding pulmonary ventilation, the transport of gases in the blood, and the exchange of gases with the tissues draws on certain gas laws of physics. These are named after their discoverers and not intuitively easy to remember by name. Table 22.1 lists them for your convenience and may be a helpful reference as you progress through respiratory physiology.

TABLE 22.1

The Gas Laws of Respiratory Physiology

Boyle's law ¹³	The pressure of a given quantity of gas is inversely proportional to its volume (assuming a constant temperature).
Charles's law ¹⁴	The volume of a given quantity of gas is directly proportional to its absolute temperature (assuming a constant pressure).
Dalton's law ¹⁵	The total pressure of a gas mixture is equal to the sum of the partial pressures of its individual gases.
Henry's law ¹⁶	At the air-water interface, the amount of gas that dissolves in water is determined by its solubility in water and its partial pressure in the air (assuming a constant temperature).

¹⁵John Dalton (1766–1844), English physicist and chemist

¹⁶William Henry (1774–1836), English chemist

¹²Heinrich Ewald Hering (1866–1948), German physiologist; Josef Breuer (1842–1925), Austrian physician

Pressure and Airflow

Respiratory airflow is governed by the same principles of flow, pressure, and resistance as blood flow. As we saw in chapter 20 (p. 764), the flow (F) of a fluid is directly proportional to the pressure difference between two points (ΔP) and inversely proportional to resistance (R): $F \propto \Delta P/R$. For the moment, we will focus especially on ΔP , the pressure difference that produces airflow. We will deal with resistance later.

The pressure that drives respiration is **atmospheric (barometric) pressure**—the weight of the air above us. At sea level, the average atmospheric pressure is 760 mm Hg, or by definition, *1 atmosphere (1 atm)*. It fluctuates from day to day and is lower at higher elevations, but we will use this value as a reference point for discussion.

One way to change the pressure of an enclosed gas is to change the volume of its container. This fact is summarized by **Boyle's law**, which states that at a constant temperature, *the pressure of a given quantity of gas is inversely proportional to its volume*. If the lungs contain a quantity of gas and lung volume increases, their internal pressure, called **intrapulmonary pressure**, falls. Conversely, if lung volume decreases, intrapulmonary pressure rises. (Compare this to the syringe analogy.)

If the intrapulmonary pressure drops lower than the atmospheric pressure surrounding the body, then air tends to flow down its pressure gradient into the lungs. Conversely, if intrapulmonary pressure rises above atmospheric pressure, air flows out of the lungs. Therefore, all we have to do to breathe is to cyclically raise and lower the intrapulmonary pressure, employing the neuromuscular mechanisms recently described.

The following discussion uses measurements of relative gas pressures within the body and in the atmosphere. Atmospheric pressure varies with location and weather, so we cannot assume one constant atmospheric pressure (760 mm Hg) pertaining to all situations. But what matters to airflow is the *difference* between atmospheric pressure and intrapulmonary pressure. Thus, we will think in terms of relative pressures. A relative pressure of -3 mm Hg, for example, means 3 mm Hg below atmospheric pressure; a relative pressure of $+3$ mm Hg is 3 mm Hg above atmospheric pressure. At an atmospheric pressure of 760 mm Hg, these would represent absolute pressures of 757 and 763 mm Hg, respectively.

Inspiration

Now consider the flow of air into the lungs—inspiration. Figure 22.16 traces the events and pressure changes that occur throughout a respiratory cycle.

At the beginning, there is no movement of the thoracic cage, no difference between the air pressure within the lungs and external to the body, and no airflow. What happens when the thoracic cage expands? Why do the lungs not remain the same size and simply occupy less space in the chest? Consider the two layers of the pleura: the parietal

pleura forms the inner lining of the rib cage, and the visceral pleura forms the outer surface of the lung. They are firmly connected to those structures. Although they are not anatomically attached to each other along their surfaces, they are wet and therefore tend to cling together like sheets of wet paper.

When the ribs swing upward and outward during inspiration, the parietal pleura follows them. The visceral pleura clings to it by the cohesion of water, and as it follows the parietal pleura, it stretches the alveoli within the lung. Thus the entire lung expands along with the thoracic cage. As it increases in volume, its internal pressure drops, and air flows in.

The pressures involved are well known. Between the two layers of pleura, there is normally a slight vacuum called the **intrapleural pressure**, measuring about -4 mm Hg. This drops to about -6 mm Hg during inspiration, as the parietal pleura pulls away. Some of this pressure change transfers to the interior of the lungs, where pressure within the alveoli, the intrapulmonary pressure, drops to about -3 mm Hg. Thus, if the atmospheric pressure was 760 mm Hg, the intrapleural pressure would be 754 mm Hg and the intrapulmonary pressure 757 mm Hg. The pressure gradient of $760 \rightarrow 757$ mm Hg from atmosphere to alveoli makes air flow into the lungs.

Yet this is not the only force that expands the lungs. Another is warming of the inhaled air. As we see from **Charles's law** (see table 22.1), the volume of a given quantity of gas is directly proportional to its absolute temperature. Inhaled air is warmed to 37°C (99°F), by the time it reaches the alveoli. This means that on a cool day when the outdoor temperature is, say, 16°C (60°F), the air temperature will increase by 21°C (39°F) during inspiration. An inhaled volume of 500 mL will expand to 536 mL and this thermal expansion will contribute to inflation of the lungs.

When the respiratory muscles stop contracting, the inflowing air quickly achieves an intrapulmonary pressure equal to atmospheric pressure, and flow stops. In quiet breathing, the dimensions of the thoracic cage increase by only a few millimeters in each direction, but this is enough to increase its total volume by 500 mL. Thus, 500 mL of air flows into the respiratory tract.

Think About It

When you inhale, does your chest expand because your lungs inflate, or do your lungs inflate because your chest expands? Explain.

Expiration

Relaxed expiration is a passive process achieved, as we have seen, mainly by the elastic recoil of the thoracic cage. This recoil compresses the lungs and raises the intrapulmonary pressure to about $+3$ mm Hg. Air thus flows down its pressure gradient, out of the lungs. In forced breathing, the accessory muscles raise intrapulmonary pressure to as high as $+30$ mm Hg.

2 In inspiration, the thoracic cavity expands laterally, vertically, and anteriorly; intrapulmonary pressure drops 3 mm Hg below atmospheric pressure, and air flows into the lungs.

3 In expiration, the thoracic cavity contracts in all three directions; intrapulmonary pressure rises 3 mm Hg above atmospheric pressure, and air flows out of the lungs.

FIGURE 22.16 The Respiratory Cycle. The pressures given here are based on an assumed atmospheric pressure of 760 mm Hg (1 atm). Values with plus and minus signs are relative to atmospheric pressure. Like bucket handles, each rib is attached at both ends (to the spine and sternum) and swings up and down during inspiration and expiration.

The effect of pulmonary elasticity is evident in a pathological state of pneumothorax and atelectasis. **Pneumothorax** is the presence of air in the pleural cavity. If the thoracic wall is punctured, for example, inspiration sucks air through the wound into the pleural cavity, and the visceral and parietal pleurae separate; what was a *potential space* between them becomes an air-filled cavity. Without the negative intrapleural pressure to keep the lungs inflated, the lungs recoil and collapse. The collapse of part or all of a lung is called **atelectasis**¹⁷ (AT-eh-LEC-tasis). Atelectasis can also result from airway obstruction—for example, by a lung tumor, aneurysm, swollen lymph node, or aspirated object. Blood absorbs gases from the alveoli distal to the obstruction, and that part of the lung collapses because it cannot be reinflated.

Resistance to Airflow

Pressure is one determinant of airflow; the other is resistance. The greater the resistance, the slower the flow. But what governs resistance? Three factors are of particular importance:

1. **Diameter of the bronchioles.** Like arterioles, the large number of bronchioles, their small diameter, and their ability to change diameter make them the primary means of controlling resistance. The trachea and bronchi can also change diameter to a degree, but are more constrained by the supporting cartilages in their walls. An increase in the diameter of a bronchus or bronchiole is called **bronchodilation**, and a reduction in diameter is called **bronchoconstriction**. Epinephrine and the sympathetic nerves (norepinephrine) stimulate bronchodilation and increase airflow. Histamine, parasympathetic nerves (acetylcholine), cold air, and chemical irritants are among the factors that stimulate bronchoconstriction. Many people have suffocated from the extreme bronchoconstriction brought on by anaphylactic shock or asthma (see Insight 21.3, p. 851).
2. **Pulmonary compliance.** This means the ease with which the lungs expand, or more exactly, the change in lung volume relative to a given pressure change. The thoracic cage may produce the same intrapleural pressure in two different people, but the lungs will expand less in a person with poorer pulmonary compliance (stiffer lungs). Compliance can be reduced by degenerative lung diseases such as tuberculosis and black lung disease, in which the lungs are stiffened by scar tissue. In such conditions, the thoracic cage expands normally but the lungs expand relatively little.
3. **Surface tension of the alveoli and distal bronchioles.** The alveoli are relatively dry, but they have a thin film of water over the epithelium. This film is necessary

for gas exchange, but creates a potential problem for pulmonary ventilation. Water molecules are attracted to each other by hydrogen bonds, creating surface tension, as we saw in chapter 2. You can appreciate the strength of this attraction if you reflect on the difficulty of separating two sheets of wet paper compared with two sheets of dry paper. Such a force draws the walls of the alveoli inward toward the lumen. If it went unchecked, the alveoli would collapse with each expiration and would strongly resist reflation.

The solution to this problem takes us back to the great alveolar cells and their surfactant. A *surfactant* is an agent that disrupts the hydrogen bonds of water and reduces surface tension; soaps and detergents are everyday examples. The pulmonary surfactant is composed of amphiphilic proteins and phospholipids. These molecules are partially hydrophobic, so they spread out over the surface of the water film, partially embedded in it like ice cubes floating in a bowl of water. As an alveolus begins to deflate, the surfactants are squeezed closer together, like the ice cubes being pushed together into a smaller area. If the alveolus were covered with a film of water only, it could continue collapsing, because water molecules can pile up into a thicker film of moisture. The physical structure of the surfactants resists compression, however. They cannot pile up into a thicker layer, because their hydrophilic regions resist separation from the water below. As they become crowded into a small area and resist layering, they retard and then halt the collapse of the alveolus.

The importance of this surfactant is especially apparent when it is lacking. Premature infants often have a deficiency of pulmonary surfactant and experience great difficulty breathing (see chapter 29). The resulting *infant respiratory distress syndrome (IRDS)* is often treated by administering artificial surfactant.

Alveolar Ventilation

Air that actually enters the alveoli becomes available for gas exchange, but not all inhaled air gets that far. About 150 mL of it (typically 1 mL per pound of body weight) fills the conducting division of the airway. Since this air cannot exchange gases with the blood, the conducting division is called the **anatomical dead space**. In pulmonary diseases, some alveoli may be unable to exchange gases because they lack blood flow or because the pulmonary membrane is thickened by edema or fibrosis. **Physiological (total) dead space** is the sum of anatomical dead space and any pathological alveolar dead space that may exist. In healthy people, few alveoli are nonfunctional, and the anatomical and physiological dead spaces are identical.

The anatomical dead space varies with circumstances. In a state of relaxation, parasympathetic stimulation

¹⁷ *atel* = imperfect, incomplete + *ectasis* = expansion

keeps the airway somewhat constricted. This minimizes the dead space so that more of the inhaled air ventilates the alveoli. In a state of arousal, by contrast, the sympathetic nervous system dilates the airway, which increases airflow. The increased airflow outweighs the air that is wasted by filling the increased dead space.

If a person inhales 500 mL of air and 150 mL of it stays in the dead space, then 350 mL of air ventilates the alveoli. Multiplying this by the respiratory rate gives the **alveolar ventilation rate (AVR)**—for example, 350 mL/breath \times 12 breaths/min = 4,200 mL/min. Of all measures of pulmonary ventilation, this one is most directly relevant to the body's ability to get oxygen to the tissues and dispose of carbon dioxide.

The alveoli never completely empty during expiration. There is always some leftover air called the *residual volume*, typically about 1,300 mL that one cannot exhale even with maximum effort. This air mixes with fresh air

arriving on the next inspiration, so the same oxygen-depleted air does not remain in the lungs cycle after cycle.

Measurements of Ventilation

It is often important to measure a person's pulmonary ventilation in order to assess the severity of a respiratory disease or monitor a patient's improvement or deterioration. Measurements are made by having the subject breathe into a device called a **spirometer**,¹⁸ which recaptures the expired breath and records such variables as the rate and depth of breathing, speed of expiration, and rate of oxygen consumption. Representative measurements for a healthy adult are given in table 22.2 and explained in figure 22.17.

¹⁸ *spiro* = breath + *meter* = measuring device

TABLE 22.2 Respiratory Volumes and Capacities for an Average Young Adult Male

Measurement	Typical Value	Definition
Respiratory volumes		
Tidal volume (TV)	500 mL	Amount of air inhaled and exhaled in one cycle during quiet breathing
Inspiratory reserve volume (IRV)	3,000 mL	Amount of air in excess of tidal volume that can be inhaled with maximum effort
Expiratory reserve volume (ERV)	1,200 mL	Amount of air in excess of tidal volume that can be exhaled with maximum effort
Residual volume (RV)	1,300 mL	Amount of air remaining in the lungs after maximum expiration; the amount that can never voluntarily be exhaled
Respiratory capacities		
Vital capacity (VC)	4,700 mL	The amount of air that can be inhaled and then exhaled with maximum effort; the deepest possible breath (VC = ERV + TV + IRV)
Inspiratory capacity (IC)	3,500 mL	Maximum amount of air that can be inhaled after a normal tidal expiration (IC = TV + IRV)
Functional residual capacity (FRC)	2,500 mL	Amount of air remaining in the lungs after a normal tidal expiration (FRC = RV + ERV)
Total lung capacity (TLC)	6,000 mL	Maximum amount of air the lungs can contain (TLC = RV + VC)

FIGURE 22.17 Respiratory Volumes and Capacities. The wavy line indicates inspiration when it rises and expiration when it falls. Compare with table 22.2.

Four of them are called *respiratory volumes*: tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume. **Tidal volume (TV)** is the amount of air inhaled and exhaled in one cycle of quiet breathing, normally about 500 mL. Beyond the amount normally inhaled, it is typically possible to inhale another 3,000 mL with maximum effort; this is the **inspiratory reserve volume (IRV)**. Similarly, with maximum effort, one can normally exhale another 1,200 mL beyond the amount normally exhaled; this is the **expiratory reserve volume (ERV)**. Even after a maximum voluntary expiration, there remains a **residual volume (RV)** of about 1,300 mL.

Four other measurements, called *respiratory capacities*, are obtained by adding two or more of the respiratory volumes: **vital capacity** (ERV + TV + IRV), **inspiratory capacity** (TV + IRV), **functional residual capacity** (RV + ERV), and **total lung capacity** (RV + VC). Vital capacity, the maximum ability to ventilate the lungs in one breath, is an especially important measure of pulmonary health. In general, respiratory volumes and capacities are proportional to body size; consequently, they are generally higher for men than for women.

Spirometry, the measurement of pulmonary function, is an aid to the diagnosis and assessment of *restrictive* and *obstructive* lung disorders. **Restrictive disorders** are those that reduce pulmonary compliance, thus limiting the amount to which the lungs can be inflated. They show in spirometry as a reduced vital capacity. Any disease that produces pulmonary fibrosis has a restrictive effect: black lung disease and tuberculosis, for example. **Obstructive disorders** are those that interfere with airflow by narrowing or blocking the airway. They make it harder to inhale or exhale a given amount of air. Asthma and chronic bronchitis are the most common examples. Emphysema (see p. 897) combines elements of restrictive and obstructive disorders. Obstructive disorders can be measured by having the subject exhale as rapidly as possible into a spirometer and measuring **forced expiratory volume (FEV)**—the percentage of the vital capacity that can be exhaled in a given time interval. A healthy adult should be able to expel 75% to 85% of the vital capacity in 1.0 second (a value called the FEV_{1.0}). At home, asthma patients and others can monitor their respiratory function by blowing into a handheld meter that measures **peak flow**, the maximum speed of expiration.

The amount of air inhaled per minute is the **minute respiratory volume (MRV)**. MRV largely determines the alveolar ventilation rate. It can be measured directly with a spirometer or obtained by multiplying tidal volume by respiratory rate. For example, if a person has a tidal volume of 500 mL per breath and a rate of 12 breaths per minute, the MRV would be 500 × 12 = 6,000 mL/min. During heavy exercise, MRV may be as high as 125 to 170 L/min. This is called **maximum voluntary ventilation (MVV)**, formerly called *maximum breathing capacity*.

Variations in the Respiratory Rhythm

Relaxed, quiet breathing is called **eupnea**¹⁹ (YOOP-nee-uh). It is typically characterized by a tidal volume of about 500 mL and a respiratory rate of 12 to 15 breaths per minute. Conditions ranging from exercise or anxiety to various disease states can cause deviations such as abnormally fast, slow, or labored breathing. Table 22.3 defines the clinical terms for several such variations. You should familiarize yourself with these before proceeding, because later discussions in this chapter assume a working knowledge of some of these terms.

Other variations in pulmonary ventilation serve the purposes of speaking, expressing emotion (laughing, crying), yawning, hiccuping, expelling noxious fumes, coughing,

TABLE 22.3

Variations in the Respiratory Rhythm

Apnea ²⁰ (AP-nee-uh)	Temporary cessation of breathing (one or more skipped breaths)
Dyspnea ²¹ (DISP-nee-uh)	Labored, gasping breathing; shortness of breath
Hyperpnea ²² (HY-purp-NEE-uh)	Increased rate and depth of breathing in response to exercise, pain, or other conditions
Hyperventilation	Increased pulmonary ventilation in excess of metabolic demand, frequently associated with anxiety; expels CO ₂ faster than it is produced, thus lowering the blood CO ₂ concentration and raising the blood pH
Hypoventilation ²³	Reduced pulmonary ventilation; leads to an increase in blood CO ₂ concentration if ventilation is insufficient to expel CO ₂ as fast as it is produced
Kussmaul ²⁴ respiration	Deep, rapid breathing often induced by acidosis; seen in diabetes mellitus
Orthopnea ²⁵ (or-thop-NEE-uh)	Dyspnea that occurs when a person is lying down or in any position other than standing or sitting erect; seen in heart failure, asthma, emphysema, and other conditions
Respiratory arrest	Permanent cessation of breathing (unless there is medical intervention)
Tachypnea ²⁶ (tack-ip-NEE-uh)	Accelerated respiration

¹⁹eu = easy, normal + pnea = breathing

²⁰a = without + pnea = breathing

²¹dys = difficult, abnormal, painful + pnea = breathing

²²hyper = above normal

²³hypo = below normal

²⁶tachy = fast + pnea = breathing

sneezing, and expelling abdominal contents. Coughing is induced by irritants in the lower respiratory tract. To cough, we close the glottis and contract the muscles of expiration, producing high pressure in the lower respiratory tract. We then suddenly open the glottis and release an explosive burst of air at speeds over 900 km/h (600 mi./h). This drives mucus and foreign matter toward the pharynx and mouth. Sneezing is triggered by irritants in the nasal cavity. Its mechanism is similar to coughing except that the glottis is continually open, the soft palate and tongue block the flow of air while thoracic pressure builds, and then the soft palate is depressed to direct part of the airstream through the nose. These actions are coordinated by coughing and sneezing centers in the medulla oblongata.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

6. Explain why contraction of the diaphragm causes inspiration but contraction of the transverse abdominal muscle causes expiration.
7. Which brainstem respiratory nucleus is indispensable to respiration? What do the other nuclei do?
8. Explain why Boyle's law is relevant to the action of the respiratory muscles.
9. Explain why eupnea requires little or no action by the muscles of expiration.
10. Identify a benefit and a disadvantage of normal (non-pathological) bronchoconstriction.
11. Suppose a healthy person has a tidal volume of 650 mL, an anatomical dead space of 160 mL, and a respiratory rate of 14 breaths per minute. Calculate her alveolar ventilation rate.
12. Suppose a person has a total lung capacity of 5,800 mL, a residual volume of 1,200 mL, an inspiratory reserve volume of 2,400 mL, and an expiratory reserve volume of 1,400 mL. Calculate his tidal volume.

- explain how gas exchange is adjusted to the metabolic needs of different tissues; and
- discuss the effect of blood gases and pH on the respiratory rhythm.

Ultimately, respiration is about gases, especially oxygen and carbon dioxide. We will turn our attention now to the behavior of these gases in the human body: how oxygen is obtained from inspired air and delivered to the tissues, and how carbon dioxide is removed from the tissues and released into the expired air. First, however, it is necessary to understand the composition of the air we inhale and how gases behave in contact with the water film that lines the alveoli.

Composition of Air

Air consists of about 78.6% nitrogen; 20.9% oxygen; 0.04% carbon dioxide; several quantitatively minor gases such as argon, neon, helium, methane, and ozone; and a variable amount of water vapor. Water vapor constitutes from 0% to 4%, depending on temperature and humidity; we will use a value of 0.5%, typical of a cool clear day.

The total atmospheric pressure is a sum of the contributions of these individual gases—a principle known as **Dalton's law** (see table 22.1). The separate contribution of each gas in a mixture is called its **partial pressure** and is symbolized with a P followed by the formula of the gas, such as P_{N_2} . If we assume the average sea-level pressure of 760 mm Hg and nitrogen is 78.6% of this, then P_{N_2} is simply $0.786 \times 760 \text{ mm Hg} = 597 \text{ mm Hg}$. Applying Dalton's law to the mixture of gases in the preceding paragraph, $P_{N_2} + P_{O_2} + P_{H_2O} + P_{CO_2} \approx 597 + 159 + 3.7 + 0.3 = 760.0 \text{ mm Hg}$.

This is the composition of the air we inhale, but it is not the composition of air in the alveoli. Alveolar air can be sampled with an apparatus that collects the last 10 mL of expired air. As we see in table 22.4, its composition differs from that of the atmosphere because of three influences: (1) It is humidified by contact with the mucous membranes, so its P_{H_2O} is more than 10 times

22.3 Gas Exchange and Transport

Objectives

When you have completed this section, you should be able to

- define *partial pressure* and discuss its relationship to a gas mixture such as air;
- contrast the composition of inspired and alveolar air;
- discuss how partial pressure affects gas transport by the blood;
- describe the mechanisms of transporting O_2 and CO_2 ;
- describe the factors that govern gas exchange in the lungs and systemic capillaries;

TABLE 22.4

Composition of Inspired (Atmospheric) and Alveolar Air

Gas	Inspired Air*		Alveolar Air	
N_2	78.6%	597 mm Hg	74.9%	569 mm Hg
O_2	20.9%	159 mm Hg	13.7%	104 mm Hg
H_2O	0.5%	3.7 mm Hg	6.2%	47 mm Hg
CO_2	0.04%	0.3 mm Hg	5.3%	40 mm Hg
Total	100%	760 mm Hg	100%	760 mm Hg

*Typical values for a cool clear day; values vary with temperature and humidity. Other gases present in small amounts are disregarded.

higher than that of the inhaled air. (2) Freshly inspired air mixes with residual air left from the previous respiratory cycle, so its oxygen is diluted and it is enriched with CO_2 from the residual air. (3) Alveolar air exchanges O_2 and CO_2 with the blood. Thus, the PO_2 of alveolar air is about 65% that of inhaled air, and its PCO_2 is more than 130 times higher.

Think About It

Expired air considered as a whole (not just the last 10 mL) is about 15.3% O_2 and 4.2% CO_2 . Why would these values differ from the ones for alveolar air?

Alveolar Gas Exchange

Air in the alveolus is in contact with the film of water covering the alveolar epithelium. For oxygen to get into the blood, it must dissolve in this water and pass through the respiratory membrane separating the air from the bloodstream. For carbon dioxide to leave the blood, it must pass the other way and diffuse out of the water film into the alveolar air. This back-and-forth traffic of O_2 and CO_2 across the respiratory membrane is called **alveolar gas exchange**.

The reason that O_2 can diffuse in one direction and CO_2 in the other is that each gas diffuses down its own pressure gradient. Whenever air and water are in contact with each other, gases diffuse down their gradients until the partial pressure of each gas in the air is equal to its partial pressure in the water. If a gas has a greater partial pressure in the water than in the air, it diffuses into the air; the smell of chlorine near a swimming pool is evidence of this. If its partial pressure is greater in the air, it diffuses into the water.

Henry's law states that *at the air–water interface, for a given temperature, the amount of gas that dissolves in the water is determined by its solubility in water and its partial pressure in the air* (fig. 22.18). Thus, the greater the PO_2 in the alveolar air, the more O_2 the blood picks up. And since blood arriving at an alveolus has a higher PCO_2 than air, it releases CO_2 into the air. At the alveolus, the blood is said to *unload* CO_2 and *load* O_2 . Each gas in a mixture behaves independently; the diffusion of one gas does not influence the diffusion of another.

Both O_2 loading and CO_2 unloading involve erythrocytes (RBCs). The efficiency of these processes therefore depends on how long an RBC spends in an alveolar capillary compared with how long it takes for each gas to be fully loaded or unloaded—that is, for them to reach equilibrium concentrations in the capillary blood. It takes about 0.25 s to reach equilibrium. At rest, when blood circulates at its slowest speed, an RBC passes through an alveolar capillary in about 0.75 s—plenty of time. Even in vigorous exercise, when the blood flows faster, an erythrocyte is in the alveolar capillary for about 0.3 s, which is still adequate.

(a) Oxygen

(b) Carbon dioxide

FIGURE 22.18 Henry's Law and Its Relationship to Alveolar Gas Exchange. (a) The PO_2 of alveolar air is initially higher than the PO_2 of the blood arriving at an alveolus. Oxygen diffuses into the blood until the two are in equilibrium. (b) The PCO_2 of the arriving blood is initially higher than the PCO_2 of alveolar air. Carbon dioxide diffuses into the alveolus until the two are in equilibrium. It takes about 0.25 s for both gases to reach equilibrium.

Several variables affect the efficiency of alveolar gas exchange, and under abnormal conditions, some of these can prevent the complete loading and unloading of gases:

- **Pressure gradients of the gases.** The PO_2 is about 104 mm Hg in the alveolar air and 40 mm Hg in the blood arriving at an alveolus. Oxygen therefore diffuses from the air into the blood, where it reaches a PO_2 of 104 mm Hg. Before the blood leaves the lung, however, this drops to about 95 mm Hg. This oxygen dilution occurs because the pulmonary veins anastomose with the bronchial veins in the lungs, so there is some mixing of the oxygen-rich pulmonary blood with the oxygen-poor systemic blood.

The PCO_2 is about 46 mm Hg in the blood arriving at the alveolus and 40 mm Hg in the alveolar air.

Carbon dioxide therefore diffuses from the blood into the alveoli. These changes are summarized here and at the middle of figure 22.19:

Blood entering lungs		Blood leaving lungs	
PO_2	40 mm Hg	PO_2	95 mm Hg
PCO_2	46 mm Hg	PCO_2	40 mm Hg

These gradients differ under special circumstances such as high elevation and *hyperbaric*

oxygen therapy (treatment with oxygen at greater than 1 atm of pressure) (fig. 22.20). At high elevations, the partial pressures of all atmospheric gases are lower. Atmospheric PO_2 , for example, is 159 mm Hg at sea level but only 110 mm Hg at 3,000 m (10,000 feet). The O_2 gradient from air to blood is proportionately less, and as we can predict from Henry's law, less O_2 diffuses into the blood. In a hyperbaric oxygen chamber, by contrast, a patient is exposed to 3 to 4 atm of oxygen to treat such

FIGURE 22.19 Changes in PO_2 and PCO_2 Along the Circulatory Route.

Trace the partial pressure of oxygen from inspired air to expired air and explain each change in PO_2 along the way. Do the same for PCO_2 .

conditions as gangrene (to kill anaerobic bacteria) and carbon monoxide poisoning (to displace the carbon monoxide from hemoglobin). The PO_2 ranges between 2,300 and 3,000 mm Hg. Thus, there is a very steep gradient of PO_2 from alveolus to blood and diffusion into the blood is accelerated.

- **Solubility of the gases.** Gases differ in their ability to dissolve in water. Carbon dioxide is about 20 times as soluble as oxygen, and oxygen is about twice as soluble as nitrogen. Even though the pressure gradient of O_2 is much greater than that of CO_2 across the respiratory membrane, equal amounts of the two gases are exchanged because CO_2 is so much more soluble and diffuses more rapidly.
- **Membrane thickness.** The respiratory membrane between the blood and alveolar air is only 0.5 μm

thick in most places—much less than the 7 to 8 μm diameter of a single RBC. Thus, it presents little obstacle to diffusion (fig. 22.21a). In such heart conditions as left ventricular failure, however, blood pressure backs up into the lungs and promotes capillary filtration into the connective tissues, causing the respiratory membranes to become edematous and thickened (similar to their condition in pneumonia; fig. 22.21b). The gases have farther to travel between blood and air and cannot equilibrate fast enough to keep pace with blood flow. Under these circumstances, blood leaving the lungs has an unusually high PCO_2 and low PO_2 .

- **Membrane area.** In good health, each lung has about 70 m^2 of respiratory membrane available for gas

FIGURE 22.20 Oxygen Loading in Relation to Partial Pressure Gradient. The rate of loading depends on the steepness of the gradient from alveolar air to the venous blood arriving at the alveolar capillaries. Compared with the oxygen gradient at sea level (blue line), the gradient is less steep at high elevation (red line) because the PO_2 of the atmosphere is lower. Thus, oxygen loading of the pulmonary blood is slower. In a hyperbaric chamber with 100% oxygen, the gradient from air to blood is very steep (green line), and oxygen loading is correspondingly rapid. This is an illustration of Henry's law and has important effects in diving, aviation, mountain climbing, and oxygen therapy.

FIGURE 22.21 Pulmonary Alveoli in Health and Disease. (a) In a healthy lung, the alveoli are small and have thin respiratory membranes. (b) In pneumonia, the respiratory membranes (alveolar walls) are thick with edema, and the alveoli contain fluid and blood cells. (c) In emphysema, alveolar membranes break down and neighboring alveoli join to form larger, fewer alveoli with less total surface area.

exchange. Since the alveolar capillaries contain a total of only 100 mL of blood at any one time, this blood is spread very thinly. Several pulmonary diseases, however, decrease the alveolar surface area and thus lead to low blood P_{O_2} —for example, emphysema (fig. 22.21c), lung cancer, and tuberculosis.

- **Ventilation–perfusion coupling.** Gas exchange requires not only good ventilation of the alveolus, but also good perfusion of its capillaries. As a whole, the lungs have a *ventilation–perfusion ratio* of about 0.8—a flow of 4.2 L of air and 5.5 L of blood per minute (at rest). The ratio is somewhat higher in the apex of the lung and lower in the base because more blood is drawn toward the base by gravity. **Ventilation–perfusion coupling** is the ability to match ventilation and perfusion to each other (fig. 22.22). If part of a lung is poorly ventilated

because of tissue destruction or airway obstruction, there is little point in directing much blood there. This blood would leave the lung carrying less oxygen than it should. But poor ventilation causes local constriction of the pulmonary arteries, reducing blood flow to that area and redirecting this blood to better-ventilated alveoli. Good ventilation, by contrast, dilates the arteries and increases perfusion so that most blood is directed to regions of the lung where it can pick up the most oxygen. This is opposite from the reactions of systemic arteries, where hypoxia (O_2 deficiency) causes vasodilation so that blood flow to a tissue will increase and reverse the hypoxia.

Ventilation is also adjustable. Poor ventilation causes local CO_2 accumulation, which stimulates local bronchodilation and improves airflow. Low PCO_2 causes local bronchoconstriction.

Gas Transport

Gas transport is the process of carrying gases from the alveoli to the systemic tissues and vice versa. This section explains how the blood loads and transports oxygen and carbon dioxide.

Oxygen

Arterial blood carries about 20 mL of oxygen per deciliter. About 98.5% of it is bound to hemoglobin in the RBCs and 1.5% is dissolved in the blood plasma. Hemoglobin is a molecule specialized for oxygen transport. It consists of four protein (globin) chains, each with one heme group (see fig. 18.5, p. 690). Each heme can bind 1 O_2 to the ferrous ion (Fe^{2+}) at its center; thus, one hemoglobin molecule can carry up to 4 O_2 . If one or more molecules of O_2 are bound to hemoglobin, the compound is called **oxyhemoglobin (HbO_2)**, whereas hemoglobin with no oxygen bound to it is **deoxyhemoglobin (HHb)**. When hemoglobin is 100% saturated, every molecule of it carries 4 O_2 ; if it is 75% saturated, there is an average of 3 O_2 per hemoglobin molecule; if it is 50% saturated, there is

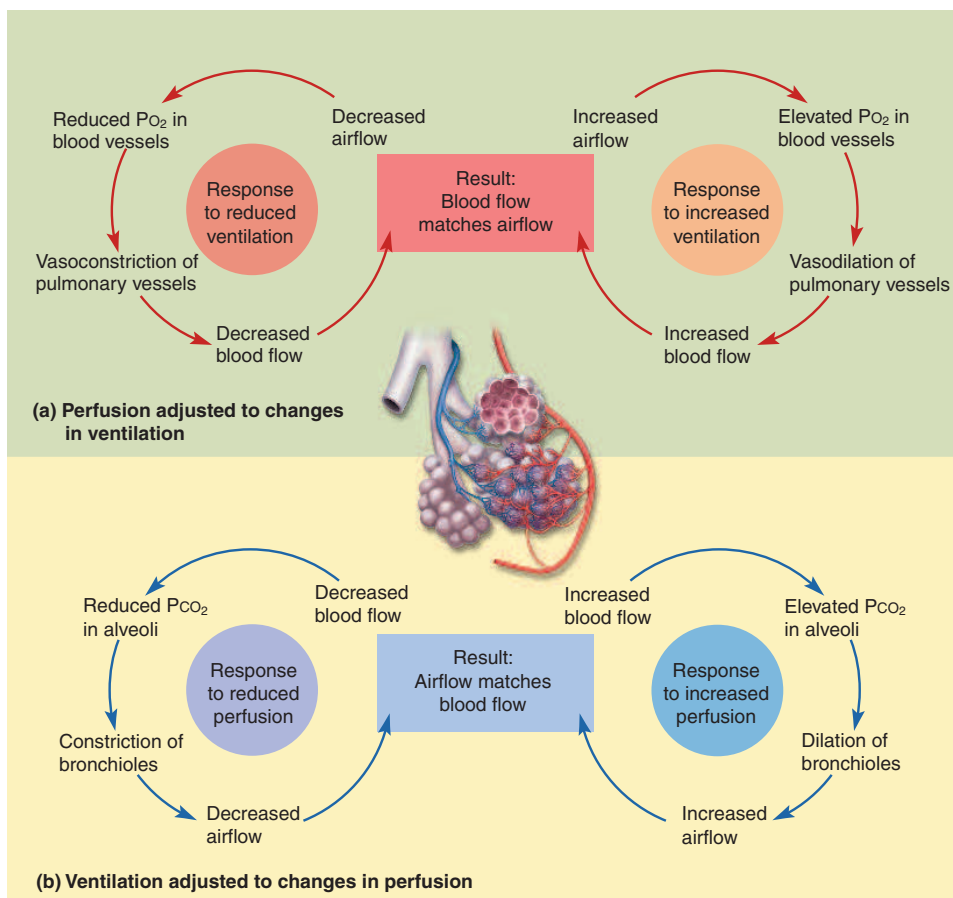

FIGURE 22.22 Ventilation–Perfusion Coupling. Negative feedback loops adjust airflow and blood flow to each other. (a) Blood circulation can be adjusted to above- or below-normal ventilation of a part of the lung. (b) Ventilation can be adjusted to above- or below-normal blood circulation to a part of the lung.

INSIGHT 22.3 Clinical Application

Carbon Monoxide Poisoning

The lethal effect of carbon monoxide (CO) is well known. This colorless, odorless gas occurs in cigarette smoke, engine exhaust, and fumes from furnaces and space heaters. It binds to the ferrous ion of hemoglobin to form *carboxyhemoglobin* (HbCO). Thus, it competes with oxygen for the same binding site. Not only that, but it binds 210 times as tightly as oxygen. Thus, CO tends to tie up hemoglobin for a long time. Less than 1.5% of the hemoglobin is occupied by carbon monoxide in most nonsmokers, but this figure rises to as much as 3% in residents of heavily polluted cities and 10% in heavy smokers. An atmospheric concentration of 0.1% CO, as in a closed garage, is enough to bind 50% of a person's hemoglobin, and an atmospheric concentration of 0.2% is quickly lethal.

an average of 2 O₂ per hemoglobin; and so forth. The poisonous effect of carbon monoxide stems from its competition for the O₂ binding site (see Insight 22.3).

The relationship between hemoglobin saturation and P_{O₂} is shown by the **oxyhemoglobin dissociation curve** (fig. 22.23). As you can see, it is not a simple linear

FIGURE 22.23 The Oxyhemoglobin Dissociation Curve. This curve shows the relative amount of hemoglobin that is saturated with oxygen (y-axis) as a function of ambient (surrounding) oxygen partial pressure (x-axis). As it passes through the alveolar capillaries where the P_{O₂} is high, hemoglobin becomes saturated with oxygen. As it passes through the systemic capillaries where the P_{O₂} is low, it typically gives up about 22% of its oxygen (color bar at top of graph).

What would be the approximate utilization coefficient if the systemic tissues had a P_{O₂} of 20 mm Hg?

relationship. At low P_{O₂}, the curve rises slowly; then there is a rapid increase in oxygen loading as P_{O₂} rises further. This reflects the way hemoglobin loads oxygen. When the first heme group binds a molecule of O₂, hemoglobin changes shape in a way that facilitates uptake of the second O₂ by another heme group. This, in turn, promotes the uptake of the third and then the fourth O₂—hence the rapidly rising midportion of the curve. At high P_{O₂} levels, the curve levels off because the hemoglobin approaches 100% saturation and cannot load much more oxygen.

Think About It

Is oxygen loading a positive or negative feedback process? Explain.

Carbon Dioxide

Carbon dioxide is transported in three forms: carbonic acid, carbamino compounds, and dissolved gas.

- About 90% of the CO₂ is hydrated (reacts with water) to form **carbonic acid**, which then dissociates into bicarbonate and hydrogen ions:

More will be said about this reaction shortly.

- About 5% binds to the amino groups of plasma proteins and hemoglobin to form **carbamino compounds**—chiefly **carbamino hemoglobin (HbCO₂)**. The reaction with hemoglobin can be symbolized $\text{Hb} + \text{CO}_2 \rightarrow \text{HbCO}_2$. Carbon dioxide does not compete with oxygen because CO₂ and O₂ bind to different sites on the hemoglobin molecule—oxygen to the heme moiety and CO₂ to the polypeptide chains. Hemoglobin can therefore transport both O₂ and CO₂ simultaneously. As we will see, however, each gas somewhat inhibits transport of the other.
- The remaining 5% of the CO₂ is carried in the blood as dissolved gas, like the CO₂ in carbonated beverages.

The relative amounts of CO₂ exchanged between the blood and alveolar air differ from the percentages just given. About 70% of the *exchanged* CO₂ comes from carbonic acid, 23% from carbamino compounds, and 7% from the dissolved gas. That is, blood gives up the dissolved CO₂ gas and CO₂ from the carbamino compounds more easily than it gives up the CO₂ in bicarbonate.

Systemic Gas Exchange

Systemic gas exchange is the unloading of O₂ and loading of CO₂ at the systemic capillaries (see fig. 22.19, bottom, and fig. 22.24).

FIGURE 22.24 Systemic Gas Exchange. Blue arrows show the three mechanisms of CO₂ loading and transport; their thickness represents the relative amounts of CO₂ loaded in each of the three forms. Red arrows show the two mechanisms of O₂ unloading; their thickness indicates the relative amounts unloaded by each mechanism. Note that CO₂ loading releases hydrogen ions in the erythrocyte, and hydrogen ions promote O₂ unloading.

Carbon Dioxide Loading

Aerobic respiration produces a molecule of CO₂ for every molecule of O₂ it consumes. The tissue fluid therefore contains a relatively high P_{CO₂} and there is typically a CO₂ gradient of 46 → 40 mm Hg from tissue fluid to blood. Consequently, CO₂ diffuses into the bloodstream, where it is carried in the three forms already noted. Most of it reacts with water to produce bicarbonate (HCO₃⁻) and hydrogen (H⁺) ions. This reaction occurs slowly in the blood plasma but much faster in the RBCs, where it is catalyzed by the enzyme *carbonic anhydrase*. An antiport called the *chloride–bicarbonate exchanger* then pumps most of the HCO₃⁻ out of the RBC in exchange for Cl⁻ from the blood plasma. This exchange is called the **chloride shift**. Most of the H⁺ binds to hemoglobin or oxyhemoglobin, which thus buffers the intracellular pH.

Oxygen Unloading

When H⁺ binds to oxyhemoglobin (HbO₂), it reduces the affinity of hemoglobin for O₂ and tends to make hemoglobin release it. Oxygen consumption by respiring tissues keeps the P_{O₂} of tissue fluid relatively low, so there is typically a

pressure gradient of 95 → 40 mm Hg of oxygen from the arterial blood to the tissue fluid. Thus, the liberated oxygen—along with some that was carried as dissolved gas in the plasma—diffuses from the blood into the tissue fluid.

As blood arrives at the systemic capillaries, its oxygen concentration is about 20 mL/dL and the hemoglobin is about 97% saturated. As it leaves the capillaries of a typical resting tissue, its oxygen concentration is about 15.6 mL/dL and the hemoglobin is about 75% saturated. Thus, it has given up 4.4 mL/dL—about 22% of its oxygen load. This fraction is called the **utilization coefficient**. The oxygen remaining in the blood after it passes through the capillary bed provides a **venous reserve** of oxygen, which can sustain life for 4 to 5 minutes even in the event of respiratory arrest. At rest, the circulatory system releases oxygen to the tissues at an overall rate of about 250 mL/min.

Alveolar Gas Exchange Revisited

The processes illustrated in figure 22.24 make it easier to understand alveolar gas exchange more fully. As shown in figure 22.25, the reactions that occur in the lungs are essentially the reverse of systemic gas exchange. As

hemoglobin loads oxygen, its affinity for H^+ declines. Hydrogen ions dissociate from the hemoglobin and bind with bicarbonate (HCO_3^-) ions transported from the plasma into the RBCs. Chloride ions are transported back out of the RBC (a reverse chloride shift). The reaction of H^+ and HCO_3^- reverses the hydration reaction and generates free CO_2 . This diffuses into the alveolus to be exhaled—as does the CO_2 released from carbaminohemoglobin and CO_2 gas that was dissolved in the plasma.

Adjustment to the Metabolic Needs of Individual Tissues

Hemoglobin does not unload the same amount of oxygen to all tissues. Some tissues need more and some less, depending on their state of activity. Hemoglobin responds to such variations and unloads more oxygen to the tissues that need it most. In exercising skeletal muscles, for example, the utilization coefficient may be as high as 80%. Four factors adjust the rate of oxygen unloading to the metabolic rates of different tissues:

1. **Ambient PO_2 .** Since an active tissue consumes oxygen rapidly, the PO_2 of its tissue fluid remains low.

From the oxyhemoglobin dissociation curve (see fig. 22.23), you can see that at a low PO_2 , HbO_2 releases more oxygen.

2. **Temperature.** When temperature rises, the oxyhemoglobin dissociation curve shifts to the right (fig. 22.26a); in other words, elevated temperature promotes oxygen unloading. Active tissues are warmer than less active ones and thus extract more oxygen from the blood passing through them.
3. **The Bohr effect.** Active tissues also generate extra CO_2 , which raises the H^+ concentration and lowers the pH of the blood. Like elevated temperatures, a drop in pH shifts the oxygen–hemoglobin dissociation curve to the right (fig. 22.26b) and promotes oxygen unloading. The increase in HbO_2 dissociation in response to low pH is called the **Bohr²⁷ effect**. It is less pronounced at the high PO_2 present in the lungs, so pH has relatively little effect on pulmonary oxygen loading. In the systemic capillaries, however, PO_2 is lower and the Bohr effect is more pronounced.

²⁷Christian Bohr (1855–1911), Danish physiologist

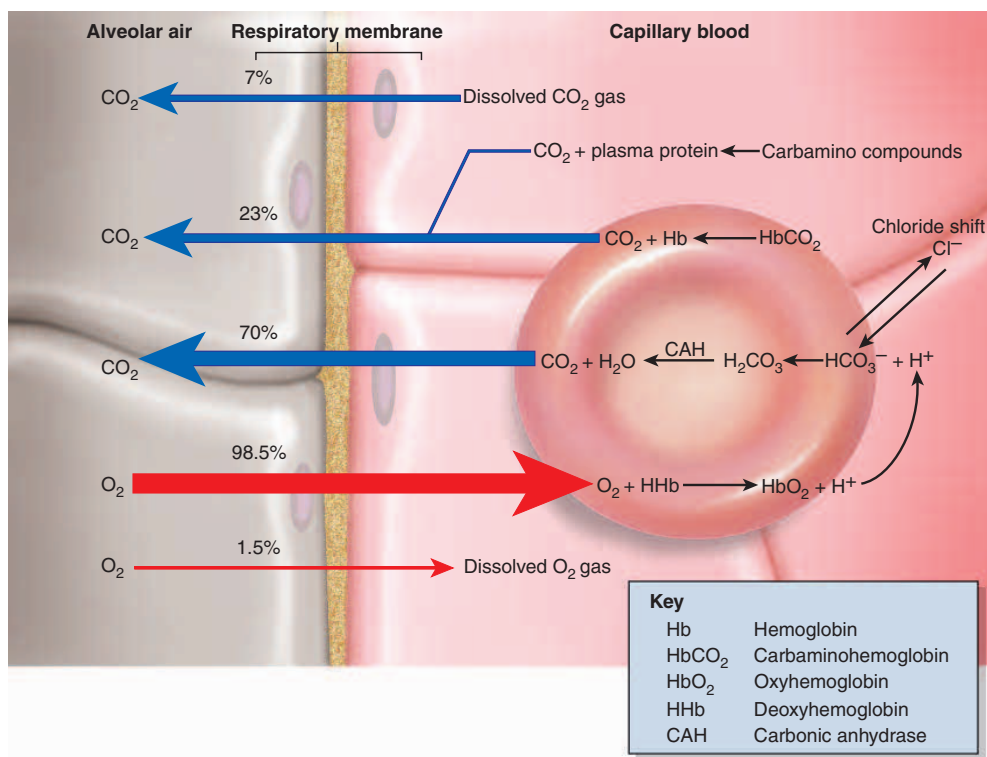

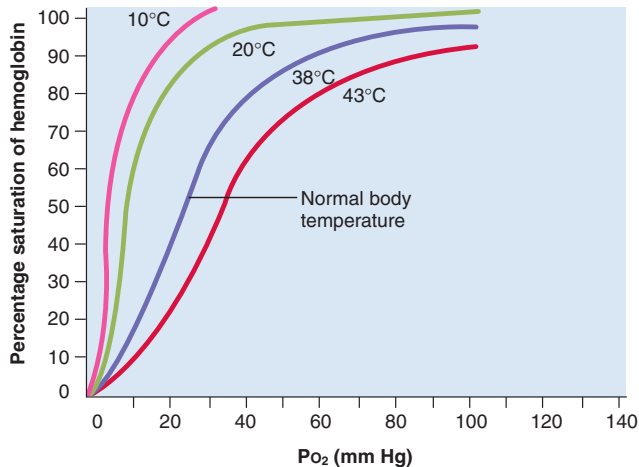

FIGURE 22.25 Alveolar Gas Exchange. Arrow colors and thicknesses represent the same variables as in figure 22.24. Note that O_2 loading promotes the decomposition of carbonic acid into H_2O and CO_2 , and most exhaled CO_2 comes from the erythrocytes.

◀ In what fundamental way does this differ from the preceding figure? Following alveolar gas exchange, will the blood contain a higher or lower concentration of bicarbonate ions than it did before?

(a) Effect of temperature

(b) Effect of pH

FIGURE 22.26 Effects of Temperature and pH on Oxyhemoglobin Dissociation. (a) For a given PO_2 , hemoglobin unloads more oxygen at higher temperatures. (b) For a given PO_2 , hemoglobin unloads more oxygen at lower pH (the Bohr effect). Both mechanisms cause hemoglobin to release more oxygen to tissues with higher metabolic rates.

Why is it physiologically beneficial to the body that the curves in part (a) shift to the right as temperature increases?

- BPG.** Erythrocytes have no mitochondria and meet their energy needs solely by anaerobic fermentation. One of their metabolic intermediates is **bisphosphoglycerate (BPG)**, which binds to hemoglobin and promotes oxygen unloading. An elevated body temperature (as in fever) stimulates BPG synthesis, as do thyroxine, growth hormone, testosterone, and epinephrine. All of these hormones thus promote oxygen unloading to the tissues.

The rate of CO_2 loading is also adjusted to varying needs of the tissues. A low level of oxyhemoglobin (HbO_2) enables the blood to transport more CO_2 , a phenomenon known as the **Haldane effect**.²⁸ It occurs for two reasons: (1) HbO_2 does not bind CO_2 as well as deoxyhemoglobin (HHb) does. (2) HHb binds more hydrogen ions than HbO_2 does, and by removing H^+ from solution, HHb shifts the carbonic acid reaction ($H_2O + CO_2 \rightarrow HCO_3^- + H^+$) to the right. A high metabolic rate keeps oxyhemoglobin levels relatively low and thus allows more CO_2 to be transported by these two mechanisms.

Blood Gases and the Respiratory Rhythm

Normally the systemic arterial blood has a PO_2 of 95 mm Hg, a PCO_2 of 40 mm Hg, and a pH of 7.40 ± 0.05 . The rate and depth of breathing are adjusted to maintain these values. This is possible only because the brainstem respiratory centers receive input from central and peripheral chemoreceptors that monitor the composition of the blood and CSF, as described on p. 879. Of these three chemical stimuli, the most potent stimulus for breathing is pH, followed by CO_2 ; perhaps surprisingly, the least significant is O_2 .

Hydrogen Ions

Ultimately, pulmonary ventilation is adjusted to maintain the pH of the brain. The central chemoreceptors in the medulla oblongata produce about 75% of the change in respiration induced by pH shifts, and yet H^+ does not cross the blood–brain barrier very easily. However, CO_2 does, and once it is in the CSF, it reacts with water to produce carbonic acid, and the carbonic acid dissociates into bicarbonate and hydrogen ions. The CSF contains relatively little protein to buffer the hydrogen ions, so most H^+ remains free, and it strongly stimulates the central chemoreceptors. Hydrogen ions are also a potent stimulus to the peripheral chemoreceptors, which produce about 25% of the respiratory response to pH changes.

It is significant to ask how we know it is the H^+ that stimulates the central chemoreceptors and not primarily the CO_2 that diffuses into the CSF. Experimentally, it is possible to vary the pH or the PCO_2 of the CSF while holding the other variable steady. When pH alone changes, there is a strong effect on respiration; when PCO_2 alone changes, the effect is weaker. Therefore, even though these two variables usually change together, we can see that the chemoreceptors react primarily to the H^+ .

A blood pH lower than 7.35 is called **acidosis**, and a pH greater than 7.45 is called **alkalosis**. The PCO_2 of arterial blood normally ranges from 37 to 43 mm Hg.

²⁸John Scott Haldane (1860–1936), Scottish physiologist

A P_{CO_2} less than 37 mm Hg is called **hypocapnia**,²⁹ and is the most common cause of alkalosis. The most common cause of acidosis is **hypercapnia**, a P_{CO_2} greater than 43 mm Hg. When these pH imbalances result from a mismatch between the rate of pulmonary ventilation and the rate of CO_2 production, they are called *respiratory acidosis* and *respiratory alkalosis* (further discussed in chapter 24).

The corrective homeostatic response to acidosis is hyperventilation, “blowing off” CO_2 faster than the body produces it. As CO_2 is eliminated from the body, the carbonic acid reaction shifts to the left:

Thus, the H^+ on the right is consumed, and as H^+ concentration declines, the pH rises and ideally returns the blood from the acidotic range to normal.

The corrective response to alkalosis is hypoventilation, which allows CO_2 to accumulate in the body fluids faster than we exhale it. Hypoventilation shifts the reaction to the right, raising the H^+ concentration and lowers the pH to normal:

Although pH changes usually result from P_{CO_2} changes, they can have other causes. In diabetes mellitus, for example, rapid fat oxidation releases acidic ketone bodies, causing an abnormally low pH called *ketoacidosis*. Ketoacidosis tends to induce a form of dyspnea called *Kussmaul respiration* (see table 22.3). Hyperventilation cannot reduce the level of ketone bodies in the blood, but by blowing off CO_2 , it reduces the concentration of CO_2 -generated H^+ and compensates to some degree for the H^+ released by the ketone bodies.

Carbon Dioxide

Although the arterial P_{CO_2} has a strong influence on respiration, we have seen that it is mostly an indirect one, mediated through its effects on the pH of the CSF. Yet the experimental evidence described earlier shows that CO_2 has some effect even when pH remains stable. At the beginning of exercise, the rising blood CO_2 level may directly stimulate the peripheral chemoreceptors and trigger an increase in ventilation more quickly than the central chemoreceptors do.

Oxygen

The partial pressure of oxygen usually has little effect on respiration. Even in eupnea, the hemoglobin is 97% saturated with O_2 , so little can be added by increasing pulmonary ventilation. Arterial PO_2 significantly affects respiration only if it drops below 60 mm Hg. At low elevations, such a low PO_2 seldom occurs even in prolonged

holding of the breath. A moderate drop in PO_2 does stimulate the peripheral chemoreceptors, but another effect overrides this: as the level of HbO_2 falls, hemoglobin binds more H^+ (see fig. 22.24). This raises the blood pH, which inhibits respiration and counteracts the effect of low PO_2 .

At about 10,800 feet (3,300 m), PO_2 falls to 60 mm Hg and the stimulatory effect of hypoxemia on the carotid bodies overrides the inhibitory effect of the pH increase. This produces heavy breathing in people who are not acclimated to high elevation. Long-term hypoxemia can lead to a condition called **hypoxic drive**, in which respiration is driven more by the low PO_2 than by CO_2 or pH. This occurs in situations such as emphysema and pneumonia, which interfere with alveolar gas exchange, and in mountain climbing of at least 2 or 3 days' duration.

Respiration and Exercise

It is common knowledge that we breathe more heavily during exercise, and it's tempting to think this occurs because exercise raises CO_2 levels, lowers the blood pH, and lowers blood O_2 levels. However, this is not true; all these values remain essentially the same in exercise as they do at rest. It appears that the increased respiration has other causes: (1) When the brain sends motor commands to the muscles (via the lower motor neurons of the spinal cord), it also sends this information to the respiratory centers, so they increase pulmonary ventilation in anticipation of the needs of the exercising muscles. (2) Exercise stimulates proprioceptors of the muscles and joints, and they transmit excitatory signals to the brainstem respiratory centers. Thus, the respiratory centers increase breathing because they are informed that the muscles have been told to move or are actually moving. The increase in pulmonary ventilation keeps blood gas values at their normal levels in spite of the elevated O_2 consumption and CO_2 generation by the muscles.

In summary, the main chemical stimulus to pulmonary ventilation is the H^+ in the CSF and tissue fluid of the brain. These hydrogen ions arise mainly from CO_2 diffusing into the CSF and brain and generating H^+ through the carbonic acid reaction. Therefore, the P_{CO_2} of the arterial blood is an important driving force in respiration, even though its action on the chemoreceptors is indirect. Ventilation is adjusted to maintain arterial pH at about 7.40 and arterial P_{CO_2} at about 40 mm Hg. This automatically ensures that the blood is at least 97% saturated with O_2 as well. Under ordinary circumstances, arterial PO_2 has relatively little effect on respiration. When it drops below 60 mm Hg, however, it excites the peripheral chemoreceptors and stimulates an increase in ventilation. This can be significant at high elevations and in certain lung diseases. The increase in respiration during exercise results from the expected or actual activity of the muscles, not from any change in blood gas pressures or pH.

²⁹capn = smoke

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

13. Why is the composition of alveolar air different from that of the atmosphere?
14. What four factors affect the efficiency of alveolar gas exchange?
15. Explain how perfusion of a pulmonary lobule changes if it is poorly ventilated.
16. How is most oxygen transported in the blood, and why does carbon monoxide interfere with this?
17. What are the three ways in which blood transports CO_2 ?
18. Give two reasons why highly active tissues can extract more oxygen from the blood than less active tissues do.
19. Define hypocapnia and hypercapnia. Name the pH imbalances that result from these conditions and explain the relationship between Pco_2 and pH.
20. What is the most potent chemical stimulus to respiration, and where are the most effective chemoreceptors for it located?
21. Explain how changes in pulmonary ventilation can correct pH imbalances.

Some of its root causes include atmospheric deficiency of oxygen at high elevations; impaired ventilation, as in drowning or aspiration of foreign matter; respiratory arrest; and the degenerative lung diseases discussed shortly. It also occurs in carbon monoxide poisoning, which prevents hemoglobin from transporting oxygen.

- **Ischemic hypoxia** results from inadequate circulation of the blood, as in congestive heart failure.
- **Anemic hypoxia** is due to anemia and the resulting inability of the blood to carry adequate oxygen.
- **Histotoxic hypoxia** occurs when a metabolic poison such as cyanide prevents the tissues from using the oxygen delivered to them.

Hypoxia is often marked by **cyanosis**, blueness of the skin. Whatever the cause, its primary effect is the necrosis of oxygen-starved tissues. This is especially critical in organs with the highest metabolic demands, such as the brain, heart, and kidneys.

An oxygen excess is also dangerous. It is safe to breathe 100% oxygen at 1 atm for a few hours, but **oxygen toxicity** rapidly develops when pure oxygen is breathed at 2.5 atm or greater. Excess oxygen generates hydrogen peroxide and free radicals that destroy enzymes and damage nervous tissue; thus, it can lead to seizures, coma, and death. This is why scuba divers breathe a mixture of oxygen and nitrogen rather than pure compressed oxygen (see Insight 22.4). Hyperbaric oxygen was formerly used to treat premature infants for respiratory distress syndrome, but it caused retinal deterioration and blinded many infants before the practice was discontinued.

22.4 Respiratory Disorders

Objectives

When you have completed this section, you should be able to

- describe the forms and effects of oxygen deficiency and oxygen excess;
- describe the chronic obstructive pulmonary diseases and their consequences; and
- explain how lung cancer begins, progresses, and exerts its lethal effects.

The delicate lungs are exposed to a wide variety of inhaled pathogens and debris, so it is not surprising that they are prone to a host of diseases. Several already have been mentioned in this chapter and some others are briefly described in table 22.5. The effects of aging on the respiratory system are discussed on page 1143.

Oxygen Imbalances

Hypoxia is a deficiency of oxygen in a tissue or the inability to use oxygen. It is not a respiratory disease in itself but is often a consequence of respiratory diseases. Hypoxia is classified according to cause:

- **Hypoxemic hypoxia**, a state of low arterial Po_2 , is usually due to inadequate pulmonary gas exchange.

Chronic Obstructive Pulmonary Diseases

Chronic obstructive pulmonary disease (COPD) refers to any disorder in which there is a long-term obstruction of airflow and a substantial reduction in pulmonary ventilation. The major COPDs are *chronic bronchitis* and *emphysema*. They are almost always caused by cigarette smoking, but occasionally result from air pollution or occupational exposure to airborne irritants. Some authorities also classify asthma as a COPD, but the National Institutes of Health no longer do so.

Beginning smokers exhibit inflammation and hyperplasia of the bronchial mucosa. In **chronic bronchitis**, the cilia are immobilized and reduced in number, while goblet cells enlarge and produce excess mucus. With extra mucus and fewer cilia to dislodge it, smokers develop a chronic cough that brings up **sputum** (SPEW-tum), a mixture of mucus and cellular debris. Thick, stagnant mucus in the respiratory tract provides a growth medium for bacteria, while cigarette smoke incapacitates the alveolar macrophages and reduces defense mechanisms against respiratory infections. Smokers therefore develop chronic infection

and bronchial inflammation, with symptoms that include dyspnea, hypoxia, cyanosis, and attacks of coughing.

In **emphysema**³⁰ (EM-fih-SEE-muh), alveolar walls break down and the lung exhibits larger but fewer alveoli (see fig. 22.21c). Thus, there is much less respiratory membrane available for gas exchange. The lungs become fibrotic and less elastic; in advanced cases, parts of the lung may look like flabby, empty air bags instead of showing the normal spongy texture seen in figure 22.11b. The air passages open adequately during inspiration, but they tend to collapse and obstruct the outflow of air. Air therefore becomes trapped in the lungs, and over a period of time a person becomes barrel-chested. The overly stretched thoracic muscles contract weakly, which further contributes to the difficulty of expiration. People with emphysema become exhausted because they expend three to four times the normal amount of energy just to breathe. Even slight physical exertion, such as walking across a room, can cause severe shortness of breath.

Think About It

Explain how the length-tension relationship of skeletal muscle (see p. 420) accounts for the weakness of the respiratory muscles in emphysema.

³⁰emphys = inflamed

COPD tends to reduce pulmonary compliance and vital capacity and causes hypoxemia, hypercapnia, and respiratory acidosis. Hypoxemia stimulates the kidneys to secrete erythropoietin, which leads to accelerated erythrocyte production and polycythemia, as discussed in chapter 18. COPD also leads to **cor pulmonale**—hypertrophy and potential failure of the right heart due to obstruction of the pulmonary circulation (see chapter 19).

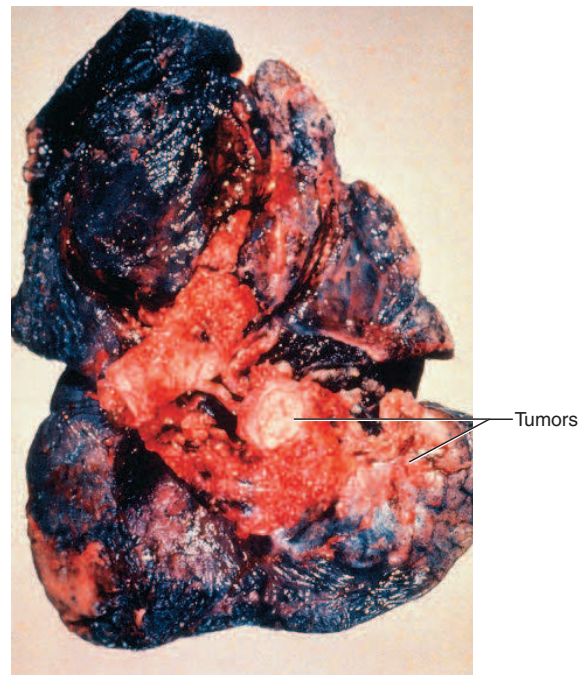

Smoking and Lung Cancer

Lung cancer (fig. 22.27) accounts for more deaths than any other form of cancer. The most important cause of lung cancer is cigarette smoking, distantly followed by air pollution. Cigarette smoke contains at least 15 carcinogenic compounds. Lung cancer commonly follows or accompanies COPD.

There are three forms of lung cancer, the most common of which is **squamous-cell carcinoma**. In its early stage, basal cells of the bronchial epithelium multiply and the ciliated pseudostratified epithelium transforms into the stratified squamous type. As the dividing epithelial cells invade the underlying tissues of the bronchial wall, the bronchus develops bleeding lesions. Dense swirled masses of keratin appear in the lung parenchyma and replace functional respiratory tissue.

(a) Healthy lung, mediastinal surface

(b) Smoker's lung with carcinoma

FIGURE 22.27 Effect of Smoking.

A second form of lung cancer, nearly as common, is **adenocarcinoma**,³¹ which originates in the mucous glands of the lamina propria. The least common (10%–20% of malignancies) but most dangerous form is **small-cell (oat-cell) carcinoma**, named for clusters of cells that resemble oat grains. This originates in the main bronchi but invades the mediastinum and metastasizes quickly to other organs.

Over 90% of lung tumors originate in the mucous membranes of the large bronchi. As a tumor invades the bronchial wall and grows around it, it compresses the airway and may cause atelectasis (collapse) of more distal parts of the lung. Growth of the tumor produces a cough, but coughing is such an everyday occurrence among smokers it seldom causes much alarm. Often, the first sign

of serious trouble is coughing up blood. Lung cancer metastasizes so rapidly that it has usually spread to other organs by the time it is diagnosed. Common sites of metastasis are the pericardium, heart, bones, liver, lymph nodes, and brain. The chance of recovery is poor, with only 7% of patients surviving for 5 years after diagnosis.

• Before You Go On

Answer the following questions to test your understanding of the preceding section.

22. Describe the four classes of hypoxia.
23. Name and compare two COPDs and describe some pathological effects that they have in common.
24. In what lung tissue does lung cancer originate? How does it kill?

³¹ *adeno* = gland + *carcino* = cancer + *oma* = tumor

TABLE 22.5

Some Disorders of the Respiratory System

Acute rhinitis	The common cold. Caused by many types of viruses that infect the upper respiratory tract. Symptoms include congestion, increased nasal secretion, sneezing, and dry cough. Transmitted especially by contact of contaminated hands with mucous membranes; not transmitted orally.
Adult respiratory distress syndrome	Acute lung inflammation and alveolar injury stemming from trauma, infection, burns, aspiration of vomit, inhalation of noxious gases, drug overdoses, and other causes. Alveolar injury is accompanied by severe pulmonary edema and hemorrhaging, followed by fibrosis that progressively destroys lung tissue. Fatal in about 40% of cases under age 60 and in 60% of cases over age 65.
Pneumonia	A lower respiratory infection caused by any of several viruses, fungi, or protozoans (most often the bacterium <i>Streptococcus pneumoniae</i>). Causes filling of alveoli with fluid and dead leukocytes and thickening of the respiratory membrane, which interferes with gas exchange and causes hypoxemia. Especially dangerous to infants, the elderly, and people with compromised immune systems, such as AIDS and leukemia patients.
Sleep apnea	Cessation of breathing for 10 s or longer during sleep; sometimes occurs hundreds of times per night, often accompanied by restlessness and alternating with snoring. Can result from altered function of CNS respiratory centers, airway obstruction, or both. Over time, may lead to daytime drowsiness, hypoxemia, polycythemia, pulmonary hypertension, congestive heart failure, and cardiac arrhythmia. Most common in obese people and in men.
Tuberculosis (TB)	Pulmonary infection with the bacterium <i>Mycobacterium tuberculosis</i> , which invades the lungs by way of air, blood, or lymph. Stimulates the lung to form fibrous nodules called tubercles around the bacteria. Progressive fibrosis compromises the elastic recoil and ventilation of the lungs. Especially common among impoverished and homeless people and becoming increasingly common among people with AIDS.

INSIGHT 22.4 Clinical Application**Diving Physiology and Decompression Sickness**

Because of the rise in popularity of scuba diving in recent decades, many people now know something about the scientific aspects of breathing under high pressure. But diving is by no means a new fascination. As early as the fifth century BCE, Aristotle described divers using snorkels and taking containers of air underwater in order to stay down longer. Some Renaissance artists depicted divers many meters deep breathing from tubes to the water surface. In reality, this would be physically impossible. For one thing, such tubes would have so much dead space that fresh air from the surface would not reach the diver. The short snorkels used today are about the maximum length that will work for surface breathing. Another reason snorkels cannot be used at greater depths is that water pressure increases by 1 atm for every 10 m of depth, and even at 1 m the pressure is so great that a diver cannot expand the chest muscles without help. This is one reason why scuba divers use pressurized air tanks. The tanks create a positive intrapulmonary pressure and enable the diver to inhale with only slight assistance from the thoracic muscles. Scuba tanks also have regulators that adjust the outflow pressure to the diver's depth and the opposing pressure of the surrounding water.

But breathing pressurized (hyperbaric) gas presents its own problems. Divers cannot use pure oxygen because of the problem of oxygen toxicity. Instead, they use compressed air—a mixture of 21% oxygen and 79% nitrogen. On land, nitrogen presents no physiological problems; it dissolves poorly in blood and it is physiologically inert. But under hyperbaric conditions, larger amounts of nitrogen dissolve in the blood. (Which of the gas laws applies here?) Even more dissolves in adipose tissue and the myelin of the brain, since nitrogen is more soluble in lipids. In the brain, it causes *nitrogen narcosis*, or what Jacques Cousteau termed “rapture of the deep.” A diver can become dizzy, euphoric, and dangerously disoriented; for every 15 to 20 m of depth, the effect is said to be equivalent to that of one martini on an empty stomach.

Strong currents, equipment failure, and other hazards sometimes make scuba divers panic, hold their breath, and quickly swim to the surface (a *breath-hold ascent*). Ambient (surrounding) pressure falls rapidly as a diver ascends, and the air in the lungs expands just as rapidly. (Which gas law is demonstrated here?) It is imperative that an ascending diver keep his or her airway open to exhale the expanding gas; otherwise it is likely

to cause *pulmonary barotrauma*—ruptured alveoli. Then, when the diver takes a breath of air at the surface, alveolar air goes directly into the bloodstream and causes air embolism. After passing through the heart, the emboli tend to enter the cerebral circulation because the diver is head-up and air bubbles rise in liquid. The resulting cerebral embolism can cause motor and sensory dysfunction, seizures, unconsciousness, and drowning.

Barotrauma can be fatal even at the depths of a backyard swimming pool. In one case, children trapped air in a bucket 1 m underwater and then swam under the bucket to breathe from the air space. Because the bucket was under water, the air in it was compressed. One child filled his lungs under the bucket, did a “mere” 1 m breath-hold ascent, and his alveoli ruptured. He died in the hospital, partly because the case was mistaken for drowning and not treated for what it really was. This would not have happened to a person who inhaled at the surface, did a breath-hold dive, and then resurfaced—nor is barotrauma a problem for those who do breath-hold dives to several meters. (Why? What is the difference?)

Even when not holding the breath, but letting the expanding air escape from the mouth, a diver must ascend slowly and carefully to allow for decompression of the nitrogen that has dissolved in the tissues. *Decompression tables* prescribe safe rates of ascent based on the depth and the length of time a diver has been down. When pressure drops, nitrogen dissolved in the tissues can go either of two places—it can diffuse into the alveoli and be exhaled, or it can form bubbles like the CO₂ in a bottle of soda when the cap is removed. The diver's objective is to ascend slowly, allowing for the former and preventing the latter. If a diver ascends too rapidly, nitrogen “boils” from the tissues—especially in the 3 m just below the surface, where the relative pressure change is greatest. A diver may double over in pain from bubbles in the joints, bones, and muscles—a disease called the *bends*, or *decompression sickness (DCS)*. Nitrogen bubbles in the pulmonary capillaries cause *chokes*—substernal pain, coughing, and dyspnea. DCS is sometimes accompanied by mood changes, seizures, numbness, and itching. These symptoms usually occur within an hour of surfacing, but they are sometimes delayed for up to 36 hours. DCS is treated by putting the individual in a hyperbaric chamber to be recompressed and then *slowly* decompressed.

DCS is also called *caisson disease*. A caisson is a watertight underwater chamber filled with pressurized air. Caissons are used in underwater construction work on bridges, tunnels, ships' hulls, and so forth. Caisson disease was first reported in the late 1800s among workmen building the foundations of the Brooklyn Bridge.

CONNECTIVE ISSUES

Interactions Between the RESPIRATORY SYSTEM and Other Organ Systems

■ indicates ways in which this system affects other systems

■ indicates ways in which other systems affect this system

ALL SYSTEMS

The respiratory system serves all other systems by supplying O₂, removing CO₂, and maintaining acid-base balance

INTEGUMENTARY SYSTEM

Nasal guard hairs reduce inhalation of dust and other foreign matter ←

SKELETAL SYSTEM

Thoracic cage protects lungs; movement of ribs produces pressure changes that ventilate lungs ←

MUSCULAR SYSTEM

Skeletal muscles ventilate lungs, control position of larynx during swallowing, and control vocal cords during speech; exercise strongly stimulates respiration because of the CO₂ generated by active muscles ←

NERVOUS SYSTEM

Produces the respiratory rhythm, monitors blood gases and pH, monitors stretching of lungs; phrenic, intercostal, and other nerves control respiratory muscles ←

ENDOCRINE SYSTEM

Lungs produce angiotensin-converting enzyme (ACE), which converts angiotensin I to the hormone angiotensin II →

Epinephrine and norepinephrine dilate bronchioles and stimulate ventilation ←

CIRCULATORY SYSTEM

Regulates blood pH; thoracic pump aids in venous return; proplatelets break up into blood platelets during passage through the lungs; production of angiotensin II by lungs is important in control of blood volume and pressure; obstruction of pulmonary circulation leads to right-side heart failure →

CIRCULATORY SYSTEM (cont.)

Blood transports O₂ and CO₂; mitral stenosis or left-side heart failure can cause pulmonary edema; emboli from peripheral sites often lodge in lungs ←

LYMPHATIC/IMMUNE SYSTEMS

Thoracic pump promotes lymph flow →
Lymphatic drainage from lungs is important in keeping alveoli dry; immune cells protect lungs from infection ←

URINARY SYSTEM

Valsalva maneuver aids in emptying bladder →
Disposes of wastes from respiratory organs; collaborates with lungs in controlling blood pH ←

DIGESTIVE SYSTEM

Valsalva maneuver aids in defecation →
Provides nutrients for growth and maintenance of respiratory system ←

REPRODUCTIVE SYSTEM

Valsalva maneuver aids in childbirth →
Sexual arousal increases pulmonary ventilation ←

CHAPTER REVIEW

Review of Key Concepts

22.1 Anatomy of the Respiratory System (p. 864)

1. *Respiration* means ventilation of the lungs, gas exchange with the blood, and oxygen use by the tissues.
2. The respiratory system serves for gas exchange, vocalization, smell, pH balance, and angiotensin II synthesis, and aids in lymph and blood flow and expulsion of the contents of abdominal viscera.
3. The *conducting division* of the respiratory system consists of the nose, pharynx, larynx, trachea, bronchi, and the largest bronchioles; it serves only for airflow. The *respiratory division* consists of the alveoli and other distal gas-exchange regions of the lungs.
4. The *upper respiratory tract* consists of the organs in the head and neck (nose through larynx); the *lower respiratory tract* consists of the organs in the chest (trachea through alveoli).
5. The nose extends from the anterior *nares* to the *posterior nasal apertures* and is divided by the nasal septum into right and left *nasal fossae*.
6. Each fossa has three scroll-like *nasal conchae* covered with a ciliated mucous membrane. The conchae warm, humidify, and cleanse the air flowing over them.
7. The *pharynx* is a muscular passage divided into *nasopharynx*, *oropharynx*, and *laryngopharynx*.
8. The *larynx* is a cartilaginous chamber that contains the vocal cords and keeps food and drink out of the airway. Muscles of the larynx function in speech and swallowing.
9. The *trachea* is a 12 cm tube, supported by cartilage, ending where it branches into the two main bronchi. Its ciliated mucosa acts as a *mucociliary escalator* to remove inhaled debris from the respiratory tract.
10. Each lung is a conical organ extending from the superior *apex* to the inferior, broad *base*. The left lung is divided into two lobes and the right lung into three. The bronchi, blood vessels, nerves, and lymphatics enter and leave by a slit called the *hilum* on the mediastinal surface.
11. One *main bronchus* supplies each lung; it divides into one *lobar bronchus* for each lobe of the lung, and this divides into smaller *segmental bronchi*.
12. *Bronchioles* are finer divisions of the airway lacking cartilage. The smallest members of the conducting division are the *terminal bronchioles*. Beyond this, thin-walled *respiratory bronchioles* begin the respiratory division. Respiratory bronchioles have alveoli along their walls and branch distally into *alveolar ducts*.
13. An *alveolus* is a thin-walled sac surrounded by a basket of blood capillaries. It is composed of *squamous* and *great alveolar cells* and contains *alveolar macrophages*, the last line of defense against inhaled debris. Alveoli are the site of gas exchange with the blood.
14. The surface of each lung is a serous membrane called the *visceral pleura*. It continues as the *parietal pleura*, which lines the inside of the rib cage. The space between the pleurae is the *pleural cavity*, and is lubricated with *pleural fluid*. The pleurae reduce friction during breathing, contribute to the pressure gradients that move air into and out of the lungs, and help compartmentalize the thoracic cavity.

22.2 Pulmonary Ventilation (p. 875)

1. The lungs are ventilated in repetitive *respiratory cycles* of *inspiration* and *expiration*.
2. Airflow is driven by changes in lung volume produced by the respiratory muscles. Inspiration is achieved mainly by contraction of the diaphragm and external intercostal muscles. Expiration is achieved mainly by elastic recoil of the thoracic cage rather than muscular effort. Several thoracic and abdominal muscles act as *accessory muscles* of respiration in deep breathing.
3. The respiratory rhythm is governed by a group of neurons called the *ventral respiratory group (VRG)* in the reticular formation of the medulla oblongata. The nearby *dorsal respiratory group (DRG)* of the medulla integrates input from several other sources and modifies the rhythm of the VRG. The *pontine respiratory group* in the pons receives input from higher brain centers and transmits signals to the VRG and DRG that modify the timing of the transition from inspiration to expiration.
4. The DRG and VRG receive input from *central chemoreceptors* in the medulla, *peripheral chemoreceptors* in the aortic arch and carotid bodies, stretch receptors in the airway, and irritant receptors in the respiratory mucosa. This enables adjustments of the respiratory rhythm to maintain blood chemistry and avoid irritants and overstretching of the lungs.
5. Voluntary control of respiration is achieved by cerebral output that bypasses the brainstem centers and goes directly to the lower motor neurons of the spinal cord, whose axons supply the respiratory muscles.
6. Airflow is directly proportional to the pressure difference between two points and inversely proportional to resistance.
7. When inspiratory muscles expand the chest, the lungs enlarge and the intrapulmonary pressure drops (*Boyle's law*). When intrapulmonary pressure is lower than atmospheric pressure, air flows down its pressure gradient into the lungs. The lungs are also inflated in part by the warming and expansion of inspired air (*Charles's law*).
8. Expiration occurs when elastic recoil of the thoracic cage compresses the lungs and raises the intrapulmonary pressure above atmospheric pressure. Air flows down its pressure gradient out of the lungs.
9. The speed of airflow depends on resistance of the airway, especially in the vast number of small, muscular

902 PART FOUR Regulation and Maintenance

bronchioles. Thus, it is increased by *bronchodilation* and reduced by *bronchoconstriction*. *Pulmonary compliance* and *alveolar surfactant* help to minimize resistance.

10. In a typical 500 mL inspiration, about 150 mL fills the anatomical dead space. Only the other 350 mL ventilates the alveoli and participates in gas exchange with the blood. *Alveolar ventilation rate* is the product of the latter amount and the respiratory rate.
11. Pulmonary ventilation is measured with a device called a *spirometer*. Table 22.2 defines the volumes and capacities of principal interest.
12. *Restrictive disorders* of respiration reduce pulmonary compliance and vital capacity. *Obstructive disorders* reduce the speed of airflow, measured by such values as *forced expiratory volume*.
13. Normal quiet respiration is called *eupnea*. Variations such as *dyspnea*, *hyperventilation*, and others are defined in table 22.3.

22.3 Gas Exchange and Transport (p. 886)

1. Air is composed of approximately 79% N₂, 21% O₂, and 0.04% CO₂. Water vapor is a significant but highly variable component (0%–4%, typically 0.5% on a cool clear day).
2. Each of these gases contributes a *partial pressure* to the total gas pressure. Total pressure is the sum of the partial pressures of the gases in the mixture (*Dalton's law*).
3. Alveolar air is significantly higher in CO₂ and H₂O than inspired air, and lower in O₂.
4. The O₂ in inspired air must dissolve in the water film on the alveolar wall before it can pass through the respiratory membrane into the blood. Henry's law states that the amount of gas that diffuses from air into water is proportional to its solubility and partial pressure.
5. The efficiency of O₂ loading and CO₂ unloading in the alveolus depends on the pressure gradients of the gases, their solubility in water, thickness of the respiratory membrane, and alveolar surface area.
6. *Ventilation–perfusion coupling* matches airflow to blood flow in individual regions of the lung, thus ensuring optimal gas exchange between air and blood.
7. About 1.5% of the O₂ in the blood is dissolved in the plasma and 98.5% is bound to hemoglobin in the RBCs. Each hemoglobin can carry up to 4 O₂. It is called *oxyhemoglobin (HbO₂)* if it carries one or more O₂ molecules.
8. The relationship between oxygen partial pressure (P_{O₂}) and percentage HbO₂ is the *oxyhemoglobin dissociation curve* (see fig. 22.23). It shows that binding of the first oxygen to hemoglobin accelerates the binding of more O₂, until the Hb becomes saturated.
9. About 90% of the CO₂ in the blood is carried as bicarbonate ions (HCO₃⁻), 5% is bound to proteins as *carbamino* compounds, and 5% is dissolved in the blood plasma.
10. The loading of CO₂ from the tissue fluids is promoted by *carbonic anhydrase*, an enzyme in the RBCs that promotes the reaction of CO₂ and water to form carbonic acid. The carbonic acid breaks down to HCO₃⁻ and H⁺. Most of the H⁺ binds to hemoglobin, while the HCO₃⁻ is exchanged for Cl⁻ from the blood plasma.
11. This binding of H⁺ to hemoglobin promotes the unloading of O₂ to the systemic tissues. In one pass through the capillaries of a resting tissue, the blood gives up about 22% of its O₂ to the tissue (the *utilization coefficient*).
12. In the alveoli, Hb loads O₂. This causes H⁺ to dissociate from the Hb and recombine with HCO₃⁻ to produce carbonic acid. The carbonic acid is then broken down by carbonic anhydrase into water and CO₂. The CO₂ is exhaled.
13. Hemoglobin unloads varying amounts of O₂ to different tissues according to their needs. Hemoglobin adjusts O₂ unloading in response to variations in the tissue's P_{O₂}, temperature, and pH (the *Bohr effect*), and the RBC's own temperature and hormone-sensitive concentration of bisphosphoglycerate (BPG).
14. CO₂ loading is enhanced by the unloading of O₂ (the *Haldane effect*), so hemoglobin picks up more CO₂ from highly active tissues than from less active ones.
15. The strongest chemical influence on breathing is H⁺ sensed by the central chemoreceptors of the medulla. CO₂ and H⁺ also stimulate breathing by acting on the peripheral chemoreceptors. CO₂ acts mainly by generating H⁺ through the reaction CO₂ + H₂O ⇌ H₂CO₃ ⇌ HCO₃⁻ + H⁺. A low P_{O₂} has little influence on breathing except at unusually low values (< 60 mm Hg).
16. Normally, the blood pH ranges from 7.35 to 7.45. A pH below 7.35 is called *acidosis* and a pH above 7.45 is *alkalosis*. These are usually caused, respectively, by a CO₂ excess (*hypercapnia*) or deficiency (*hypocapnia*). Thus, pH imbalances can be corrected by changing the respiratory rate.
17. Exercise increases respiration by means of input to the respiratory center from the cerebrum or from muscle and joint proprioceptors, not by changing blood chemistry.

22.4 Respiratory Disorders (p. 896)

1. Hypoxia, a deficiency of O₂ in the tissues, can be of *hypoxemic*, *ischemic*, *anemic*, or *histotoxic* origin. It can cause cyanosis and, if severe and prolonged, tissue necrosis.
2. Oxygen excess can generate hydrogen peroxide and free radicals that cause oxygen toxicity.
3. The *chronic obstructive pulmonary diseases (COPDs)* are chronic bronchitis and emphysema. They are usually caused by tobacco smoke. *Chronic bronchitis* entails congestion of the airway with thick mucus, and susceptibility to respiratory infection. *Emphysema* entails destruction of pulmonary alveoli and air retention in expiration.
4. Lung cancer also is usually caused by tobacco smoke. Its variations are *squamous-cell carcinoma*, *adenocarcinoma*, and *small-cell carcinoma*. It tends to metastasize rapidly.

Testing Your Recall

- The nasal cavity is divided by the nasal septum into right and left
 - nares.
 - vestibules.
 - fossae.
 - choanae.
 - conchae.
- The intrinsic laryngeal muscles regulate speech by rotating
 - the extrinsic laryngeal muscles.
 - the corniculate cartilages.
 - the arytenoid cartilages.
 - the hyoid bone.
 - the vocal cords.
- The largest air passages that engage in gas exchange with the blood are
 - the respiratory bronchioles.
 - the terminal bronchioles.
 - the primary bronchi.
 - the alveolar ducts.
 - the alveoli.
- Respiratory arrest would most likely result from a tumor of the
 - pons.
 - midbrain.
 - thalamus.
 - cerebellum.
 - medulla oblongata.
- Which of these values would normally be the highest?
 - tidal volume
 - inspiratory reserve volume
 - expiratory reserve volume
 - residual volume
 - vital capacity
- The _____ protects the lungs from injury by excessive inspiration.
 - pleura
 - rib cage
 - inflation reflex
 - Haldane effect
 - Bohr effect
- According to _____, the warming of air as it is inhaled helps to inflate the lungs.
 - Boyle's law
 - Charles's law
 - Dalton's law
 - the Bohr effect
 - the Haldane effect
- Poor blood circulation causes _____ hypoxia.
 - ischemic
 - histotoxic
 - hemolytic
 - anemic
 - hypoxemic
- Most of the CO₂ that diffuses from the blood into an alveolus comes from
 - dissolved gas.
 - carbaminohemoglobin.
 - carboxyhemoglobin.
 - carbonic acid.
 - expired air.
- The duration of an inspiration is set by
 - the pneumotaxic center.
 - the phrenic nerves.
 - the vagus nerves.
 - the I neurons.
 - the E neurons.
- The superior opening into the larynx is guarded by a tissue flap called the _____.
- Within each lung, the airway forms a branching complex called the _____.
- The great alveolar cells secrete a phospholipid-protein mixture called _____.
- Intrapulmonary pressure must be lower than _____ pressure for inspiration to occur.
- _____ disorders reduce the speed of airflow through the airway.
- Some inhaled air does not participate in gas exchange because it fills the _____ of the respiratory tract.
- Inspiration depends on the ease of pulmonary inflation, called _____, whereas expiration depends on _____, which causes pulmonary recoil.
- Inspiration is caused by the firing of I neurons in the _____ of the medulla oblongata.
- The matching of airflow to blood flow in any region of the lung is called _____.
- A blood pH > 7.45 is called _____ and can be caused by a CO₂ deficiency called _____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- The phrenic nerves fire during inspiration only.
- The lungs contain more respiratory bronchioles than terminal bronchioles.
- In alveolar capillaries, oncotic pressure is greater than the mean blood pressure.
- If you increase the volume of a given quantity of gas, its pressure increases.
- Pneumothorax is the only cause of atelectasis.
- Obstruction of the bronchial tree results in a reduced FEV.
- At a given Po₂ and pH, hemoglobin carries less oxygen at warmer temperatures than it does at cooler temperatures.
- Most of the air one inhales never makes it to the alveoli.
- The greater the Pco₂ of the blood is, the lower its pH is.
- Most of the CO₂ transported by the blood is in the form of dissolved gas.

Answers in appendix B

Testing Your Comprehension

1. Discuss how the different functions of the conducting division and respiratory division relate to differences in their histology.
2. State whether hyperventilation would raise or lower each of the following—the blood P_{O_2} , P_{CO_2} , and pH—and explain why. Do the same for emphysema.
3. Some competitive swimmers hyperventilate before a race, thinking they can “load up extra oxygen” and hold their breaths longer underwater. While they can indeed hold their breaths longer, it is not for the reason they think. Furthermore, some have lost consciousness and drowned because of this practice. What is wrong with this thinking, and what accounts for the loss of consciousness?
4. Consider a man in good health with a 650 mL tidal volume and a respiratory rate of 11 breaths per minute. Report his minute respiratory volume in liters per minute. Assuming his anatomical dead space is 185 mL, calculate his alveolar ventilation rate in liters per minute.
5. An 83-year-old woman is admitted to the hospital, where a critical care nurse attempts to insert a nasogastric tube (“stomach tube”) for feeding. The patient begins to exhibit dyspnea, and a chest X-ray reveals air in the right pleural cavity and a collapsed right lung. The patient dies 5 days later from respiratory complications. Name the conditions revealed by the X-ray and explain how they could have resulted from the nurse’s procedure.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Osmosis, tonicity, and osmolarity (pp. 101-103)
- Carrier-mediated transport mechanisms, especially symports and antiports (p. 104)
- Osmotic diuresis (p. 674)
- Blood pressure, resistance, and flow (p. 764)
- Capillary filtration and reabsorption (p. 772)

To live is to metabolize, and metabolism unavoidably produces a variety of waste products that are not merely unneeded by the body, but indeed toxic if they are allowed to accumulate. We rid the body of some of these wastes through the respiratory and digestive tracts and the sweat glands, but the urinary system is the principal means of waste excretion. The kidneys are compound tubular glands that separate metabolic wastes from the blood. The rest of the urinary system serves only for the transport, storage, and elimination of urine. Most of our focus in this chapter is therefore on the kidneys.

Their task goes far beyond waste excretion, though. As we will see, they also play indispensable roles in regulating blood volume and pressure, erythrocyte count, blood gases, blood pH, and electrolyte and acid-base balance. In performing these tasks, they have a very close physiological relationship with the endocrine, circulatory, and respiratory systems, covered in recent chapters.

Anatomically, the urinary system is closely associated with the reproductive system. In many animals, the eggs and sperm are emitted through the urinary tract, and the two systems have a shared embryonic development and adult anatomical relationship. This is reflected in humans, where the systems develop together in the embryo and, in the male, the urethra continues to serve as a passage for both urine and sperm. Thus, the urinary and reproductive systems are often collectively called the *urogenital (U-G) system*, and *urologists* treat both urinary and reproductive disorders. We examine the anatomical relationship between the urinary and reproductive systems in chapter 27, but the physiological link to the circulatory and respiratory systems is more important to consider at this time.

- name the major nitrogenous wastes and identify their sources; and
- define *excretion* and identify the systems that excrete wastes.

The **urinary system** consists of six organs: two **kidneys**, two **ureters**, the **urinary bladder**, and the **urethra**. Figure 23.1 shows these organs in anterior and posterior views. The urinary tract has important spatial relationships with the vagina and uterus in females and the prostate gland in males. These relationships are best appreciated from the sagittal views of figures 27.11 and 28.1 (pp. 1058 and 1078) and can be seen in the cadaver in figure A.22 (p. 48).

Functions of the Kidneys

Although the primary role of the kidneys is excretion, they play more roles than are commonly realized:

- They filter blood plasma, separate wastes from the useful chemicals, and eliminate the wastes while returning the rest to the bloodstream.
- They regulate blood volume and pressure by eliminating or conserving water as necessary.
- They regulate the osmolarity of the body fluids by controlling the relative amounts of water and solutes eliminated.
- They secrete the enzyme *renin*, which activates hormonal mechanisms that control blood pressure and electrolyte balance.
- They secrete the hormone *erythropoietin*, which stimulates the production of red blood cells and thus supports the oxygen-carrying capacity of the blood.
- They collaborate with the lungs to regulate the PCO_2 and acid-base balance of the body fluids.
- They carry out the final step in synthesizing the hormone calcitriol and thereby contribute to calcium homeostasis.
- In conditions of extreme starvation, they carry out *gluconeogenesis*; they *deaminate* amino acids (remove the $-\text{NH}_2$ group), excrete the amino group as ammonia (NH_3), and synthesize glucose from the rest of the molecule.

23.1 Functions of the Urinary System

Objectives

When you have completed this section, you should be able to

- name and locate the organs of the urinary system;
- list several functions of the kidneys in addition to urine formation;

Nitrogenous Wastes

A **waste** is any substance that is useless to the body or present in excess of the body's needs. A **metabolic waste**, more specifically, is a waste substance produced by the body. Thus, the food residue in feces, for example, is a waste but not a metabolic waste, since it was not produced by the body and, indeed, never entered the body's tissues.

FIGURE 23.1 The Urinary System. Organs of the urinary system are indicated in boldface.

FIGURE 23.2 The Major Nitrogenous Wastes.

How is each of these wastes produced in the body?

Among the most toxic of our metabolic wastes are small nitrogen-containing compounds called **nitrogenous wastes** (fig. 23.2). About 50% of the nitrogenous waste is urea, a by-product of protein catabolism. Proteins are broken down to amino acids, and then the $-\text{NH}_2$ group is removed from each amino acid. The $-\text{NH}_2$ forms ammonia, which is exceedingly toxic but which the liver

quickly converts to urea, $\text{CO}(\text{NH}_2)_2$, a somewhat less toxic waste:

Other nitrogenous wastes in the urine include **uric acid** and **creatinine** (cree-AT-ih-noon), produced by the catabolism of nucleic acids and creatine phosphate, respectively. Although less toxic than ammonia and less abundant than urea, these too are far from harmless.

The level of nitrogenous waste in the blood is typically expressed as **blood urea nitrogen (BUN)**. The normal concentration of blood urea is 10 to 20 mg/dL. An elevated BUN is called **azotemia**¹ (AZ-oh-TEE-me-uh) and may indicate renal insufficiency. It can progress to **uremia** (you-REE-me-uh), a syndrome of diarrhea, vomiting, dyspnea, and cardiac arrhythmia stemming from the toxicity of the nitrogenous wastes. Convulsions, coma,

¹azot = nitrogen + emia = blood condition

and death can follow within a few days. Treatment for renal insufficiency can entail *hemodialysis* or organ transplant (see Insight 23.5, p. 936).

Excretion

Excretion is the process of separating wastes from the body fluids and eliminating them. It is carried out by four organ systems:

1. The respiratory system excretes carbon dioxide, small amounts of other gases, and water.
2. The integumentary system excretes water, inorganic salts, lactic acid, and urea in the sweat.
3. The digestive system not only *eliminates* food residue (which is not a process of excretion) but also actively *excretes* water, salts, carbon dioxide, lipids, bile pigments, cholesterol, and other metabolic wastes.
4. The urinary system excretes a broad variety of metabolic wastes, toxins, drugs, hormones, salts, hydrogen ions, and water.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. State four functions of the kidneys other than forming urine.
2. List four nitrogenous wastes and their metabolic sources.
3. Name some wastes eliminated by three systems other than the urinary system.

23.2 Anatomy of the Kidney

Objectives

When you have completed this section, you should be able to

- describe the location and general appearance of the kidney;
- identify the major external and internal features of the kidney;
- trace the flow of blood through the kidney;
- trace the flow of fluid through the renal tubules; and
- describe the nerve supply to the kidney.

Position and Associated Structures

The kidneys lie against the posterior abdominal wall at the level of vertebrae T12 to L3. The right kidney is slightly lower than the left because of the space occupied

by the large right lobe of the liver above it. Rib 12 crosses the approximate middle of the left kidney. The kidneys are retroperitoneal, along with the ureters, urinary bladder, renal artery and vein, and the adrenal glands (fig. 23.3).

Gross Anatomy

Each kidney weighs about 150 g and measures about 11 cm long, 6 cm wide, and 3 cm thick—about the size of a bar of bath soap. The lateral surface is convex, and the medial surface is concave and has a slit, the **hilum**, where it receives the renal nerves, blood vessels, lymphatics, and ureter (see fig. 23.1).

The kidney is protected by three layers of connective tissue (fig. 23.3): (1) A fibrous **renal fascia**, immediately deep to the parietal peritoneum, binds the kidney and associated organs to the abdominal wall; (2) the **perirenal fat capsule**, a layer of adipose tissue, cushions the kidney and holds it in place; and (3) the **fibrous capsule** encloses the kidney like a cellophane wrapper anchored at the hilum, and protects it from trauma and infection. The kidneys are suspended by collagen fibers that extend from the fibrous capsule, through the fat, to the renal fascia. The renal fascia is fused with the peritoneum anteriorly and with the fascia of the lumbar muscles posteriorly. In spite of all this, the kidneys drop about 3 cm when one goes from lying down to standing, as when getting out of bed in the morning. Under some circumstances, they become detached and drift even lower, with pathological results (see nephroptosis, or “floating kidney,” in table 23.3, p. 935).

The renal parenchyma—the glandular tissue that forms the urine—appears C-shaped in frontal section (fig. 23.4). It encircles a medial cavity, the **renal sinus**, occupied by blood and lymphatic vessels, nerves, and urine-collecting structures. Adipose tissue fills the remaining space in the sinus and holds these structures in place.

The parenchyma is divided into two zones: an outer **renal cortex** about 1 cm thick and an inner **renal medulla** facing the sinus. Extensions of the cortex called **renal columns** project toward the sinus and divide the medulla into 6 to 10 **renal pyramids**. Each pyramid is conical, with a broad base facing the cortex and a blunt point called the **renal papilla** facing the sinus. One pyramid and the overlying cortex constitute one *lobe* of the kidney.

The papilla of each renal pyramid is nestled in a cup called a **minor calyx**² (CAY-lix), which collects its urine. Two or three minor calyces (CAY-lih-seez) converge to form a **major calyx**, and two or three major calyces converge in the sinus to form the funnel-like **renal pelvis**.³ The ureter is a tubular continuation of the renal pelvis that drains the urine down to the urinary bladder.

²calyx = cup
³pelvis = basin

FIGURE 23.3 Retroperitoneal Position of the Kidney. Cross section of the abdomen at the level of vertebra L1.

◀ If the kidney was not retroperitoneal, where on this figure would you have to relocate it?

FIGURE 23.4 Gross Anatomy of the Kidney. Posterior views. (a) Photograph of frontal section. (b) Major anatomical features.

Renal Circulation

Although the kidneys account for only 0.4% of the body weight, they receive about 21% of the cardiac output (the *renal fraction*). This is a hint of how important the kidneys are in regulating blood volume and composition.

The larger divisions of the renal circulation are shown in figure 23.5. Each kidney is supplied by a **renal artery** arising from the aorta. Just before or after entering the hilum, the renal artery divides into a few **segmental arteries**, and each of these further divides into a few **interlobar arteries**. An interlobar artery penetrates each renal column and travels between the pyramids toward the *corticomedullary junction*, the boundary between the cortex and medulla. Along the way, it branches again to form **arcuate arteries**, which make a sharp 90° bend and travel along the base of the pyramid. Each arcuate artery gives rise to several **interlobular (cortical radiate) arteries**, which pass upward into the cortex.

The finer branches of the renal circulation are shown in figure 23.6. As an interlobular artery ascends through the cortex, a series of **afferent arterioles** arise from it at nearly right angles like limbs arising from the trunk of a

pine tree. Each afferent arteriole supplies one functional unit of the kidney called a **nephron**⁴ (NEF-ron). The afferent arteriole leads to a ball of capillaries called a **glomerulus**⁵ (glo-MERR-you-lus), enclosed in a nephron structure called the *glomerular capsule*. Blood leaves the glomerulus by way of an **efferent arteriole**.

The efferent arteriole usually leads to a plexus of **peritubular capillaries**, named for the fact that they form a network around another part of the nephron, the *renal tubule*. The renal tubule reabsorbs most of the water and solutes that filtered out of the blood at the glomerulus and returns these to the bloodstream by way of these peritubular capillaries. The peritubular capillaries carry it away to the **interlobular (cortical radiate) veins**, **arcuate veins**, **interlobar veins**, and the **renal vein**, in that order. These veins travel parallel to the arteries of the same names. (There are, however, no segmental veins corresponding to the segmental arteries.) The renal vein leaves the hilum and drains into the inferior vena cava.

⁴nephro = kidney

⁵glomer = ball + ulus = little

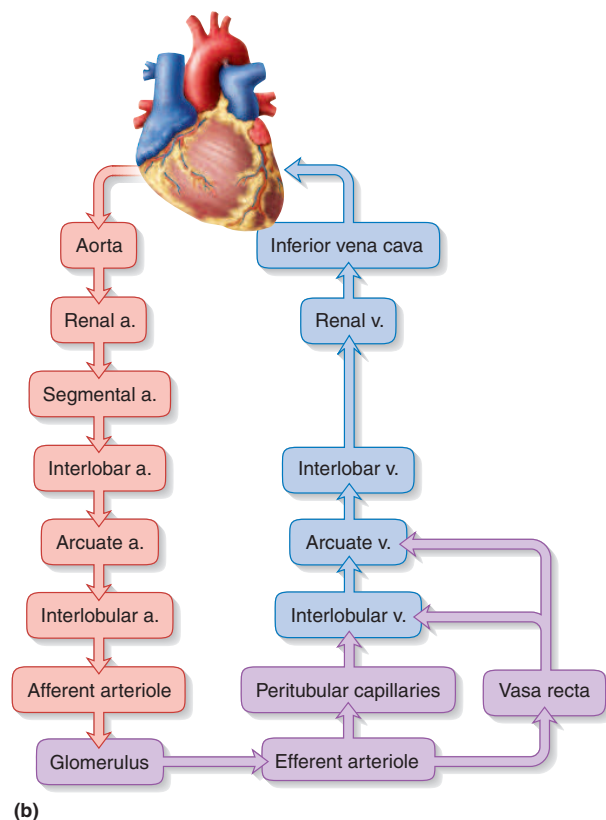

FIGURE 23.5 Renal Circulation. (a) The larger blood vessels of the kidney. (b) Flowchart of renal circulation. The pathway through the vasa recta (instead of peritubular capillaries) applies only to the juxtamedullary nephrons.

FIGURE 23.6 Microcirculation of the Kidney. For clarity, vasa recta are shown only on the left and peritubular capillaries only on the right. In the juxtamedullary nephron (left), the efferent arteriole gives rise to the vasa recta of the medulla. In the cortical nephron (right), the nephron loop barely dips into the renal medulla and the efferent arteriole gives rise to peritubular capillaries. (DCT = distal convoluted tubule; PCT = proximal convoluted tubule)

The renal medulla receives only 1% to 2% of the total renal blood flow, supplied by a network of vessels called the **vasa recta**⁶ (VAH-za REC-ta). These arise from nephrons in the deep cortex close to the medulla. Here, the efferent arterioles descend immediately into the medulla and give rise to the vasa recta instead of peritubular capillaries. Capillaries of the vasa recta lead into venules that ascend and empty into the arcuate and interlobular veins. Capillaries of the vasa recta are wedged into the tight spaces between the medullary parts of the renal tubule, and carry away water and solutes reabsorbed by those sections of the tubule. Figure 23.5b summarizes the route of renal blood flow.

⁶vasa = vessels + recta = straight

Think About It

Can you identify a portal system in the renal circulation?

The Nephron

Each kidney has about 1.2 million nephrons. To understand how just one of these works is to understand nearly everything about how the whole kidney works. Each nephron is composed of two principal parts: a *renal corpuscle*, which filters the blood plasma, and a long coiled *renal tubule*, which converts the filtrate to urine.

The Renal Corpuscle

The **renal corpuscle** (fig. 23.7) consists of the glomerulus described earlier and a two-layered **glomerular (Bowman⁷) capsule** that encloses it. The parietal (outer) layer of the capsule is a simple squamous epithelium, and the visceral (inner) layer consists of elaborate cells called **podocytes⁸** wrapped around the capillaries of the glomerulus. The two layers are separated by a filtrate-collecting **capsular space**. In tissue sections, this space appears as an empty circular or C-shaped space around the glomerulus.

Opposite sides of the renal corpuscle are called the vascular and urinary poles. At the **vascular pole**, the afferent arteriole enters the capsule, bringing blood to the glomerulus, and the efferent arteriole leaves the capsule and carries blood away. The afferent arteriole is significantly larger than the efferent arteriole. Thus, the glomerulus has a large inlet and a small outlet—a point whose functional significance will become apparent later. At the **urinary pole**, the parietal wall of the capsule turns away from the corpuscle and gives rise to the renal tubule. The simple squamous epithelium of the capsule becomes simple cuboidal in the tubule.

The Renal Tubule

The **renal (uriniferous⁹) tubule** is a duct that leads away from the glomerular capsule and ends at the tip of a medullary pyramid. It is about 3 cm long and divided into four

regions: the *proximal convoluted tubule*, *nephron loop*, *distal convoluted tubule*, and *collecting duct* (fig. 23.8). The first three of these are parts of one nephron; the collecting duct receives fluid from many nephrons. Each region of the tubule has unique physiological properties and roles in the production of urine.

1. The **proximal convoluted tubule (PCT)** arises from the glomerular capsule. It is the longest and most coiled of the four regions and thus dominates histological sections of renal cortex. It has a simple cuboidal epithelium with prominent microvilli (a brush border), which attests to the great deal of absorption that occurs here. The microvilli give the epithelium a distinctively shaggy look in tissue sections.
2. The **nephron loop (loop of Henle¹⁰)** is a long U-shaped portion of the renal tubule found mostly in the medulla. It begins where the PCT straightens out and dips toward or into the medulla, forming the **descending limb** of the loop. At its deep end, the loop turns 180° and forms the **ascending limb**, which returns to the cortex, traveling parallel and close to the descending limb. The loop is divided into thick and thin segments. The **thick segments** have a simple cuboidal epithelium. They form the initial part of the descending limb and part or all of the ascending limb. The cells here are heavily engaged in active transport of salts, so they have very high metabolic activity and are loaded with

⁸*podo* = foot + *cyte* = cell

⁹*urin* = urine + *fer* = to carry

¹⁰Friedrich G. J. Henle (1809–85), German anatomist

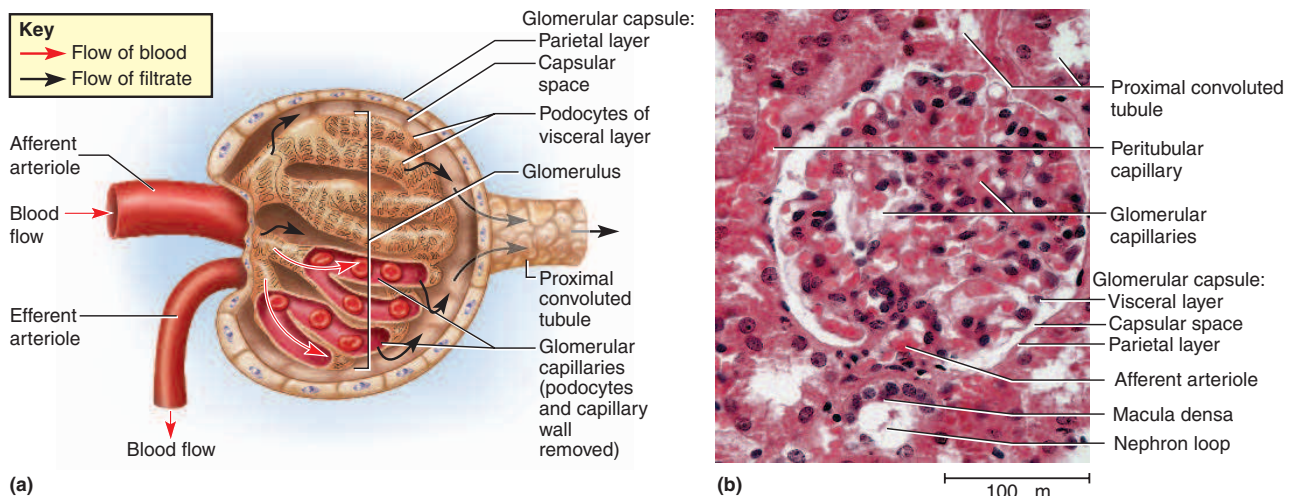

FIGURE 23.7 The Renal Corpuscle. (a) Anatomy of the corpuscle. (b) Light micrograph of the renal corpuscle and sections of the surrounding renal tubule.

FIGURE 23.8 Microscopic Anatomy of the Nephron. (a) Location of the nephrons in one wedge-shaped lobe of the kidney. (b) Structure of a nephron. For clarity, the nephron is stretched out to separate the convoluted tubules. The nephron loop is greatly shortened for the purpose of illustration. (c) The true proportions of the nephron loops relative to the convoluted tubules. Three nephrons are shown. Their proximal and distal convoluted tubules are commingled in a single tangled mass in each nephron. Note the extreme lengths of the nephron loops.

mitochondria, accounting for their thickness. The **thin segment** has a simple squamous epithelium. It forms the lower part of the descending limb, and in some nephrons, it rounds the bend and continues partway up the ascending limb. The cells here have low metabolic activity, but the thin segment of the descending limb is very permeable to water.

3. The **distal convoluted tubule (DCT)** begins shortly after the ascending limb reenters the cortex. It is shorter and less coiled than the proximal convoluted tubule, so fewer sections of it are seen in histological sections. It has a cuboidal epithelium with smooth-surfaced cells nearly devoid of microvilli. The DCT is the end of the nephron.
4. The **collecting duct** receives fluid from the DCTs of several nephrons as it passes back into the medulla. Numerous collecting ducts converge toward the tip of a medullary pyramid, and near the papilla, they merge to form a larger **papillary duct**. About 30 papillary ducts end in pores at the conical tip of each papilla. Urine drains from these pores into the minor calyx that encloses the papilla. The collecting and papillary ducts are lined with simple cuboidal epithelium.

The flow of fluid from the point where the glomerular filtrate is formed to the point where urine leaves the body is: glomerular capsule → proximal convoluted tubule → nephron loop → distal convoluted tubule → collecting duct → papillary duct → minor calyx → major calyx → renal pelvis → ureter → urinary bladder → urethra.

Cortical and Juxtamedullary Nephrons

Not all nephrons are identical. Those just beneath the renal capsule, close to the kidney surface, are called **cortical nephrons**. They have relatively short nephron loops that dip only slightly into the outer medulla before turning back (see fig. 23.6) or turn back even before leaving the cortex. Some of them have no nephron loops at all. Nephrons close to the medulla are called **juxtamedullary¹¹ nephrons**. They have very long nephron loops that extend to the apex of the renal pyramid. As you will see later, nephron loops are responsible for maintaining a salinity gradient in the medulla that helps the body conserve water. Although only 15% of the nephrons are juxtamedullary, they are almost solely responsible for maintaining this gradient.

Renal Innervation

Wrapped around each renal artery is a **renal plexus** of nerves and ganglia (see fig. 15.6, p. 573). The plexus follows branches of the renal artery into the parenchyma of the kidney, issuing nerve fibers to the blood vessels and

convoluted tubules of the nephrons. The renal plexus carries sympathetic innervation from the abdominal aortic plexus and parasympathetic innervation from the vagus nerves, as well as afferent pain fibers from the kidneys en route to the spinal cord. Stimulation from the sympathetic fibers of the renal plexus tends to reduce glomerular blood flow and therefore the rate of urine production, although these rates are influenced by other factors as well. Another role of the sympathetic fibers is to respond to falling blood pressure by stimulating the kidneys to secrete *renin*, an enzyme that activates hormonal mechanisms for restoring blood pressure. The function of the parasympathetic innervation of the kidneys is unknown.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

4. Arrange the following in order from the most numerous to the least numerous structures in a kidney: glomeruli, major calyces, minor calyces, interlobular arteries, interlobar arteries.
5. Trace the path taken by one red blood cell from the renal artery to the renal vein.
6. Consider one molecule of urea in the urine. Trace the route that it took from the point where it left the bloodstream to the point where it left the body.

23.3 Urine Formation I: Glomerular Filtration

Objectives

When you have completed this section, you should be able to

- describe the process by which the kidney filters the blood plasma, including the relevant cellular structure of the glomerulus;
- explain the forces that promote and oppose filtration, and calculate the filtration pressure if given the magnitude of these forces; and
- describe how the nervous system, hormones, and the kidney itself regulate filtration.

The kidney converts blood plasma to urine in three stages: glomerular filtration, tubular reabsorption and secretion, and water conservation (fig. 23.9), which are the themes for these next three sections of the chapter. As we trace fluid through the nephron, we will refer to it by different names that reflect its changing composition: (1) The fluid in the capsular space, called **glomerular filtrate**, is similar to blood plasma except that it has almost no

¹¹juxta = next to

FIGURE 23.9 Basic Steps in the Formation of Urine.

protein. (2) The fluid from the proximal convoluted tubule through the distal convoluted tubule will be called **tubular fluid**. It differs from the glomerular filtrate because of substances removed and added by the tubule cells. (3) The fluid will be called **urine** once it enters the collecting duct, since it undergoes little alteration beyond that point except for a change in water content.

The Filtration Membrane

Glomerular filtration, discussed in this section, is a special case of the capillary fluid exchange process described in chapter 20. It is a process in which water and some solutes in the blood plasma pass from the capillaries of the glomerulus into the capsular space of the nephron. To do so, fluid passes through three barriers that constitute the **filtration membrane** (figs. 23.10 and 23.11):

1. The **fenestrated endothelium of the capillary**. Endothelial cells of the glomerular capillaries are honeycombed with large filtration pores about 70 to 90 nm in diameter (see fig. 20.6, p. 761). Like fenestrated capillaries elsewhere, these are highly

permeable, although their pores are small enough to exclude blood cells from the filtrate.

2. The **basement membrane**. This membrane consists of a proteoglycan gel. Passing large molecules through it would be like trying to pass sand through a kitchen sponge. A few particles may penetrate its small spaces, but most are held back. On the basis of size alone, the basement membrane would exclude any molecules larger than 8 nm. Some smaller molecules, however, are also held back by a negative electrical charge on the proteoglycans. Blood albumin is slightly less than 7 nm in diameter, but it is also negatively charged and thus repelled by the basement membrane. Although the blood plasma is 7% protein, the glomerular filtrate is only 0.03% protein. It has traces of albumin and smaller polypeptides, including some hormones.
3. **Filtration slits**. A podocyte of the glomerular capsule is shaped somewhat like an octopus, with a bulbous cell body and several thick arms. Each arm has numerous little extensions called **foot processes (pedicels¹²)** that wrap around the capillaries and interdigitate with each other, like wrapping your hands around a pipe and lacing your fingers together. The foot processes have negatively charged **filtration slits** about 30 nm wide between them, which are an additional obstacle to large anions.

Almost any molecule smaller than 3 nm can pass freely through the filtration membrane into the capsular space. This includes water, electrolytes, glucose, fatty acids, amino acids, nitrogenous wastes, and vitamins. Such substances have about the same concentration in the glomerular filtrate as in the blood plasma. Some substances of low molecular weight are retained in the bloodstream, however, because they are bound to plasma proteins that cannot get through the membrane. For example, most calcium, iron, and thyroid hormone in the blood are bound to plasma proteins that retard their filtration by the kidneys. The small fraction that is unbound, however, passes freely through the filtration membrane and appears in the urine.

Kidney infections and trauma can damage the filtration membrane and allow albumin or blood cells to filter through. Kidney disease is sometimes marked by the presence of protein (especially albumin) or blood in the urine—conditions called **proteinuria (albuminuria)** and **hematuria**,¹³ respectively. Distance runners and swimmers often experience temporary proteinuria and hematuria. Strenuous exercise greatly reduces perfusion of the kidneys, and the glomerulus deteriorates under the prolonged hypoxia, thus leaking protein and sometimes blood into the filtrate.

¹²*pedi* = foot + *cel* = little

❏ Which is larger, the efferent arteriole or the afferent arteriole? How does the difference affect the function of the glomerulus?

Filtration Pressure

Glomerular filtration follows the same principles that govern filtration in other blood capillaries (see pp. 771–773), but there are significant differences in the magnitude of the forces involved:

- The blood hydrostatic pressure (BHP) is much higher here than elsewhere—about 60 mm Hg compared with 10 to 15 mm Hg in most other capillaries. This results from the fact that the afferent arteriole is substantially larger than the efferent arteriole, giving the glomerulus a large inlet and small outlet (fig. 23.10a).
- The hydrostatic pressure in the capsular space is about 18 mm Hg, compared with the slightly negative interstitial pressures elsewhere. This results from the high rate of filtration and continual accumulation of fluid in the capsule.
- The colloid osmotic pressure (COP) of the blood is about the same here as anywhere else, 32 mm Hg.
- The glomerular filtrate is almost protein-free and has no significant COP. (This can change markedly in kidney diseases that allow protein to filter into the capsular space.)

FIGURE 23.11 The Glomerular Filtration Membrane.

On balance, then, we have a high outward pressure of 60 mm Hg, opposed by two inward pressures of 18 and 32 mm Hg (fig. 23.12), giving a net filtration pressure (NFP) of

$$60_{\text{out}} - 18_{\text{in}} - 32_{\text{in}} = 10 \text{ mm Hg}_{\text{out}}$$

In most blood capillaries, the BHP drops low enough at the venous end that osmosis overrides filtration and the capillaries reabsorb fluid. Although BHP also drops along

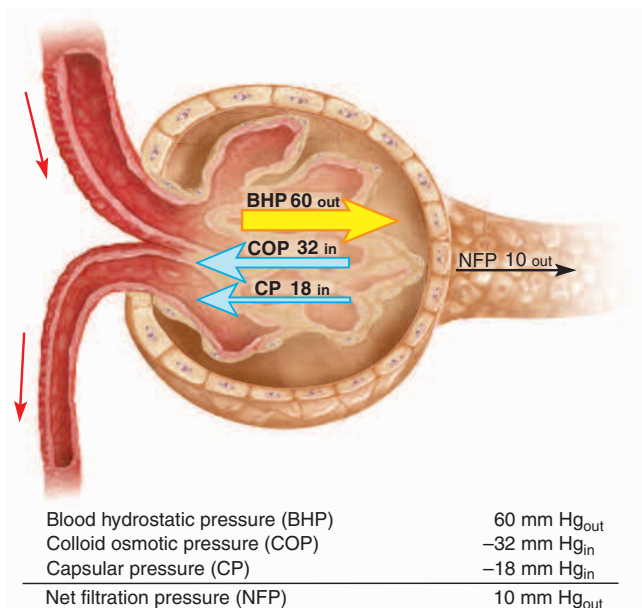

FIGURE 23.12 The Forces Involved in Glomerular Filtration.

the course of the glomerular capillaries, it remains high enough that these capillaries are engaged solely in filtration. They reabsorb little or no fluid.

The high blood pressure in the glomeruli makes the kidneys especially vulnerable to hypertension, which can have devastating effects on renal function. Hypertension ruptures glomerular capillaries and leads to scarring of the kidneys (*nephrosclerosis*). It promotes atherosclerosis of the renal blood vessels just as it does elsewhere in the body and thus diminishes renal blood supply. Over time, hypertension often leads to renal failure.

Glomerular Filtration Rate

Glomerular filtration rate (GFR) is the amount of filtrate formed per minute by the two kidneys combined. For every 1 mm Hg of net filtration pressure, the kidneys produce about 12.5 mL of filtrate per minute. This value, called the *filtration coefficient* (K_f), depends on the permeability and surface area of the filtration barrier. K_f is about 10% lower in women than in men. For the reference man (defined on p. 16),

$$\text{GFR} = \text{NFP} \times K_f = 10 \times 12.5 = 125 \text{ mL/min}$$

In the reference woman, the GFR is about 105 mL/min. These rates are equivalent to 180 L/day in males and 150 L/day in females—impressive numbers considering that this is about 60 times the amount of blood in the body and 50 to 60 times the amount of filtrate produced by all other capillaries combined. Obviously only a small portion of this is eliminated as urine. An average adult reabsorbs 99% of the filtrate and excretes 1 to 2 L of urine per day.

Regulation of Glomerular Filtration

GFR must be precisely controlled. If it is too high, fluid flows through the renal tubules too rapidly for them to reabsorb the usual amount of water and solutes. Urine output rises and creates a threat of dehydration and electrolyte depletion. If GFR is too low, fluid flows sluggishly through the tubules, they reabsorb wastes that should be eliminated in the urine, and azotemia may occur. The only way to adjust GFR from moment to moment is to change glomerular blood pressure. This is achieved by three homeostatic mechanisms: renal autoregulation, sympathetic control, and hormonal control.

Renal Autoregulation

Renal autoregulation is the ability of the nephrons to adjust their own blood flow and GFR without external (nervous or hormonal) control. It enables them to maintain a relatively stable GFR in spite of changes in arterial blood pressure. If the mean arterial pressure (MAP) rose from 100 to 125 mm Hg and there were no renal autoregulation,

urine output would increase from the normal 1 to 2 L/day to more than 45 L/day. Because of renal autoregulation, however, urine output increases only a few percent even if MAP rises as high as 160 mm Hg. Renal autoregulation thus helps to ensure stable fluid and electrolyte balance in spite of the many circumstances that substantially alter one's blood pressure. There are two mechanisms of autoregulation: the myogenic mechanism and tubuloglomerular feedback.

The Myogenic¹⁴ Mechanism This mechanism of stabilizing the GFR is based on the tendency of smooth muscle to contract when stretched. When arterial blood pressure rises, it stretches the afferent arteriole. The arteriole constricts and prevents blood flow into the glomerulus from changing very much. Conversely, when blood pressure falls, the afferent arteriole relaxes and allows blood to flow more easily into the glomerulus. Either way, glomerular blood flow and filtration remain fairly stable.

Tubuloglomerular Feedback This is a mechanism by which the glomerulus receives feedback on the status of the downstream tubular fluid and adjusts filtration to regulate the composition of the fluid, stabilize its own performance, and compensate for fluctuations in blood pressure. It involves a complex of structures called the **juxtaglomerular (JUX-tuh-glo-MER-you-lur) apparatus**, found at the very end of the nephron loop where it has just reentered the renal cortex. Here, the loop comes into contact with the afferent and efferent arterioles at the vascular pole of the renal corpuscle (fig. 23.13). Three special cell types occur here:

1. The **macula densa**.¹⁵ A patch of slender, closely spaced epithelial cells at the end of the nephron loop on the side of the tubule facing the arterioles.
2. **Juxtaglomerular (JG) cells**. Enlarged smooth muscle cells in the afferent arteriole and to some extent in the efferent arteriole, directly across from the macula densa. When stimulated by the macula, they dilate or constrict the arterioles. They also contain granules of *renin*, which they secrete in response to a drop in blood pressure. This initiates the renin-angiotensin-aldosterone mechanism described shortly, which raises blood pressure.
3. **Mesangial**¹⁶ (mez-AN-jee-ul) **cells**. Cells in the cleft between the afferent and efferent arterioles and among capillaries of the glomerulus. They are connected to the macula densa and JG cells by gap junctions and communicate with them by means of

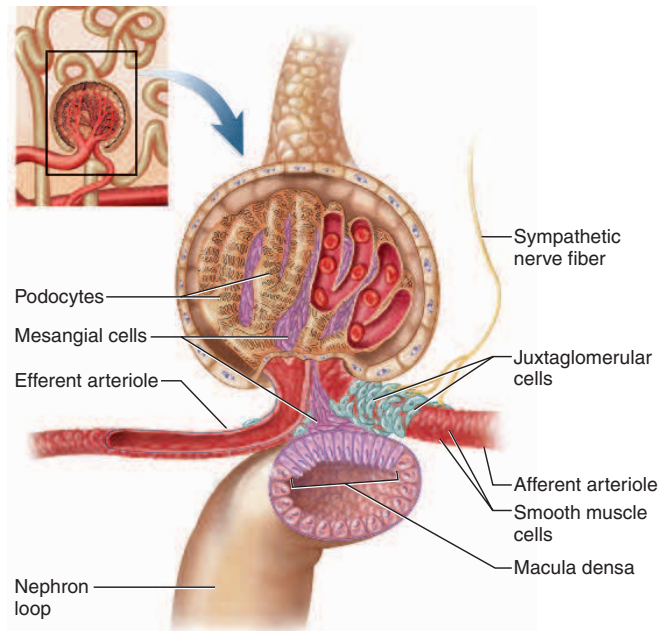

FIGURE 23.13 The Juxtaglomerular Apparatus.

paracrine (hormonelike) secretions. They also build a supportive matrix for the glomerulus, constrict or relax its capillaries to regulate blood flow and GFR, and phagocytize tissue debris.

The details of tubuloglomerular feedback are still obscure. If GFR rises, however, it increases the flow of tubular fluid and the rate of sodium chloride reabsorption by the proximal convoluted tubule. The macula densa apparently senses variations in flow or fluid composition and secretes a paracrine messenger that stimulates the JG cells. Contraction of the JG cells constricts the afferent arteriole, thus reducing GFR to normal (fig. 23.14). The mesangial cells amid the glomerular capillaries may also contract, constricting the capillaries and reducing filtration. Conversely, if GFR falls, the macula densa may secrete a different messenger, causing the afferent arteriole and mesangial cells to relax, blood flow to increase, and GFR to rise back to normal.

Think About It

Describe or diagram a negative feedback loop similar to figure 23.14 to show how the macula densa could compensate for a drop in systemic blood pressure.

Two important points must be noted about renal autoregulation. First, it does not completely prevent changes in the GFR. Like any other homeostatic mechanism, it maintains a *dynamic equilibrium*; the GFR fluctuates

¹⁴myo = muscle + genic = produced by

¹⁵macula = spot, patch + densa = dense

¹⁶mes = in the middle + angi = vessel

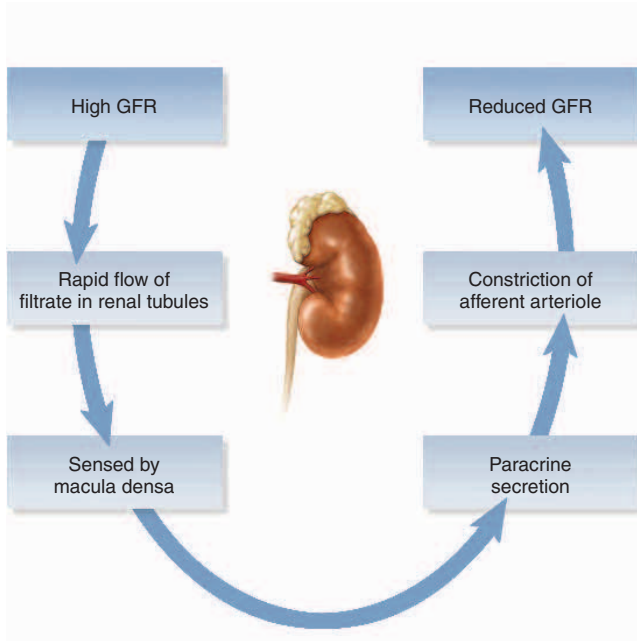

FIGURE 23.14 Negative Feedback Control of Glomerular Filtration Rate.

within narrow limits. Changes in blood pressure *do* affect the GFR and urine output. Second, renal autoregulation cannot compensate for extreme blood pressure variations. Over an MAP range of 90 to 180 mm Hg, the GFR remains quite stable. Below 70 mm Hg, however, glomerular filtration and urine output cease. This can happen in hypovolemic shock (p. 776).

Sympathetic Control

Sympathetic nerve fibers richly innervate the renal blood vessels. In strenuous exercise or acute conditions such as circulatory shock, the sympathetic nervous system and adrenal epinephrine constrict the afferent arterioles. This reduces GFR and urine production, while redirecting blood from the kidneys to the heart, brain, and skeletal muscles, where it is more urgently needed. Under such conditions, GFR may be as low as a few milliliters per minute.

The Renin-Angiotensin-Aldosterone Mechanism

When blood pressure drops because of blood loss or other causes, the sympathetic renal nerves stimulate the juxtaglomerular cells to secrete the enzyme **renin** (REEnin). Renin acts on *angiotensinogen*, a protein in the blood plasma, to split off a 10-amino-acid peptide called angiotensin I. In the lungs and kidneys, **angiotensin-converting enzyme (ACE)** removes two more amino acids, converting it to **angiotensin II**, a hormone that acts

in several ways to restore fluid volume and blood pressure (fig. 23.15):

- It is a potent vasoconstrictor. Widespread vasoconstriction raises the mean arterial blood pressure throughout the body.
- In the kidneys, it constricts the efferent arterioles and to a somewhat lesser degree, the afferent arterioles. By constricting the glomerular outlet more than the inlet, it raises glomerular blood pressure and GFR, or at least prevents a drastic reduction in GFR,

FIGURE 23.15 The Renin-Angiotensin-Aldosterone Mechanism. This chain of events is activated by a drop in blood pressure and acts to raise it again.

thus ensuring continued filtration of wastes from the blood even when blood pressure has fallen.

- Constriction of the efferent arteriole lowers the blood pressure (BP) in the peritubular capillaries. Since capillary BP normally opposes fluid reabsorption, this reduction in BP strongly enhances the reabsorption of NaCl and water from the nephron. More water is returned to the bloodstream instead of being lost in the urine.
- Angiotensin II stimulates the adrenal cortex to secrete aldosterone, which promotes sodium and water reabsorption by the distal convoluted tubule and collecting duct. Angiotensin II also directly stimulates sodium and water reabsorption in the proximal convoluted tubule.
- It stimulates the posterior pituitary gland to secrete antidiuretic hormone, which promotes water reabsorption by the collecting duct.
- It stimulates the sense of thirst and encourages water intake.

Some of these effects are explained more fully later in this chapter and in chapter 24. Collectively, they raise blood pressure by reducing water loss, encouraging water intake, and constricting blood vessels.

Think About It

Would you expect ACE inhibitors (see p. 769) to increase or reduce urine output? Why?

To summarize the events thus far: Glomerular filtration occurs because the high blood pressure of the glomerular capillaries overrides reabsorption. The filtration membrane allows most plasma solutes into the capsular space while retaining formed elements and protein in the bloodstream. Glomerular filtration is maintained at a fairly steady rate of about 125 mL/min in spite of variations in systemic blood pressure. This stability is achieved by renal autoregulation, sympathetic control, and hormonal control.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. Name the four major processes in urine production.
8. Trace the movement of a urea molecule from the blood to the capsular space, and name the barriers it passes through.
9. Calculate the net filtration pressure in a patient whose blood COP is only 10 mm Hg because of hypoproteinemia. Assume other relevant variables to be normal.
10. Assume a person is moderately dehydrated and has low blood pressure. Describe the homeostatic mechanisms that would help the kidneys maintain a normal GFR.

23.4 Urine Formation II: Tubular Reabsorption and Secretion

Objectives

When you have completed this section, you should be able to

- describe how the renal tubules reabsorb useful solutes from the glomerular filtrate and return them to the blood;
- describe how the tubules secrete solutes from the blood into the tubular fluid; and
- describe how the nephron regulates water excretion.

Conversion of the glomerular filtrate to urine involves the removal and addition of chemicals by tubular reabsorption and secretion, to be described in this section. Here we trace the course of the tubular fluid through the nephron, from proximal convoluted tubule through distal convoluted tubule, and see how the filtrate is modified at each point along the way. Refer to figure 23.9 to put these processes into perspective.

The Proximal Convoluted Tubule

The proximal convoluted tubule (PCT) reabsorbs about 65% of the glomerular filtrate, while it also removes some substances from the blood and secretes them into the tubule for disposal in the urine. The importance of the PCT is reflected in its relatively great length and prominent microvilli, which increase its absorptive surface area. Its cells also contain abundant large mitochondria that provide ATP for active transport. The PCTs alone account for about 6% of one's resting ATP and calorie consumption.

Tubular reabsorption is the process of reclaiming water and solutes from the tubular fluid and returning them to the blood. The PCT reabsorbs a greater variety of chemicals than any other part of the nephron.

There are two routes of reabsorption: (1) the **transcellular**¹⁷ route, in which substances pass through the cytoplasm and out the base of the epithelial cells; and (2) the **paracellular**¹⁸ route, in which substances pass between the cells. The “tight” junctions between the epithelial cells are quite leaky and allow significant amounts of water to pass through. As it travels through the epithelium, water carries with it a variety of dissolved solutes—a process called **solvent drag**. Whether by the transcellular or paracellular route, such materials enter the tissue fluid at the base of the epithelium, and from there they are taken up by the peritubular

¹⁷trans = across

¹⁸para = next to

capillaries. In the following discussion and figure 23.16, we examine mechanisms for the reabsorption of water and some individual solutes.

Sodium Chloride Sodium reabsorption is the key to everything else, because it creates an osmotic and electrical gradient that drives the reabsorption of water and the other solutes. It is the most abundant cation in the glomerular filtrate, with a concentration of 140 mEq/L in the fluid entering the proximal convoluted tubule and only 12 mEq/L in the cytoplasm of the epithelial cells. This is a very steep concentration gradient, favoring its diffusion into the epithelial cells.

Two types of transport proteins in the apical cell surface are responsible for sodium uptake: (1) various *symports* that simultaneously bind Na^+ and another solute such as glucose, amino acids, or lactate; and (2) an Na^+-H^+ *antiport* that pulls Na^+ into the cell while pumping H^+ out of the cell into the tubular fluid. This antiport is a means not only of reabsorbing sodium, but also of eliminating acid from the body fluids. (See p. 104 for a refresher on symports and antiports.) Angiotensin II activates the Na^+-H^+ antiport and thereby exerts a strong influence on sodium reabsorption.

Sodium is prevented from accumulating in the epithelial cells by Na^+-K^+ pumps in the basal surface of the epithelium, which pump Na^+ out into the extracellular fluid. From there, it is picked up by the peritubular capillaries, thus returning to the bloodstream. These Na^+-K^+

pumps, like those anywhere, are ATP-consuming active transport pumps. Although the sodium-transporting symports in the apical cell membrane do not consume ATP, they are considered an example of **secondary active transport** because of their dependence on the Na^+-K^+ pumps at the base of the cell.

Chloride ions, being negatively charged, are attracted to the positively charged Na^+ and follow it by electrical attraction. There also are various antiports in the apical cell membrane that absorb Cl^- in exchange for other anions that they eject into the tubular fluid. Chloride and potassium ions are driven out through the basal cell surface by a K^+-Cl^- symport. Both sodium and chloride ions also diffuse through the tubule epithelium by the paracellular route between cells.

Other Electrolytes Potassium, magnesium, and phosphate ions diffuse through the paracellular route with water. Phosphate is also cotransported into the epithelial cells with Na^+ . Some calcium is reabsorbed through the paracellular route in the proximal tubule, but most Ca^{2+} absorption occurs later in the nephron, as we will see.

Glucose Glucose is cotransported with Na^+ by symports called **sodium-glucose transport proteins (SGLTs)**. It is then removed from the basolateral surface of the cell by facilitated diffusion. Normally all glucose in the tubular fluid is reabsorbed and there is none in the urine.

FIGURE 23.16 Reabsorption in the Proximal Convoluted Tubule. Water and solutes in the tubular fluid (right) are carried through the tubule epithelium by various means including symports, antiports, aquaporins, and the paracellular route between cells. They enter the tissue fluid at the base of the epithelium and are picked up by the peritubular capillaries (left). Many other solutes not shown here are reabsorbed by similar means.

How would increased Na^+ reabsorption affect the pH of the urine? Why?

Nitrogenous Wastes Urea diffuses through the tubule epithelium with water. The nephron as a whole reabsorbs 40% to 60% of the urea in the tubular fluid, but since it reabsorbs 99% of the water, urine has a substantially higher urea concentration than blood or glomerular filtrate. When blood enters the kidney, its urea concentration is about 20 mg/dL; when it leaves the kidney, it is typically down to 10.4 mg/dL. Thus the kidney removes about half of the urea, keeping its concentration down to a safe level but not completely clearing the blood of it.

The PCT reabsorbs nearly all the uric acid entering it, but later parts of the nephron secrete it back into the tubular fluid. Creatinine is not reabsorbed at all, but stays in the tubule and is all passed in the urine.

Water The kidneys reduce about 180 L of glomerular filtrate to 1 or 2 L of urine each day, so obviously water reabsorption is a significant function. About two-thirds of the water is reabsorbed by the PCT. The reabsorption of all the salt and organic solutes as just described makes the tubule cells and tissue fluid hypertonic to the tubular fluid. Water follows the solutes by osmosis through both the paracellular and transcellular routes. Transcellular absorption occurs by way of water channels called **aquaporins** in the plasma membrane.

Because the PCT reabsorbs proportionate amounts of solutes and water, the osmolarity of the tubular fluid remains unchanged here. Elsewhere in the nephron, the amount of water reabsorption is continually modulated by hormones according to the body's state of hydration. In the PCT, however, water is reabsorbed at a constant rate called **obligatory water reabsorption**.

Uptake by the Peritubular Capillaries

After water and solutes leave the basal surface of the tubule epithelium, they are reabsorbed into the blood by the peritubular capillaries. The mechanisms of capillary absorption are osmosis and solvent drag. Three factors promote osmosis into these capillaries: (1) The accumulation of reabsorbed fluid around the basolateral sides of the epithelial cells creates a high interstitial fluid pressure that physically drives water into the capillaries. (2) The narrowness of the efferent arteriole lowers the blood hydrostatic pressure (BHP) from 60 mm Hg in the glomerulus to only 8 mm Hg in the peritubular capillaries, so there is less resistance to reabsorption here than in most systemic capillaries. (3) As blood passes through the glomerulus, a lot of water is filtered out but nearly all of the protein remains in the blood. Therefore, the blood has an elevated colloid osmotic pressure (COP) by the time it leaves the glomerulus. With a high COP and

low BHP in the capillaries and a high hydrostatic pressure in the tissue fluid, the balance of forces in the peritubular capillaries strongly favors reabsorption. This tendency is even further accentuated by angiotensin II. By constricting the afferent and efferent arterioles, this hormone reduces blood pressure in the peritubular capillaries and thus reduces their resistance to fluid reabsorption (fig. 23.17).

As water on the basal side of the tubule epithelium diffuses into the capillaries, it carries with it the solutes reabsorbed by the PCT. Such solutes are said to follow the water by **solvent drag**.

The Transport Maximum

There is a limit to the amount of solute that the renal tubule can reabsorb because there are limited numbers of transport proteins in the plasma membranes. If all the transporters are occupied as solute molecules pass through, some solute will escape reabsorption and appear in the urine. The maximum rate of reabsorption is the **transport maximum (T_m)**, which is reached when the transporters are saturated (see p. 104).

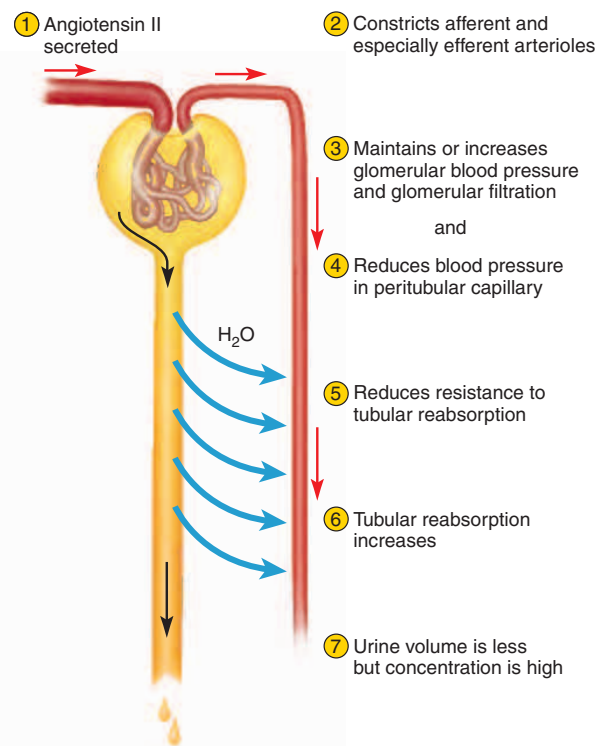

FIGURE 23.17 The Effect of Angiotensin II on Tubular Reabsorption.

Each organic solute reabsorbed by the renal tubule has its own T_m . Glucose, for example, has a T_m of 320 mg/min. It normally enters the renal tubule at a rate of 125 mg/min, well within the T_m ; thus all of it is reabsorbed. But at any blood glucose level above 220 mg/dL or so, glucose is filtered faster than the renal tubule can reabsorb it, and the excess passes in the urine—a condition called **glycosuria**¹⁹ (GLY-co-soo-ree-uh) (fig. 23.18). In untreated diabetes mellitus, the plasma glucose concentration may exceed 400 mg/dL, so glycosuria is one of the classic signs of this disease.

Tubular Secretion

Tubular secretion is a process in which the renal tubule extracts chemicals from the capillary blood and secretes them into the tubular fluid (see fig. 23.9). In the proximal convoluted tubule and nephron loop, it serves two purposes:

1. **Waste removal.** Urea, uric acid, bile acids, ammonia, catecholamines, prostaglandins, and a little creatinine are secreted into the tubule. Tubular secretion of uric acid compensates for its reabsorption earlier in the PCT and accounts for all of the uric acid in the urine. Tubular secretion also clears the blood of pollutants, morphine, penicillin, aspirin, and other drugs. One reason that so many drugs must be taken three or four times a day is to keep pace with this rate of clearance and maintain a therapeutically effective drug concentration in the blood.
2. **Acid–base balance.** Tubular secretion of hydrogen and bicarbonate ions regulates the pH of the body fluids. The details are discussed in chapter 24.

The Nephron Loop

The primary function of the nephron loop is to generate a salinity gradient that enables the collecting duct to concentrate the urine and conserve water, as discussed later. But in addition, the loop reabsorbs about 25% of the Na^+ , K^+ , and Cl^- and 15% of the water in the glomerular filtrate. Cells in the thick segment of the loop have proteins in the apical membranes that simultaneously bind 1 Na^+ , 1 K^+ , and 2 Cl^- from the tubular fluid and cotransport them into the cytoplasm. These ions leave the basolateral cell surfaces by active transport of Na^+ and diffusion of K^+ and Cl^- . Potassium reenters the cell by means of the Na^+-K^+ pump and then reenters the tubular fluid, but NaCl remains in the tissue fluid of the renal medulla. The thick segment of the loop is

FIGURE 23.18 The Transport Maximum. (a) At a normal blood glucose concentration (normoglycemia), all glucose filtered by the glomerulus is reabsorbed by glucose-transport proteins in the proximal convoluted tubule, and the urine is glucose-free. (b) At a high blood glucose concentration (hyperglycemia), more glucose is filtered than the transport proteins, now saturated, are able to absorb. The glomerular filtration of glucose now exceeds the transport maximum (T_m) of the renal tubule. Excess glucose escapes reabsorption and appears in the urine (glycosuria). Urine volume is elevated because of water osmotically retained in the renal tubule with the glucose.

impermeable to water; thus water cannot follow the reabsorbed electrolytes, and tubular fluid becomes very dilute by the time it passes from the nephron loop into the distal convoluted tubule.

The Distal Convoluted Tubule and Collecting Duct

Fluid arriving in the DCT still contains about 20% of the water and 7% of the salts from the glomerular filtrate. If this were all passed as urine, it would amount to 36 L/day, so obviously a great deal of fluid reabsorption is still to

¹⁹glycos = sugar + uria = urine condition

come. The DCT and collecting duct reabsorb variable amounts of water and salts and are regulated by several hormones—particularly aldosterone, atrial natriuretic peptide, antidiuretic hormone, and parathyroid hormone.

There are two kinds of cells in the DCT and collecting duct. The **principal cells** are the more abundant; they have receptors for the foregoing hormones and are involved chiefly in salt and water balance. The **intercalated cells** are fewer in number. They have a high density of mitochondria, reabsorb K^+ , secrete H^+ into the tubule lumen, and are involved mainly in acid–base balance, as discussed in chapter 24. The major hormonal influences on the DCT and collecting duct are as follows.

Aldosterone

Aldosterone, the “salt-retaining hormone,” is a steroid secreted by the adrenal cortex when the blood Na^+ concentration falls or its K^+ concentration rises. A drop in blood pressure also induces aldosterone secretion, but indirectly—it stimulates the kidney to secrete renin; this leads to the production of angiotensin II; and angiotensin II stimulates aldosterone secretion (see fig. 23.15).

Aldosterone acts on the thick segment of the ascending limb of the nephron loop, on the DCT, and on the cortical portion of the collecting duct. It stimulates these regions of the nephron to reabsorb more Na^+ and secrete more K^+ . Water and Cl^- follow the Na^+ , so the net effect is that the body retains $NaCl$ and water, the urine volume is reduced, and the urine has an elevated K^+ concentration. The retention of salt and water helps to maintain blood volume and pressure. Chapter 24 deals further with the action of aldosterone.

Natriuretic Peptides

Atrial natriuretic peptide (ANP) is secreted by the atrial myocardium of the heart in response to high blood pressure. It has four actions that result in the excretion of more salt and water in the urine, thus reducing blood volume and pressure:

1. It dilates the afferent arteriole and constricts the efferent arteriole, thus increasing the glomerular filtration rate.
2. It antagonizes the renin–angiotensin–aldosterone mechanism by inhibiting renin and aldosterone secretion.
3. It inhibits the secretion of antidiuretic hormone (ADH) and the action of ADH on the kidney.
4. It inhibits $NaCl$ reabsorption by the collecting duct.

Brain natriuretic peptide (BNP), another cardiac secretion in spite of its name, has similar effects but is secreted in much lower amounts.

Antidiuretic Hormone

ADH is secreted by the posterior lobe of the pituitary gland in response to dehydration and rising blood osmolarity. Its mechanism of action is explained later in more detail. In short, it makes the collecting duct more permeable to water, so water in the tubular fluid reenters the tissue fluid and bloodstream rather than being lost in the urine.

Parathyroid Hormone

A calcium deficiency (hypocalcemia) stimulates the parathyroid glands to secrete parathyroid hormone (PTH). PTH acts in several ways to restore calcium homeostasis. Its effect on bone metabolism was described in chapter 7. In the kidney, it acts on the PCT to increase phosphate excretion, and acts on the thick segment of the ascending limb of the nephron loop and on the DCT to increase calcium reabsorption. Thus, it increases the phosphate content and lowers the calcium content of the urine. This helps to minimize any further decline in the blood calcium level. Because phosphate is not retained along with the calcium, the calcium ions stay in circulation rather than precipitating into the bone tissue as calcium phosphate. Calcitriol and calcitonin have similar but weaker effects on the DCT. PTH also stimulates calcitriol synthesis by the epithelial cells of the PCT.

In summary, the PCT reabsorbs about 65% of the glomerular filtrate and returns it to the blood of the peritubular capillaries. Much of this reabsorption occurs by osmotic and cotransport mechanisms linked to the active transport of sodium ions. The nephron loop reabsorbs another 25% of the filtrate, although its primary role, detailed later, is to aid the function of the collecting duct. The DCT reabsorbs more sodium, chloride, and water, but its rates of reabsorption are subject to control by hormones, especially aldosterone and ANP. These tubules also extract drugs, wastes, and some other solutes from the blood and secrete them into the tubular fluid. The DCT essentially completes the process of determining the chemical composition of the urine. The principal function left to the collecting duct is to conserve water.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

11. The reabsorption of water, Cl^- , and glucose by the PCT is linked to the reabsorption of Na^+ , but in three very different ways. Contrast these three mechanisms.
12. Explain why a substance appears in the urine if its rate of glomerular filtration exceeds the T_m of the renal tubule.
13. Contrast the effects of aldosterone and ANP on the renal tubule.

23.5 Urine Formation III: Water Conservation

Objectives

When you have completed this section, you should be able to

- explain how the collecting duct and antidiuretic hormone regulate the volume and concentration of urine; and
- explain how the kidney maintains an osmotic gradient in the renal medulla that enables the collecting duct to function.

The kidney serves not just to eliminate metabolic waste from the body but also to prevent excessive water loss in doing so, and thus to support the body's fluid balance. As the kidney returns water to the tissue fluid and bloodstream, the fluid remaining in the renal tubule, and ultimately passed as urine, becomes more and more concentrated. In this section, we examine the kidney's mechanisms for conserving water and concentrating the urine.

The Collecting Duct

The collecting duct (CD) begins in the cortex, where it receives tubular fluid from numerous nephrons. As it passes through the medulla, it usually reabsorbs water and concentrates the urine. When urine enters the upper end of the CD, it is isotonic with blood plasma (300 mOsm/L), but by the time it leaves the lower end, it can be up to four times as concentrated—that is, highly hypertonic to the plasma. This ability to concentrate wastes and control water loss was crucial to the evolution of terrestrial animals such as ourselves (see Insight 23.1).

Two facts enable the collecting duct to produce such hypertonic urine: (1) the osmolarity of the extracellular fluid is four times as high in the lower medulla as it is in the cortex, and (2) the medullary portion of the CD is more permeable to water than to solutes. Therefore, as urine passes down the CD through the increasingly salty medulla, water leaves the tubule by osmosis, most NaCl and other wastes remain behind, and the urine becomes more and more concentrated (fig. 23.19).

FIGURE 23.19 Water Reabsorption by the Collecting Duct. Note that the osmolarity of the tissue fluid increases four-fold from 300 mOsm/L in the cortex to 1,200 mOsm/L deep in the medulla. Urine concentration increases proportionately as water leaves the duct through its aquaporins.

INSIGHT 23.1 Evolutionary Medicine

The Kidney and Life on Dry Land

Physiologists first suspected that the nephron loop plays a role in water conservation because of their studies of a variety of animal species. Animals that must conserve water have longer, more numerous nephron loops than animals with little need to conserve it. Fish and amphibians lack nephron loops and produce urine that is isotonic to their blood plasma. Aquatic mammals such as beavers have short nephron loops and only slightly hypertonic urine.

But the kangaroo rat, a desert rodent, provides an instructive contrast. It lives on seeds and other dry foods and needs never drink water. Its kidneys are so efficient that it can live entirely on the water produced by aerobic respiration. They have extremely long nephron loops and produce urine that is 10 to 14 times as concentrated as the blood plasma (compared with about 4 times, at most, in humans).

Comparative studies thus suggested a hypothesis for the function of the nephron loop and prompted many years of difficult research that led to the discovery of the countercurrent multiplier mechanism for water conservation. This shows how comparative anatomy provides suggestions and insights into function and why physiologists do not study human function in isolation from other species.

Control of Water Loss

Just *how* concentrated the urine becomes depends on the body's state of hydration. For example, if you drink a large volume of water, you will soon produce a large volume of hypotonic urine. This response is called *water diuresis*²⁰ (DY-you-REE-sis). Under such conditions, the cortical portion of the CD reabsorbs NaCl but is impermeable to water. Thus salt is removed from the urine, water stays in the CD, and urine concentration may be as low as 50 mOsm/L.

Dehydration, on the other hand, causes the urine to be scanty and more concentrated. The high blood osmolarity of a dehydrated person stimulates the pituitary to release ADH. ADH induces the renal tubule cells to synthesize aquaporins (water-channel proteins) and install them in the plasma membrane, so more water can pass through the epithelial cells. The CD then reabsorbs more water, which is carried away by the vasa recta. Urine output is consequently reduced. By contrast, when you are well hydrated, ADH secretion falls and the tubule cells remove aquaporins from the plasma membrane. The duct is then less permeable to water, so more water remains in the duct and the kidney produces abundant, dilute urine.

In extreme cases, the blood pressure of a dehydrated person is low enough to significantly reduce the glomerular filtration rate. When the GFR is low, fluid flows more slowly through the renal tubules and there is more time for tubular reabsorption. Less salt remains in the urine as it enters the collecting duct, so there is less opposition to the osmosis of water out of the duct and into the ECF. More water is reabsorbed and less urine is produced.

The Countercurrent Multiplier

The ability of the CD to concentrate urine depends on the salinity gradient of the renal medulla. It may seem surprising that the ECF is four times as salty deep in the medulla as it is in the cortex. We would expect the salt to diffuse toward the cortex until it was evenly distributed through the kidney. However, there is a mechanism that overrides this—the nephron loop acts as a **countercurrent multiplier**, which continually recaptures salt and returns it to the deep medullary tissue. It is called a *multiplier* because it multiplies the salinity deep in the medulla, and a *countercurrent* mechanism because it is based on fluid flowing in opposite directions in two adjacent tubules—downward in the descending limb and upward in the ascending limb.

Figure 23.20 shows how the countercurrent multiplier works. Steps 2 through 5 form a positive feedback loop. As fluid flows down the descending limb of the nephron loop, it passes through an environment of increasing osmolarity. Most of the descending limb is very permeable to water but not to NaCl; therefore, water passes by osmosis from the tubule into the extracellular fluid (ECF), leaving the NaCl behind. The tubule contents increase in osmolarity, reaching about 1,200 mOsm/L by the time the fluid rounds the bend at the lower end of the loop.

Most or all of the ascending limb (its thick segment), by contrast, is impermeable to water, but has active transport pumps that cotransport Na⁺, K⁺, and Cl⁻ into the ECF. This keeps the osmolarity of the renal medulla high. Since water remains in the tubule, the tubular fluid becomes more and more dilute as it approaches the cortex and is only about 100 mOsm/L at the top of the loop.

About 40% of the high osmolarity in the deep medullary tissue, however, is due not to sodium and potassium chloride, but to urea—which is continually cycled from the collecting duct to the nephron loop and back (fig. 23.21). The lower end of the collecting duct is somewhat permeable to urea, permitting it to diffuse out into the extracellular fluid. Some of it enters the descending

FIGURE 23.20 The Countercurrent Multiplier of the Nephron Loop. The numbers in the tubule are in mOsm/L.

²⁰diuresis = passing urine

FIGURE 23.21 Functional Relationship of the Nephron Loop, Vasa Recta, and Collecting Duct. These three structures work together to maintain a gradient of osmolarity in the renal medulla. The numbers in the tubule are in mOsm/L.

thin segment of the nephron loop and travels through the loop and distal convoluted tubule back to the collecting duct. Neither the thick segment of the loop nor the DCT is permeable to urea. Combined with new urea constantly added by glomerular filtration, urea remains concentrated in the collecting duct and some of it always diffuses out into the medulla, adding to its osmolarity.

The Countercurrent Exchange System

The renal medulla must have a blood supply to meet its metabolic needs, and this creates a potential problem—capillaries of the medulla could carry away the urea and salt that produce the high osmolarity. The vasa recta that supply the medulla, however, form a countercurrent system of their own that prevents this from happening. Blood flows in opposite directions in adjacent parallel capillaries, forming a **countercurrent exchange system**. Blood flowing downward in the vasa recta exchanges water for salt—water diffuses out of the capillaries and salt diffuses in. As the blood flows back up to the cortex, the opposite occurs—it exchanges salt for water. Thus, the vasa recta give the salt back and do not subtract from the osmolarity of the medulla.

Indeed, they absorb more water on the way out than they unload on the way in; they carry away the water reabsorbed from the urine by the collecting duct and nephron loop.

To summarize what we have studied in this section, the collecting duct can adjust water reabsorption to produce urine as hypotonic as 50 mOsm/L or as hypertonic as 1,200 mOsm/L, depending on the body's need for water conservation or removal. In a state of hydration, ADH is not secreted and the cortical part of the CD reabsorbs salt without reabsorbing water; the water remains to be excreted in the dilute urine. In a state of dehydration, ADH is secreted, the medullary part of the CD reabsorbs water, and the urine is more concentrated. The CD is able to do this because it passes through a salinity gradient in the medulla from 300 mOsm/L near the cortex to 1,200 mOsm/L near the papilla. This gradient is produced by a countercurrent multiplier of the nephron loop, which concentrates NaCl in the lower medulla, and by the diffusion of urea from the collecting duct into the medulla. The vasa recta are arranged as a countercurrent exchange system that enables them to supply blood to the medulla without subtracting from its salinity gradient.

TABLE 23.1 Hormones Affecting Renal Function		
Hormone	Renal targets	Effects
Aldosterone	Nephron loop, DCT, CD	Promotes Na ⁺ reabsorption and K ⁺ secretion; indirectly promotes Cl ⁻ and H ₂ O reabsorption; maintains blood volume and reduces urine volume
Angiotensin II	Afferent and efferent arterioles, PCT	Reduces water loss, encourages water intake, and constricts blood vessels, thus raising blood pressure. Acts as a generalized vasoconstrictor; raises GFR; stimulates PCT to reabsorb NaCl and H ₂ O; stimulates aldosterone and ADH secretion; stimulates thirst
Antidiuretic hormone	Collecting duct	Promotes H ₂ O reabsorption; reduces urine volume, increases concentration
Natriuretic peptides	Afferent and efferent arterioles, collecting duct	Dilate afferent arteriole, constrict efferent arteriole, increase GFR; inhibit secretion of renin, ADH, and aldosterone; inhibit NaCl reabsorption by collecting duct; increase urine volume and lower blood pressure
Calcitonin	DCT	Weak effects similar to those of PTH
Calcitriol	DCT	Weak effects similar to those of PTH
Epinephrine and norepinephrine	Juxtaglomerular apparatus, afferent arteriole	Induce renin secretion; constrict afferent arteriole; reduce GFR and urine volume
Parathyroid hormone	PCT, DCT, nephron loop	Promotes Ca ²⁺ reabsorption by loop and DCT; increases phosphate excretion by PCT; promotes calcitriol synthesis

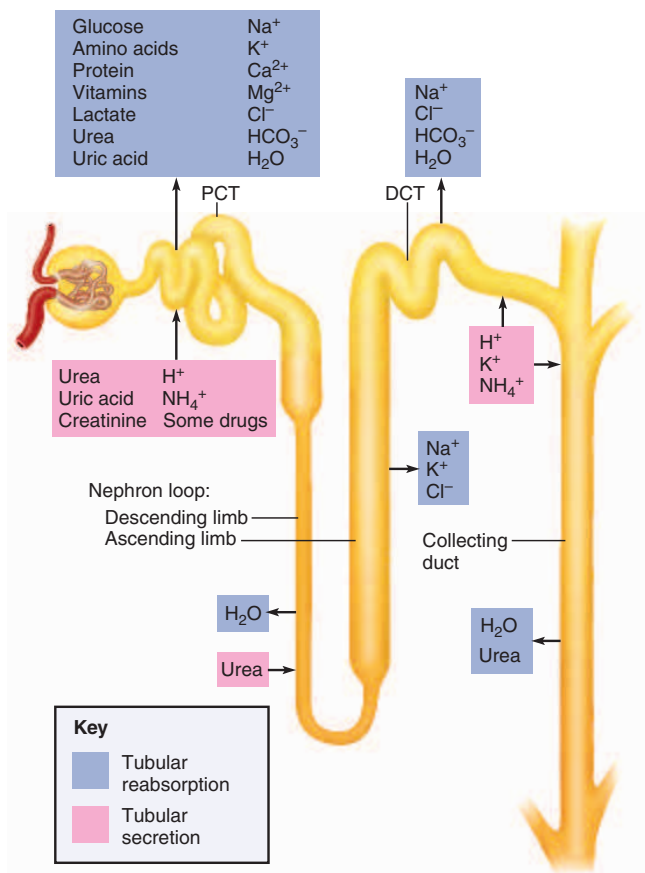

FIGURE 23.22 Solutes Reabsorbed and Secreted in Each Portion of the Renal Tubule.

Figure 23.22 summarizes the major solutes reabsorbed and secreted in each part of the renal tubule. Table 23.1 summarizes the hormones that affect renal function.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Predict how ADH hypersecretion would affect the sodium concentration of the urine, and explain why.
- Concisely contrast the role of the countercurrent multiplier with that of the countercurrent exchanger.
- How would the function of the collecting duct change if the nephron loop did not exist?

23.6 Urine and Renal Function Tests

Objectives

When you have completed this section, you should be able to

- describe the composition and properties of urine; and
- carry out some calculations to evaluate renal function.

Medical diagnosis often rests on determining the current and recent physiological state of the tissues. No two fluids are as valuable for this purpose as blood and urine.

Urinalysis, the examination of the physical and chemical properties of urine, is therefore one of the most routine procedures in medical examinations. The principal characteristics of urine and certain tests used to evaluate renal function are described here.

Composition and Properties of Urine

The basic composition and properties of urine are as follows:

- **Appearance.** Urine varies from almost colorless to deep amber, depending on the body's state of hydration. The yellow color of urine is due to **urochrome**,²¹ a pigment produced by the breakdown of hemoglobin from expired erythrocytes. Pink, green, brown, black, and other colors result from certain foods, vitamins, drugs, and metabolic diseases. Urine is normally clear but turns cloudy upon standing because of bacterial growth. Pus in the urine (**pyuria**²²) makes it cloudy and suggests kidney infection. Blood in the urine (hematuria) may be due to a urinary tract infection, trauma, or kidney stones. Cloudiness or blood in a urine specimen sometimes, however, simply indicates contamination with semen or menstrual fluid.
- **Odor.** Fresh urine has a distinctive but not repellent odor. As it stands, however, bacteria multiply, degrade urea to ammonia, and produce the pungent odor typical of stale wet diapers. Asparagus and other foods can impart distinctive aromas to the urine. Diabetes mellitus gives it a sweet, fruity odor of acetone. A mousy odor suggests phenylketonuria (PKU), and a rotten odor may indicate urinary tract infection.
- **Specific gravity.** This is a ratio of the density (g/mL) of a substance to the density of distilled water. Distilled water has a specific gravity of 1.000, and urine ranges from 1.001 when it is very dilute to 1.028 when it is very concentrated. Multiplying the last two digits of the specific gravity by a proportionality constant of 2.6 gives an estimate of the grams of solid matter per liter of urine. For example, a specific gravity of 1.025 indicates a solute concentration of $25 \times 2.6 = 65$ g/L.
- **Osmolarity.** Urine can have an osmolarity as low as 50 mOsm/L in a very hydrated person or as high as 1,200 mOsm/L in a dehydrated person. Compared with the osmolarity of blood (300 mOsm/L), then, urine can be either hypotonic or hypertonic under different conditions.
- **pH.** The pH of urine ranges from 4.5 to 8.2 but is usually about 6.0 (mildly acidic). The regulation of urine pH is discussed extensively in chapter 24.

- **Chemical composition.** Urine averages 95% water and 5% solutes by volume (table 23.2). Normally, the most abundant solute is urea, followed by sodium chloride, potassium chloride, and lesser amounts of creatinine, uric acid, phosphates, sulfates, and traces of calcium, magnesium, and sometimes bicarbonate. Urine contains urochrome and a trace of bilirubin from the breakdown of hemoglobin and related products, and urobilin, a brown oxidized derivative of bilirubin. It is abnormal to find glucose, free hemoglobin, albumin, ketones, or bile pigments in the urine; their presence is an important indicator of disease.

Urine Volume

An average adult produces 1 to 2 L of urine per day. An output in excess of 2 L/day is called diuresis or **polyuria**²³ (POL-ee-YOU-ree-uh). Fluid intake and some drugs

²³poly = many, much + ur = urine + ia = condition

TABLE 23.2

Properties and Composition of Urine

Physical Properties		
Specific gravity	1.001-1.028	
Osmolarity	50-1,200 mOsm/L	
pH	6.0 (range 4.5-8.2)	
Solute	Concentration*	Output**
Inorganic ions		
Chloride	533 mg/dL	6.4 g/day
Sodium	333 mg/dL	4.0 g/day
Potassium	166 mg/dL	2.0 g/day
Phosphate	83 mg/dL	1 g/day
Ammonia	60 mg/dL	0.68 g/day
Calcium	17 mg/dL	0.2 g/day
Magnesium	13 mg/dL	0.16 g/day
Nitrogenous wastes		
Urea	1.8 g/dL	21 g/day
Creatinine	150 mg/dL	1.8 g/day
Uric acid	40 mg/dL	0.5 g/day
Urobilin	125 µg/dL	1.52 mg/day
Bilirubin	20 µg/dL	0.24 mg/day
Other organics		
Amino acids	288 µg/dL	3.5 mg/day
Ketones	17 µg/dL	0.21 mg/day
Carbohydrates	9 µg/dL	0.11 mg/day
Lipids	1.6 µg/dL	0.02 mg/day

*Typical values for a reference man

**Assuming a urine output of 1.2 L/day

²¹uro = urine + chrom = color

²²py = pus + ur = urine + ia = condition

can temporarily increase output to as much as 20 L/day. Chronic diseases such as diabetes (see next) can do so over a long term. **Oliguria**²⁴ (oĭl-ih-GUE-ree-uh) is an output of less than 500 mL/day, and **anuria**²⁵ is an output of 0 to 100 mL/day. Low output can result from kidney disease, dehydration, circulatory shock, prostate enlargement, and other causes. If urine output drops to less than 400 mL/day, the body cannot maintain a safe, low concentration of wastes in the blood plasma. The result is azotemia.

Diabetes

Diabetes²⁶ is any metabolic disorder resulting in chronic polyuria. There are at least four forms of diabetes: *diabetes mellitus type 1* and *type 2*, *gestational diabetes*, and *diabetes insipidus*. In most cases, the polyuria results from a high concentration of glucose in the renal tubule. Glucose opposes the osmotic reabsorption of water, so more water is passed in the urine (*osmotic diuresis*) and a person may become severely dehydrated. In diabetes mellitus and gestational diabetes, the high glucose concentration in the tubule is a result of hyperglycemia, a high concentration of glucose in the blood. About 1% to 3% of pregnant women experience gestational diabetes, in which pregnancy reduces the mother's insulin sensitivity, resulting in hyperglycemia and glycosuria. Diabetes insipidus results from ADH hyposecretion. Without ADH, the collecting duct does not reabsorb as much water as normal, so more water passes in the urine.

Diabetes mellitus and gestational diabetes are characterized by glycosuria. Before chemical tests for urine glucose were developed, physicians diagnosed diabetes mellitus²⁷ by tasting the patient's urine for sweetness. Tests for glycosuria are now as simple as dipping a chemical test strip into the urine specimen—an advance in medical technology for which urologists are no doubt grateful. In diabetes insipidus,²⁸ the urine contains no glucose and, by the old diagnostic method, would not taste sweet.

Diuretics

A **diuretic** is any chemical that increases urine volume. Some diuretics act by increasing glomerular filtration rate, such as caffeine, which dilates the afferent arteriole. Others act by reducing tubular reabsorption of water. Alcohol, for example, inhibits ADH secretion and thereby reduces reabsorption in the collecting duct. **Loop diuretics** such as furosemide (Lasix) act on the nephron loop to inhibit the $\text{Na}^+ - \text{K}^+ - \text{Cl}^-$ symport. This

impairs the countercurrent multiplier, thus reducing the osmotic gradient in the renal medulla and making the collecting duct unable to reabsorb as much water as usual. Diuretics are commonly administered to treat hypertension and congestive heart failure by reducing the body's fluid volume and blood pressure.

Renal Function Tests

There are several tests for diagnosing kidney diseases, evaluating their severity, and monitoring their progress. Here we examine two methods used to determine renal clearance and glomerular filtration rate.

Renal Clearance

Renal clearance is the volume of blood plasma from which a particular waste is completely removed in 1 minute. It represents the net effect of three processes:

$$\begin{array}{l} \text{Glomerular filtration of the waste} \\ + \text{Amount added by tubular secretion} \\ - \text{Amount removed by tubular reabsorption} \\ \hline \text{Renal clearance} \end{array}$$

In principle, we could determine renal clearance by sampling blood entering and leaving the kidney and comparing their waste concentrations. In practice, it is not practical to draw blood samples from the renal vessels, but clearance can be assessed indirectly by collecting samples of blood and urine, measuring the waste concentration in each, and measuring the rate of urine output.

Suppose the following values were obtained for urea:

$$\begin{array}{ll} U \text{ (urea concentration in urine)} & = 6.0 \text{ mg/mL} \\ V \text{ (rate of urine output)} & = 2 \text{ mL/min} \\ P \text{ (urea concentration in plasma)} & = 0.2 \text{ mg/mL} \end{array}$$

Renal clearance (C) is

$$\begin{aligned} C &= UV/P \\ &= (6.0 \text{ mg/mL})(2 \text{ mL/min})/0.2 \text{ mg/mL} \\ &= 60 \text{ mL/min} \end{aligned}$$

This means the equivalent of 60 mL of blood plasma is completely cleared of urea per minute. If this person has a normal GFR of 125 mL/min, then the kidneys have cleared urea from $60/125 = 48\%$ of the glomerular filtrate. This is a normal rate of urea clearance and is sufficient to maintain safe levels of urea in the blood.

Think About It

What would you expect the value of renal clearance of glucose to be in a healthy individual? Why?

²⁴oligo = few, a little + ur = urine + ia = condition

²⁵an = without + ur = urine + ia = condition

²⁶diabetes = passing through

²⁷melli = honey, sweet

²⁸insipid = tasteless

Glomerular Filtration Rate

Assessment of kidney disease often calls for a measurement of GFR. We cannot determine GFR from urea excretion for two reasons: (1) some of the urea in the urine is secreted by the renal tubule, not filtered by the glomerulus, and (2) much of the urea filtered by the glomerulus is reabsorbed by the tubule. To measure GFR ideally requires a substance that is not secreted or reabsorbed at all, so that all of it in the urine gets there by glomerular filtration.

There doesn't appear to be a single urine solute produced by the body that is not secreted or reabsorbed to some degree. However, several plants, including garlic and artichoke, produce a polysaccharide called inulin that is useful for GFR measurement. All inulin filtered by the glomerulus remains in the renal tubule and appears in the urine; none is reabsorbed, nor does the tubule secrete it. GFR can be measured by injecting inulin and subsequently measuring the rate of urine output and the concentrations of inulin in the blood and urine.

For inulin, GFR is equal to the renal clearance. Suppose, for example, that a patient's plasma concentration of inulin is $P = 0.5$ mg/mL, the urine concentration is $U = 30$ mg/mL, and urine output is $V = 2$ mL/min. This person has a normal GFR:

$$\begin{aligned} \text{GFR} &= UV/P \\ &= (30 \text{ mg/mL})(2 \text{ mL/min})/0.5 \text{ mg/mL} \\ &= 120 \text{ mL/min} \end{aligned}$$

In clinical practice, GFR is more often estimated from creatinine excretion. This has a small but acceptable error of measurement, and is an easier procedure than injecting inulin and drawing blood to measure its blood concentration.

A solute that is reabsorbed by the renal tubules will have a renal clearance *less* than the GFR (provided its tubular secretion is less than its rate of reabsorption). This is why the renal clearance of urea is about 60 mL/min. A solute that is secreted by the renal tubules will have a renal clearance *greater* than the GFR (provided its reabsorption does not exceed its secretion). Creatinine, for example, has a renal clearance of 140 mL/min.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

17. Define oliguria and polyuria. Which of these is characteristic of diabetes?
18. Identify a cause of glycosuria other than diabetes mellitus.
19. How is the diuresis produced by furosemide like the diuresis produced by diabetes mellitus? How are they different?
20. Explain why GFR cannot be determined by measuring the amount of NaCl in the urine.

23.7 Urine Storage and Elimination

Objectives

When you have completed this section, you should be able to

- describe the functional anatomy of the ureters, urinary bladder, and male and female urethra; and
- explain how the nervous system and urethral sphincters control the voiding of urine.

Urine is produced continually, but fortunately it does not drain continually from the body. Urination is episodic—occurring when we allow it. This is made possible by an apparatus for storing urine and by neural controls for its timely release.

The Ureters

The renal pelvis funnels urine into the ureter, a retroperitoneal, muscular tube that extends to the urinary bladder. The ureter is about 25 cm long and reaches a maximum diameter of about 1.7 cm near the bladder. The ureters pass posterior to the bladder and enter it from below, passing obliquely through its muscular wall and opening onto its floor. A small flap of mucosa acts as a valve at the opening of each ureter into the bladder, preventing urine from backing up into the ureter when the bladder contracts.

The ureter has three layers: an adventitia, muscularis, and mucosa. The adventitia is a connective tissue layer that binds it to the surrounding tissues. The muscularis consists of two layers of smooth muscle over most of its length, but a third layer appears in the lower ureter. When urine enters the ureter and stretches it, the muscularis contracts and initiates a peristaltic wave that milks the urine from the renal pelvis down to the bladder. These contractions occur every few seconds to few minutes, proportional to the rate at which urine enters the ureter. The mucosa has a transitional epithelium that begins in the minor calyces of the kidney and extends from there through the bladder. The lumen of the ureter is very narrow and is easily obstructed or injured by kidney stones (see Insight 23.2).

The Urinary Bladder

The urinary bladder (fig. 23.23) is a muscular sac on the floor of the pelvic cavity, inferior to the peritoneum and posterior to the pubic symphysis. It is covered by parietal peritoneum on its flattened superior surface and by a fibrous adventitia elsewhere. Its muscularis, called the **detrusor**²⁹ (deh-TROO-zur) **muscle**, consists of three

²⁹de = down + trus = push

FIGURE 23.23 The Urinary Bladder and Urethra. Frontal sections.

Why are women more susceptible than men to bladder infections?

INSIGHT 23.2 Clinical Application

Kidney Stones

A *renal calculus*³⁰ (kidney stone) is a hard granule composed usually of calcium phosphate or calcium oxalate, but sometimes uric acid or a magnesium salt called struvite. Renal calculi form in the renal pelvis and are usually small enough to pass unnoticed in the urine flow. Some, however, grow as large as several centimeters and block the renal pelvis or ureter, which can lead to the destruction of nephrons as pressure builds in the kidney. A large, jagged calculus passing down the ureter stimulates strong contractions that can be excruciatingly painful. It can also damage the ureter and cause hematuria. Causes of renal calculi include hypercalcemia, dehydration, pH imbalances, frequent urinary tract infections, or an enlarged prostate gland causing urine retention. Calculi are sometimes treated with stone-dissolving drugs, but often they require surgical removal. A nonsurgical technique called *lithotripsy*³¹ uses ultrasound to pulverize the calculi into fine granules easily passed in the urine.

layers of smooth muscle. The mucosa has a transitional epithelium, and in the relaxed bladder it has conspicuous wrinkles called **rugae**³² (ROO-gee). The openings of the two ureters and the urethra mark a smooth-surfaced triangular area called the **trigone**³³ (TRY-goan) on the bladder floor. This is a common site of bladder infection (see Insight 23.3).

The bladder is highly distensible. As it fills, it expands superiorly, the rugae flatten, and the epithelium thins from five or six cell layers to only two or three. A moderately full bladder contains about 500 mL of urine and extends about 12.5 cm from top to bottom. The maximum capacity is 700 to 800 mL.

The Urethra

The urethra conveys urine out of the body. In the female, it is a tube 3 to 4 cm long bound to the anterior wall of

³⁰*calc* = calcium, stone + *ul* = little

³¹*litho* = stone + *tripsy* = crushing

³²*ruga* = fold, wrinkle

³³*tri* = three + *gon* = angle

INSIGHT 23.3 Clinical Application**Urinary Tract Infection (UTI)**

Infection of the urinary bladder is called *cystitis*.³⁴ It is especially common in females because bacteria such as *Escherichia coli* can travel easily from the perineum up the short urethra. Because of this risk, young girls should be taught never to wipe the anus in a forward direction. Cystitis is frequently triggered in women by sexual intercourse (“honeymoon cystitis”). If cystitis is untreated, bacteria can spread up the ureters and cause *pyelitis*,³⁵ infection of the renal pelvis. If it reaches the renal cortex and nephrons, it is called *pyelonephritis*. Kidney infections can also result from invasion by blood-borne bacteria. Urine stagnation due to renal calculi or prostate enlargement increases the risk of infection.

the vagina by fibrous connective tissue. Its opening, the **external urethral orifice**, lies between the vaginal orifice and clitoris. The male urethra is about 18 cm long and has three regions: (1) The **prostatic urethra** begins at the urinary bladder and passes for about 2.5 cm through the prostate gland. During orgasm, it receives semen from the reproductive glands. (2) The **membranous urethra** is a short (0.5 cm), thin-walled portion where the urethra passes through the muscular floor of the pelvic cavity. (3) The **spongy (penile) urethra** is about 15 cm long and passes through the penis to the external urethral orifice. It is named for the *corpus spongiosum* of the penis, through which it passes. The male urethra assumes an S shape: it passes downward from the bladder, turns anteriorly as it enters the root of the penis, and then turns about 90° downward again as it enters the external, pendant part of the penis. The mucosa has a transitional epithelium near the bladder, a pseudostratified epithelium for most of its length, and finally a stratified squamous epithelium near the external urethral orifice. There are mucous **urethral glands** in its wall.

In both sexes, the detrusor muscle is thickened near the urethra to form an **internal urethral sphincter**, which compresses the urethra and retains urine in the bladder. Since this sphincter is composed of smooth muscle, it is under involuntary control. Where the urethra passes through the pelvic floor, it is encircled by an **external urethral sphincter** of skeletal muscle, which provides voluntary control over the voiding of urine.

Voiding Urine

Between acts of urination, when the bladder is filling, it is important that the detrusor muscle relax and the

urethral sphincters remain tightly closed. This is ensured by sympathetic pathways that originate in the upper lumbar spinal cord. Postganglionic fibers travel through the hypogastric nerve to the detrusor muscle and internal urethral sphincter. Owing to different types of adrenergic receptors on these two muscles, these fibers *relax* the detrusor and *excite* the internal urethral sphincter. The external urethral sphincter is also held closed, but since this is skeletal muscle, it receives somatic innervation. Somatic motor fibers course from the upper sacral spinal cord via the pudendal nerve to the external sphincter.

The act of urinating, also called **micturition**³⁶ (MIC-too-RISH-un), is controlled partly by an spinal **micturition reflex**, depicted in figure 23.24, steps 1 through 4. Filling of the bladder to about 200 mL or more excites stretch receptors in the bladder wall. They issue signals by way of sensory fibers in the pelvic nerve to the sacral spinal cord (usually segments S2–S3). Efferent signals from the spinal cord travel back to the bladder by way of motor fibers in the pelvic nerve and a parasympathetic ganglion in the bladder wall. Output from the ganglion excites the detrusor muscle and relaxes the internal urethral sphincter. This results in emptying of the bladder. If there was no voluntary control over urination, this reflex would be the only means of control—which is the case in very young children and in people with spinal cord injuries that disconnect the brain from the lower spinal cord.

Normally, however, one also has voluntary control over urination (steps 5–8). Some input from the stretch receptors ascends the spinal cord to a nucleus in the pons called the **micturition center**. This nucleus integrates information about bladder tension with information from other brain centers such as the amygdala and cerebrum. Thus, urination can be prompted by fear or inhibited by knowledge that the circumstances are inappropriate for urination.

Fibers from the micturition center descend the spinal cord through the reticulospinal tracts. Some of these fibers inhibit sympathetic neurons that normally keep the internal urethral sphincter contracted, thus allowing for its relaxation. Others descend farther to the sacral spinal cord and excite the parasympathetic neurons that stimulate the detrusor and relax the internal urethral sphincter. The initial contraction of the detrusor raises pressure in the bladder, further exciting the stretch receptors that started the process; thus, a positive feedback loop is established and intensifies bladder contraction as urination proceeds.

For the bladder to begin emptying, however, one final obstacle must be overcome—the external urethral

³⁴cyst = bladder + itis = inflammation

³⁵pyel = pelvis + itis = inflammation

³⁶mictur = to urinate

**Involuntary micturition reflex**

- 1 Stretch receptors detect filling of bladder, transmit afferent signals to spinal cord.
- 2 Signals return to bladder from spinal cord segments S2 and S3 via parasympathetic fibers in pelvic nerve.
- 3 Efferent signals excite detrusor muscle.
- 4 Efferent signals relax internal urethral sphincter. Urine is involuntarily voided if not inhibited by brain.

Voluntary control

- 5 For voluntary control, micturition center in pons receives signals from stretch receptors.
- 6 If it is timely to urinate, pons returns signals to spinal interneurons that excite detrusor and relax internal urethral sphincter. Urine is voided.
- 7 If it is untimely to urinate, signals from pons excite spinal interneurons that keep external urethral sphincter contracted. Urine is retained in bladder.
- 8 If it is timely to urinate, signals from pons cease and external urethral sphincter relaxes. Urine is voided.

FIGURE 23.24 Neural Control of Micturition.

sphincter. Nerve fibers from the cerebral cortex descend by way of the corticospinal tracts and inhibit sacral somatic motor neurons that normally keep that sphincter constricted. It is this voluntary component of micturition that gives a person conscious control of when to urinate and the ability to stop urination in midstream. Voluntary control develops as the nervous system matures in early childhood. Males expel the last few milliliters of urine by voluntarily contracting the bulbocavernosus muscle that ensheathes the root of the penis. This helps to reduce the retention of urine in the longer male urethra.

If the urge to urinate arises at an inconvenient time and one must suppress it, the stretch receptors fatigue and stop firing. As bladder tension increases, however, the signals return with increasing frequency and

INSIGHT 23.4 Clinical Application**Urination and Spinal Cord Injuries**

Knowledge of the neural control of micturition is particularly important for understanding and treating persons with spinal cord injuries. Transection of the spinal cord, as in many cervical fractures, disconnects the *supraspinal* control centers (cerebrum and pons) from the spinal cord circuits that control urination. During the period of spinal shock (see p. 510), a person is generally incontinent—lacking any control over urination. Bladder control returns as the spinal cord recovers, but is limited to the involuntary micturition reflex. The bladder often cannot empty completely, and there is consequently an increased incidence of cystitis.

persistence. Conversely, there are times when the bladder is not full enough to trigger the micturition reflex, but one wishes to “go” anyway because of a long drive or lecture coming up. In this case, the Valsalva maneuver (p. 877) is used to compress the bladder and excite the stretch receptors early, thereby getting the reflex started. The Valsalva maneuver also aids in emptying the bladder.

The effects of aging on the urinary system are discussed on page 1143. Some disorders of this system are briefly described in table 23.3.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe the location and function of the detrusor muscle.
- Compare and contrast the functions of the internal and external urethral sphincters.
- In males, the sympathetic nervous system triggers ejaculation and, at the same time, stimulates constriction of the internal urethral sphincter. What purpose is served by the latter action?

TABLE 23.3 Some Disorders of the Urinary System

Acute glomerulonephritis	An autoimmune inflammation of the glomeruli, often following a streptococcus infection. Results in destruction of glomeruli leading to hematuria, proteinuria, edema, reduced glomerular filtration, and hypertension. Can progress to chronic glomerulonephritis and renal failure, but most individuals recover from acute glomerulonephritis without lasting effect.		
Acute renal failure	An abrupt decline in renal function, often due to traumatic damage to the nephrons or a loss of blood flow stemming from hemorrhage or thrombosis.		
Chronic renal failure	Long-term, progressive, irreversible loss of nephrons; see Insight 23.5 for a variety of causes. Requires a kidney transplant or hemodialysis.		
Hydronephrosis ³⁷	Increase in fluid pressure in the renal pelvis and calyces owing to obstruction of the ureter by kidney stones, nephroptosis, or other causes. Can progress to complete cessation of glomerular filtration and atrophy of nephrons.		
Nephroptosis ³⁸ (NEFF-rop-TOE-sis)	Slippage of the kidney to an abnormally low position (floating kidney). Occurs in people with too little body fat to hold the kidney in place and in people who subject the kidneys to prolonged vibration, such as truck drivers, equestrians, and motorcyclists. Can twist or kink the ureter, which causes pain, obstructs urine flow, and potentially leads to hydronephrosis.		
Nephrotic syndrome	Excretion of large amounts of protein in the urine (≥ 3.5 g/day) due to glomerular injury. Can result from trauma, drugs, infections, cancer, diabetes mellitus, lupus erythematosus, and other diseases. Loss of plasma protein leads to edema, ascites, hypotension, and susceptibility to infection (because of immunoglobulin loss).		
Urinary incontinence	Inability to hold the urine; involuntary leakage from the bladder. Can result from incompetence of the urinary sphincters; bladder irritation; pressure on the bladder in pregnancy; an obstructed urinary outlet so that the bladder is constantly full and dribbles urine (<i>overflow incontinence</i>); uncontrollable urination due to brief surges in bladder pressure, as in laughing or coughing (<i>stress incontinence</i>); and neurological disorders such as spinal cord injuries.

INSIGHT 23.5 Clinical Application

Renal Insufficiency and Hemodialysis

Renal insufficiency is a state in which the kidneys cannot maintain homeostasis due to extensive destruction of their nephrons. Some causes of nephron destruction include

- Hypertension.
- Chronic or repetitive kidney infections.
- Trauma from such causes as blows to the lower back or continual vibration from machinery.
- Prolonged ischemia and hypoxia, as in long-distance runners and swimmers.
- Poisoning by heavy metals such as mercury and lead and solvents such as carbon tetrachloride, acetone, and paint thinners. These are absorbed into the blood from inhaled fumes or by skin contact and then filtered by the glomeruli. They kill renal tubule cells.
- Blockage of renal tubules with proteins small enough to be filtered by the glomerulus—for example, myoglobin released by skeletal muscle damage and hemoglobin released by a transfusion reaction.
- Atherosclerosis, which reduces blood flow to the kidney.
- Glomerulonephritis, an autoimmune disease of the glomerular capillaries.

Nephrons can regenerate and restore kidney function after short-term injuries. Even when some of the nephrons are irreversibly destroyed, others hypertrophy and compensate for their lost function. Indeed, a person can survive on as little as

Artery
Vein
Shunt

FIGURE 23.25 Hemodialysis. Blood is pumped into a dialysis chamber, where it flows through a selectively permeable membrane surrounded by dialysis fluid. Blood leaving the chamber passes through a bubble trap to remove air before it is returned to the patient's body. The fluid picks up excess water and metabolic wastes from the patient's blood and may contain medications that diffuse into the blood.

one-third of one kidney. When 75% of the nephrons are lost, however, urine output may be as low as 30 mL/h compared with the normal rate of 50 to 60 mL/h. This is insufficient to maintain homeostasis and is accompanied by azotemia and acidosis. Uremia develops when there is 90% loss of renal function. Renal insufficiency also tends to cause anemia because the diseased kidneys produce too little erythropoietin (EPO), the hormone that stimulates red blood cell formation.

Hemodialysis is a procedure for artificially clearing wastes from the blood when the kidneys are not adequately doing so (fig. 23.25). Blood is pumped from the radial artery to a *dialysis machine* (artificial kidney) and returned to the patient by way of a vein. In the dialysis machine, the blood flows through a semi-permeable cellophane tube surrounded by dialysis fluid. Urea, potassium, and other solutes that are more concentrated in the blood than in the dialysis fluid diffuse through the membrane into the fluid, which is discarded. Glucose, electrolytes, and drugs can be administered by adding them to the dialysis fluid so they will diffuse through the membrane into the blood. People with renal insufficiency accumulate substantial amounts of excess body water between treatments, and dialysis serves also to remove it. Patients are typically given erythropoietin (EPO) to compensate for the lack of EPO from the failing kidneys.

Hemodialysis patients typically have three sessions per week for 4 to 8 hours per session. In addition to inconvenience, hemodialysis carries risks of infection and thrombosis. Blood tends to clot when exposed to foreign surfaces, so an anticoagulant such as heparin is added during dialysis. Unfortunately, this inhibits clotting in the patient's body as well, and dialysis patients sometimes suffer internal bleeding.

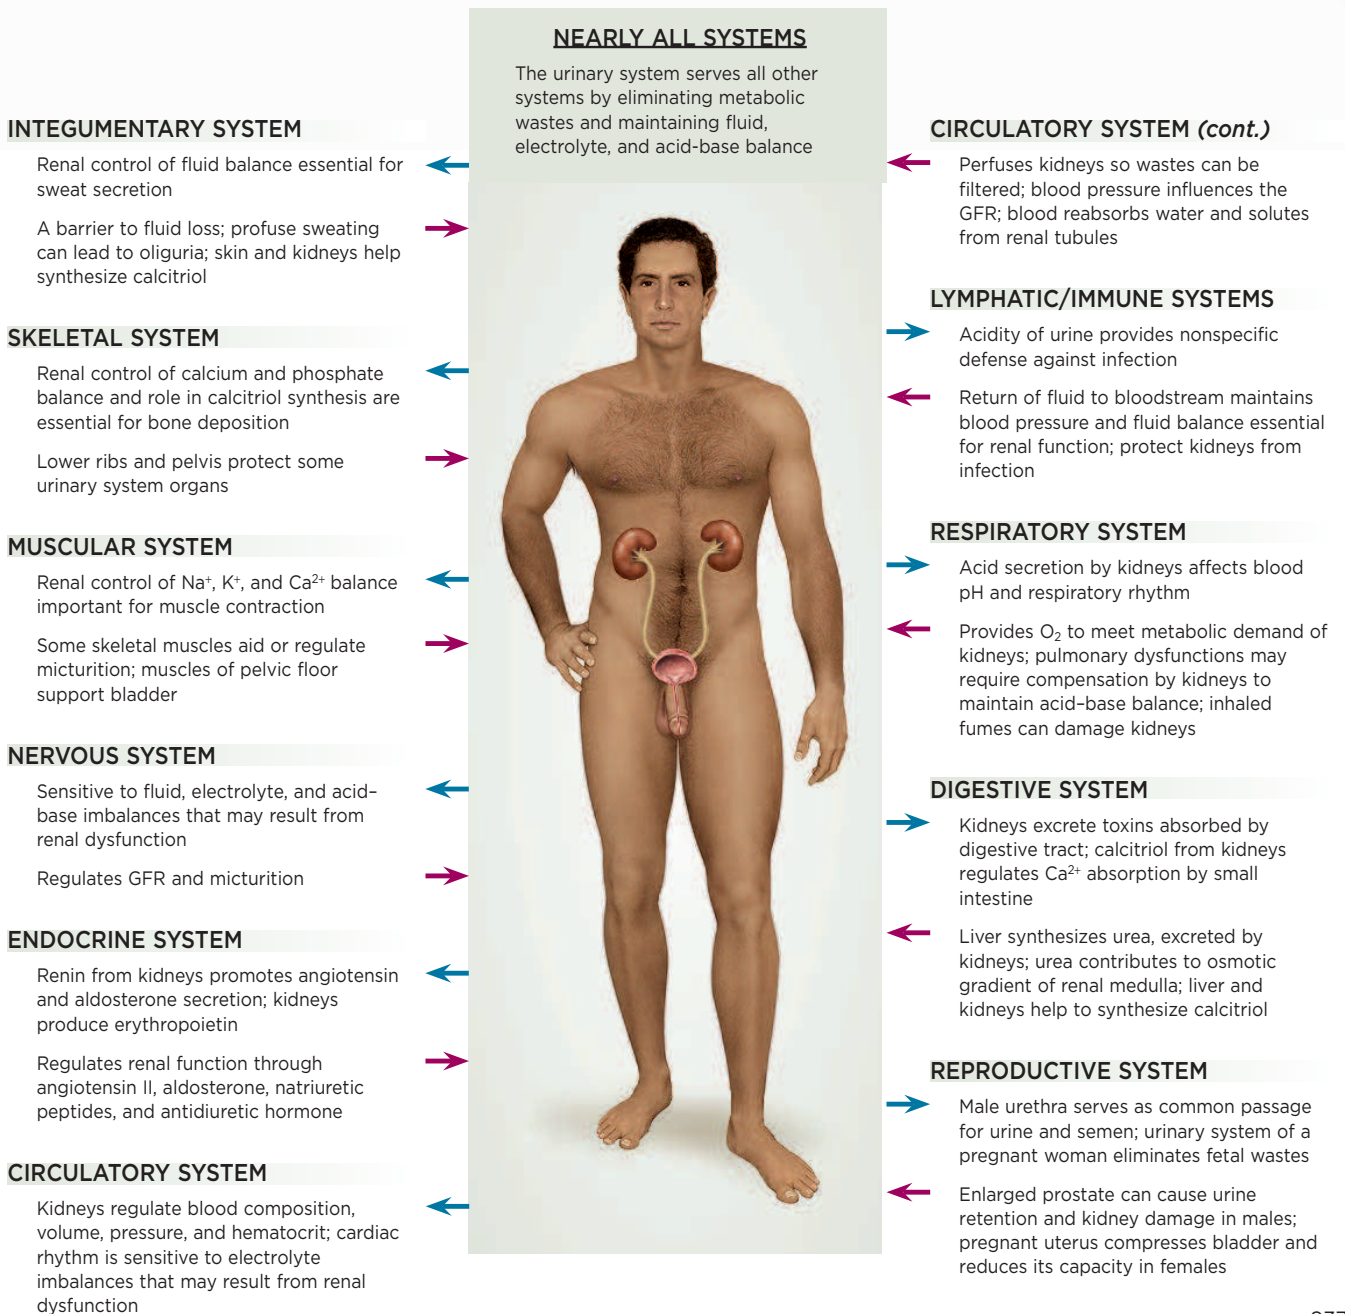

A procedure called *continuous ambulatory peritoneal dialysis (CAPD)* is more convenient. It can be carried out at home by the patient, who is provided with plastic bags of dialysis fluid. Fluid is introduced into the abdominal cavity through an indwelling catheter. Here, the peritoneum provides over 2 m² of blood-rich semipermeable membrane. The fluid is left in the body cavity for 15 to 60 minutes to allow the blood to equilibrate with it; then it is drained, discarded, and replaced with fresh dialysis fluid. The patient is not limited by a stationary dialysis machine and can go about most normal activities. CAPD is less expensive and promotes better morale than conventional hemodialysis, but it is less efficient in removing wastes and it is more often complicated by infection.

CHAPTER REVIEW

Review of Key Concepts

23.1 Functions of the Urinary System (p. 906)

1. The urinary system consists of two kidneys, two ureters, the urinary bladder, and the urethra.
2. The kidneys filter blood plasma, separate wastes from useful chemicals, regulate blood volume and pressure, secrete renin and erythropoietin, regulate blood pH, synthesize calcitriol, and generate glucose in times of starvation.
3. Metabolic wastes are chemicals produced by the body and either useless to it or present in excess. CO₂ and nitrogenous wastes are among them. The main human nitrogenous wastes are *urea*, *uric acid*, and *creatinine*.
4. The level of nitrogenous wastes in the blood is often expressed as *blood urea nitrogen (BUN)*. An elevated BUN is called *azotemia*, and may progress to a serious toxic syndrome called *uremia*.
5. *Excretion* is the process of separating wastes from the body fluids and eliminating them from the body. It is carried out by the respiratory, integumentary, digestive, and urinary systems.

23.2 Anatomy of the Kidney (p. 908)

1. The kidneys are located retroperitoneally against the posterior abdominal wall, along with the renal arteries, renal veins, and adrenal glands.
2. The kidney has a slit called the *hilum* on its concave side, where it receives renal nerves, blood and lymphatic vessels, and the ureter.
3. From superficial to deep, the kidney is enclosed by the renal fascia, perirenal fat capsule, and fibrous capsule.
4. The renal parenchyma is a C-shaped tissue enclosing a space called the *renal sinus*. The parenchyma is divided into an outer *renal cortex* and inner *renal medulla*. The medulla consists of 6 to 10 *renal pyramids*.
5. The apex, or *renal papilla*, of each pyramid projects into a receptacle called a *minor calyx*, which collects the urine from that pyramid. Minor calyces converge to form *major*

calyces, and these converge on the *renal pelvis*, where the ureter arises.

6. Each kidney contains about 1.2 million functional units called *nephrons*.
7. The renal artery branches and gives rise to *segmental arteries*, *interlobar arteries*, *arcuate arteries*, and then *interlobular arteries*, which penetrate into the cortex. For each nephron, an *afferent arteriole* arises from the interlobular artery and supplies the capillaries of the *glomerulus*. An *efferent arteriole* leaves the glomerulus and usually gives rise to a bed of *peritubular capillaries* around the renal tubules. Blood then flows through a series of *interlobular*, *arcuate*, and *interlobar veins*, before leaving the kidney by way of the *renal vein*.
8. The renal medulla is supplied by vessels called the *vasa recta*, which arise from the efferent arterioles of juxtamedullary nephrons and empty into arcuate and interlobular veins.
9. A nephron begins with a double-walled *glomerular capsule* enclosing the glomerulus; the glomerulus and capsule constitute the *renal corpuscle*. The capsule consists of a parietal layer with a simple squamous epithelium and a visceral layer composed of *podocytes* wrapped around the capillaries of the glomerulus.
10. Filtrate collects in the *capsular space* between the capsule layers and then flows into the *renal tubule* leading away from the capsule.
11. The renal tubule consists of a highly coiled *proximal convoluted tubule (PCT)*, a U-shaped *nephron loop*, a coiled *distal convoluted tubule (DCT)*, and a *collecting duct*. The first three of these belong to a single nephron; the collecting duct receives fluid from many nephrons.
12. *Renal nerves* follow the renal artery and innervate the afferent and efferent arterioles. They provide sympathetic control over blood flow to the glomerulus, and thus regulate the rate of glomerular filtration and urine formation. They also stimulate renin secretion.

23.3 Urine Formation I: Glomerular Filtration (p. 914)

1. A nephron produces urine in three stages: *glomerular filtration*, *tubular reabsorption* and *secretion*, and *water conservation*.
2. The first step in urine production is to filter the blood plasma, which occurs at the glomerulus.
3. In passing from the blood capillaries into the capsular space, fluid must pass through the filtration pores of the capillary endothelium, the basement membrane, and filtration slits between the *foot processes* of the podocytes. These barriers hold back blood cells and most protein, but allow water and small solutes to pass.
4. Glomerular filtration is driven mainly by the high blood pressure in the glomerular capillaries.
5. *Glomerular filtration rate (GFR)*, an important measure of renal health, is typically about 125 mL/min in men and 105 mL/min in women.
6. *Renal autoregulation* is the ability of the kidneys to maintain a stable GFR independently of nervous or hormonal control.
7. The *myogenic mechanism* of autoregulation occurs when high blood pressure stretches the afferent arteriole. The arteriole constricts in response to stretch, preventing a rise in GFR proportional to the rise in blood pressure.
8. The *tubuloglomerular feedback* mechanism of autoregulation employs a structure called the *juxtaglomerular apparatus*. *Macula densa* cells in the nephron loop monitor the fluid in the renal tubule and communicate with enlarged smooth muscle *juxtaglomerular cells* in the afferent and efferent arterioles. Constriction or dilation of those arterioles modifies the GFR.
9. The sympathetic nervous system also regulates GFR by controlling vasomotion of the afferent arterioles.
10. GFR is also controlled by hormones. A drop in blood pressure causes the kidneys to secrete *renin*. Renin and *angiotensin-converting enzyme*

convert a plasma protein, *angiotensinogen*, into *angiotensin II*.

- Angiotensin II helps to raise blood pressure by constricting the blood vessels, especially the efferent arteriole, raising GFR; stimulating the PCT to reabsorb NaCl and water; promoting secretion of antidiuretic hormone (ADH) and aldosterone; and stimulating the sense of thirst.
- ADH promotes water retention by the kidneys. Aldosterone promotes sodium retention, which in turn leads to water retention.

23.4 Urine Formation II: Tubular Reabsorption and Secretion (p. 920)

- The GFR is far in excess of the rate of urine output. Ninety-eight to 99% of the filtrate is reabsorbed by the renal tubules and only 1% to 2% is excreted as urine.
- About 65% of the glomerular filtrate is reabsorbed by the PCT.
- PCT cells absorb Na⁺ from the tubular fluid through the apical cell surface and pump it out the basolateral cell surfaces by active transport. Cl⁻ follows Na⁺ because of their opposite electrical charges, and glucose is cotransported with Na⁺ by a symport, the *sodium-glucose transport protein (SGLT)*. Water follows these solutes by osmosis. Other electrolytes and urea follow water through the tubule epithelium.
- The peritubular capillaries pick up the reabsorbed water by osmosis, and other solutes follow by *solvent drag*.
- The *transport maximum (T_m)* is the fastest rate at which the PCT can reabsorb a given solute. If a solute such as glucose is filtered by the glomerulus faster than the PCT can reabsorb it, the excess passes in the urine (as in diabetes mellitus).
- The PCT also carries out *tubular secretion*, removing solutes from the blood and secreting them into the tubular fluid. Secreted solutes include urea, uric acid, bile salts, ammonia, catecholamines, prostaglandins, creatinine, H⁺, HCO₃⁻, and drugs such as aspirin and penicillin.
- The nephron loop serves mainly to generate an osmotic gradient in the renal medulla, which is necessary for collecting duct function; but it also reabsorbs a significant amount of water, Na⁺, K⁺, and Cl⁻.
- The DCT reabsorbs salt and water, and is regulated by several hormones.

- Aldosterone stimulates the DCT to reabsorb Na⁺ and secrete K⁺. Water and Cl⁻ are reabsorbed with Na⁺.
- Atrial natriuretic peptide and brain natriuretic peptide increase salt and water excretion by increasing GFR, antagonizing aldosterone and ADH, and inhibiting NaCl reabsorption by the collecting duct.
- Parathyroid hormone acts on the nephron loop and DCT to promote Ca²⁺ reabsorption, and acts on the PCT to promote phosphate excretion. Calcitonin and calcitriol have similar but weaker effects on the DCT.

23.5 Urine Formation III: Water Conservation (p. 925)

- The collecting duct (CD) reabsorbs varying amounts of water to leave the urine as dilute as 50 mOsm/L or as concentrated as 1,200 mOsm/L.
- The CD is permeable to water but not to NaCl. As it passes down the increasingly salty renal medulla, it loses water to the tissue fluid and the urine in the duct becomes more concentrated.
- The rate of water loss from the CD is controlled by antidiuretic hormone (ADH). ADH stimulates the installation of water-channel proteins called *aquaporins* in the CD cells, increasing permeability of the CD to water. At high ADH concentrations, the urine is scanty and highly concentrated; at low ADH concentrations, the urine is dilute.
- The salinity gradient of the renal medulla, which is essential to the ability of the CD to concentrate the urine, is maintained by the *countercurrent multiplier* mechanism of the nephron loop.
- The vasa recta supply a blood flow to the renal medulla and employ a *countercurrent exchange* system to prevent them from removing salt from the medulla.

23.6 Urine and Renal Function Tests (p. 928)

- The yellow color of urine is due to *urochrome* derived from hemoglobin breakdown products.
- Urine normally has a specific gravity from 1.001 to 1.028, an osmolarity from 50 to 1,200 mOsm/L, and a pH from 4.5 to 8.2 (usually about 6.0).
- A foul odor to the urine is abnormal and may result from bacterial degradation, some foods, urinary tract infection, or metabolic diseases such as diabetes mellitus or phenylketonuria.

- The most abundant solutes in urine are urea, NaCl, and KCl. Urine normally contains no glucose, hemoglobin, albumin, ketones, or bile pigments, but may do so in some diseases.
- Most adults produce 1 to 2 L of urine per day. Abnormally low urine output is *anuria* or *oliguria*; abnormally high output is *polyuria*.
- Diabetes* is any chronic polyuria of metabolic origin. Forms of diabetes include diabetes mellitus types 1 and 2, gestational diabetes, and diabetes insipidus.
- Diuretics* are chemicals that increase urine output by increasing GFR or reducing tubular reabsorption. Caffeine exerts a diuretic effect by dilating the afferent arteriole, alcohol by inhibiting ADH secretion, and *loop diuretics* by inhibiting the Na⁺-K⁺-Cl⁻ pump of the nephron loop, thereby reducing the osmotic gradient of the renal medulla.
- Renal function can be assessed by making clinical measurements of GFR or *renal clearance*. The latter is the amount of blood completely freed of a given solute in 1 minute.

23.7 Urine Storage and Elimination (p. 931)

- Peristalsis of the ureters causes urine to flow from the kidneys to the urinary bladder.
- The urinary bladder has a smooth muscle layer called the *detrusor muscle*, with a thickened ring, the *internal urethral sphincter*, around the origin of the urethra.
- The urethra is 3 to 4 cm long in the female, but in the male it is 18 cm long and divided into *prostatic*, *membranous*, and *spongy* (penile) segments. An *external urethral sphincter* of skeletal muscle encircles the urethra in both sexes where it passes through the pelvic floor.
- Emptying of the bladder is controlled in part by a spinal *micturition reflex* initiated by stretch receptors in the bladder wall. Parasympathetic nerve fibers relax the internal urethral sphincter and stimulate the detrusor muscle to contract.
- Supraspinal centers also regulate micturition. The *micturition center* in the pons inhibits the sympathetic neurons that suppress urination and stimulates the parasympathetic neurons that trigger it. The cerebrum issues signals that relax the external urethral sphincter.

Testing Your Recall

- Micturition occurs when the _____ contracts.
 - detrusor muscle
 - internal urethral sphincter
 - external urethral sphincter
 - muscularis of the ureter
 - all of the above
- The compact ball of capillaries in a nephron is called
 - the nephron loop.
 - the peritubular plexus.
 - the renal corpuscle.
 - the glomerulus.
 - the vasa recta.
- Which of these is the most abundant nitrogenous waste in the blood?
 - uric acid
 - urea
 - ammonia
 - creatinine
 - albumin
- Which of these lies closest to the renal cortex?
 - the parietal peritoneum
 - the renal fascia
 - the fibrous capsule
 - the perirenal fat capsule
 - the renal pelvis
- Most sodium is reabsorbed from the glomerular filtrate by
 - the vasa recta.
 - the proximal convoluted tubule.
 - the distal convoluted tubule.
 - the nephron loop.
 - the collecting duct.
- A glomerulus and glomerular capsule make up one
 - renal capsule.
 - renal corpuscle.
 - kidney lobule.
 - kidney lobe.
 - nephron.
- The kidney has more _____ than any of the other structures listed.
 - arcuate arteries
 - minor calyces
 - medullary pyramids
 - afferent arterioles
 - collecting ducts
- The renal clearance of _____ is normally zero.
 - sodium
 - potassium
 - uric acid
 - urea
 - amino acids
- Beavers have relatively little need to conserve water and could therefore be expected to have _____ than humans do.
 - fewer nephrons
 - longer nephron loops
 - shorter nephron loops
 - longer collecting ducts
 - longer convoluted tubules
- Increased ADH secretion should cause the urine to have
 - a higher specific gravity.
 - a lighter color.
 - a higher pH.
 - a lower urea concentration.
 - a lower potassium concentration.
- The _____ reflex is an autonomic reflex activated by pressure in the urinary bladder.
 - _____ is the ability of a nephron to adjust its GFR independently of nervous or hormonal influences.
- The two ureters and the urethra form the boundaries of a smooth area called the _____ on the floor of the urinary bladder.
 - The _____ is a group of epithelial cells of the nephron loop that monitors the flow or composition of the tubular fluid.
- To enter the capsular space, filtrate must pass between foot processes of the _____, cells that form the visceral layer of the glomerular capsule.
 - Glycosuria occurs if the rate of glomerular filtration of glucose exceeds the _____ of the proximal convoluted tubule.
- _____ is a hormone that regulates the amount of water reabsorbed by the collecting duct.
 - The _____ sphincter is under involuntary control and relaxes during the micturition reflex.
- Very little _____ is found in the glomerular filtrate because it is negatively charged and is repelled by the basement membrane of the glomerulus.
 - Blood flows through the _____ arteries just before entering the interlobular arteries.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. The proximal convoluted tubule is not subject to hormonal influence.
2. Sodium is the most abundant solute in the urine.
3. The kidney has more distal convoluted tubules than collecting ducts.
4. Tight junctions prevent material from leaking between the epithelial cells of the renal tubule.
5. All forms of diabetes are characterized by glucose in the urine.
6. If all other conditions remain the same, constriction of the afferent arteriole reduces the glomerular filtration rate.
7. Angiotensin II reduces urine output.
8. The minimum osmolarity of urine is 300 mOsm/L, equal to the osmolarity of the blood.
9. A sodium deficiency (hyponatremia) could cause glycosuria.
10. Micturition depends on contraction of the detrusor muscle.

Answers in appendix B

Testing Your Comprehension

1. How would the glomerular filtration rate be affected by kwashiorkor (see p. 688)?
2. A patient produces 55 mL of urine per hour. Urea concentration is 0.25 mg/mL in her blood plasma and 8.6 mg/mL in her urine. (a) What is her rate of renal clearance for urea? (b) About 95% of adults excrete urea at a rate of 12.6 to 28.6 g/day. Is this patient above, within, or below this range? Show how you calculated your answers.
3. A patient with poor renal perfusion is treated with an ACE inhibitor and goes into renal failure. Explain the reason for the renal failure.
4. Drugs called *renin inhibitors* are used to treat hypertension. Explain how they would have this effect.
5. Discuss how the unity of form and function is exemplified by differences between (a) the thin and thick segments of the nephron loop; (b) between the proximal and distal convoluted tubules; and (c) between the afferent and efferent arterioles.

- 24.1 Clinical Application:** Fluid Balance in Cold Weather 947
- 24.2 Clinical Application:** Fluid Replacement Therapy 961

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Measurement of electrolyte concentrations (p. 63)
- Acids, bases, and the pH scale (p. 63)
- Osmolarity (p. 102)
- Role of electrolytes in plasma membrane potentials (p. 455)
- Depolarization and hyperpolarization of plasma membranes (fig. 12.24, p. 468)
- The hypothalamus and posterior pituitary (pp. 642-647)
- Influence of CO₂ and pH on pulmonary ventilation (pp. 894-895)
- Structure and physiology of the nephron (pp. 911-927)

Cellular function requires a fluid medium with a carefully controlled composition. If the quantity, osmolarity, electrolyte concentration, or pH of this medium is altered, life-threatening disorders of cellular function may result. Consequently, the body has several mechanisms for keeping these variables within narrow limits and maintaining three types of homeostatic balance:

1. *water balance*, in which average daily water intake and loss are equal;
2. *electrolyte balance*, in which the amount of electrolytes absorbed by the small intestine balance the amount lost from the body, chiefly through the urine; and
3. *acid-base balance*, in which the body rids itself of acid (hydrogen ions) at a rate that balances its metabolic production, thus maintaining a stable pH.

These balances are maintained by the collective action of the urinary, respiratory, digestive, integumentary, endocrine, nervous, cardiovascular, and lymphatic systems. This chapter describes the homeostatic regulation of water, electrolyte, and acid-base balance and shows the close relationship of these variables to each other. These balances are so crucial that fluid therapy, aimed at restoring one or more of these, is often a critical aspect of patient care. Problems of fluid and electrolyte balance also arise frequently in sports and recreational medicine, in situations ranging from summer football practice to back-country hiking.

We enter the world in a rather soggy condition, having swallowed, excreted, and floated in amniotic fluid for months. At birth, a baby's weight is as much as 75% water; infants normally lose a little weight in the first day or two as they excrete the excess. Young adult men average 55% to 60% water; women average slightly less because they have more adipose tissue, which is nearly free of water. Obese and elderly people are as little as 45% water by weight. The **total body water (TBW)** content of a 70 kg (150 lb) young male is about 40 L.

Fluid Compartments

Body water is distributed among certain **fluid compartments**, areas separated by selectively permeable membranes and differing from each other in chemical composition. The major fluid compartments are:

- 65% *intracellular fluid (ICF)* and
- 35% *extracellular fluid (ECF)*, subdivided into
 - 25% *tissue (interstitial) fluid*,
 - 8% *blood plasma and lymph*, and
 - 2% *transcellular fluid*, a catch-all category for cerebrospinal, synovial, peritoneal, pleural, and pericardial fluids; vitreous and aqueous humors of the eye; bile; and fluid in the digestive, urinary, and respiratory tracts.

Fluid is continually exchanged between compartments by way of capillary walls and plasma membranes (fig. 24.1). Water moves by osmosis from the digestive tract to the bloodstream and by capillary filtration from the blood to the tissue fluid. From the tissue fluid, it may be reabsorbed by the capillaries, osmotically absorbed into cells, or taken up by the lymphatic system, which returns it to the bloodstream.

Because water moves so easily through plasma membranes, osmotic gradients between the ICF and ECF never last for very long. If a local imbalance arises, osmosis usually restores the balance within seconds so that intracellular and extracellular osmolarity are equal. If the osmolarity of the tissue fluid rises, water moves out of the cells; if it falls, water moves into the cells.

Osmosis from one fluid compartment to another is determined by the relative concentration of solutes in each compartment. The most abundant solute particles by far are the electrolytes—especially sodium salts in the ECF and potassium salts in the ICF. Electrolytes play the principal role in governing the body's water distribution and total water content; the subjects of water and electrolyte balance are therefore inseparable.

Water Gain and Loss

A person is in a state of **fluid balance** when daily gains and losses are equal. We typically gain and lose about 2,500 mL/day (fig. 24.2). The gains come from two sources.

24.1 Water Balance

Objectives

When you have completed this section, you should be able to

- name the major fluid compartments and explain how water moves from one to another;
- list the body's sources of water and routes of water loss;
- describe the mechanisms of regulating water intake and output; and
- describe some conditions in which the body has a deficiency or excess of water or an improper distribution of water among the fluid compartments.

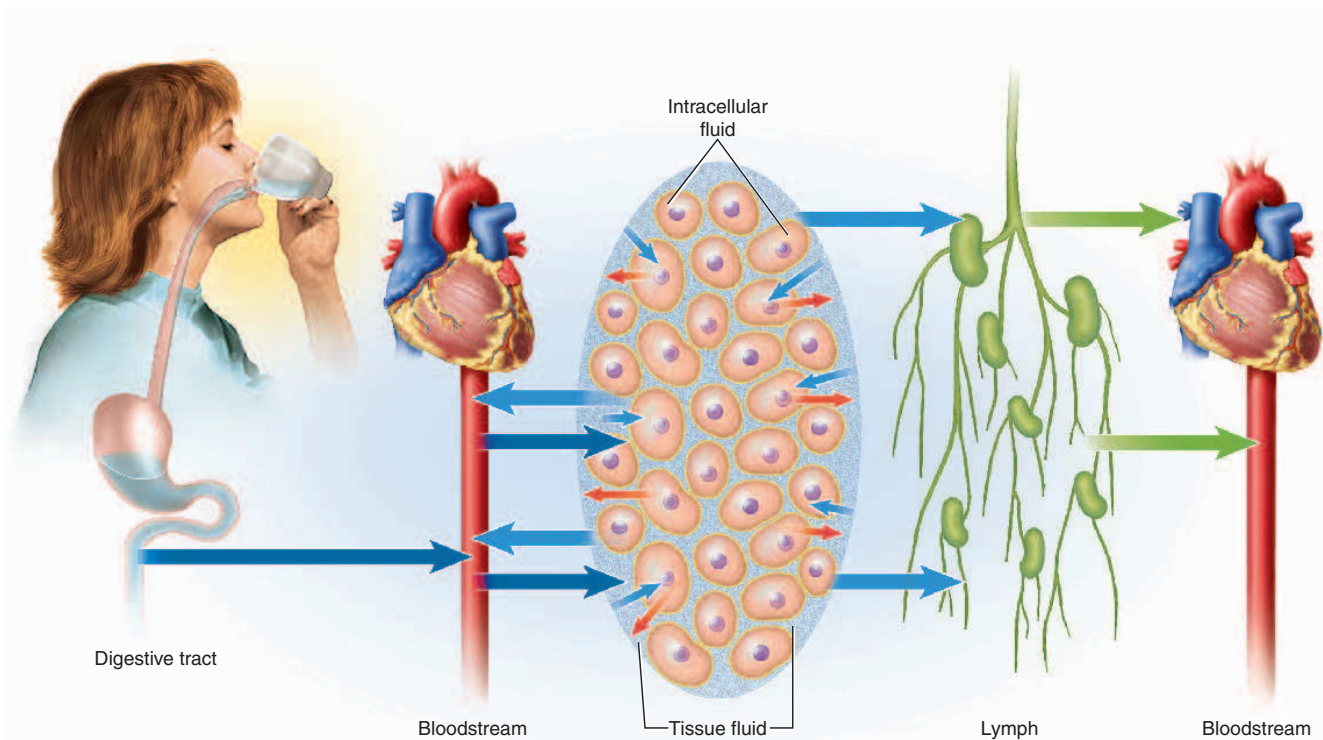

FIGURE 24.1 The Movement of Water Between the Major Fluid Compartments. Ingested water is absorbed by the bloodstream. There is a two-way exchange of water between the blood and tissue fluid and between the tissue fluid and intracellular fluids. Excess tissue fluid is picked up by the lymphatic system, which returns it to the bloodstream.

❖ In which of these compartments would fluid accumulate in edema?

One of these is **metabolic water** (about 200 mL/day), which is produced as a by-product of dehydration synthesis reactions and aerobic respiration:

The other is **preformed water**, which is ingested in food (700 mL/day) and drink (1,600 mL/day).

The routes of water loss are more varied:

- 1,500 mL/day is excreted as urine.
- 200 mL/day is eliminated in the feces.
- 300 mL/day is lost in the expired breath. You can easily visualize this by breathing onto a cool surface such as a mirror.
- 100 mL/day of sweat is secreted by a resting adult at an ambient air temperature of 20°C (68°F).
- 400 mL/day is lost as **cutaneous transpiration**,¹ water that diffuses through the epidermis and evaporates. This is not the same as sweat; it is not a glandular secretion. A simple way to observe it is to cup the palm of your hand for a minute against a cool nonporous surface such as a laboratory benchtop or mirror. When you take your hand away, you will notice the water that transpired through the skin and condensed on that surface, even in places that were not in contact with your skin.

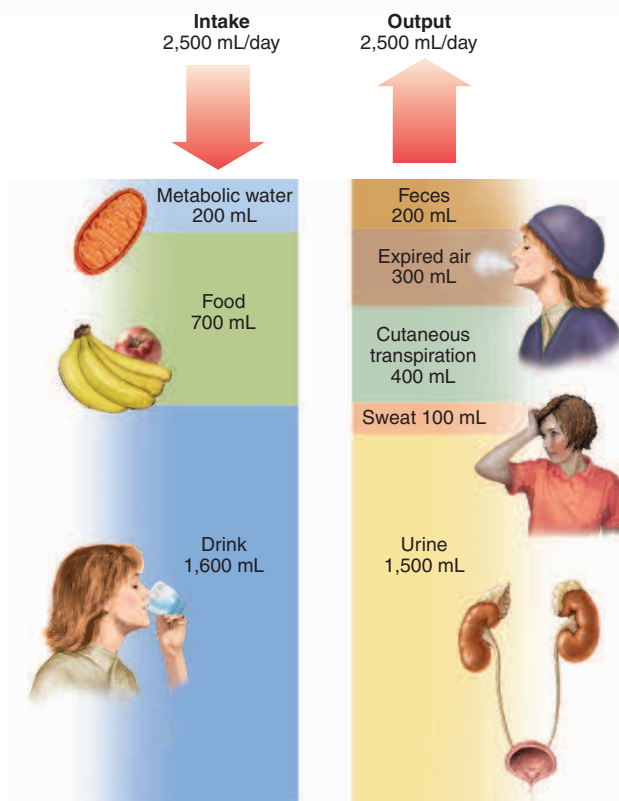

FIGURE 24.2 Typical Water Intake and Output in a State of Fluid Balance.

¹trans = ation = through + spiration = breathing

Water loss varies greatly with physical activity and environmental conditions. Respiratory loss increases in cold weather, for example, because cold air is drier and absorbs more body water from the respiratory tract. Hot, humid weather slightly reduces the respiratory loss but increases perspiration to as much as 1,200 mL/day. Prolonged, heavy work can raise the respiratory loss to 650 mL/day and perspiration to as much as 5 L/day, though it reduces urine output by nearly two-thirds.

Output through the breath and cutaneous transpiration is called **insensible water loss** because we are not usually conscious of it. **Sensible water loss** is noticeable output, particularly through the urine and in case of sufficient sweating to produce obvious wetness of the skin. **Obligatory water loss** is output that is relatively unavoidable: expired air, cutaneous transpiration, sweat, fecal moisture, and the minimum urine output, about 400 mL/day, needed to prevent azotemia. Even dehydrated individuals cannot prevent such losses; thus they become further dehydrated.

Regulation of Intake

Fluid intake is governed mainly by thirst, which is controlled by the mechanisms shown in figure 24.3. Dehydration reduces blood volume and pressure and raises blood osmolarity. The hypothalamus has at least three groups of neurons called **osmoreceptors** that respond to angiotensin II and to rising osmolarity of the ECF—both of which are signs that the body has a water deficit. The osmoreceptors communicate with other hypothalamic neurons that produce antidiuretic hormone (ADH) (see fig. 17.4a, p. 643), thus promoting water conservation; and they apparently communicate with the cerebral cortex to produce a conscious sense of thirst. A 2% to 3% increase in plasma osmolarity makes a person intensely thirsty, as does a 10% to 15% blood loss.

When we are thirsty, we salivate less. There are two reasons for this: (1) The osmoreceptor response leads to sympathetic output from the hypothalamus that inhibits the salivary glands. (2) Saliva is produced primarily by capillary filtration, but in a dehydrated person, this is opposed by the lower capillary blood pressure and higher osmolarity of the blood. Reduced salivation gives us a dry, sticky-feeling mouth and a desire to drink, but it is by no means certain that this is our primary motivation to drink. Some people do not secrete saliva, yet they do not drink more than normal individuals except when eating, when they need water to moisten the food. The same is true of experimental animals that have the salivary ducts tied off.

Long-term satiation of thirst depends on absorbing water from the small intestine and lowering the osmolarity of the blood. Reduced osmolarity stops the osmoreceptor response, promotes capillary filtration, and makes the saliva more abundant and watery. However, these changes

FIGURE 24.3 Dehydration, Thirst, and Rehydration.

require 30 minutes or longer to take effect, and it would be rather impractical if we had to drink that long while waiting to feel satisfied. Water intake would be grossly excessive. Fortunately, there are mechanisms that act more quickly to temporarily quench the thirst and allow time for the change in blood osmolarity to occur.

Experiments with rats and dogs have isolated the stimuli that quench the thirst. One of these is cooling and moistening the mouth; rats drink less if their water is cool than if it is warm, and simply moistening the mouth temporarily satisfies an animal even if the water is drained from its esophagus before it reaches the stomach. Distension of the stomach and small intestine is another inhibitor of thirst. If a dog is allowed to drink while the water is drained from its esophagus but its stomach is inflated with a balloon, its thirst is satisfied for a time. If the water is drained away but the stomach is not inflated, satiation does not last as long. Such fast-acting stimuli as coolness, moisture, and filling of the stomach stop an

animal (and presumably a human) from drinking an excessive amount of liquid, but they are effective for only 30 to 45 minutes. If they are not soon followed by absorption of water into the bloodstream, the thirst soon returns. Only a drop in blood osmolarity produces a lasting effect.

Regulation of Output

The only way to control water output significantly is through variations in urine volume. It must be realized, however, that the kidneys cannot completely prevent water loss, nor can they replace lost water or electrolytes. Therefore, they never restore fluid volume or osmolarity, but in dehydration they can support existing fluid levels and slow down the rate of loss until water and electrolytes are ingested.

To understand the effect of the kidneys on water and electrolyte balance, it is also important to bear in mind that if a substance is reabsorbed by the kidneys, it is kept in the body and returned to the ECF, where it will affect fluid volume and composition. If a substance is filtered by the glomerulus or secreted by the renal tubules and not reabsorbed, then it is excreted in the urine and lost from the body fluids.

Changes in urine volume are usually linked to adjustments in sodium reabsorption. As sodium is reabsorbed or excreted, proportionate amounts of water accompany it. The total volume of fluid remaining in the body may change, but its osmolarity remains stable. Controlling water balance by controlling sodium excretion is best understood in the context of electrolyte balance, discussed later in the chapter.

Antidiuretic hormone (ADH), however, provides a means of controlling water output independently of sodium (fig. 24.4). In true dehydration (defined shortly), blood volume declines and sodium concentration rises. The increased osmolarity of the blood stimulates the hypothalamic osmoreceptors, which stimulate the posterior pituitary to release ADH. In response to ADH, cells of the collecting ducts of the kidneys synthesize the proteins called aquaporins. When installed in the plasma membrane, these serve as channels that allow water to diffuse out of the duct into the hypertonic tissue fluid of the renal medulla. The kidneys then reabsorb more water and produce less urine. Sodium continues to be excreted, so the *ratio* of sodium to water in the urine increases (the urine becomes more concentrated). By helping the kidneys retain water, ADH slows down the decline in blood volume and the rise in its osmolarity. Thus, the ADH mechanism forms a negative feedback loop.

Conversely, if blood volume and pressure are too high or blood osmolarity is too low, ADH release is inhibited. The renal tubules reabsorb less water, urine output increases, and total body water declines. This is an effective way of compensating for hypertension. Since the lack

FIGURE 24.4 The Action of Antidiuretic Hormone. Pathways shown in red represent negative feedback.

of ADH increases the ratio of water to sodium in the urine, it raises the sodium concentration and osmolarity of the blood.

Disorders of Water Balance

The body is in a state of fluid imbalance if there is an abnormality of total *volume*, *concentration*, or *distribution* of fluid among the compartments.

Fluid Deficiency

Fluid deficiency arises when output exceeds intake over a long enough period of time. The two kinds of deficiency—volume depletion and dehydration—differ in the relative loss of water and electrolytes and the resulting osmolarity of the ECF. This important distinction calls for different strategies of fluid replacement therapy (see Insight 24.2 at the end of the chapter).

Volume depletion (hypovolemia²) occurs when proportionate amounts of water *and* sodium are lost without replacement. Total body water declines but osmolarity remains normal. Volume depletion occurs in cases of hemorrhage, severe burns, and chronic vomiting or diarrhea. A less common cause is aldosterone hyposecretion (Addison disease), which results in inadequate sodium and water reabsorption by the kidneys.

Dehydration (negative water balance) occurs when the body eliminates significantly more water than sodium, so the ECF osmolarity rises. The simplest cause of dehydration is a lack of drinking water; for example, when stranded in a desert or at sea. It can be a serious problem for elderly and bedridden people who depend on others to provide them with water—especially for those who cannot express their need or whose caretakers are insensitive to it. Diabetes mellitus, ADH hyposecretion (diabetes insipidus), profuse sweating, and overuse of diuretics are additional causes of dehydration. Prolonged exposure to cold weather can dehydrate a person just as much as exposure to hot weather (see Insight 24.1).

For three reasons, infants are more vulnerable to dehydration than adults: (1) Their high metabolic rate produces toxic metabolites faster, and they must excrete more water to eliminate them. (2) Their kidneys are not fully mature and cannot concentrate urine as effectively.

²*hypo* = below normal + *vol* = volume + *emia* = blood condition

INSIGHT 24.1 Clinical Application

Fluid Balance in Cold Weather

Hot weather and profuse sweating are obvious threats to fluid balance, but so is cold weather. The body conserves heat by constricting the blood vessels of the skin and subcutaneous tissue, thus forcing blood into the deeper circulation. This raises the blood pressure, which inhibits the secretion of antidiuretic hormone and increases the secretion of atrial natriuretic peptide. These hormonal changes increase urine output and reduce blood volume. In addition, cold air is relatively dry and increases respiratory water loss. This is why exercise causes the respiratory tract to “burn” more in cold weather than in warm.

These cold-weather respiratory and urinary losses can cause significant hypovolemia. Furthermore, the onset of exercise stimulates vasodilation in the skeletal muscles. In a hypovolemic state, there may not be enough blood to supply them, and a person may experience weakness, fatigue, or fainting (hypovolemic shock). In winter sports and other activities such as snow shoveling, it is important to maintain fluid balance. Even if you do not feel thirsty, it is beneficial to take ample amounts of warm liquids such as soup or cider. Coffee, tea, and alcohol, however, have diuretic effects that defeat the purpose of fluid intake.

(3) They have a greater ratio of body surface to volume; consequently, compared with adults, they lose twice as much water per kilogram of body weight by evaporation.

Dehydration affects all fluid compartments. Suppose, for example, that you play a strenuous tennis match on a hot summer day and lose a liter of sweat. Where does this fluid come from? Most of it filters out of the bloodstream through the capillaries of the sweat glands. In principle, 1 L of sweat would amount to about one-third of the blood plasma. However, as the blood loses water, its osmolarity rises and water from the tissue fluid enters the bloodstream to balance the loss. This raises the osmolarity of the tissue fluid, so water moves out of the cells to balance that (fig. 24.5). Ultimately, all three fluid compartments (the ICF, blood, and tissue fluid) lose water. To excrete 1 L of sweat, about 300 mL of water would come from the tissue fluid and 700 mL from the ICF. Immoderate exercise without fluid replacement can lead to losses greater than 1 L per hour.

FIGURE 24.5 Effects of Profuse Sweating on the Fluid Compartments. In extreme dehydration, the loss of intracellular fluid can cause cellular shrinkage and dysfunction.

The most serious effects of fluid deficiency are circulatory shock due to loss of blood volume and neurological dysfunction due to dehydration of brain cells. Volume depletion by diarrhea is a major cause of infant mortality, especially under unsanitary conditions that lead to intestinal infections such as cholera.

Fluid Excess

Fluid excess is less common than fluid deficiency because the kidneys are highly effective at compensating for excessive intake by excreting more urine (fig. 24.6). Renal failure and other causes, however, can lead to excess fluid retention.

Fluid excesses are of two types called volume excess and hypotonic hydration. In **volume excess**, both sodium and water are retained and the ECF remains isotonic. This can result from aldosterone hypersecretion or renal failure. In **hypotonic hydration** (also called **water intoxication** or **positive water balance**), more water than sodium is retained or ingested and the ECF becomes hypotonic. This can occur if you lose a large amount of water *and* salt through urine and sweat and you replace it by drinking plain water. Without a proportionate intake of electrolytes, water dilutes the ECF, makes it hypotonic, and causes cellular swelling. ADH hypersecretion can cause hypotonic hydration by stimulating excessive water retention as sodium continues to be excreted. Among the most serious effects of either type of fluid excess are pulmonary and cerebral edema.

Fluid Sequestration

Fluid sequestration³ (seh-ques-TRAY-shun) is a condition in which excess fluid accumulates in a particular location. Total body water may be normal, but the volume of circulating blood may drop to the point of causing circulatory shock. The most common form of sequestration is *edema*, the abnormal accumulation of fluid in the interstitial spaces, causing swelling of a tissue (discussed in detail in chapter 20). Hemorrhage can be another cause of fluid sequestration; blood that pools and clots in the tissues is lost to circulation. Yet another example is *pleural effusion*, caused by some lung infections, in which as much as several liters of fluid accumulate in the pleural cavity.

The four principal forms of fluid imbalance are summarized and compared in table 24.1.

Think About It

Some tumors of the brain, pancreas, and small intestine secrete ADH. What type of water imbalance would this produce? Explain why.

FIGURE 24.6 The Relationship of Blood Volume to Fluid Intake. The kidneys cannot compensate very well for inadequate fluid intake. Below an intake of about 1 L/day, blood volume drops significantly and there may be a threat of death from hypovolemic shock. The kidneys compensate very well, on the other hand, for abnormally high fluid intake; they eliminate the excess by water diuresis and maintain a stable blood volume.

TABLE 24.1

Forms of Fluid Imbalance

Form	Total Body Water	Osmolarity
Fluid deficiency		
Volume depletion (hypovolemia)	Reduced	Isotonic (normal)
Dehydration (negative water balance)	Reduced	Hypertonic (elevated)
Fluid excess		
Volume excess	Elevated	Isotonic (normal)
Hypotonic hydration (positive water balance, water intoxication)	Elevated	Hypotonic (reduced)

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- List five routes of water loss. Which one accounts for the greatest loss? Which one is most controllable?
- Explain why even a severely dehydrated person inevitably experiences further fluid loss.
- Suppose there were no mechanisms to stop the sense of thirst until the blood became sufficiently hydrated. Explain why we would routinely suffer hypotonic hydration.
- Summarize the effect of ADH on total body water and blood osmolarity.
- Name and define the four types of fluid imbalance, and give an example of a situation that could produce each type.

³sequestr = to isolate

24.2 Electrolyte Balance

Objectives

When you have completed this section, you should be able to

- describe the physiological roles of sodium, potassium, calcium, chloride, and phosphate;
- describe the hormonal and renal mechanisms that regulate the concentrations of these electrolytes; and
- state the term for an excess or deficiency of each electrolyte and describe the consequences of these imbalances.

Electrolytes are physiologically important for multiple reasons: they are chemically reactive and participate in metabolism, they determine the electrical potential (charge difference) across cell membranes, and they strongly affect the osmolarity of the body fluids and the body's water content and distribution. Strictly speaking, electrolytes are salts such as sodium chloride, not just sodium or chloride ions. In common usage, however, the individual ions are often referred to as electrolytes. The major cations are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and hydrogen (H^+); the major anions are chloride (Cl^-), bicarbonate (HCO_3^-), and phosphates (P_i). Hydrogen and bicarbonate regulation are discussed later under acid-base balance. Here we focus on the other five.

The typical concentrations of these ions in the blood plasma and intracellular fluid are compared in figure 24.7. Notice that in spite of great differences in electrolyte concentrations, the two fluid compartments have the same osmolarity (300 mOsm/L). Blood plasma is the most accessible fluid for measurements of electrolyte concentration, so excesses and deficiencies are defined with reference to normal plasma concentrations. Concentrations in the tissue fluid differ only slightly from those in the plasma. The prefix *normo-* denotes a normal electrolyte concentration (for example, *normokalemia*), and *hyper-* and *hypo-* denote concentrations that are, respectively, sufficiently above or below normal to cause physiological disorders.

Sodium

Functions

Sodium is one of the principal ions responsible for the resting membrane potentials of cells, and the inflow of sodium through membrane gates is an essential event in the depolarization that underlies nerve and muscle function. Sodium is the principal cation of the ECF; sodium salts account for 90% to 95% of its osmolarity. Sodium is therefore the most significant solute in determining total body water and the distribution of water among fluid

FIGURE 24.7 Electrolyte Concentrations in the Blood Plasma and Intracellular Fluid. P_i collectively represents inorganic phosphates in the forms of PO_4^{3-} , HPO_4^{2-} , and H_2PO_4^- . Electrolyte concentrations in mmol/L are the same for Na^+ , K^+ , and Cl^- ; one-half of the illustrated values for Ca^{2+} ; and one-third for PO_4^{3-} . Osmolarity (yellow bars) is given in mOsm/L.

compartments. Sodium gradients across the plasma membrane provide the potential energy that is tapped to cotransport other solutes such as glucose, potassium, and calcium. The Na^+-K^+ pump is an important mechanism

for generating body heat. Sodium bicarbonate (NaHCO_3) plays a major role in buffering the pH of the ECF.

Homeostasis

An adult needs about 0.5 g of sodium per day, whereas the typical American diet contains 3 to 7 g/day. Thus a dietary sodium deficiency is rare, and the primary concern is adequate excretion of the excess. This is one of the most important roles of the kidneys. There are multiple mechanisms for controlling sodium concentration, tied to its effects on blood pressure and osmolarity and coordinated by aldosterone, antidiuretic hormone, and the natriuretic peptides.

Aldosterone, the “salt-retaining hormone,” plays the primary role in adjustment of sodium excretion. Hyponatremia and hyperkalemia directly stimulate the adrenal cortex to secrete aldosterone, and hypotension stimulates its secretion by way of the renin–angiotensin–aldosterone mechanism (fig. 24.8).

Only cells in the ascending limb of the nephron loop, the distal convoluted tubule, and the cortical part of the collecting duct have aldosterone receptors. Aldosterone, a steroid, binds to nuclear receptors and activates transcription of a gene for the Na^+ – K^+ pump. In 10 to 30 minutes, enough Na^+ – K^+ pumps are synthesized and installed in the plasma membrane to produce a noticeable effect—sodium concentration in the urine begins to fall and potassium concentration rises as the tubules reabsorb more sodium and secrete more hydrogen and potassium ions. Water and chloride passively follow sodium. Thus, the primary effects of aldosterone are that the urine contains less NaCl and more potassium and has a lower pH. An average adult male excretes 5 g of sodium per day, but the urine can be virtually sodium-free when aldosterone level is high. Although aldosterone strongly influences sodium reabsorption, it has little effect on plasma sodium concentration because reabsorbed sodium is accompanied by a proportionate amount of water.

Elevated blood pressure inhibits the renin–angiotensin–aldosterone mechanism. The kidneys then reabsorb almost no sodium beyond the proximal convoluted tubule (PCT), and the urine contains up to 30 g of sodium per day.

Aldosterone has only slight effects on urine volume, blood volume, and blood pressure in spite of the tendency of water to follow sodium osmotically. Even in aldosterone hypersecretion, blood volume is rarely more than 5% to 10% above normal. An increase in blood volume increases blood pressure and glomerular filtration rate (GFR). Even though aldosterone increases the tubular reabsorption of sodium and water, this is offset by the rise in GFR and there is only a small drop in urine output.

Antidiuretic hormone modifies water excretion independently of sodium excretion. Thus, unlike aldosterone, it can change sodium concentration. A high concentration of sodium in the blood stimulates the posterior lobe of the pituitary gland to release ADH. The kidneys then reabsorb

FIGURE 24.8 The Action of Aldosterone. The pathway shown in red represents negative feedback.

What is required, in addition to aldosterone, to increase blood volume?

more water, which slows down any further increase in blood sodium concentration. ADH alone cannot lower the concentration; this requires water ingestion to dilute the existing sodium. A drop in sodium concentration, by contrast, inhibits ADH release. More water is excreted, thereby raising the relative amount of sodium that remains in the blood.

The atrial and brain natriuretic peptides (ANP and BNP) inhibit sodium and water reabsorption and the secretion of renin and ADH. The kidneys then eliminate more sodium and water and lower the blood pressure. Angiotensin II, by contrast, activates the Na^+ – H^+ antiporter in the PCT and thereby increases sodium reabsorption and reduces urinary sodium output.

Several other hormones also affect sodium homeostasis. Estrogen mimics the effect of aldosterone and causes women to retain water during pregnancy and part of the

menstrual cycle. Progesterone reduces sodium reabsorption and has a diuretic effect. High levels of glucocorticoids promote sodium reabsorption and edema.

In some cases, sodium homeostasis is achieved by regulation of salt intake. A craving for salt occurs in people who are depleted of sodium—for example, by blood loss or Addison disease. Pregnant women sometimes develop a craving for salty foods. Salt craving is not limited to humans; many animals ranging from elephants to butterflies seek out wet salty soil where they can obtain this vital mineral.

Imbalances

True imbalances in sodium concentration are relatively rare because sodium excess or depletion is almost always accompanied by proportionate changes in water volume. **Hypernatremia**⁴ is a plasma sodium concentration in excess of 145 mEq/L. It can result from the administration of intravenous saline (see Insight 24.2, p. 961). Its major consequences are water retention, hypertension, and edema. **Hyponatremia** (less than 130 mEq/L) is usually the result of excess body water rather than excess sodium excretion, as in the case mentioned earlier of a person

⁴natr = sodium + emia = blood condition

who loses large volumes of sweat or urine and replaces it by drinking plain water. Usually, hyponatremia is quickly corrected by excretion of the excess water, but if uncorrected it produces the symptoms of hypotonic hydration described earlier.

Potassium

Functions

Potassium is the most abundant cation of the ICF and is the greatest determinant of intracellular osmolarity and cell volume. Along with sodium, it produces the resting membrane potentials and action potentials of nerve and muscle cells (fig. 24.9a). Potassium is as important as sodium to the $\text{Na}^+ - \text{K}^+$ pump and its functions of cotransport and thermogenesis (heat production). It is an essential cofactor for protein synthesis and some other metabolic processes.

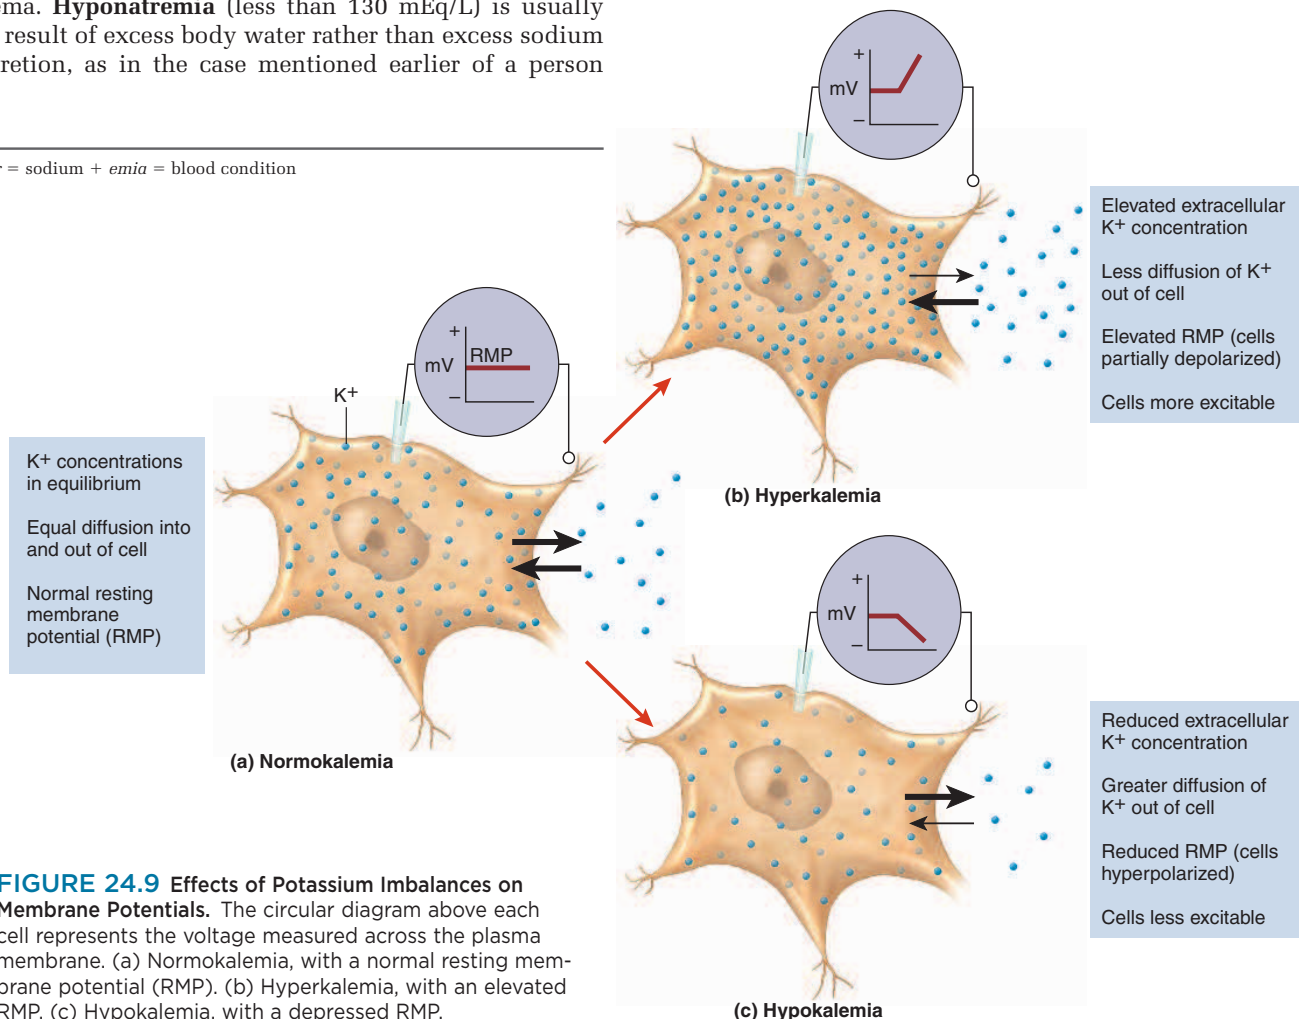

FIGURE 24.9 Effects of Potassium Imbalances on Membrane Potentials. The circular diagram above each cell represents the voltage measured across the plasma membrane. (a) Normokalemia, with a normal resting membrane potential (RMP). (b) Hyperkalemia, with an elevated RMP. (c) Hypokalemia, with a depressed RMP.

Homeostasis

Potassium homeostasis is closely linked to that of sodium. Regardless of the body's state of potassium balance, about 90% of the potassium filtered by the glomerulus is reabsorbed by the PCT and the rest is excreted in the urine. Variations in potassium excretion are controlled later in the nephron by changing the amount of potassium returned to the tubular fluid by the distal convoluted tubule and cortical portion of the collecting duct (CD). When potassium concentration is high, they secrete more potassium into the filtrate and the urine may contain more potassium than the glomerulus filters from the blood. When blood potassium level is low, the CD secretes less. The distal convoluted tubule and collecting duct reabsorb potassium through their intercalated cells.

Aldosterone regulates potassium balance along with sodium (fig. 24.8). A rise in potassium concentration stimulates the adrenal cortex to secrete aldosterone. Aldosterone stimulates renal secretion of potassium at the same time that it stimulates reabsorption of sodium. The more sodium there is in the urine, the less potassium, and vice versa.

Imbalances

Potassium imbalances are the most dangerous of all electrolyte imbalances. **Hyperkalemia**⁵ (> 5.5 mEq/L) can have completely opposite effects depending on whether potassium concentration rises quickly or slowly. It can rise quickly when, for example, a crush injury or hemolytic anemia releases large amounts of potassium from ruptured cells. This can also result from a transfusion with outdated, stored blood because potassium leaks from erythrocytes into the plasma during storage. A sudden increase in extracellular potassium tends to make nerve and muscle cells abnormally excitable. Normally, potassium continually passes into and out of cells at equal rates—leaving by diffusion and reentering by the Na⁺-K⁺ pump. But in hyperkalemia, there is less concentration difference between the ICF and ECF, so the outward diffusion of potassium is reduced. More potassium remains in the cell than normal, and the plasma membrane therefore has a less negative resting potential and is closer to the threshold at which it will set off action potentials (fig. 24.9b). This is a very dangerous condition that can quickly produce cardiac arrest. High-potassium solutions are sometimes used by veterinarians to euthanize animals and are used in some states as a lethal injection for capital punishment.

Hyperkalemia can also have a slower onset stemming from such causes as aldosterone hyposecretion, renal failure, or acidosis. (The relationship of acid-base imbalances to potassium imbalances is explained later.) Paradoxically, if the extracellular potassium concentration rises slowly,

nerve and muscle become *less* excitable. *Slow* depolarization of a cell inactivates voltage-regulated sodium gates, and the gates do not become excitable again until the membrane repolarizes. Inactivated sodium gates cannot produce action potentials.

Hypokalemia (< 3.5 mEq/L) rarely results from a dietary deficiency, because most diets contain ample amounts of potassium; it can occur, however, in people with depressed appetites. Hypokalemia more often results from heavy sweating, chronic vomiting or diarrhea, excessive use of laxatives, aldosterone hypersecretion, or alkalosis. As ECF potassium concentration falls, more potassium moves from the ICF to the ECF. With the loss of these cations from the cytoplasm, cells become hyperpolarized and nerve and muscle cells are less excitable (fig. 24.9c). This is reflected in muscle weakness, loss of muscle tone, depressed reflexes, and irregular electrical activity of the heart.

Think About It

Some tumors of the adrenal cortex secrete excess aldosterone and may cause paralysis. Explain this effect and identify the electrolyte and fluid imbalances you would expect to observe in such a case.

Chloride

Functions

Chloride ions are the most abundant anions of the ECF and thus make a major contribution to its osmolarity. Chloride ions are required for the formation of stomach acid (HCl), and they are involved in the chloride shift that accompanies carbon dioxide loading and unloading by the erythrocytes (see chapter 22). By a similar mechanism explained later, chloride ions play a major role in the regulation of body pH.

Homeostasis

Chloride ions are strongly attracted to Na⁺, K⁺, and Ca²⁺. It would require great expenditure of energy to keep it separate from these cations, so chloride homeostasis is achieved primarily as an effect of sodium homeostasis—as sodium is retained or excreted, chloride ions passively follow.

Imbalances

Hyperchloremia (> 105 mEq/L) is usually the result of dietary excess or administration of intravenous saline. **Hypochloremia** (< 95 mEq/L) is usually a side effect of hyponatremia but sometimes results from hyperkalemia or acidosis. In the latter case, the kidneys retain potassium by excreting more sodium, and sodium takes chloride with it. The primary effects of chloride imbalances are disturbances in acid-base balance, but this works both

⁵kal = potassium + emia = blood condition

ways—a pH imbalance arising from some other cause can also produce a chloride imbalance. Chloride balance is therefore discussed further in connection with acid-base balance.

Calcium

Functions

Calcium lends strength to the skeleton, activates the sliding filament mechanism of muscle contraction, serves as a second messenger for some hormones and neurotransmitters, activates exocytosis of neurotransmitters and other cellular secretions, and is an essential factor in blood clotting. Cells maintain a very low intracellular calcium concentration because they require a high concentration of phosphate ions (for reasons discussed shortly). If calcium and phosphate were both very concentrated in a cell, calcium phosphate crystals would precipitate in the cytoplasm. To maintain a high phosphate concentration but avoid crystallization of calcium phosphate, cells must pump out Ca^{2+} and keep it at a low intracellular concentration, or else sequester Ca^{2+} in the smooth ER and release it only when needed. Cells that store Ca^{2+} often have a protein called *calsequestrin*, which binds the stored Ca^{2+} and keeps it chemically unreactive.

Homeostasis

Calcium concentration is regulated chiefly by parathyroid hormone, calcitriol, and in children, calcitonin. These hormones work through their effects on bone deposition and resorption, intestinal absorption of calcium, and urinary excretion. For flowcharts of calcium homeostasis, see figure 7.18 (p. 233); the associated discussion gives further details on the mode of action of these hormones.

Imbalances

Hypercalcemia (> 5.8 mEq/L) can result from alkalosis, hyperparathyroidism, or hypothyroidism. It reduces the sodium permeability of plasma membranes and inhibits the depolarization of nerve and muscle cells. At concentrations ≥ 12 mEq/dL, hypercalcemia causes muscular weakness, depressed reflexes, and cardiac arrhythmia.

Hypocalcemia (< 4.5 mEq/L) can result from vitamin D deficiency, diarrhea, pregnancy, lactation, acidosis, hypoparathyroidism, or hyperthyroidism. It increases the sodium permeability of plasma membranes, causing the nervous and muscular systems to be overly excitable. Tetany occurs when calcium concentration drops to 6 mg/dL and may be lethal at 4 mg/dL (2 mEq/L) due to laryngospasm and suffocation.

Phosphates

Functions

The inorganic phosphates (P_i) of the body fluids are an equilibrium mixture of phosphate (PO_4^{3-}), monohydrogen phosphate (HPO_4^{2-}), and dihydrogen phosphate (H_2PO_4^-) ions. Phosphates are relatively concentrated in the ICF, where they are generated by the hydrolysis of ATP and other phosphate compounds. They are a component of nucleic acids, phospholipids, ATP, GTP, cAMP, creatine phosphate, and related compounds. Every process that depends on ATP depends on phosphate ions. Phosphates activate many metabolic pathways by phosphorylating enzymes and substrates such as glucose. They are also important as buffers that help stabilize the pH of the body fluids.

Homeostasis

The average diet provides ample amounts of phosphate ions, which are readily absorbed by the small intestine. Plasma phosphate concentration is usually maintained at about 4 mEq/L, with continual loss of excess phosphate by glomerular filtration. If plasma phosphate concentration drops much below this level, however, the renal tubules reabsorb all filtered phosphate.

Parathyroid hormone increases the excretion of phosphate as part of the mechanism for increasing the concentration of free calcium ions in the ECF. Lowering the ECF phosphate concentration minimizes the formation of calcium phosphate and thus helps support plasma calcium concentration. Rates of phosphate excretion are also strongly affected by the pH of the urine, as discussed shortly.

Imbalances

Phosphate homeostasis is not as critical as that of other electrolytes. The body can tolerate broad variations several times above or below the normal concentration with little immediate effect on physiology.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Which do you think would have the most serious effect, and why—a 5 mEq/L increase in the plasma concentration of sodium, potassium, chloride, or calcium?
- Answer the same question for a 5 mEq/L decrease.
- Explain why ADH is more likely than aldosterone to change the osmolarity of the blood plasma.
- Explain why aldosterone hyposecretion could cause hypochloremia.
- Why are more phosphate ions required in the ICF than in the ECF? How does this affect the distribution of calcium ions between these fluid compartments?

24.3 Acid–Base Balance

Objectives

When you have completed this section, you should be able to

- define *buffer* and write chemical equations for the bicarbonate, phosphate, and protein buffer systems;
- discuss the relationship between pulmonary ventilation, pH of the extracellular fluids, and the bicarbonate buffer system;
- explain how the kidneys secrete hydrogen ions and how these ions are buffered in the tubular fluid;
- identify some types and causes of acidosis and alkalosis, and describe the effects of these pH imbalances; and
- explain how the respiratory and urinary systems correct acidosis and alkalosis, and compare their effectiveness and limitations.

As we saw in chapter 2, metabolism depends on the functioning of enzymes, and enzymes are very sensitive to pH. Slight deviations from the normal pH can shut down metabolic pathways as well as alter the structure and function of other macromolecules. Consequently, acid–base balance is one of the most important aspects of homeostasis.

The blood and tissue fluid normally have a pH of 7.35 to 7.45. Such a narrow range of variation is remarkable considering that our metabolism constantly produces acid: lactic acid from anaerobic fermentation, phosphoric acids from nucleic acid catabolism, fatty acids and ketones from fat catabolism, and carbonic acid from carbon dioxide. Here we examine mechanisms for resisting these challenges and maintaining acid–base balance.

Think About It

In the systemic circulation, arterial blood has a mean pH of 7.40 and venous blood has a mean of 7.35. What do you think causes this difference?

Acids, Bases, and Buffers

The pH of a solution is determined solely by its hydrogen ions (H^+). An acid is any chemical that releases H^+ in solution. A **strong acid** such as hydrochloric acid (HCl) ionizes freely, gives up most of its hydrogen ions, and can markedly lower the pH of a solution. A **weak acid** such as carbonic acid (H_2CO_3) ionizes only slightly and keeps most hydrogen in a chemically bound form that does not affect pH. A base is any chemical that accepts H^+ . A **strong base** such as the hydroxide ion (OH^-) has a strong tendency to bind H^+ and raise the pH, whereas a **weak**

base such as the bicarbonate ion (HCO_3^-) binds less of the available H^+ and has less effect on pH.

A **buffer**, broadly speaking, is any mechanism that resists changes in pH by converting a strong acid or base to a weak one. The body has both physiological and chemical buffers. A **physiological buffer** is a system—namely, the respiratory or urinary system—that stabilizes pH by controlling the body's output of acids, bases, or CO_2 . Of all buffer systems, the urinary system buffers the greatest quantity of acid or base, but it requires several hours to days to exert an effect. The respiratory system exerts an effect within a few minutes but cannot alter the pH as much as the urinary system can.

A **chemical buffer** is a substance that binds H^+ and removes it from solution as its concentration begins to rise, or releases H^+ into solution as its concentration falls. Chemical buffers can restore normal pH within a fraction of a second. They function as mixtures called **buffer systems** composed of a weak acid and a weak base. The three major chemical buffer systems of the body are the bicarbonate, phosphate, and protein systems.

The amount of acid or base that can be neutralized by a chemical buffer system depends on two factors: the concentration of the buffers and the pH of their working environment. Each system has an optimum pH at which it functions best; its effectiveness is greatly reduced if the pH of its environment deviates too far from this. The relevance of these factors will become apparent as you study the following buffer systems.

The Bicarbonate Buffer System

The **bicarbonate buffer system** is a solution of carbonic acid and bicarbonate ions. Carbonic acid (H_2CO_3) forms by the hydration of carbon dioxide and then dissociates into bicarbonate (HCO_3^-) and H^+ :

This is a reversible reaction. When it proceeds to the right, carbonic acid acts as a weak acid by releasing H^+ and lowering pH. When the reaction proceeds to the left, bicarbonate acts as a weak base by binding H^+ , removing the ions from solution, and raising pH.

At a pH of 7.4, the bicarbonate system would not ordinarily have a particularly strong buffering capacity outside of the body. This is too far from its optimum pH of 6.1. If a strong acid was added to a beaker of carbonic acid–bicarbonate solution at pH 7.4, the preceding reaction would shift only slightly to the left. Much surplus H^+ would remain and the pH would be substantially lower. In the body, by contrast, the bicarbonate system works quite well because the lungs and kidneys constantly remove CO_2 and prevent an equilibrium from being reached. This keeps the reaction moving to the left, and more H^+ is neutralized. Conversely, if there is a need to lower the pH, the kidneys excrete HCO_3^- , keep this

reaction moving to the right, and elevate the H^+ concentration of the ECF. Thus, you can see that the physiological and chemical buffers of the body function together in maintaining acid-base balance.

The Phosphate Buffer System

The **phosphate buffer system** is a solution of HPO_4^{2-} and $H_2PO_4^-$. It works in much the same way as the bicarbonate system. The following reaction can proceed to the right to liberate H^+ and lower pH, or it can proceed to the left to bind H^+ and raise pH:

The optimal pH for this system is 6.8, closer to the actual pH of the ECF (7.4). Thus, the phosphate buffer system has a stronger buffering effect than an equal amount of bicarbonate buffer. However, phosphates are much less concentrated in the ECF than bicarbonate, so they are less important in buffering the ECF. They are more important in the renal tubules and ICF, where not only are they more concentrated, but the pH is lower and closer to their functional optimum. In the ICF, the constant production of metabolic acids creates pH values ranging from 4.5 to 7.4, probably averaging 7.0. The reason for the low pH in the renal tubules is discussed later.

The Protein Buffer System

Proteins are more concentrated than either bicarbonate or phosphate buffers, especially in the ICF. The **protein buffer system** accounts for about three-quarters of all chemical buffering in the body fluids. The buffering ability of proteins is due to certain side groups of their amino acid residues. Some have carboxyl ($-COOH$) side groups, which release H^+ when pH begins to rise and thus lower pH:

Others have amino ($-NH_2$) side groups, which bind H^+ when pH falls too low, thus raising pH toward normal:

Think About It

What protein do you think is the most important buffer in blood plasma? In erythrocytes?

Respiratory Control of pH

The equation for the bicarbonate buffer system shows that the addition of CO_2 to the body fluids raises H^+ concentration and lowers pH, while the removal of CO_2 has the opposite effects. This is the basis for the strong buffering capacity of the respiratory system. Indeed, this system can neutralize two or three times as much acid as the chemical buffers can.

Carbon dioxide is constantly produced by aerobic metabolism and is normally eliminated by the lungs at an equivalent rate. As explained in chapter 22, rising CO_2 concentration and falling pH stimulate peripheral and central chemoreceptors, which stimulate an increase in pulmonary ventilation. This expels excess CO_2 and thus reduces H^+ concentration. The free H^+ becomes part of the water molecules produced by this reaction:

Conversely, a drop in H^+ concentration raises pH and reduces pulmonary ventilation. This allows metabolic CO_2 to accumulate in the ECF faster than it is expelled, thus lowering pH to normal.

These are classic negative feedback mechanisms that result in acid-base homeostasis. Respiratory control of pH has some limitations, however, that are discussed later under acid-base imbalances.

Renal Control of pH

The kidneys can neutralize more acid or base than either the respiratory system or the chemical buffers. The essence of this mechanism is that the renal tubules secrete H^+ into the tubular fluid, where most of it binds to bicarbonate, ammonia, and phosphate buffers. Bound and free H^+ are then excreted in the urine. Thus the kidneys, in contrast to the lungs, actually expel H^+ from the body. The other buffer systems only reduce its concentration by binding it to another chemical.

Figure 24.10 shows how the renal tubule secretes and neutralizes H^+ . The hydrogen ions are colored so you can trace them from the blood (step 1) to the tubular fluid (step 6). Notice that it is not a simple matter of transporting free H^+ across the tubule cells; rather, the H^+ travels in the form of carbonic acid and water molecules.

The tubular secretion of H^+ takes place at step 6, where the ion is pumped out of the tubule cell into the tubular fluid. This can happen only if there is a steep enough concentration gradient between a high H^+ concentration within the cell and a lower concentration in the tubular fluid. If the pH of the tubular fluid drops any lower than 4.5, H^+ concentration in the fluid is so high that tubular secretion ceases. Thus, pH 4.5 is the **limiting pH** for tubular secretion. This has added significance later in our discussion.

In a person with normal acid-base balance, all bicarbonate ions (HCO_3^-) in the tubular fluid are consumed by neutralizing H^+ ; thus there is no HCO_3^- in the urine. Bicarbonate ions are filtered by the glomerulus, gradually disappear from the tubular fluid, and appear in the peritubular capillary blood. It *appears* as if HCO_3^- is reabsorbed by the renal tubules, but this is not the case; indeed, the renal tubules are incapable of reabsorbing HCO_3^- directly. The cells of the proximal convoluted tubule, however, have carbonic anhydrase (CAH) on their

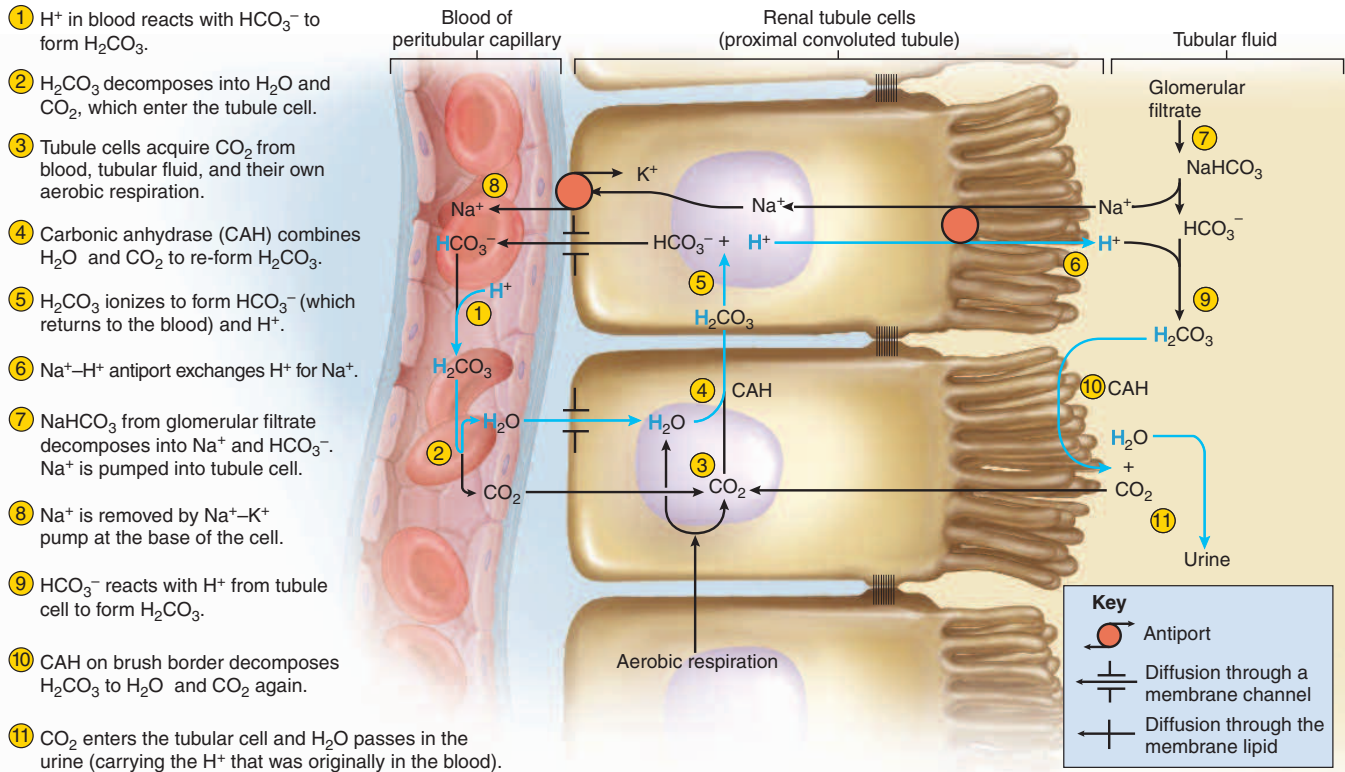

FIGURE 24.10 Secretion and Neutralization of Hydrogen Ions in the Kidneys. The colored hydrogen symbols allow you to trace hydrogen from H^+ in the blood to H_2O in the urine.

● If the pH of the tubular fluid went down, how would its Na^+ concentration change?

brush borders facing the lumen. This breaks down the H_2CO_3 in the tubular fluid to $\text{CO}_2 + \text{H}_2\text{O}$ (step 10). It is the CO_2 that is reabsorbed, not the bicarbonate. For every CO_2 reabsorbed, however, a new bicarbonate ion is formed in the tubule cell and released into the blood (step 5). The effect is the same as if the tubule cells had reabsorbed bicarbonate itself.

Note that for every bicarbonate ion that enters the peritubular capillaries, a sodium ion does too. Thus, the reabsorption of Na^+ by the renal tubules is part of the process of neutralizing acid. The more acid the kidneys excrete, the less sodium the urine contains.

The tubules secrete somewhat more H^+ than the available bicarbonate can neutralize. The urine therefore contains a slight excess of free H^+ , which gives it a pH of about 5 to 6. Yet if all of the excess H^+ secreted by the tubules remained in this free ionic form, the pH of the tubular fluid would drop far below the limiting pH of 4.5, and H^+ secretion would stop. This must be prevented, and there are additional buffers in the tubular fluid to do so.

The glomerular filtrate contains Na_2HPO_4 (dibasic sodium phosphate), which reacts with some of the H^+

(fig. 24.11). A hydrogen ion replaces one of the sodium ions in the buffer, forming NaH_2PO_4 (monobasic sodium phosphate). This is passed in the urine, and the displaced Na^+ is transported into the tubule cell and from there to the bloodstream.

In addition, tubule cells catabolize certain amino acids and release ammonia (NH_3) as a product (fig. 24.11). Ammonia diffuses into the tubular fluid, where it acts as a base to neutralize acid. It reacts with H^+ and Cl^- (the most abundant anion in the glomerular filtrate) to form ammonium chloride (NH_4Cl), which is passed in the urine.

Since there is so much chloride in the tubular fluid, you might ask why H^+ is not simply excreted as hydrochloric acid (HCl). Why involve ammonia? The reason is that HCl is a strong acid—it dissociates almost completely, so most of its hydrogen would be in the form of free H^+ . The pH of the tubular fluid would drop below the limiting pH and prevent excretion of more acid. Ammonium chloride, by contrast, is a weak acid—most of its hydrogen remains bound to it and does not lower the pH of the tubular fluid.

FIGURE 24.11 Acid Buffering in the Urine. Reactions in the tubule cells are the same as in figure 24.10 but are simplified in this diagram. The essential differences are the buffering mechanisms shown in the tubular fluid. Hydrogen symbols are colored to allow tracing them from carbonic acid to the urine.

Disorders of Acid-Base Balance

Figure 24.12 represents acid-base balance with an instructive metaphor to show its dependence on the bicarbonate buffer system. At a normal pH of 7.4, the ECF has a 20:1 ratio of HCO_3^- to H_2CO_3 . Excess hydrogen ions convert HCO_3^- to H_2CO_3 and tip the balance to a lower pH. A pH below 7.35 is considered to be a state of **acidosis**. On the other hand, an H^+ deficiency causes H_2CO_3 to dissociate into H^+ and HCO_3^- , thus tipping the balance to a higher pH. A pH above 7.45 is a state of **alkalosis**. Either of these imbalances has potentially fatal effects. A person cannot live more than a few hours if the blood pH is below 7.0 or above 7.7, and a pH below 6.8 or above 8.0 is quickly fatal.

In acidosis, H^+ diffuses down its concentration gradient into cells, and to maintain electrical balance, K^+ diffuses out (fig. 24.13a). The H^+ is buffered by intracellular proteins, so this exchange results in a net loss of cations from the cell. This makes the resting membrane potential more negative than usual (hyperpolarized) and makes nerve and muscle cells more difficult to stimulate. This is why acidosis depresses the central nervous system and causes such symptoms as confusion, disorientation, and coma.

FIGURE 24.12 The Relationship of Bicarbonate-Carbonic Acid Ratio to pH. At a normal pH of 7.40, there is a 20:1 ratio of bicarbonate ions (HCO_3^-) to carbonic acid (H_2CO_3) in the blood plasma. An excess of HCO_3^- tips the balance toward alkalosis, whereas an excess of H_2CO_3 tips it toward acidosis.

In alkalosis, the extracellular H^+ concentration is low. Hydrogen ions diffuse out of the cells and K^+ diffuses in to replace them (fig. 24.13b). The net gain in positive intracellular charges shifts the membrane potential closer to firing level and makes the nervous system hyperexcitable. Neurons fire spontaneously and overstimulate skeletal muscles, causing muscle spasms, tetanus, convulsions, or respiratory paralysis.

Acid-base imbalances fall into two categories, respiratory and metabolic (table 24.2). **Respiratory acidosis** occurs when the rate of alveolar ventilation fails to keep

pace with the body's rate of CO_2 production. Carbon dioxide accumulates in the ECF and lowers its pH. This occurs in such conditions as emphysema, in which there is a severe reduction in the number of functional alveoli. **Respiratory alkalosis** results from hyperventilation, in which CO_2 is eliminated faster than it is produced.

Metabolic acidosis can result from increased production of organic acids, such as lactic acid in anaerobic fermentation and ketone bodies in alcoholism and diabetes mellitus. It can also result from the excessive ingestion of acidic drugs such as aspirin or from the loss of base due

FIGURE 24.13 The Relationship Between Acid-Base Imbalances and Potassium Imbalances. (a) In acidosis, H^+ diffuses into the cells and drives out K^+ , elevating the K^+ concentration of the ECF. (b) In alkalosis, H^+ diffuses out of the cells and K^+ diffuses in to replace it, lowering the K^+ concentration of the ECF.

• How would you change part (a) to show the effect of hyperkalemia on the pH of the ECF?

TABLE 24.2 Some Causes of Acidosis and Alkalosis

	Acidosis	Alkalosis
Respiratory	Hypoventilation, apnea, or respiratory arrest; asthma; emphysema; cystic fibrosis; chronic bronchitis; narcotic overdose	Hyperventilation due to pain or emotions such as anxiety; oxygen deficiency (as at high elevation)
Metabolic	Excess production of organic acids as in diabetes mellitus and starvation; long-term anaerobic fermentation; hyperkalemia; chronic diarrhea; excessive alcohol consumption; drugs such as aspirin and laxatives	Rare but can result from chronic vomiting; overuse of bicarbonates (antacids); aldosterone hypersecretion

to chronic diarrhea or overuse of laxatives. Dying persons also typically exhibit acidosis. **Metabolic alkalosis** is rare but can result from overuse of bicarbonates (such as oral antacids and intravenous bicarbonate solutions) or from the loss of stomach acid by chronic vomiting.

Compensation for Acid–Base Imbalances

In **compensated** acidosis or alkalosis, either the kidneys compensate for pH imbalances of respiratory origin, or the respiratory system compensates for pH imbalances of metabolic origin. **Uncompensated** acidosis or alkalosis is a pH imbalance that the body cannot correct without clinical intervention.

In **respiratory compensation**, changes in pulmonary ventilation correct the pH of the body fluids by expelling or retaining CO_2 . If there is a CO_2 excess (hypercapnia), pulmonary ventilation increases to expel CO_2 and bring the blood pH back up to normal. If there is a CO_2 deficiency (hypocapnia), ventilation is reduced to allow CO_2 to accumulate in the blood and lower the pH to normal.

This is very effective in correcting pH imbalances due to abnormal PCO_2 but not very effective in correcting other causes of acidosis and alkalosis. In diabetic acidosis, for example, the lungs cannot reduce the concentration of ketone bodies in the blood, although one can somewhat compensate for the H^+ that ketones release by increasing pulmonary ventilation and exhausting extra CO_2 . The respiratory system can adjust a blood pH of 7.0 back to 7.2 or 7.3 but not all the way back to the normal 7.4. Although the respiratory system has a very powerful buffering effect, its ability to stabilize pH is therefore limited.

Renal compensation is an adjustment of pH by changing the rate of H^+ secretion by the renal tubules. The kidneys are slower to respond to pH imbalances but better at restoring a fully normal pH. Urine usually has a pH of 5 to 6, but in acidosis it may fall as low as 4.5 because of excess H^+ , whereas in alkalosis it may rise as high as 8.2 because of excess HCO_3^- . The kidneys cannot act quickly enough to compensate for short-term pH imbalances, such as the acidosis that might result from an asthmatic attack lasting an hour or two, or the alkalosis resulting from a brief episode of emotional hyperventilation. They are effective, however, at compensating for pH imbalances that last for a few days or longer.

In acidosis, the renal tubules increase the rate of H^+ secretion. The extra H^+ in the tubular fluid must be buffered; otherwise, the fluid pH could exceed the limiting

pH and H^+ secretion would stop. Therefore, in acidosis, the renal tubules secrete more ammonia to buffer the added H^+ , and the amount of ammonium chloride in the urine may rise to 7 to 10 times normal.

Think About It

Suppose you measured the pH and ammonium chloride concentration of urine from a person with emphysema and urine from a healthy individual. How would you expect the two to differ, and why?

In alkalosis, the bicarbonate concentration and pH of the urine are elevated. This is partly because there is more HCO_3^- in the blood and glomerular filtrate and partly because there is not enough H^+ in the tubular fluid to neutralize all the HCO_3^- in the filtrate.

Acid–Base Imbalances in Relation to Electrolyte and Water Imbalances

The foregoing discussion once again stresses a point made early in this chapter—we cannot understand or treat imbalances of water, electrolyte, or acid–base balance in isolation from each other, because each of these frequently affects the other two. Table 24.3 itemizes and explains a few of these interactions. This is by no means a complete list of how fluid, electrolytes, and pH affect each other, but it does demonstrate their interdependence. Note that many of these relationships are reciprocal—for example, acidosis can cause hyperkalemia, and conversely, hyperkalemia can cause acidosis.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

11. Write two chemical equations that show how the bicarbonate buffer system compensates for acidosis and alkalosis and two equations that show how the phosphate buffer system compensates for these imbalances.
12. Why are phosphate buffers more effective in the cytoplasm than in the blood plasma?
13. Renal tubules cannot reabsorb HCO_3^- ; yet HCO_3^- concentration in the tubular fluid falls while in the blood plasma it rises. Explain this apparent contradiction.
14. In acidosis, the renal tubules secrete more ammonia. Why?

TABLE 24.3 Some Relationships Among Fluid, Electrolyte, and Acid-Base Imbalances

Cause	Potential Effect	Reason
Acidosis →	Hyperkalemia	H ⁺ diffuses into cells and displaces K ⁺ (see fig. 24.13a). As K ⁺ leaves the ICF, K ⁺ concentration in the ECF rises.
Hyperkalemia →	Acidosis	Opposite from the above; high K ⁺ concentration in the ECF causes less K ⁺ to diffuse out of the cells than normally. H ⁺ diffuses out to compensate, and this lowers the extracellular pH.
Alkalosis →	Hypokalemia	H ⁺ diffuses from ICF to ECF. More K ⁺ remains in the ICF to compensate for the H ⁺ loss, causing a drop in ECF K ⁺ concentration (see fig. 24.13b).
Hypokalemia →	Alkalosis	Opposite from the above; low K ⁺ concentration in the ECF causes K ⁺ to diffuse out of cells. H ⁺ diffuses in to replace K ⁺ , lowering the H ⁺ concentration of the ECF and raising its pH.
Acidosis →	Hypochloremia	More Cl ⁻ is excreted as NH ₄ Cl to buffer the excess acid in the renal tubules, leaving less Cl ⁻ in the ECF.
Alkalosis →	Hyperchloremia	More Cl ⁻ is reabsorbed from the renal tubules, so ingested Cl ⁻ accumulates in the ECF rather than being excreted.
Hyperchloremia →	Acidosis	More H ⁺ is retained in the blood to balance the excess Cl ⁻ , causing hyperchloremic acidosis.
Hypovolemia →	Alkalosis	More Na ⁺ is reabsorbed by the kidney. Na ⁺ reabsorption is coupled to H ⁺ secretion (see fig. 24.10), so more H ⁺ is secreted and pH of the ECF rises.
Hypervolemia →	Acidosis	Less Na ⁺ is reabsorbed, so less H ⁺ is secreted into the renal tubules. H ⁺ retained in the ECF causes acidosis.
Acidosis →	Hypocalcemia	Acidosis causes more Ca ²⁺ to bind to plasma protein and citrate ions, lowering the concentration of free, ionized Ca ²⁺ and causing symptoms of hypocalcemia.
Alkalosis →	Hypercalcemia	Alkalosis causes more Ca ²⁺ to dissociate from plasma protein and citrate ions, raising the concentration of free Ca ²⁺ .

INSIGHT 24.2 Clinical Application**Fluid Replacement Therapy**

One of the most significant problems in the treatment of seriously ill patients is the restoration and maintenance of proper fluid volume, composition, and distribution among the fluid compartments. Fluids may be administered to replenish total body water, restore blood volume and pressure, shift water from one fluid compartment to another, or restore and maintain electrolyte and acid-base balance.

Drinking water is the simplest method of fluid replacement, but it does not replace electrolytes. Heat exhaustion can occur when you lose water and salt in the sweat and replace the fluid by drinking plain water. Broths, juices, and sports drinks replace water, carbohydrates, and electrolytes.

Patients who cannot take fluids by mouth must be treated by alternative routes. Some fluids can be given by enema and absorbed through the colon. All routes of fluid administration other than the digestive tract are called *parenteral*⁶ routes. The most common of these is the intravenous (I.V.) route, but for various reasons, including inability to find a suitable vein, fluids are sometimes given by subcutaneous (sub-Q), intramuscular (I.M.), or other parenteral routes. Many kinds of sterile solutions are available to meet the fluid replacement needs of different patients.

In cases of extensive blood loss, there may not be time to type and cross-match blood for a transfusion. The more urgent need is to replenish blood volume and pressure. *Normal saline* (isotonic, 0.9% NaCl) is a relatively quick and simple way to raise blood volume while maintaining normal osmolarity, but it has significant shortcomings. It takes three to five times as much saline as whole blood to rebuild normal volume because much of the saline escapes the circulation into the interstitial fluid compartment or is excreted by the kidneys. In addition, normal saline can induce hyponatremia and hyperchloremia, because the body excretes the water but retains much of the NaCl. Hyperchloremia can, in turn, produce acidosis. Normal saline also lacks potassium, magnesium, and calcium. Indeed, it dilutes those electrolytes that are already present and creates a risk of cardiac arrest from hypocalcemia. Saline also dilutes plasma albumin and RBCs, creating still greater risks for patients who have suffered extensive blood loss. Nevertheless, the emergency maintenance of blood volume sometimes takes temporary precedence over these other considerations.

Fluid therapy is also used to correct pH imbalances. Acidosis may be treated with *Ringer's lactate solution*, which includes sodium to rebuild ECF volume, potassium to rebuild ICF volume, lactate to balance the cations, and enough glucose to make the solution isotonic. Alkalosis can be treated with

potassium chloride. This must be administered very carefully, because potassium ions can cause painful venous spasms, and even a small potassium excess can cause cardiac arrest. High-potassium solutions should never be given to patients in renal failure or whose renal status is unknown, because in the absence of renal excretion of potassium, they can bring on lethal hyperkalemia. Ringer's lactate or potassium chloride also must be administered very cautiously, with close monitoring of blood pH, to avoid causing a pH imbalance opposite the one that was meant to be corrected. Too much Ringer's lactate causes alkalosis and too much KCl causes acidosis.

Plasma volume expanders are hypertonic solutions or colloids that are retained in the bloodstream and draw interstitial water into it by osmosis. They include albumin, sucrose, mannitol, and dextran. Plasma expanders are also used to combat hypotonic hydration by drawing water out of swollen cells, averting such problems as seizures and coma. A plasma expander can draw several liters of water out of the intracellular compartment within a few minutes.

Patients who cannot eat are often given isotonic 5% dextrose (glucose). A fasting patient loses as much as 70 to 85 g of protein per day from the tissues as protein is broken down to fuel the metabolism. Giving 100 to 150 g of I.V. glucose per day reduces this by half and is said to have a *protein-sparing effect*. More than glucose is needed in some cases—for example, if a patient has not eaten for several days and cannot be fed by nasogastric tube (due to lesions of the digestive tract, for example) or if large amounts of nutrients are needed for tissue repair following severe trauma, burns, or infections. In *total parenteral nutrition (TPN)*, or *hyperalimentation*,⁷ a patient is provided with complete I.V. nutritional support, including a protein hydrolysate (amino acid mixture), vitamins, electrolytes, 20% to 25% glucose, and on alternate days, a fat emulsion.

The water from parenteral solutions is normally excreted by the kidneys. If the patient has renal insufficiency, however, excretion may not keep pace with intake, and there is a risk of hypotonic hydration. Intravenous fluids are usually given slowly, by *I.V. drip*, to avoid abrupt changes or overcompensation for the patient's condition. In addition to pH, the patient's heart rate, blood pressure, hematocrit, and plasma electrolyte concentrations are monitored, and the patient is examined periodically for respiratory sounds indicating pulmonary edema.

The delicacy of fluid replacement therapy underscores the close relationships among fluids, electrolytes, and pH. It is dangerous to manipulate any one of these variables without close attention to the others. Parenteral fluid therapy is usually used for persons who are seriously ill. Their homeostatic mechanisms are already compromised and leave less room for error than in a healthy person.

⁷*hyper* = above normal + *aliment* = nourishment

CHAPTER REVIEW

Review of Key Concepts

24.1 Water Balance (p. 943)

- The young adult male body contains about 40 L of water. About 65% is in the intracellular fluid (ICF) and 35% in the extracellular fluid (ECF).
- Water moves osmotically from one fluid compartment to another so that osmolarities of the ECF and ICF seldom differ.
- In a state of water balance, average daily fluid gains and losses are equal (typically about 2,500 mL each). Water is gained from the metabolism and by ingestion of food and drink; water is lost in urine, feces, expired breath, sweat, and by cutaneous transpiration.
- Fluid intake is governed mainly by hypothalamic neurons called *osmoreceptors*, which monitor blood osmolarity and angiotensin level. When they sense a fluid deficit, they activate ADH secretion (water conservation) and the sense of thirst.
- Long-term satiation of thirst depends on hydration of the blood, although thirst is briefly suppressed by wetting and cooling of the mouth and filling of the stomach.
- Fluid loss is governed mainly by the factors that control urine output. ADH, for example, is secreted in response to dehydration and reduces urine output.
- Fluid deficiency* occurs when fluid output exceeds intake. In a form of fluid deficiency called *volume depletion (hypovolemia)*, total body water is reduced but its osmolarity remains normal, because proportionate amounts of water and salt are lost. In the other form, true *dehydration*, volume is reduced and osmolarity is elevated because the body has lost more water than salt. Severe fluid deficiency can result in circulatory shock and death.
- Fluid excess* occurs in two forms called *volume excess* (retention of excess fluid with normal osmolarity) and *hypotonic hydration* (retention of

more water than salt, so osmolarity is low).

- Fluid sequestration* is a state in which total body water may be normal, but the water is maldistributed in the body. *Edema* and *pleural effusion* are examples of fluid sequestration.

24.2 Electrolyte Balance (p. 949)

- Sodium is the major cation of the ECF and is important in osmotic fluid balance, nerve and muscle activity, cotransport, acid-base balance, and heat generation.
- Aldosterone promotes Na^+ reabsorption. ADH reduces Na^+ concentration by promoting water reabsorption independently of Na^+ . Natriuretic peptides promote Na^+ excretion whereas angiotensin II promotes its reabsorption.
- A Na^+ excess (*hyponatremia*) tends to cause water retention, hypertension, and edema. A Na^+ deficiency (*hyponatremia*) is usually a result of hypotonic hydration.
- Potassium is the major cation of the ICF. It is important for the same reasons as Na^+ and is a cofactor for some enzymes.
- Aldosterone promotes K^+ excretion.
- A K^+ excess (*hyperkalemia*) tends to cause nerve and muscle dysfunction, including cardiac arrest. A K^+ deficiency (*hypokalemia*) inhibits nerve and muscle function.
- Chloride ions are the major anions of the ECF. They are important in osmotic balance, formation of stomach acid, and the chloride shift mechanism in respiratory and renal function.
- Cl^- follows Na^+ and other cations and is regulated as a side effect of Na^+ homeostasis. The primary effect of chloride imbalances (*hyper-* and *hypochloremia*) is a pH imbalance.
- Calcium is necessary for muscle contraction, neurotransmission and other cases of exocytosis, blood clotting, some hormone actions, and bone and tooth development.

- Calcium homeostasis is regulated by parathyroid hormone, calcitonin, and calcitriol (see chapter 7).
- Hypercalcemia causes muscular weakness, depressed reflexes, and cardiac arrhythmia. Hypocalcemia causes potentially fatal muscle tetanus.
- Inorganic phosphate (P_i) is a mixture of PO_4^{3-} , HPO_4^{2-} , and H_2PO_4^- ions. P_i is required for the synthesis of nucleic acids, phospholipids, ATP, GTP, and cAMP; it activates many metabolic pathways by phosphorylating such substances as enzymes and glucose; and it is an important acid-base buffer.
- Phosphate levels are regulated by parathyroid hormone, but phosphate imbalances are not as critical as imbalances of other electrolytes.

24.3 Acid-Base Balance (p. 954)

- The pH of the ECF is normally maintained between 7.35 and 7.45.
- pH is determined largely by the tendency of weak and strong acids to give up H^+ to solution, and weak and strong bases to absorb H^+ .
- A *buffer* is any system that resists changes in pH by converting a strong acid or base to a weak one. The *physiological buffers* are the urinary and respiratory systems; the *chemical buffers* are the bicarbonate, phosphate, and protein buffer systems.
- The respiratory system buffers pH by adjusting pulmonary ventilation. Reduced ventilation allows CO_2 to accumulate in the blood and lower its pH by the reaction $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3 \rightarrow \text{HCO}_3^- + \text{H}^+$ (generating the H^+ that lowers the pH). Increased ventilation expels CO_2 , reversing this reaction, lowering H^+ concentration, and raising the pH.
- The kidneys neutralize more acid or base than any other buffer system. They secrete H^+ into the tubular fluid, where it binds to chemical buffers and is voided from the body in the urine.

6. This H^+ normally neutralizes all the HCO_3^- in the tubular fluid, making the urine bicarbonate-free. Excess H^+ in the tubular fluid can be buffered by phosphate and ammonia.
7. Acidosis is a $pH < 7.35$. *Respiratory acidosis* occurs when pulmonary gas exchange is insufficient to expel CO_2 as fast as the body produces it. *Metabolic acidosis* is the result of lactic acid or ketone accumulation, excessive use of acidic drugs such as aspirin, or loss of base in such cases as diarrhea.
8. Alkalosis is a $pH > 7.45$. *Respiratory alkalosis* results from hyperventilation. *Metabolic alkalosis* is rare but can be caused by overuse of antacids or loss of stomach acid through vomiting.
9. *Uncompensated* acidosis or alkalosis is a pH imbalance that the body's homeostatic mechanisms cannot correct on their own; it requires clinical intervention.
10. *Compensated* acidosis or alkalosis is an imbalance that the body's homeostatic mechanisms can correct. *Respiratory compensation* is correction of the pH through changes in pulmonary ventilation. *Renal compensation* is correction of pH by changes in H^+ secretion by the kidneys.
11. Water, electrolyte, and acid-base imbalances are deeply interconnected; an imbalance in one area can cause or result from an imbalance in another (see table 24.3).

Testing Your Recall

1. The greatest percentage of the body's water is in
 - a. the blood plasma.
 - b. the lymph.
 - c. the intracellular fluid.
 - d. the interstitial fluid.
 - e. the extracellular fluid.
2. Hypertension is likely to increase the secretion of
 - a. atrial natriuretic peptide.
 - b. antidiuretic hormone.
 - c. bicarbonate ions.
 - d. aldosterone.
 - e. ammonia.
3. _____ increases water reabsorption without increasing sodium reabsorption.
 - a. Antidiuretic hormone
 - b. Aldosterone
 - c. Atrial natriuretic peptide
 - d. Parathyroid hormone
 - e. Calcitonin
4. Hypotonic hydration can result from
 - a. ADH hypersecretion.
 - b. ADH hyposecretion.
 - c. aldosterone hypersecretion.
 - d. aldosterone hyposecretion.
 - e. *a* and *d* only.
5. Tetanus is most likely to result from
 - a. hypernatremia.
 - b. hypokalemia.
 - c. hyperkalemia.
 - d. hypocalcemia.
 - e. *c* and *d* only.
6. The principal determinant of intracellular osmolarity and cellular volume is
 - a. protein.
 - b. phosphate.
 - c. potassium.
 - d. sodium.
 - e. chloride.
7. Increased excretion of ammonium chloride in the urine most likely indicates
 - a. hypercalcemia.
 - b. hyponatremia.
 - c. hypochloremia.
 - d. alkalosis.
 - e. acidosis.
8. The most effective buffer in the intracellular fluid is
 - a. phosphate.
 - b. protein.
 - c. bicarbonate.
 - d. carbonic acid.
 - e. ammonia.
9. Tubular secretion of hydrogen is directly linked to
 - a. tubular secretion of potassium.
 - b. tubular secretion of sodium.
 - c. tubular reabsorption of potassium.
 - d. tubular reabsorption of sodium.
 - e. tubular secretion of chloride.
10. Hyperchloremia is most likely to result in
 - a. alkalosis.
 - b. acidosis.
 - c. hypernatremia.
 - d. hyperkalemia.
 - e. hypovolemia.
11. The most abundant cation in the ECF is _____.
12. The most abundant cation in the ICF is _____.
13. Water produced by the body's chemical reactions is called _____.
14. The skin loses water by two processes, sweating and _____.
15. Any abnormal accumulation of fluid in a particular place in the body is called _____.
16. An excessive concentration of potassium ions in the blood is called _____.
17. A deficiency of sodium ions in the blood is called _____.
18. A blood pH of 7.2 caused by inadequate pulmonary ventilation would be classified as _____.
19. Tubular secretion of hydrogen ions would cease if the acidity of the tubular fluid fell below a value called the _____.
20. Long-term satiation of thirst depends on a reduction of the _____ of the blood.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Hypokalemia lowers the resting membrane potentials of nerve and muscle cells and makes them less excitable.
- Aldosterone promotes sodium and water retention and can therefore greatly increase blood pressure.
- Injuries that rupture a lot of cells tend to elevate the K^+ concentration of the ECF.
- It is possible for a person to suffer circulatory shock even without losing a significant amount of fluid from the body.
- Parathyroid hormone promotes calcium and phosphate reabsorption by the kidneys.
- The bicarbonate system buffers more acid than any other chemical buffer.
- The more sodium the renal tubules reabsorb, the more hydrogen ion they secrete into the tubular fluid.
- The body compensates for respiratory acidosis by increasing the respiratory rate.
- In true dehydration, the body fluids remain isotonic although total body water is reduced.
- Long-term quenching of thirst results primarily from wetting and cooling of the mouth when one drinks.

Answers in appendix B

Testing Your Comprehension

- A duck hunter is admitted to the hospital with a shotgun injury to the abdomen. He has suffered extensive blood loss but is conscious. He complains of being intensely thirsty. Explain the physiological mechanism connecting his injury to his thirst.
- A woman living at poverty level finds bottled water at the grocery store next to the infant formula. The label on the water states that it is made especially for infants, and she construes this to mean that it can be used as a nutritional supplement. The water is much cheaper than formula, so she gives her baby several ounces of bottled water a day as a substitute for formula. After several days the baby has seizures and is taken to the hospital, where it is found to have edema, acidosis, and a plasma sodium concentration of 116 mEq/L. The baby is treated with anticonvulsants followed by normal saline and recovers. Explain each of the signs.
- Explain why the respiratory and urinary systems are both necessary for the bicarbonate buffer system to work effectively in the blood plasma.
- A 4-year-old child is caught up in tribal warfare in Africa. In a refugee camp, the only drinking water is from a sewage-contaminated pond. The child soon develops severe diarrhea and dies 10 days later of cardiac arrest. Explain the possible physiological cause(s) of his death.
- The left column indicates some increases or decreases in blood plasma values. In the right column, replace the question mark with an up or down arrow to indicate the expected effect. Explain each effect.

Cause	Effect
a. $\uparrow H_2O$? Na^+
b. $\uparrow Na^+$? Cl^-
c. $\downarrow K^+$? H^+
d. $\uparrow H^+$? K^+
e. $\downarrow Ca^{2+}$? PO_4^{3-}

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Hydrolysis reactions (p. 69)
- Carbohydrate, fat, and protein structures (pp. 69–76)
- pH and enzyme function (p. 79)
- Brush borders and microvilli (p. 96)
- Membrane transport processes (pp. 100–109)
- The Valsalva maneuver (p. 877)

Digestive System

Most of the nutrients we eat cannot be used in their existing form. They must be broken down into smaller components, such as amino acids and monosaccharides, that are universal to all species. Consider what happens if you eat a piece of beef, for example. The myosin of beef differs very little from that of your own muscles, but the two are not identical, and even if they were, beef myosin could not be absorbed, transported in the blood, and incorporated into your muscles. Like any other dietary protein, it must be broken down into amino acids before it can be used. Since beef and human proteins are made of the same 20 amino acids, those of beef proteins might indeed become part of your own myosin but could equally well end up in your insulin, fibrinogen, collagen, or any other protein. The digestive system is essentially a disassembly line—its primary purpose is to break nutrients down into forms that can be used by the body and to absorb them so they can be distributed to the tissues. The study of the digestive tract and the diagnosis and treatment of its disorders is called **gastroenterology**.¹

25.1 General Anatomy and Digestive Processes

Objectives

When you have completed this section, you should be able to

- list the functions and major physiological processes of the digestive system;
- distinguish between mechanical and chemical digestion;
- describe the basic chemical process underlying all chemical digestion, and name the major substrates and products of this process;
- list the regions of the digestive tract and the accessory organs of the digestive system;
- identify the layers of the digestive tract and describe its relationship to the peritoneum; and
- describe the general neural and chemical controls over digestive function.

Digestive Function

The **digestive system** is the organ system that processes food, extracts nutrients from it, and eliminates the residue. It does this in five stages:

1. **ingestion**, the selective intake of food;
2. **digestion**, the mechanical and chemical breakdown of food into a form usable by the body;
3. **absorption**, the uptake of nutrient molecules into the epithelial cells of the digestive tract and then into the blood or lymph;
4. **compaction**, absorbing water and consolidating the indigestible residue into feces; and finally,
5. **defecation**, the elimination of feces.

The digestion stage itself has two facets, mechanical and chemical. **Mechanical digestion** is the physical breakdown of food into smaller particles. It is achieved by the cutting and grinding action of the teeth and the churning contractions of the stomach and small intestine. Mechanical digestion exposes more food surface to the action of digestive enzymes. **Chemical digestion** is a series of hydrolysis reactions that break dietary macromolecules into their monomers (*residues*): polysaccharides into monosaccharides, proteins into amino acids, fats into monoglycerides and fatty acids, and nucleic acids into nucleotides. It is carried out by digestive enzymes produced by the salivary glands, stomach, pancreas, and small intestine. Some nutrients are already present in usable form in the ingested food and are absorbed without being digested: vitamins, free amino acids, minerals, cholesterol, and water.

General Anatomy

The digestive system has two anatomical subdivisions, the digestive tract and the accessory organs (fig. 25.1). The **digestive tract** is a muscular tube extending from mouth to anus, measuring about 9 m (30 feet) long in the cadaver. It is also known as the *alimentary*² canal. It includes the mouth, pharynx, esophagus, stomach, small intestine, and large intestine. Part of this, the stomach and intestines, constitute the *gastrointestinal (GI) tract*. The **accessory organs** are the teeth, tongue, salivary glands, liver, gallbladder, and pancreas.

The digestive tract is open to the environment at both ends. Most of the material in it has not entered any body tissues and is considered to be external to the body until it is absorbed by epithelial cells of the alimentary canal. In the strict sense, defecated food residue was never in the body.

Most of the digestive tract follows the basic structural plan shown in figure 25.2, with a wall composed of the

¹*gastro* = stomach + *entero* = intestines + *logy* = study of

²*aliment* = food

FIGURE 25.1 The Digestive System.

following tissue layers, in order from the inner to the outer surface:

- Mucosa
 - Epithelium
 - Lamina propria
 - Muscularis mucosae
- Submucosa
- Muscularis externa
 - Inner circular layer
 - Outer longitudinal layer
- Serosa
 - Areolar tissue
 - Mesothelium

Slight variations on this theme are found in different regions of the tract.

The **mucosa (mucous membrane)** lining the lumen consists of an inner epithelium, a loose connective tissue layer called the **lamina propria**, and a thin layer of smooth muscle called the **muscularis mucosae** (MUSS-cue-LERR-is mew-CO-see). The epithelium is simple columnar in most of the digestive tract, but stratified squamous from the oral cavity through the esophagus and in the lower anal canal, where the tract is subject to more abrasion. The muscularis mucosae tenses the mucosa, creating grooves and ridges that enhance its surface area and contact with food. This improves the efficiency of digestion and nutrient absorption. The mucosa exhibits an abundance of lymphocytes and lymphatic nodules—the **mucosa-associated lymphatic tissue (MALT)** (see p. 822).

The **submucosa** is a thicker layer of loose connective tissue containing blood vessels, lymphatic vessels, a nerve plexus, and in some places, glands that secrete lubricating mucus into the lumen. The MALT extends into the submucosa in some parts of the GI tract.

The **muscularis externa** consists of usually two layers of muscle near the outer surface. Cells of the inner layer encircle the tract while those of the outer layer run longitudinally. In some places, the circular layer is thickened to form valves (sphincters) that regulate the passage of material through the tract. The longitudinal layer is responsible for the motility that propels food and residue through the digestive tract.

The **serosa** is composed of a thin layer of areolar tissue topped by a simple squamous mesothelium. The serosa begins in the lower 3 to 4 cm of the esophagus and ends just before the rectum. The pharynx, most of the esophagus, and the rectum are surrounded by a fibrous connective tissue layer called the **adventitia**, which blends into the adjacent connective tissue of other organs.

The esophagus, stomach, and intestines have a nervous network called the **enteric³ nervous system**, which regulates digestive tract motility, secretion, and blood flow. This system is thought to have over 100 million neurons—more than the spinal cord! It can function completely independently of the central nervous system, although the CNS usually exerts a significant influence on its action. It is usually regarded as part of the autonomic nervous system, but opinions on this vary. The enteric nervous system is composed of two networks of neurons: the **submucosal (Meissner⁴) plexus** in the submucosa and the **myenteric (Auerbach⁵) plexus** of parasympathetic ganglia and nerve fibers between the two layers of the muscularis externa. Parasympathetic preganglionic fibers terminate in the ganglia of the myenteric plexus. Postganglionic fibers arising in this plexus not only innervate the muscularis externa,

³enter = intestine

⁴Georg Meissner (1829–1905), German histologist

⁵Leopold Auerbach (1828–97), German anatomist

FIGURE 25.2 Tissue Layers of the Digestive Tract. Cross section of the esophagus just below the diaphragm.

but also pass through its inner circular layer and contribute to the submucosal plexus. The myenteric plexus controls peristalsis and other contractions of the muscularis externa, and the submucosal plexus controls movements of the muscularis mucosae and glandular secretion of the mucosa. The enteric nervous system also includes sensory neurons that monitor tension in the gut wall and conditions in the lumen.

Relationship to the Peritoneum

In processing food, the stomach and intestines undergo such strenuous contractions that they need freedom to move in the abdominal cavity. Thus, they are not tightly bound to the abdominal wall, but over most of its length, they are loosely suspended from it by connective tissue sheets called **mesenteries**. The mesenteries also hold the abdominal viscera in their proper relationship to each other and prevent the small intestine, especially, from becoming twisted and tangled by changes in body position and by its own contractions. Furthermore, the mesenteries provide passage for the blood vessels and nerves that supply the digestive tract, and contain many lymph nodes and lymphatic vessels.

The parietal peritoneum is a serous membrane that lines the wall of the abdominal cavity (see p. 36). Along the posterior (dorsal) midline of the body, it turns inward and forms the **dorsal mesentery**, a translucent two-layered membrane extending to the digestive tract. Upon reaching an organ such as the stomach or small intestine, the two layers of the mesentery separate and pass around opposite sides of the organ, forming the serosa. In some places, the two layers come together again on the far side of that organ and continue as another sheet of tissue, the **ventral mesentery**. The ventral mesentery may hang freely in the abdominal cavity or attach to the anterior (ventral) abdominal wall or other organs. The relationship between the dorsal and ventral mesenteries and the serosa are shown in figures A.9 and A.10 (pp.36–37).

Along the right superior margin (*lesser curvature*) of the stomach, a ventral mesentery called the **lesser omentum** extends from the stomach to the liver (fig. 25.3). Another membrane, the **greater omentum**, hangs from the left inferior margin (*greater curvature*) of the stomach and loosely covers the small intestine like an apron. At its inferior margin, the greater omentum turns back on itself and passes upward, thus forming a deep pouch between its deep and superficial layers. At its inner superior margin,

FIGURE 25.3 Serous Membranes Associated with the Digestive Tract. (a) The greater and lesser omenta. (b) Greater omentum and small intestine retracted to show the mesocolon and mesentery. These membranes contain the mesenteric arteries and veins.

it forms serous membranes around the spleen and transverse colon. Beyond the transverse colon, it continues as a mesentery called the **mesocolon**, which anchors the colon to the posterior abdominal wall.

The omenta have a loosely organized, lacy appearance due partly to many holes or gaps in the membranes and partly to an irregular distribution of adipose tissue. They also contain many lymph nodes, lymphatic vessels, blood vessels, and nerves. The omenta adhere to perforations or inflamed areas of the stomach or intestines, contribute immune cells to the site, and isolate infections that might otherwise give rise to peritonitis.

When an organ is enclosed by mesentery (serosa) on both sides, it is considered to be within the peritoneal cavity, or **intraperitoneal**. When an organ lies against the posterior body wall and is covered by peritoneum on the anterior side only, it is said to be outside the peritoneal cavity, or **retroperitoneal**. The duodenum, most of the pancreas, and parts of the large intestine are retroperitoneal. The stomach, liver, and other parts of the small and large intestines are intraperitoneal.

Regulation of the Digestive Tract

The motility and secretion of the digestive tract are controlled by neural, hormonal, and paracrine mechanisms. The neural controls include short and long autonomic reflexes. In **short (myenteric) reflexes**, stretching or chemical stimulation of the digestive tract acts through the myenteric nerve plexus to stimulate contractions in nearby

regions of the muscularis externa, such as the *peristaltic* contractions of swallowing. **Long (vagovagal) reflexes** act through autonomic nerve fibers that carry sensory signals from the digestive tract to the central nervous system and motor commands back to the digestive tract. Parasympathetic fibers of the vagus nerves are especially important in stimulating digestive motility and secretion by way of these long reflexes.

The digestive tract also produces numerous hormones such as *gastrin* and *secretin*, and paracrine secretions such as *histamine* and *prostaglandins*, that stimulate digestive function. The hormones are secreted into the blood and stimulate relatively distant parts of the digestive tract. The paracrine secretions diffuse through the tissue fluids and stimulate nearby target cells.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What is the term for the serous membrane that suspends the intestines from the abdominal wall?
2. Which physiological process of the digestive system truly moves a nutrient from the outside to the inside of the body?
3. What one type of reaction is the basis of all chemical digestion?
4. Name some nutrients that are absorbed without being digested.

25.2 The Mouth Through Esophagus

Objectives

When you have completed this section, you should be able to

- describe the gross anatomy of the digestive tract from the mouth through the esophagus;
- describe the composition and functions of saliva; and
- describe the neural control of salivation and swallowing.

The Mouth

The mouth is also known as the **oral**, or **buccal** (BUCK-ul), **cavity**. Its functions include ingestion (food intake), taste and other sensory responses to food, chewing, chemical digestion (starch is partially digested in the mouth), swallowing, speech, and respiration. The mouth is enclosed by the cheeks, lips, palate, and tongue (fig. 25.4). Its anterior opening between the lips is the **oral fissure** and its posterior opening into the throat is the **fauces**⁶ (FAW-seez). The mouth is lined with stratified squamous epithelium. This epithelium is keratinized in areas subject to the greatest food abrasion, such as the gums and

⁶fauces = throat

FIGURE 25.4 The Oral Cavity. For a photographic medial view, see figure A.17 (p. 45).

hard palate, and nonkeratinized in other areas such as the floor of the mouth, the soft palate, and the inside of the cheeks and lips.

The Cheeks and Lips

The cheeks and lips retain food and push it between the teeth for chewing. They are essential for articulate speech and for sucking and blowing actions, including suckling by infants. Their fleshiness is due mainly to subcutaneous fat, the buccinator muscles of the cheeks, and the orbicularis oris muscle of the lips. A median fold called the **labial frenulum**⁷ attaches each lip to the gum, between the anterior incisors. The **vestibule** is the space between the cheeks or lips and the teeth—the space where you insert your toothbrush when brushing the outer surfaces of the teeth.

The lips are divided into three areas: (1) The *cutaneous area* is colored like the rest of the face and has hair follicles and sebaceous glands; on the upper lip, this is where a mustache grows. (2) The *red area* (*vermilion*) is the hairless region where the lips meet (where some people apply lipstick). It has unusually tall dermal papillae, which allow blood capillaries and nerve endings to come closer to the epidermal surface. Thus, this area is redder and more sensitive than the cutaneous area. (3) The *labial mucosa* is the inner surface of the lip, facing the gums and teeth.

The Tongue

The tongue, although muscular and bulky, is a remarkably agile and sensitive organ. It manipulates food between the teeth while it avoids being bitten, it can extract food particles from the teeth after a meal, and it is sensitive enough to feel a stray hair in a bite of food. Its surface is covered with nonkeratinized stratified squamous epithelium and exhibits bumps and projections called **lingual papillae**, the site of the taste buds. The types of papillae and sense of taste are discussed in chapter 16, and the general anatomy of the tongue is shown in figure 25.5.

Think About It

How does proprioception protect the tongue from being bitten?

The anterior two-thirds of the tongue, called the **body**, occupies the oral cavity and the posterior one-third, the **root**, occupies the oropharynx. The boundary between them is marked by a V-shaped row of **vallate papillae** and, behind these, a groove called the **terminal sulcus**. The body is attached to the floor of the mouth by a median fold called the **lingual frenulum**.

⁷labi = lip + frenulum = little bridle

FIGURE 25.5 The Tongue. (a) Superior surface. (b) Frontal section. For a sagittal section, see figure A.17 (p. 45).

The muscles of the tongue, which compose most of its mass, are described in chapter 10. The **intrinsic muscles**, contained entirely within the tongue, produce the relatively subtle tongue movements of speech. The **extrinsic muscles**, with origins elsewhere and insertions in the tongue, produce the stronger movements of food manipulation. The extrinsic muscles include the **genioglossus**, **hyoglossus**, **palatoglossus** and **styloglossus** (fig 25.5b; see also fig. 10.8, p. 333). Amid the muscles are serous and mucous **lingual glands**, which secrete a portion of the saliva. The lingual tonsils are contained in the root.

The Palate

The palate, separating the oral cavity from the nasal cavity, makes it possible to breathe while chewing food. Its anterior portion, the **hard (bony) palate**, is supported by the palatine processes of the maxillae and by the smaller palatine bones. It has transverse ridges called *palatine rugae* that aid the tongue in holding and manipulating food. Posterior to this is the **soft palate**, which has a more spongy texture and is composed mainly of skeletal muscle and glandular tissue, but no bone. It has a conical medial projection, the **uvula**,⁸ visible at the rear of the mouth. The uvula helps to retain food in the mouth until one is ready to swallow.

A pair of muscular arches on each side of the oral cavity begin superiorly near the uvula and follow the wall of the cavity to its floor. The anterior one is the

palatoglossal arch and the posterior one is the **palatopharyngeal arch**. The latter arch marks the beginning of the pharynx. The palatine tonsils are located on the wall between the arches.

The Teeth

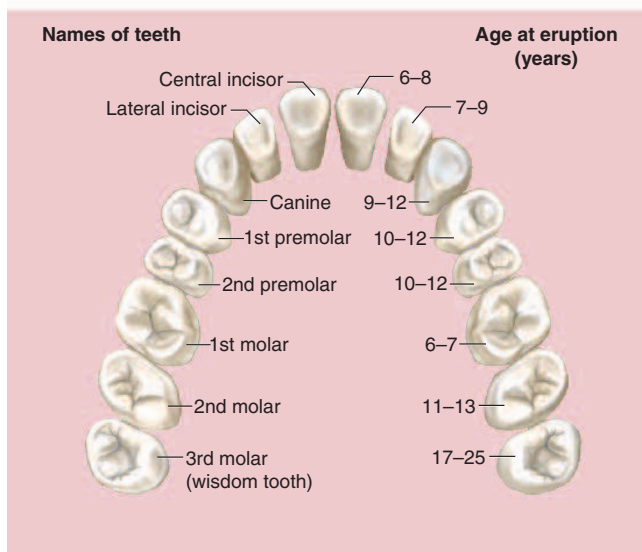

The teeth are collectively called the **dentition**. They serve to *masticate* the food, breaking it into smaller pieces. This not only makes the food easier to swallow, but also exposes more surface area to the action of digestive enzymes and thus speeds up chemical digestion. Adults normally have 16 teeth in the mandible and 16 in the maxilla. From the midline to the rear of each jaw, there are two incisors, a canine, two premolars, and up to three molars (fig. 25.6b). The **incisors** are chisel-like cutting teeth used to bite off a piece of food. The **canines** are more pointed and act to puncture and shred it. They serve as weapons in many mammals but became reduced in the course of human evolution until they now project barely beyond the other teeth. The **premolars** and **molars** have relatively broad surfaces adapted for crushing and grinding.

Each tooth is embedded in a socket called an **alveolus**, forming a joint called a *gomphosis* between the tooth and bone (fig. 25.7). The alveolus is lined by a **periodontal** (PERR-ee-oh-DON-tul) **ligament**, a modified periosteum whose collagen fibers penetrate into the bone on one side and into the tooth on the other. This anchors the tooth firmly in the alveolus but allows for slight movement under the pressure of chewing. The gum, or **gingiva** (JIN-jih-vuh), covers the alveolar bone. Regions of a tooth

⁸uvula = little grape

(a) Deciduous (baby) teeth

(b) Permanent teeth

FIGURE 25.6 The Dentition. Each figure shows only the upper teeth. The ages at eruption are composite ages for the corresponding upper and lower tooth. Generally, the lower (mandibular) teeth erupt somewhat earlier than their upper (maxillary) counterparts.

Which teeth are absent from a 3-year-old child?

are defined by their relationship to the gingiva: the **crown** is the portion above the gum, the **root** is the portion below the gum, embedded in alveolar bone, and the **neck** is the point where the crown, root, and gum meet. The space between the tooth and gum is the **gingival sulcus**. The hygiene of this sulcus is especially important to dental health (see Insight 25.1).

Most of a tooth consists of hard yellowish tissue called **dentin**, covered with **enamel** in the crown and neck and **cementum** in the root. Dentin and cementum are living connective tissues with cells or cell processes

FIGURE 25.7 Structure of a Tooth and Its Alveolus.

Shows typical anatomy of the tooth and periodontal tissues. This particular example is a molar.

Of all the components shown here, which is or are not living tissue(s)?

embedded in a calcified matrix. Cells of the cementum (*cementocytes*) are scattered more or less randomly and occupy tiny cavities similar to the lacunae of bone. Cells of the dentin (*odontoblasts*) line the pulp cavity and have slender processes that travel through tiny parallel tunnels in the dentin. Enamel is not a tissue but a cell-free secretion produced before the tooth erupts above the gum. Damaged dentin and cementum can regenerate, but damaged enamel cannot—it must be artificially repaired.

Internally, a tooth has a dilated **pulp cavity** in the crown and a narrow **root canal** in the lower root. These spaces are occupied by **pulp**—a mass of loose connective tissue, blood and lymphatic vessels, and nerves. These nerves and vessels enter the tooth through a pore, the **apical foramen**, at the basal end of each root canal.

The meeting of the teeth when the mouth closes is called **occlusion** (ah-CLUE-zhun), and the surfaces where they meet are called the **occlusal** (ah-CLUE-zul) **surfaces**. The occlusal surface of a premolar has two rounded bumps called **cusps**; thus the premolars are also known as **bicuspid**s. The molars have four to five cusps. Cusps of

INSIGHT 25.1 Clinical Application

Tooth and Gum Disease

The human mouth is home to more than 700 species of microorganisms, especially bacteria. Bacteria and sugars form a sticky residue on the teeth called *plaque*. If plaque is not thoroughly removed by brushing and flossing, bacteria multiply, metabolize the sugars, and release lactic acid and other acids. These acids dissolve the minerals of enamel and dentin, and the bacteria enzymatically digest the collagen and other organic components. The eroded “cavities” of the tooth are known as *dental caries*.⁹ If not repaired, caries may fully penetrate the dentin and spread to the pulp cavity. This requires either extraction of the tooth or *root canal therapy*, in which the pulp is removed and replaced with inert material.

When plaque calcifies on the tooth surface, it is called *calculus (tartar)*. Calculus in the gingival sulcus wedges the tooth and gum apart and allows bacterial invasion of the sulcus. This leads to *gingivitis*, or gum inflammation. Nearly everyone has gingivitis at some time. In some cases, bacteria spread from the sulcus into the alveolar bone and begin to dissolve it, producing *periodontal disease*. About 86% of people over age 70 have periodontal disease and many suffer tooth loss as a result. This accounts for 80% to 90% of adult tooth loss.

the upper and lower premolars and molars mesh when the jaws are closed and slide over each other as the jaw makes lateral chewing motions. This grinds and tears food more effectively than if the occlusal surfaces were flat.

Teeth develop beneath the gums and **erupt** (emerge) in predictable order. Twenty **deciduous teeth** (*milk teeth* or *baby teeth*) erupt from the ages of 6 to 30 months, beginning with the incisors (fig. 25.6a). Between 6 and 25 years of age, these are replaced by the 32 **permanent teeth**. As a permanent tooth grows below a deciduous tooth (fig. 25.8), the root of the deciduous tooth dissolves and leaves little more than the crown by the time it falls out. The third molars (*wisdom teeth*) erupt around ages 17 to 25, if at all. Over the course of human evolution, the face became flatter and the jaws shorter, leaving little room for the third molars. Thus, they often remain below the gum and become *impacted*—so crowded against neighboring teeth and bone that they cannot erupt.

Mastication

Mastication (chewing) breaks food into pieces small enough to be swallowed and exposes more surface to the action of digestive enzymes. It is the first step in mechanical digestion. Mastication requires little thought because food stimulates oral receptors that trigger an involuntary chewing reflex. The tongue, buccinator, and orbicularis oris muscles manipulate food and push it between the

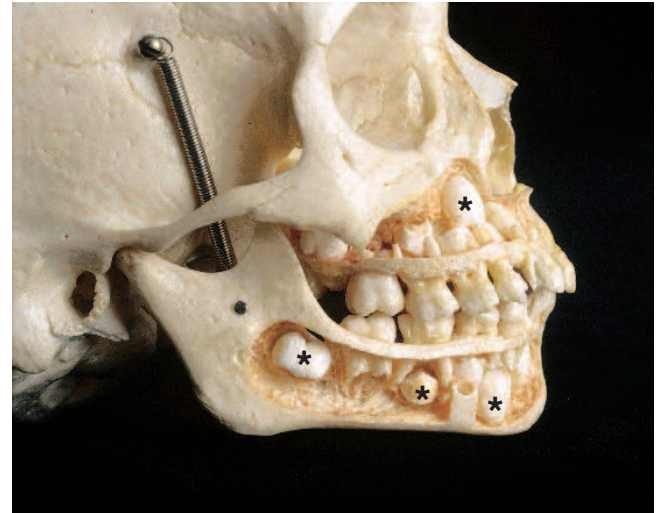

FIGURE 25.8 Permanent and Deciduous Teeth in a Child's Skull. This dissection shows erupted deciduous teeth and, deep to them and marked with asterisks, the permanent teeth waiting to erupt.

teeth. The masseter and temporalis muscles produce the up-and-down crushing action of the teeth, and the lateral and medial pterygoid muscles and masseters produce side-to-side grinding action.

Saliva and the Salivary Glands

Saliva moistens the mouth, digests a little starch and fat, cleanses the teeth, inhibits bacterial growth, dissolves molecules so they can stimulate the taste buds, and moistens food and binds particles together to aid in swallowing. It is a hypotonic solution of 97.0% to 99.5% water and the following solutes:

- **salivary amylase**, an enzyme that begins starch digestion in the mouth;
- **lingual lipase**, an enzyme that is activated by stomach acid and digests fat after the food is swallowed;
- **mucus**, which binds and lubricates the food mass and aids in swallowing;
- **lysozyme**, an enzyme that kills bacteria;
- **immunoglobulin A (IgA)**, an antibody that inhibits bacterial growth; and
- **electrolytes**, including sodium, potassium, chloride, phosphate, and bicarbonate salts.

Saliva has a pH of 6.8 to 7.0. There are striking differences in pH from one region of the digestive tract to another, with a powerful influence on the activity and deactivation of digestive enzymes. For example, salivary amylase works well at a neutral pH and is deactivated by the low pH of the stomach, whereas lingual lipase does not act in the mouth at all but is activated by the acidity

⁹*caries* = rotteness

of the stomach. Thus, saliva begins to digest starch before the food is swallowed and fat after it is swallowed.

The Salivary Glands

There are two kinds of salivary glands, intrinsic and extrinsic. The **intrinsic salivary glands** are an indefinite number of small glands dispersed amid the other oral tissues. They include *lingual glands* in the tongue, *labial glands* on the inside of the lips, and *buccal glands* on the inside of the cheeks. They secrete saliva at a fairly constant rate whether we are eating or not, but in relatively small amounts. This saliva contains lingual lipase and lysozyme and serves to moisten the mouth and inhibit bacterial growth.

The **extrinsic salivary glands** are three pairs of larger, more discrete organs located outside of the oral mucosa. They communicate with the oral cavity by way of ducts (fig. 25.9).

1. The **parotid**¹⁰ **gland** is located just beneath the skin anterior to the earlobe. Its duct passes superficially

¹⁰par = next to + ot = ear

FIGURE 25.9 The Extrinsic Salivary Glands. Part of the mandible has been removed to expose the sublingual gland medial to it.

over the masseter, pierces the buccinator, and opens into the mouth opposite the second upper molar tooth. *Mumps* is an inflammation and swelling of the parotid gland caused by a virus.

2. The **submandibular gland** is located halfway along the body of the mandible, medial to its margin, just deep to the mylohyoid muscle. Its duct empties into the mouth at a papilla on the side of the lingual frenulum, near the lower central incisors.
3. The **sublingual gland** is located in the floor of the mouth. It has multiple ducts that empty into the mouth posterior to the papilla of the submandibular duct.

These are all compound tubuloacinar glands with a treelike arrangement of branching ducts ending in acini (see pp. 175–176). Some acini have only mucous cells, some have only serous cells, and some have a mixture of both (fig. 25.10). Mucous cells secrete salivary mucus, and serous cells secrete a thinner fluid rich in amylase and electrolytes.

Salivation

The extrinsic salivary glands secrete about 1.0 to 1.5 L of saliva per day. Cells of the acini filter water and electrolytes from the blood capillaries and add amylase, mucin, and lysozyme to it. The ducts slightly modify its electrolyte composition.

Food stimulates tactile, pressure, and taste receptors in the mouth, which transmit signals to a group of **salivatory nuclei** in the medulla oblongata and pons. These nuclei also receive input from higher brain centers, so even the odor, sight, or thought of food stimulates salivation. Irritation of the stomach and esophagus by spicy foods, stomach acid, or toxins also stimulates salivation, perhaps serving to dilute and rinse away the irritants.

The salivatory nuclei send signals to the glands by way of autonomic fibers in the facial and glossopharyngeal nerves. In response to such stimuli as the aroma, taste, and texture of food, the parasympathetic nervous system stimulates the glands to produce abundant, thin saliva rich in enzymes. Sympathetic stimulation, by contrast, briefly enhances salivation but its primary effect is to produce less abundant, thicker saliva with more mucus. This is why the mouth may feel sticky or dry under conditions of stress. Sympathetic stimulation constricts the blood vessels of the salivary glands. Since saliva begins as a filtrate from the blood capillaries, this vasoconstriction reduces saliva output. Dehydration similarly reduces salivation by reducing capillary filtration.

Salivary amylase begins to digest starch as the food is chewed, while the mucus in the saliva binds food particles into a soft, slippery, easily swallowed mass

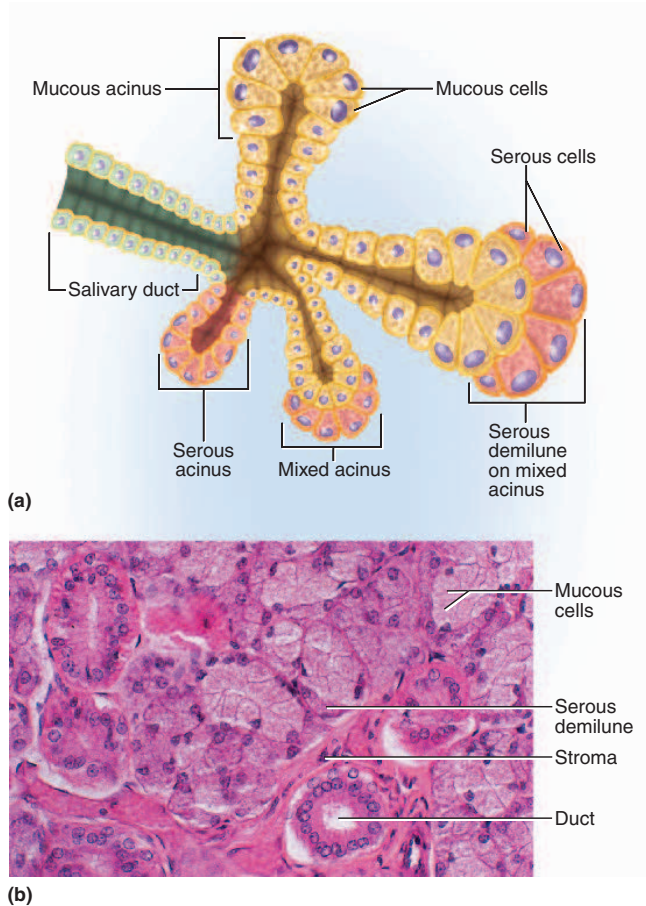

FIGURE 25.10 Microscopic Anatomy of the Salivary Glands. (a) Duct and acini of a generalized salivary gland with a mixture of mucous and serous cells. Serous cells often form crescent-shaped caps called serous demilunes over the ends of mucous acini. (b) Histology of the sublingual salivary gland.

called a **bolus**. Without mucus, one must drink a much larger volume of fluid to swallow food.

The Pharynx

The pharynx, described in chapter 22, is a muscular funnel that connects the oral cavity to the esophagus, as well as connecting the nasal cavity to the larynx; thus, it is a point where the digestive and respiratory tracts intersect. It has a deep layer of longitudinally oriented skeletal muscle and a superficial layer of circular skeletal muscle. The circular muscle is divided into superior, middle, and inferior **pharyngeal constrictors**, which force food downward during swallowing. When food is not being swallowed, the inferior constrictor remains contracted to exclude air from the esophagus. This constriction is regarded as the **upper esophageal sphincter**, although it is not an anatomical feature of the esophagus. It disappears

at the time of death when the muscle relaxes. Thus it is regarded as a *physiological sphincter* rather than a constant anatomical structure.

The Esophagus

The **esophagus** is a straight muscular tube 25 to 30 cm long (see figs. 25.1 and 25.2). It begins at a level between vertebra C6 and the cricoid cartilage, inferior to the larynx and posterior to the trachea. After passing downward through the mediastinum, the esophagus penetrates the diaphragm at an opening called the *esophageal hiatus*, continues another 3 to 4 cm, and meets the stomach at the level of vertebra T7. Its opening into the stomach is called the **cardiac orifice** (named for its proximity to the heart). Food pauses briefly at this point before entering the stomach because of a constriction called the **lower esophageal sphincter (LES)**. The LES prevents stomach contents from regurgitating into the esophagus, thus protecting the esophageal mucosa from the erosive effect of stomach acid. “Heartburn” has nothing to do with the heart, but is the burning sensation produced by acid reflux into the esophagus.

The wall of the esophagus is organized into the tissue layers described earlier, with some regional specializations. The mucosa has a nonkeratinized stratified squamous epithelium. The submucosa contains **esophageal glands** that secrete lubricating mucus into the lumen. When the esophagus is empty, the mucosa and submucosa are deeply folded into longitudinal ridges, giving the lumen a starlike shape in cross section.

The muscularis externa is composed of skeletal muscle in the upper one-third of the esophagus, a mixture of skeletal and smooth muscle in the middle one-third, and only smooth muscle in the lower one-third.

Most of the esophagus is in the mediastinum. Here, it is covered with a connective tissue adventitia, which merges into the adventitia of the trachea and thoracic aorta. The short segment below the diaphragm is partially covered by a serosa.

Swallowing

Swallowing, or **deglutition** (DEE-glu-TISH-un), is a complex action involving over 22 muscles in the mouth, pharynx, and esophagus, coordinated by the **swallowing center**, a pair of nuclei in the medulla oblongata. This center communicates with muscles of the pharynx and esophagus by way of the trigeminal, facial, glossopharyngeal, and hypoglossal nerves (cranial nerves V, VII, IX, and XII).

Swallowing occurs in two phases (fig. 25.11). The **buccal phase** is under voluntary control. The tongue collects food, presses it against the palate to form a bolus, and pushes it posteriorly. The food accumulates in the oropharynx, in front of the “blade” of the epiglottis. When

FIGURE 25.11 Swallowing. (a) Stages in the swallowing (deglutition) process. (b) X-ray of the esophagus showing a peristaltic constriction above a bolus of ingested material.

What actions prevent the pharynx from forcing food back into the mouth or nose?

the bolus reaches a critical size, the epiglottis tips posteriorly and the food bolus slides around it through a space on each side of the glottis (laryngeal opening). As the bolus enters the laryngopharynx, it stimulates tactile receptors and activates the next phase. The **pharyngo-esophageal phase** is involuntary. Three actions block food and drink from reentering the mouth or entering the nasal cavity or larynx: (1) the root of the tongue blocks the oral cavity, (2) the soft palate rises and blocks the nasopharynx, and (3) the infrahyoid muscles pull the larynx up to meet the epiglottis while the vestibular folds adduct to close the airway. The food bolus is driven downward by constriction of the upper, then the middle, and finally the lower pharyngeal constrictors. As the bolus enters the esophagus, it stretches it and triggers **peristalsis**, a wave of muscular contraction that pushes the bolus ahead of it (fig. 25.11b). This esophageal motility is an entirely involuntary reflex even though the upper esophageal muscle is of the skeletal type.

Peristalsis is moderated partly by a short reflex through the myenteric nerve plexus. The bolus stimulates stretch receptors that feed into the nerve plexus, which transmits signals to the muscularis externa behind and ahead of the bolus. The circular muscle behind the bolus constricts and pushes it downward. Ahead of the bolus, the circular muscle relaxes while the longitudinal muscle contracts. The latter action pulls the wall of the esophagus slightly upward, which makes the esophagus a little shorter and wider and able to receive the descending food.

When we are standing or sitting upright, most food and liquid drop through the esophagus by gravity faster than the peristaltic wave can keep up with it. Peristalsis, however, propels more solid food pieces and ensures that you can swallow regardless of the body's position—even standing on your head! Liquid normally reaches the stomach in 1 to 2 seconds and a food bolus in 4 to 8 seconds. As a bolus reaches the lower end of the esophagus, the lower esophageal sphincter relaxes to let it pass into the stomach.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- List as many functions of the tongue as you can.
- Imagine a line from the mandibular bone to the root canal of a tooth. Name the tissues, in order, through which this line would pass.
- What is the difference in function and location between intrinsic and extrinsic salivary glands? Name the extrinsic salivary glands and describe their locations.
- Describe the muscularis externa of the esophagus and its action in peristalsis.
- Describe the mechanisms that prevent food from entering the nasal cavity and larynx during swallowing.

25.3 The Stomach

Objectives

When you have completed this section, you should be able to

- describe the gross and microscopic anatomy of the stomach;
- state the function of each type of epithelial cell in the gastric mucosa;
- identify the secretions of the stomach and state their functions;
- explain how the stomach produces hydrochloric acid and pepsin;
- describe the contractile responses of the stomach to food; and
- describe the three phases of gastric function and how gastric activity is activated and inhibited.

The stomach is a muscular sac in the upper left abdominal cavity immediately inferior to the diaphragm. It functions primarily as a food storage organ, with an internal volume of about 50 mL when empty and 1.0 to 1.5 L after a typical meal. When extremely full, it may hold up to 4 L and extend nearly as far as the pelvis.

Well into the nineteenth century, authorities regarded the stomach as essentially a grinding chamber, fermentation vat, or cooking pot. Some even attributed digestion to a supernatural spirit in the stomach. We now know that it mechanically breaks up food particles, liquefies the food, and begins the chemical digestion of proteins and fat. This produces a soupy or pasty mixture of semidigested food called **chyme**¹¹ (pronounced “kime”). Most digestion occurs after the chyme passes on to the small intestine.

Gross Anatomy

The stomach is J-shaped (fig. 25.12), relatively vertical in tall people and more nearly horizontal in short people. The **lesser curvature** of the stomach extends the short distance (about 10 cm) from esophagus to duodenum along the medial to superior aspect, facing the liver; the **greater curvature** extends the longer distance (about 40 cm) from esophagus to duodenum on the lateral to inferior aspect.

The stomach is divided into four regions: (1) The **cardiac region (cardia)** is a small area within about 3 cm of the cardiac orifice. (2) The **fundic region (fundus)** is the dome-shaped portion superior to the esophageal attachment. (3) The **body (corpus)** makes up the greatest part of the stomach distal to the cardiac orifice. (4) The **pyloric region** is a slightly narrower pouch at the inferior end; it

¹¹chyme = juice

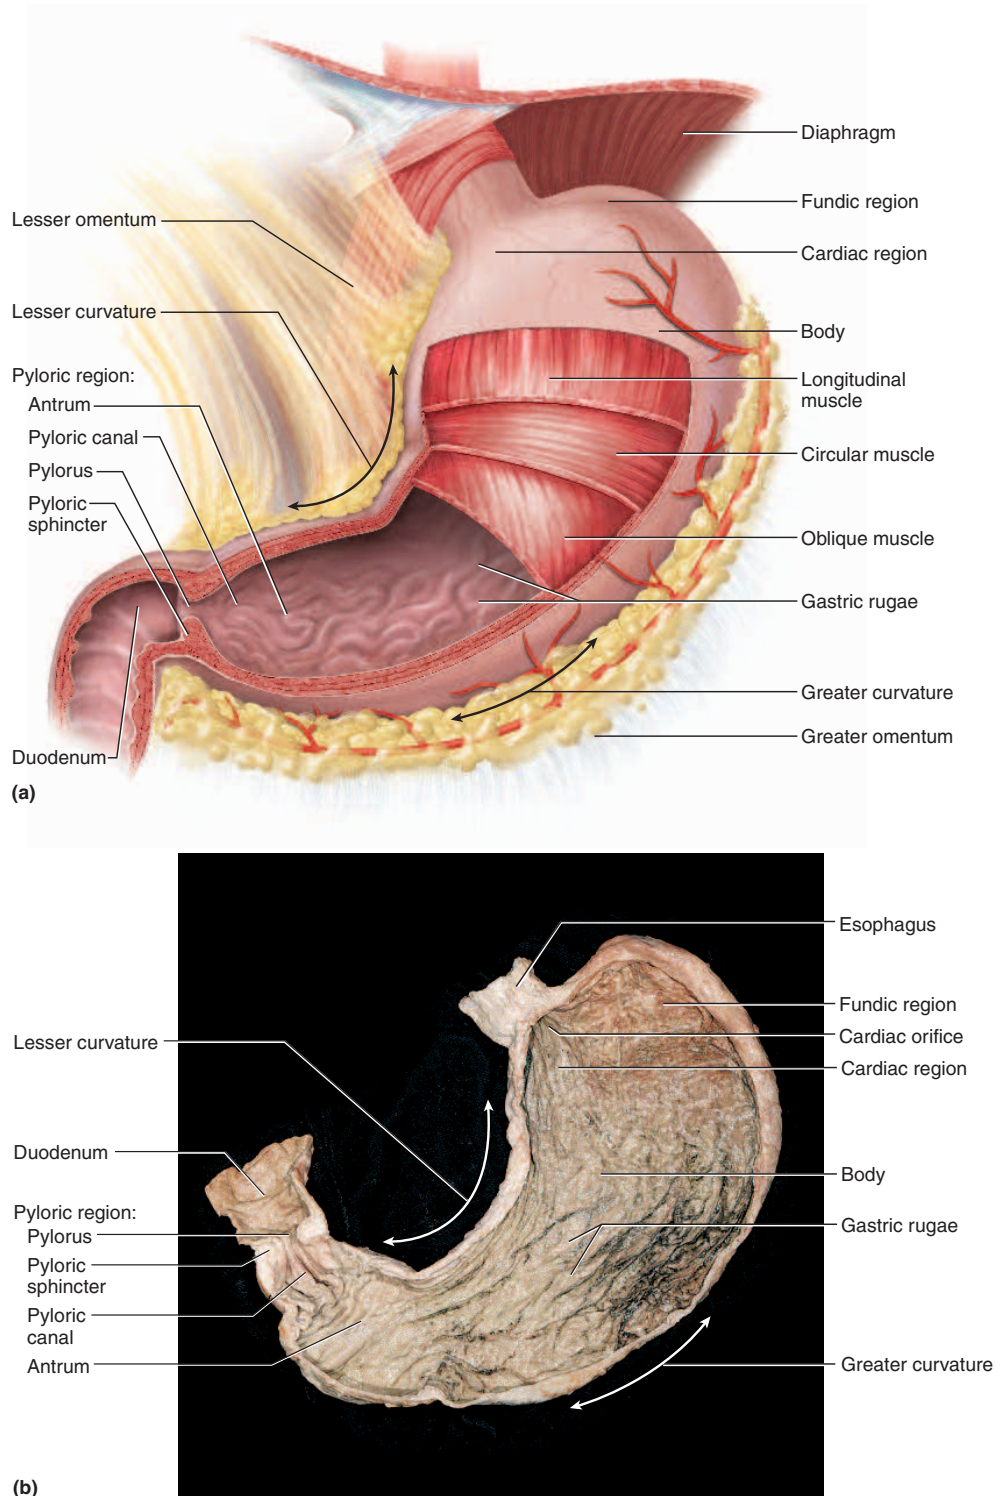

FIGURE 25.12 The Stomach. (a) Gross anatomy. (b) Photograph of the internal surface.

● How does the muscularis externa of the stomach differ from that of the esophagus?

is subdivided into a funnel-like **antrum**¹² and a narrower **pyloric canal**. The latter terminates at the **pylorus**,¹³ a narrow passage into the duodenum. The pylorus is surrounded by a thick ring of smooth muscle, the **pyloric (gastroduodenal) sphincter**, which regulates the passage of chyme into the duodenum.

Innervation and Circulation

The stomach receives parasympathetic nerve fibers from the vagus nerves and sympathetic fibers from the celiac ganglia (see p. 570). It is supplied with blood by branches of the celiac trunk (see p. 792). All blood drained from the stomach and intestines enters the hepatic portal circulation and filters through the liver before returning to the heart.

Microscopic Anatomy

The stomach wall has tissue layers similar to those of the esophagus, with some variations. The mucosa is covered with a simple columnar glandular epithelium (fig. 25.13). The apical regions of its surface cells are filled with mucin, which swells with water and becomes mucus after it is secreted. The mucosa and submucosa are flat and smooth when the stomach is full, but as it empties, these layers form conspicuous longitudinal wrinkles called **gastric rugae**¹⁴ (ROO-gee). The lamina propria is almost entirely occupied by tubular glands, to be described shortly. The muscularis externa has three layers, rather than two: an outer longitudinal, middle circular, and inner oblique layers (fig. 25.12).

Think About It

Contrast the epithelium of the esophagus with that of the stomach. Why is each epithelial type best suited to the function of its respective organ?

The gastric mucosa is pocked with depressions called **gastric pits** lined with the same columnar epithelium as the surface (fig. 25.13). Two or three tubular glands open into the bottom of each gastric pit and span the rest of the lamina propria. In the cardiac and pyloric regions, they are called **cardiac glands** and **pyloric glands**, respectively. In the rest of the stomach, they are called **gastric glands**. These three glands differ in cellular composition, but collectively have the following cell types:

- **Mucous cells**, which secrete mucus, predominate in the cardiac and pyloric glands. In gastric glands, they are called *mucous neck cells* and are concentrated in the narrow *neck* of the gland, where it opens into the gastric pit.

- **Regenerative (stem) cells**, found in the base of the pit and neck of the gland, divide rapidly and produce a continual supply of new cells. Newly generated cells migrate upward to the gastric surface as well as downward into the glands to replace cells that die.
- **Parietal cells**, found mostly in the upper half of the gland, secrete *hydrochloric acid*, *intrinsic factor*, and a hunger hormone called *ghrelin* (see p. 1014). They are found mostly in the gastric glands, but a few occur in the pyloric glands.
- **Chief cells**, so named because they are the most numerous, secrete the enzymes *gastric lipase* and *pepsinogen*. They dominate the lower half of the gastric glands but are absent from cardiac and pyloric glands.
- **Enteroendocrine cells**, concentrated especially in the lower end of a gland, secrete hormones and paracrine messengers that regulate digestion. They occur in all regions of the stomach, but are most abundant in the gastric and pyloric glands. There are at least eight kinds of enteroendocrine cells in the stomach, each of which produces a different chemical messenger.

In general, the cardiac and pyloric glands secrete mainly mucus; acid and enzyme secretion occur predominantly in the gastric glands; and hormones are secreted throughout the stomach.

Gastric Secretions

The gastric glands produce 2 to 3 L of **gastric juice** per day, composed mainly of water, hydrochloric acid, and pepsin.

Hydrochloric Acid

Gastric juice has a high concentration of hydrochloric acid (HCl) and a pH as low as 0.8. Such concentrated acid could cause a serious chemical burn to the skin. How, then, does the stomach produce and tolerate such acidity?

The reactions that produce HCl (fig. 25.14) may seem familiar by now because they have been discussed in previous chapters—most recently in connection with renal excretion of H⁺ in chapter 24. Parietal cells contain carbonic anhydrase (CAH), which catalyzes the first step in the following reaction:

Parietal cells pump the H⁺ from this reaction into the lumen of a gastric gland by an active transport protein similar to the Na⁺–K⁺ pump, called **H⁺–K⁺ ATPase**. This is an antiport that uses the energy of ATP to pump H⁺ out and K⁺ into the cell. HCl secretion does not affect the pH within the parietal cell because H⁺ is pumped out as fast

¹²antrum = cavity

¹³pylorus = gatekeeper

¹⁴rugae = folds, creases

FIGURE 25.13 Microscopic Anatomy of the Stomach Wall. (a) A block of tissue showing all layers from the mucosa (top) to the serosa (bottom). (b) A pyloric gland from the inferior end of the stomach. Note the absence of chief cells and relatively few parietal cells. (c) A gastric gland, the most widespread type in the stomach. (d) The opening of a gastric pit into the stomach, surrounded by the rounded apical surfaces of the columnar epithelial cells of the mucosa (SEM).

FIGURE 25.14 The Mode of Hydrochloric Acid Secretion. The parietal cell combines water with CO_2 from the blood to form carbonic acid (bottom line of figure). Carbonic acid breaks down into bicarbonate ion (HCO_3^-) and hydrogen ion (H^+). HCO_3^- returns to the blood. In exchange, Cl^- enters the lumen with H^+ and the two form hydrochloric acid.

◀ What role does active transport play in this process?

as it is generated. The bicarbonate ions (HCO_3^-) are exchanged for chloride ions (Cl^-) from the blood plasma—the same *chloride shift* process that occurs in the renal tubules and red blood cells—and the Cl^- is pumped into the lumen of the gastric gland to join the H^+ .

Thus HCl accumulates in the stomach while bicarbonate ions accumulate in the blood. Because of the bicarbonate, blood leaving the stomach has a higher pH when digestion is occurring than when the stomach is empty. This high-pH blood is called the *alkaline tide*.

Stomach acid has several functions: (1) It activates the enzymes pepsin and lingual lipase, as discussed shortly. (2) It breaks up connective tissues and plant cell walls, helping to liquefy food and form chyme. (3) It converts ingested ferric ions (Fe^{3+}) to ferrous ions (Fe^{2+}), a form of iron that can be absorbed and used for hemoglobin synthesis. (4) It contributes to nonspecific disease resistance by destroying most ingested pathogens.

Pepsin

Several digestive enzymes are secreted as inactive proteins called **zymogens** and then converted to active enzymes by the removal of some of their amino acids. In the stomach, chief cells secrete a zymogen called **pepsinogen**. Hydrochloric acid removes some of its amino acids and converts it to **pepsin**. Since pepsin digests protein, and pepsinogen itself is a protein, pepsin has an *autocatalytic* effect—as some pepsin is formed, it converts pepsinogen into more pepsin (fig. 25.15). The ultimate function of pepsin, however, is to digest dietary proteins

to shorter peptide chains, which then pass to the small intestine, where their digestion is completed.

Gastric Lipase

The chief cells also secrete **gastric lipase**. This enzyme and lingual lipase, which plays a minor role, digest 10% to 15% of the dietary fat in the stomach. The remainder is digested in the small intestine.

Intrinsic Factor

Parietal cells also secrete a glycoprotein called **intrinsic factor** that is essential to the absorption of vitamin B_{12} by the small intestine. Intrinsic factor binds vitamin B_{12} and the intestinal cells then absorb this complex by receptor-mediated endocytosis. Without vitamin B_{12} , hemoglobin cannot be synthesized and pernicious anemia develops (see p. 694). The secretion of intrinsic factor is the only indispensable function of the stomach. Digestion can continue following removal of the stomach (*gastrectomy*), but a person must then take vitamin B_{12} by injection, or vitamin B_{12} and intrinsic factor orally. As we age, the gastric mucosa atrophies, less intrinsic factor is secreted, and the risk of pernicious anemia rises.

Chemical Messengers

The gastric and pyloric glands have various kinds of enteroendocrine cells that collectively produce as many as 20 chemical messengers. Most of these are hormones—they travel in the bloodstream and stimulate distant target cells. Some also behave as paracrine secretions, diffusing a short distance away and stimulating other cells in the gastric mucosa. Several of them are peptides produced in both the digestive tract and the central nervous system; thus they are called **gut-brain peptides**. These include substance P, vasoactive intestinal peptide (VIP), secretin, gastric inhibitory peptide (GIP), cholecystokinin, and neuropeptide Y (NPY). The functions of some of these peptides in digestion will be explained in the following sections, and their roles in appetite regulation are discussed in chapter 26.

Several of the gastric secretions are summarized in table 25.1. Some of the functions listed there are explained later in the chapter.

Gastric Motility

As you begin to swallow, the swallowing center of the medulla oblongata signals the stomach to relax, thus preparing it to receive food. The arriving food stretches the stomach and activates the *receptive-relaxation response* of smooth muscle: the stomach briefly resists stretching but then relaxes and is able to accommodate more food.

Soon, the stomach shows a rhythm of peristaltic contractions. These are governed by pacemaker cells in the longitudinal layer of the muscularis externa of the greater

FIGURE 25.15 The Production and Action of Pepsin. The chief cells secrete pepsinogen and the parietal cells secrete HCl. HCl removes some of the amino acids from pepsinogen and converts it to pepsin. Pepsin catalyzes the production of more pepsin (autocatalytic effect), as well as partially digesting dietary protein.

TABLE 25.1 Major Secretions of the Gastric Glands		
Secretory Cells	Secretion	Function
Mucous neck cells	Mucus	Protects mucosa from HCl and enzymes
Parietal cells	Hydrochloric acid	Activates pepsin and lingual lipase; helps liquefy food; reduces dietary iron to usable form (Fe^{2+}); destroys ingested pathogens
	Intrinsic factor	Enables small intestine to absorb vitamin B_{12}
Chief cells	Pepsinogen	Converted to pepsin, which digests protein
	Gastric lipase	Digests fat
Enteroendocrine cells	Gastrin	Stimulates gastric glands to secrete HCl and enzymes; stimulates intestinal motility; relaxes ileocecal valve
	Serotonin	Stimulates gastric motility
	Histamine	Stimulates HCl secretion
	Somatostatin	Inhibits gastric secretion and motility; delays emptying of stomach; inhibits secretion by pancreas; inhibits gallbladder contraction and bile secretion; reduces blood circulation and nutrient absorption in small intestine

curvature. About every 20 seconds, a gentle ripple begins in the fundus and becomes stronger as it progresses toward the pyloric region, where the muscularis externa is thicker. After 30 minutes or so, these contractions become quite strong. They churn the food, mix it with gastric juice, and promote its physical breakup and chemical digestion.

The antrum holds about 30 mL of chyme. As a peristaltic wave passes down the antrum, it squirts about 3 mL of chyme into the duodenum at a time. When the

wave reaches the pyloric sphincter, it squeezes the sphincter shut. Chyme that does not get through this time is turned back into the antrum and body of the stomach for further digestion. Allowing only small amounts into the duodenum at a time enables the duodenum to neutralize the stomach acid and digest nutrients little by little. If the duodenum becomes overfilled, it inhibits gastric motility and postpones receiving more chyme; the mechanism for this is discussed later. A typical meal is emptied from the stomach in about 4 hours, but it takes less time

if the meal is more liquid and as long as 6 hours if the meal is high in fat.

Vomiting

Vomiting is the forceful ejection of stomach and intestinal contents (chyme) from the mouth. It involves multiple muscular actions integrated by the **emetic**¹⁵ center of the medulla oblongata. Vomiting is commonly induced by overstretching of the stomach or duodenum; chemical irritants such as alcohol and bacterial toxins; visceral trauma (especially to the pelvic organs); intense pain; or psychological and sensory stimuli that activate the emetic center (thus vomiting can be induced by repugnant sights, smells, and thoughts).

Vomiting is usually preceded by nausea and retching. In **retching**, thoracic expansion and abdominal contraction create a pressure difference that dilates the esophagus. The lower esophageal sphincter relaxes while the stomach and duodenum contract spasmodically. Chyme enters the esophagus but then drops back into the stomach as the muscles relax; it does not get past the upper esophageal sphincter. Retching is often accompanied by tachycardia, profuse salivation, and sweating. Vomiting occurs when abdominal contraction and rising thoracic pressure force the upper esophageal sphincter open, the esophagus and body of the stomach relax, and chyme is driven out of the stomach and mouth by strong abdominal contraction combined with reverse peristalsis of the gastric antrum and the duodenum. **Projectile vomiting** is sudden vomiting with no prior nausea or retching. It may be caused by neurological lesions but is also common in infants after feeding.

Chronic vomiting can cause dangerous fluid, electrolyte, and acid–base imbalances. In cases of frequent vomiting, as in the eating disorder *bulimia*, the tooth enamel becomes severely eroded by the hydrochloric acid in the chyme. Aspiration (inhalation) of this acid is very destructive to the respiratory tract. Many have died from aspiration of vomit when they were unconscious or semi-conscious. This is the reason that surgical anesthesia, which may induce nausea, must be preceded by fasting until the stomach and small intestine are empty.

Digestion and Absorption

Salivary and gastric enzymes partially digest protein and lesser amounts of starch and fat in the stomach, but most digestion and nearly all nutrient absorption occur after the chyme passes into the small intestine. The stomach does not absorb any significant amount of nutrients but does absorb aspirin and some lipid-soluble drugs. Alcohol is absorbed mainly by the small intestine, so its intoxicating effect depends partly on how rapidly the stomach is emptied.

¹⁵emet = vomiting

Protection of the Stomach

You may wonder why the stomach does not digest itself. We can digest tripe (animal stomachs) as readily as any other meat. The living stomach, however, is protected in three ways from the harsh acidic and enzymatic environment it creates:

1. **Mucous coat.** The thick, highly alkaline mucus resists the action of acid and enzymes.
2. **Tight junctions.** The epithelial cells are joined by tight junctions that prevent gastric juice from seeping between them and digesting the connective tissue of the lamina propria or beyond.
3. **Epithelial cell replacement.** In spite of these other protections, the stomach's epithelial cells live only 3 to 6 days and are then sloughed off into the chyme and digested with the food. They are replaced just as rapidly, however, by cell division in the gastric pits.

The breakdown of these protective mechanisms can result in inflammation and peptic ulcer (see Insight 25.2).

Regulation of Gastric Function

The nervous and endocrine systems collaborate to increase gastric secretion and motility when food is eaten and to suppress them as the stomach empties. Gastric activity is divided into three stages called the cephalic, gastric, and intestinal phases, based on whether the stomach is being controlled by the brain, by itself, or by the small intestine, respectively (fig. 25.17). These phases overlap and all three can occur simultaneously.

The Cephalic Phase

The **cephalic phase** is the stage in which the stomach responds to the mere sight, smell, taste, or thought of food. These sensory and mental inputs converge on the hypothalamus, which relays signals to the medulla oblongata. Vagus nerve fibers from the medulla stimulate the enteric nervous system of the stomach which, in turn, stimulates gastric secretion.

The Gastric Phase

The **gastric phase** is a period in which swallowed food and semidigested protein (peptides and amino acids) activate gastric activity. About two-thirds of gastric secretion occurs during this phase. Ingested food stimulates gastric activity in two ways: by stretching the stomach and by raising the pH of its contents. Stretch activates two reflexes: a short reflex mediated through the myenteric nerve plexus, and a long reflex mediated through the vagus nerves and brainstem.

Gastric secretion is stimulated chiefly by three chemicals: acetylcholine (ACh), histamine, and gastrin. ACh is secreted by parasympathetic nerve fibers of both the short

and long reflex pathways. Histamine is a paracrine secretion from enteroendocrine cells in the gastric glands. **Gastrin** is a hormone produced by enteroendocrine **G cells** in the pyloric glands.

All three of these stimulate parietal cells to secrete hydrochloric acid and intrinsic factor. The chief cells secrete pepsinogen in response to gastrin and especially ACh, and ACh also stimulates mucus secretion.

As dietary protein is digested, it breaks down into smaller peptides and amino acids, which directly stimulate the G cells to secrete even more gastrin—a positive feedback loop that accelerates protein digestion (fig. 25.18). Small peptides also buffer stomach acid so the pH does not fall excessively low. But as digestion continues and

these peptides are emptied from the stomach, the pH drops lower and lower. Below pH of 2, stomach acid inhibits the parietal cells and G cells—a negative feedback loop that winds down the gastric phase as the need for pepsin and HCl declines.

The Intestinal Phase

The **intestinal phase** is a stage in which the duodenum responds to arriving chyme and moderates gastric activity through hormones and nervous reflexes. The duodenum initially enhances gastric secretion, but soon inhibits it. Stretching of the duodenum accentuates vagovagal reflexes that stimulate the stomach, and peptides

INSIGHT 25.2 Clinical Application

Peptic Ulcer

Inflammation of the stomach, called *gastritis*, can lead to a *peptic ulcer* as pepsin and hydrochloric acid erode the stomach wall (fig. 25.16). Peptic ulcers occur even more commonly in the duodenum and occasionally in the esophagus. If untreated, they can perforate the organ and cause fatal hemorrhaging or peritonitis. Most such fatalities occur in people over age 65.

There is no evidence to support the popular belief that peptic ulcers result from psychological stress. Hypersecretion of acid and pepsin is sometimes involved, but even normal secretion can cause ulceration if the mucosal defense is compromised by other causes. Most ulcers involve an acid-resistant bacterium, *Helicobacter pylori*, that invades the mucosa of the stomach and duodenum and opens the way to

chemical damage to the tissue. Other risk factors include smoking and the use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs suppress the synthesis of prostaglandins, which normally stimulate the secretion of protective mucus and acid-neutralizing bicarbonate. Aspirin itself is an acid that directly irritates the gastric mucosa.

At one time, the most widely prescribed drug in the United States was cimetidine (Tagamet), which was designed to treat peptic ulcers by reducing acid secretion. Histamine stimulates acid secretion by binding to sites on the parietal cells called *H₂ receptors*; cimetidine, an *H₂ blocker*, prevents this binding. Lately, however, ulcers have been treated more successfully with antibiotics against *Helicobacter* combined with bismuth suspensions such as Pepto-Bismol. This is a much shorter and less expensive course of treatment and permanently cures about 90% of peptic ulcers, as compared with a cure rate of only 20% to 30% for H₂ blockers.

FIGURE 25.18 Feedback Control of Gastric Secretion. This positive feedback loop declines and stops as the stomach is emptied and the pH drops.

and amino acids in the chyme stimulate G cells of the duodenum to secrete more gastrin, which further stimulates the stomach.

Soon, however, the acid and semidigested fats in the duodenum trigger the **enterogastric reflex**—the duodenum sends inhibitory signals to the stomach by way of the enteric nervous system, and sends signals to the medulla that (1) inhibit the vagal nuclei, thus reducing vagal stimulation of the stomach, and (2) stimulate sympathetic neurons, which send inhibitory signals to the stomach. Chyme also stimulates duodenal enteroendocrine cells to release **secretin** and **cholecystokinin** (CO-leh-SIS-toe-KY-nin) (**CCK**). They primarily stimulate the pancreas and gallbladder, as discussed later, but also suppress gastric secretion and motility. The effect of this is that gastrin secretion declines and the pyloric sphincter contracts tightly to limit the admission of more chyme into the duodenum. This gives the duodenum time to work on the chyme it has already received before being loaded with more.

The enteroendocrine cells also secrete **glucose-dependent insulinotropic peptide (GIP)**. Originally called *gastric-inhibitory peptide* (the original source of the GIP abbreviation), it is no longer thought to have a significant effect on the stomach, but to be more concerned with stimulating insulin secretion in preparation for processing the nutrients about to be absorbed by the small intestine.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

10. Name four types of epithelial cells of the gastric and pyloric glands and state what each one secretes.
11. Explain how the gastric glands produce hydrochloric acid and why this produces an alkaline tide.
12. What positive feedback cycle can you identify in the formation and action of pepsin?
13. How does food in the duodenum inhibit motility and secretion in the stomach?

25.4 The Liver, Gallbladder, and Pancreas

Objectives

When you have completed this section, you should be able to

- describe the gross and microscopic anatomy of the liver, gallbladder, bile duct system, and pancreas;
- describe the digestive secretions and functions of the liver, gallbladder, and pancreas; and
- explain how hormones regulate secretion by the liver and pancreas.

The small intestine receives not only chyme from the stomach but also secretions from the liver and pancreas, which enter the digestive tract near the junction of the stomach and small intestine. These secretions are so important to the digestive processes of the small intestine that it is necessary to understand them before continuing with intestinal physiology.

The Liver

The liver (fig. 25.19) is a reddish brown gland located immediately inferior to the diaphragm, filling most of the right hypochondriac and epigastric regions. It is the body's largest gland, weighing about 1.4 kg (3 pounds). It has a tremendous variety of functions, but only one of them, the secretion of bile, contributes to digestion. Others are discussed in the following chapter, which provides a more thorough physiological basis for understanding nondigestive liver functions.

Gross Anatomy

The liver has four lobes called the right, left, quadrate, and caudate lobes. From an anterior view, we see only a large **right lobe** and smaller **left lobe**. They are separated from each other by the **falciform¹⁶ ligament**, a sheet of mesentery that suspends the liver from the diaphragm and anterior abdominal wall. The **round ligament (ligamentum teres)**, also visible anteriorly, is a fibrous remnant of the umbilical vein, which carries blood from the umbilical cord to the liver of a fetus.

From the inferior view, we also see a squarish **quadrate lobe** next to the gallbladder and a tail-like **caudate¹⁷ lobe** posterior to that. An irregular opening between these lobes, the **porta hepatis¹⁸**, is a point of entry for the hepatic portal vein and proper hepatic artery and a point of exit for the bile passages, all of which travel in the lesser omentum. The gallbladder adheres to a depression on the inferior surface of the liver between the right and quadrate lobes. The posterior aspect of the liver has a deep groove (sulcus) that accommodates the inferior vena cava. The superior surface has a *bare area* where it is attached to the diaphragm. The rest of the liver is covered by a serosa.

Microscopic Anatomy

The interior of the liver is filled with innumerable tiny cylinders called **hepatic lobules**, about 2 mm long by 1 mm in diameter. A lobule consists of a **central vein** passing down its core, surrounded by radiating sheets of cuboidal cells called **hepatocytes** (fig. 25.20). Imagine spreading a book wide open until its front and back covers touch. The pages of the book would fan out around the spine somewhat like the plates of hepatocytes fan out from the central vein of a liver lobule.

¹⁶falci = sickle + form = shape

¹⁷caud = tail

¹⁸porta = gateway, entrance + hepatis = of the liver

FIGURE 25.19 Gross Anatomy of the Liver.

Each plate of hepatocytes is an epithelium one or two cells thick. The spaces between the plates are blood-filled channels called **hepatic sinusoids**. These are lined by a fenestrated endothelium that separates the hepatocytes from the blood cells, but allows blood plasma into the space between the hepatocytes and endothelium. The hepatocytes have a brush border of microvilli that project into this space. Blood filtering through the sinusoids comes directly from the stomach and intestines. After a meal, the hepatocytes absorb glucose, amino acids, iron, vitamins, and other nutrients from it for metabolism or storage. They also remove and degrade hormones, toxins, bile pigments, and drugs. At the same time, they secrete albumin, lipoproteins, clotting factors, angiotensinogen, and other products into the blood. Between meals, they break down stored glycogen and release glucose into the circulation. The sinusoids also contain phagocytic cells called **hepatic macrophages (Kupffer¹⁹ cells)**, which remove bacteria and debris from the blood.

The hepatic lobules are separated by a sparse connective tissue stroma. In cross sections, the stroma is especially visible in the triangular areas where three or more lobules meet. Here there is often a **hepatic triad** of two blood vessels and a bile ductule. The blood vessels are small branches of the proper hepatic artery and hepatic portal vein. Both of them supply blood to the sinusoids, which therefore receive a mixture of nutrient-laden venous blood from the intestines and freshly oxygenated arterial blood from the celiac trunk. After filtering through the sinusoids, this blood collects in the central vein. From here, it ultimately flows into the right and left hepatic veins, which leave the liver at its superior surface and drain immediately into the inferior vena cava.

The liver secretes bile into narrow channels, the **bile canaliculi**, between the back-to-back layers of hepatocytes within each plate. Bile passes from there into the small **bile ductules** of the triads and ultimately into the **right and left hepatic ducts**. The two hepatic ducts converge on the inferior side of the liver to form the **common hepatic duct**. A short distance farther on, this is joined by

¹⁹Karl W. von Kupffer (1829–1902), German anatomist

FIGURE 25.20 Microscopic Anatomy of the Liver. (a) The hepatic lobules and their relationship to the blood vessels and bile tributaries. (b) Histological section of the liver. (c) A hepatic sinusoid.

Identify two blood vessels in chapter 20 that supply blood to the hepatic sinusoids.

the **cystic duct** coming from the gallbladder (fig. 25.21). Their union forms the **bile duct**, which descends through the lesser omentum toward the duodenum. Near the duodenum, the bile duct joins the duct of the pancreas and forms an expanded chamber called the **hepatopancreatic ampulla**. The ampulla terminates at a fold of tissue, the **major duodenal papilla**, on the duodenal wall. This papilla contains a muscular **hepatopancreatic sphincter (sphincter of Oddi²⁰)**, which regulates the passage of bile and pancreatic juice into the duodenum. Between meals, this sphincter is closed and prevents the release of bile into the intestine.

The Gallbladder and Bile

The **gallbladder** is a pear-shaped sac on the underside of the liver that serves to store and concentrate bile. It is about 10 cm long and internally lined by a highly folded mucosa with a simple columnar epithelium. Its head (*fundus*) usually projects slightly beyond the inferior margin of the liver. Its neck (*cervix*) leads into the cystic duct, which leads in turn to the bile duct.

Bile is a yellow-green fluid containing minerals, cholesterol, neutral fats, phospholipids, bile pigments, and bile acids. The principal pigment is **bilirubin**, derived from the decomposition of hemoglobin. Bacteria of the large intestine metabolize bilirubin to **urobilinogen**, which is responsible for the brown color of feces. In the absence of bile secretion, the feces are grayish white and marked with streaks of undigested fat (*acholic feces*). **Bile acids (bile salts)** are steroids synthesized from cholesterol. Bile acids and **lecithin**, a phospholipid, aid in fat digestion and absorption, as discussed later. All other components of the bile are wastes destined for excretion in the feces. When these waste products become excessively concentrated, they may form gallstones (see Insight 25.3).

Bile gets into the gallbladder by first filling the bile duct, then overflowing into the gallbladder. Between meals, the gallbladder absorbs water and electrolytes from the bile and concentrates it by a factor of 5 to 20 times. The liver secretes about 500 to 1,000 mL of bile per day.

About 80% of the bile acids are reabsorbed in the ileum, the last portion of the small intestine, and returned to the liver, where the hepatocytes absorb and resecret them. This route of secretion, reabsorption, and resecretion,

²⁰Ruggero Oddi (1864–1913), Italian physician

FIGURE 25.21 Gross Anatomy of the Gallbladder, Pancreas, and Bile Passages. The liver is omitted to show more clearly the gallbladder, which adheres to its inferior surface, and the hepatic ducts, which emerge from the liver tissue.

INSIGHT 25.3 Clinical Application**Gallstones**

Gallstones (biliary calculi) are hard masses in the gallbladder or bile ducts, usually composed of cholesterol, calcium carbonate, and bilirubin. *Cholelithiasis*, the formation of gallstones, is most common in obese women over the age of 40 and usually results from excess cholesterol. The gallbladder may contain several gallstones, some over 1 cm in diameter. Gallstones cause excruciating pain when they obstruct the bile ducts or when the gallbladder or bile ducts contract. When they block the flow of bile into the duodenum, they cause jaundice (yellowing of the skin due to bile pigment accumulation), poor fat digestion, and impaired absorption of fat-soluble vitamins. Once treated only by surgical removal, gallstones are now often treated with stone-dissolving drugs or by *lithotripsy*, the use of ultrasonic vibration to pulverize them without surgery. Reobstruction can be prevented by inserting a stent (tube) into the bile duct, which keeps it distended and allows gallstones to pass while they are still small.

called the *enterohepatic circulation*, reuses the bile acids two or more times during the digestion of an average meal. The 20% of the bile that is not reabsorbed is excreted in the feces. This is the body's only way of eliminating excess cholesterol. The liver synthesizes new bile acids from cholesterol to replace the quantity lost in the feces.

Think About It

Certain drugs designed to reduce blood cholesterol work by blocking the reabsorption of bile acids in the ileum. Explain why they would have this cholesterol-lowering effect.

The Pancreas

The pancreas (fig. 25.21) is a spongy retroperitoneal gland posterior to the greater curvature of the stomach. It measures 12 to 15 cm long and about 2.5 cm thick. It has a globose *head* encircled by the duodenum, a midportion called the *body*, and a blunt, tapered *tail* on the left. The pancreas is both an endocrine and exocrine gland. Its endocrine part is the pancreatic islets, which secrete insulin and glucagon (see chapter 17). About 99% of the pancreas is exocrine tissue, which secretes 1,200 to 1,500 mL of **pancreatic juice** per day. The cells of the secretory acini exhibit a high density of rough ER and *zymogen granules*, which are vesicles filled with secretion (fig. 25.22). These acini open into a system of larger and larger ducts that eventually converge on the main **pancreatic duct**. This duct runs lengthwise through the middle of the gland and joins the bile duct at the hepatopancreatic ampulla. The hepatopancreatic sphincter thus controls the release of both bile and pancreatic juice into

the duodenum. Usually, however, there is a smaller **accessory pancreatic duct** that branches from the main pancreatic duct and opens independently into the duodenum at the **minor duodenal papilla**, proximal to the major papilla. The accessory duct bypasses the sphincter and allows pancreatic juice to be released into the duodenum even when bile is not.

Pancreatic juice is an alkaline mixture of water, enzymes, zymogens, sodium bicarbonate, and other electrolytes. The acini secrete the enzymes and zymogens, whereas the ducts secrete the sodium bicarbonate. The bicarbonate buffers HCl arriving from the stomach.

FIGURE 25.22 Microscopic Anatomy of the Pancreas. (a) An acinus. (b) Histological section of the exocrine tissue and some of the connective tissue stroma.

FIGURE 25.23 The Activation of Pancreatic Enzymes in the Small Intestine. The pancreas secretes trypsinogen, and entero-kinase secreted by the duodenum converts it to trypsin. Trypsin not only digests dietary protein but also catalyzes the production of more trypsin and activates two other pancreatic zymo- gens—chymotrypsinogen and procarboxypeptidase.

The pancreatic zymogens are **trypsinogen** (trip-SIN-oh-jen), **chymotrypsinogen** (KY-mo-trip-SIN-o-jen), and **procarboxypeptidase** (PRO-car-BOC-see-PEP-tih-dase). When trypsinogen is secreted into the intestinal lumen, it is converted to **trypsin** by **enterokinase**, an enzyme secreted by the mucosa of the small intestine (fig. 25.23). Trypsin is autocatalytic—it converts trypsinogen into still more trypsin. It also converts the other two zymogens into **chymotrypsin** and **carboxypeptidase**, in addition to its primary role of digesting dietary protein.

Other pancreatic enzymes include **pancreatic amylase**, which digests starch; **pancreatic lipase**, which digests fat; and **ribonuclease** and **deoxyribonuclease**, which digest RNA and DNA, respectively. Unlike the zymogens, these enzymes are not altered after secretion. They become fully active, however, only upon exposure to bile or ions in the intestinal lumen.

The exocrine secretions of the pancreas are summarized in table 25.2. Their specific digestive functions are explained later in more detail.

Regulation of Secretion

Three stimuli are chiefly responsible for the release of pancreatic juice and bile.

1. **Acetylcholine (ACh)**, coming from the vagus and enteric nerves. ACh stimulates the pancreatic acini to secrete their enzymes even during the cephalic phase of gastric control, before food is swallowed.

TABLE 25.2		Exocrine Secretions of the Pancreas
Secretion	Function	
Sodium bicarbonate	Neutralizes HCl	
Zymogens	Converted to active digestive enzymes after secretion	
Trypsinogen	Becomes trypsin, which digests protein	
Chymotrypsinogen	Becomes chymotrypsin, which digests protein	
Procarboxypeptidase	Becomes carboxypeptidase, which hydrolyzes the terminal amino acid from the carboxyl (–COOH) end of small peptides	
Enzymes		
Pancreatic amylase	Digests starch	
Pancreatic lipase	Digests fat	
Ribonuclease	Digests RNA	
Deoxyribonuclease	Digests DNA	

The enzymes remain stored in the pancreatic acini and ducts, however, in preparation for release later when chyme enters the duodenum.

2. **Cholecystokinin²¹ (CCK)**, secreted by the mucosa of the duodenum and proximal jejunum (the next segment of the small intestine), primarily in response to fats in the small intestine. CCK also stimulates the pancreatic acini to secrete enzymes, but it is named for its strongly stimulatory effect on the gallbladder. It induces contractions of the gallbladder and relaxation of the hepatopancreatic sphincter, thus causing discharge of bile into the duodenum.
3. **Secretin**, produced by the same regions of the small intestine, mainly in response to the acidity of chyme arriving from the stomach. Secretin stimulates the ducts of both the liver and pancreas to secrete an abundant sodium bicarbonate solution. In the pancreas, this flushes the enzymes into the duodenum. Sodium bicarbonate buffers the hydrochloric acid arriving from the stomach, with the reaction

The carbonic acid then breaks down to carbon dioxide and water. The CO₂ is absorbed into the blood and ultimately expelled by the lungs. What is left in the small intestine, therefore, is saltwater—NaCl and H₂O. Sodium bicarbonate is therefore important in protecting the intestinal mucosa from stomach acid

²¹chole = bile + cysto = bladder (gallbladder) + kin = action

as well as raising the intestinal pH to the level needed for activity of the pancreatic and intestinal digestive enzymes.

Think About It

Draw a negative feedback loop showing how secretin influences duodenal pH.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

14. What does the liver contribute to digestion?
15. Trace the pathway taken by bile acids from the liver and back. What is this pathway called?
16. Name two hormones, four enzymes, and one buffer secreted by the pancreas, and state the function of each.
17. What stimulates cholecystikinin (CCK) secretion, and how does CCK affect other parts of the digestive system?

FIGURE 25.24 Gross Anatomy of the Small Intestine. The intestine is pulled aside to expose the mesentery and ileocecal junction.

25.5 The Small Intestine

Objectives

When you have completed this section, you should be able to

- describe the gross and microscopic anatomy of the small intestine;
- state how the mucosa of the small intestine differs from that of the stomach, and explain the functional significance of the differences;
- define *contact digestion* and describe where it occurs; and
- describe the types of movement that occur in the small intestine.

Nearly all chemical digestion and nutrient absorption occur in the small intestine. To perform these roles efficiently and thoroughly, the small intestine is the longest part of the digestive tract—about 2.7 to 4.5 m long in a living person; in the cadaver, where there is no muscle tone, it is 4 to 8 m long. The term *small intestine* refers not to its length but to its diameter—about 2.5 cm (1 in.).

Gross Anatomy

The small intestine is a coiled mass filling most of the abdominal cavity inferior to the stomach and liver. It is divided into three regions (fig. 25.24): the duodenum, jejunum, and ileum.

The **duodenum** (dew-ODD-eh-num, DEW-oh-DEE-num) constitutes the first 25 cm (10 in.). It begins at the pyloric valve, arcs around the head of the pancreas and passes to the left, and ends at a sharp bend called the **duodenojejunal flexure**. Its name refers to its length, about equal to the width of 12 fingers.²² Slightly distal to the pyloric valve, it exhibits the previously described wrinkles called the major and minor duodenal papillae, where it receives the pancreatic duct and accessory pancreatic duct, respectively. Along with the pancreas, most of the duodenum is retroperitoneal. It receives the stomach contents, pancreatic juice, and bile. Stomach acid is neutralized here, fats are physically broken up (emulsified) by the bile acids, pepsin is inactivated by the elevated pH, and pancreatic enzymes take over the job of chemical digestion.

The **jejunum** (jeh-JOO-num), by definition, is the first 40% of the small intestine beyond the duodenum—roughly 1.0 to 1.7 m in a living person. Its name refers to the fact that early anatomists typically found it to be empty.²³ The jejunum begins in the upper left quadrant of the abdomen but lies mostly within the umbilical region (see fig. A.6, p.33). It has large, tall, closely spaced circular folds. Its wall is relatively thick and muscular, and it has an especially rich blood supply, which gives it a relatively red color. Most digestion and nutrient absorption occur here.

The **ileum**²⁴ forms the last 60% of the postduodenal small intestine (about 1.6 to 2.7 m). It occupies mainly the hypogastric region and part of the pelvic cavity.

²²duoden = 12

²³jejun = empty, dry

²⁴from *eilos* = twisted

Compared with the jejunum, its wall is thinner, less muscular, less vascular, and has a paler pink color. On the side opposite from its mesenteric attachment, the ileum has prominent lymphatic nodules in clusters called **Peyer²⁵ patches** (see chapter 21), which are readily visible to the naked eye and become progressively larger approaching the large intestine.

The end of the small intestine is the **ileocecal (ILL-ee-oh-SEE-cul) junction**, where the ileum joins the *cecum* of the large intestine. The muscularis of the ileum is thickened at this point to form a sphincter, the **ileocecal (ILL-ee-oh-SEE-cul) valve**, which protrudes into the cecum and regulates the passage of food residue into the large intestine. Both the jejunum and ileum are intraperitoneal and thus covered with a serosa, which is continuous with the complex, folded mesentery that suspends the small intestine from the posterior abdominal wall.

Microscopic Anatomy

The tissue layers of the small intestine are reminiscent of those in the esophagus and stomach with modifications appropriate for nutrient digestion and absorption. The lumen is lined with simple columnar epithelium. The muscularis externa is notable for a thick inner circular layer and a thinner outer longitudinal layer.

Effective digestion and absorption require that the small intestine have a large internal surface area. This is provided by its relatively great length and by three kinds of internal folds or projections: the circular folds, villi, and microvilli. If the mucosa were smooth, like the inside of a hose, it would have a surface area of about 0.3 to 0.5 m², but with these surface elaborations, its actual surface area is about 200 m²—clearly a great advantage for nutrient absorption. The circular folds increase the surface area by a factor of 2 to 3; the villi by a factor of 10; and the microvilli by a factor of 20.

Think About It

The small intestine exhibits some of the same structural adaptations as the proximal convoluted tubule of the kidney, and for the same reasons. Discuss what they have in common, the reasons for it, and how this relates to this book's theme of the unity of form and function.

The largest folds of the intestinal wall are transverse to spiral ridges, up to 10 mm high, called **circular folds (plicae circulares)** (see fig. 25.21). These involve only the mucosa and submucosa; they are not visible on the external surface, which is smooth. They occur from the duodenum to the middle of the ileum, where they cause the chyme to flow on a spiral path along the intestine. This slows its progress, causes more contact with the mucosa,

and promotes more thorough mixing and nutrient absorption. Circular folds are relatively small and sparse in the ileum and not found in the distal half, but most nutrient absorption is completed by that point.

If the mucosa is examined closely it appears fuzzy, like a terrycloth towel. This is due to projections called **villi (VIL-eye; singular, villus)**, about 0.5 to 1.0 mm high, with tongue- to fingerlike shapes (fig. 25.25). The villi are largest in the duodenum and become progressively smaller in more distal regions of the small intestine. A villus is covered with two kinds of epithelial cells: columnar **absorptive cells (enterocytes)** and mucus-secreting **goblet cells**. Like epithelial cells of the stomach, those of the small intestine are joined by tight junctions that prevent digestive enzymes from seeping between them.

The core of a villus is filled with areolar tissue of the lamina propria. Embedded in this tissue are an arteriole, a capillary network, a venule, and a lymphatic capillary called a **lacteal (LAC-tee-ul)**. Blood capillaries of the villus absorb most nutrients, but the lacteal absorbs most lipids. They give its contents a milky appearance for which the lacteal is named.²⁶ The core of the villus also has a few smooth muscle cells that contract periodically. This enhances mixing of the chyme in the intestinal lumen and milks lymph down the lacteal to the larger lymphatic vessels of the submucosa.

Each absorptive cell of a villus has a fuzzy brush border of microvilli about 1 μm high. The brush border increases the absorptive surface area of the small intestine and contains **brush border enzymes** in the plasma membrane. They carry out some of the final stages of enzymatic digestion. They are not released into the lumen; instead, the chyme must contact the brush border for digestion to occur. This process, called **contact digestion**, is one reason that it is so important that intestinal contractions churn the chyme and ensure that it all contacts the mucosa.

On the floor of the small intestine, between the bases of the villi, there are numerous pores that open into tubular glands called **intestinal crypts (crypts of Lieberkühn²⁷; LEE-ber-koohn)**. These crypts, similar to the gastric glands, extend as far as the muscularis mucosae. In the upper half, they consist of enterocytes and goblet cells like those of the villi. The lower half is dominated by dividing stem cells. In its life span of 3 to 6 days, an epithelial cell migrates up the crypt to the tip of the villus, where it is sloughed off and digested. A few **Paneth²⁸ cells** are clustered at the base of each crypt. They secrete lysozyme, phospholipase, and defensins—defensive proteins that resist bacterial invasion of the mucosa.

The duodenum has prominent **duodenal (Brunner²⁹) glands** in the submucosa. They secrete an abundance of

²⁶*lact* = milk

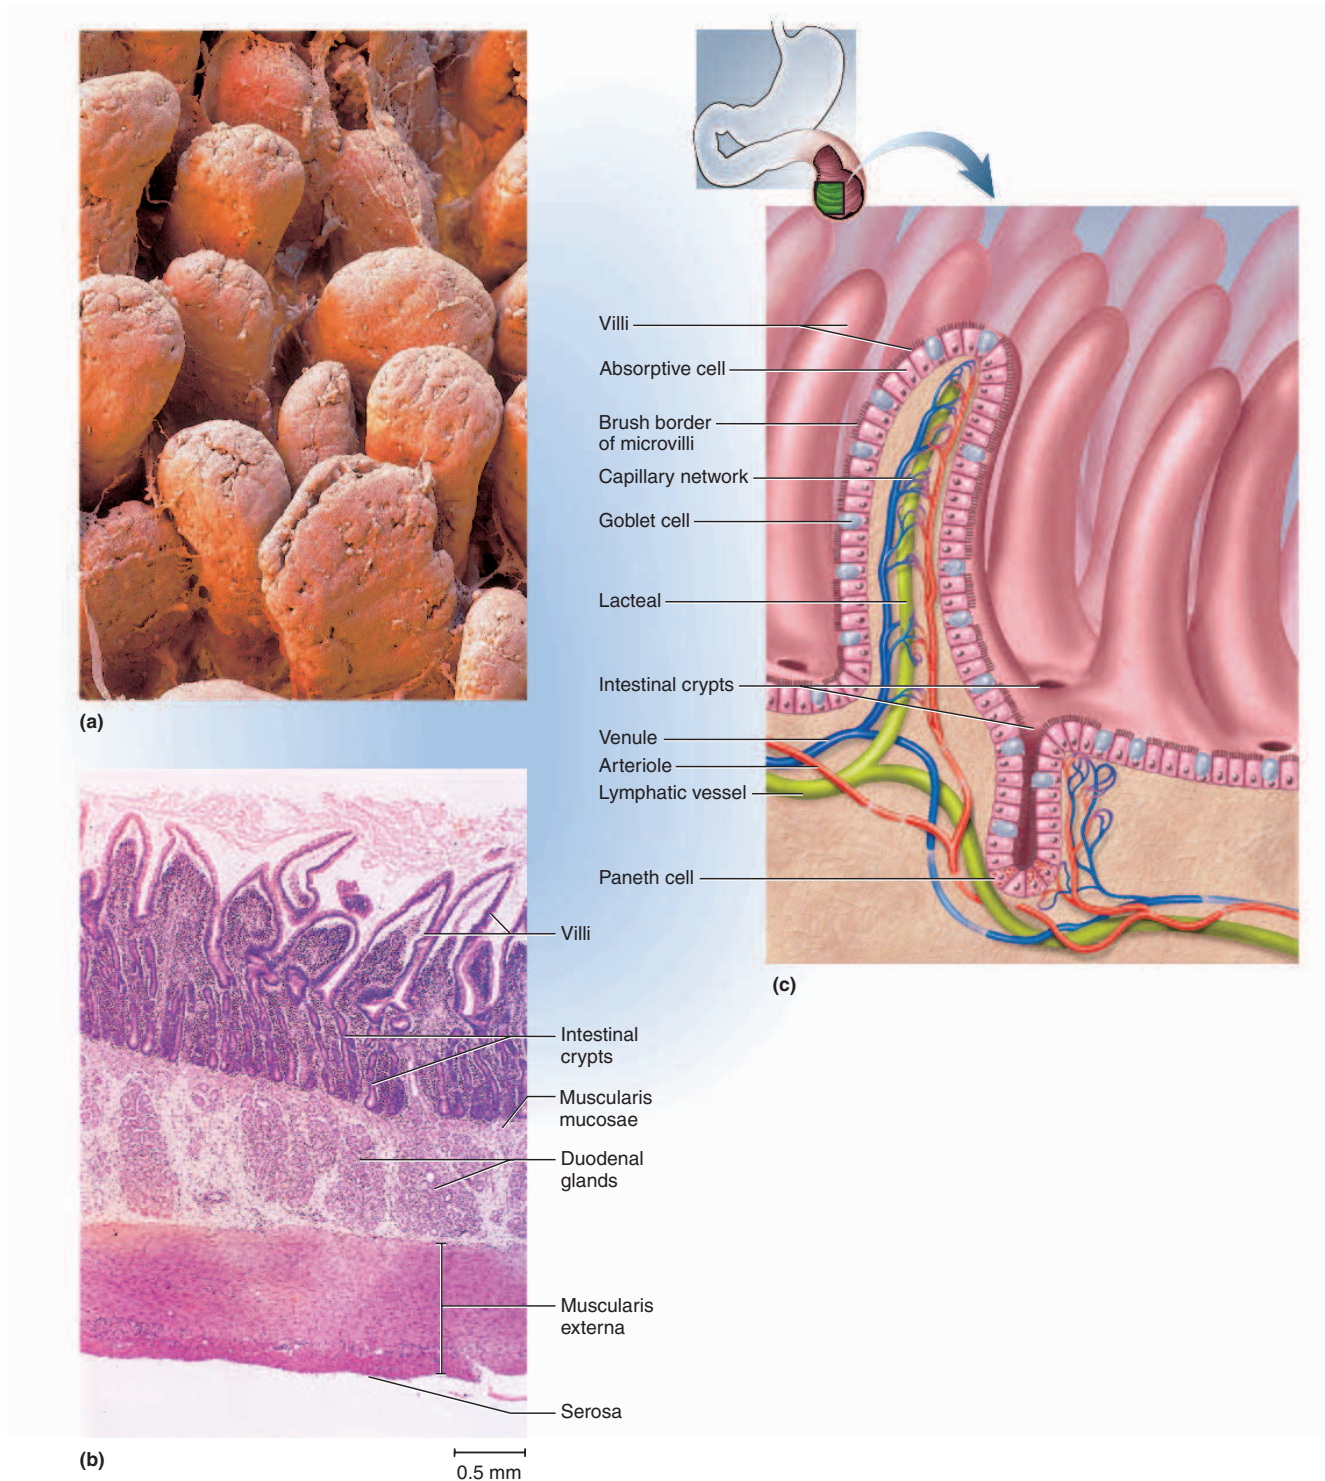

FIGURE 25.25 Intestinal Villi. (a) Villi (SEM). Each villus is about 1 mm high. (b) Histological section of the duodenum showing villi, intestinal crypts, and duodenal glands. (c) Structure of a villus.

bicarbonate-rich mucus, which neutralizes stomach acid and shields the mucosa from its erosive effects. Throughout the small intestine, the lamina propria and submucosa have a large population of lymphocytes that intercept pathogens before they can invade the bloodstream. In some places, these are aggregated into conspicuous lymphatic nodules such as the Peyer patches of the ileum.

Intestinal Secretion

The intestinal crypts secrete 1 to 2 L of **intestinal juice** per day, especially in response to acid, hypertonic chyme, and distension of the intestine. This fluid has a pH of 7.4 to 7.8. It contains water and mucus but relatively little enzyme. Most enzymes that function in the small intestine are found in the brush border and pancreatic juice.

Intestinal Motility

Contractions of the small intestine serve three functions: (1) to mix chyme with intestinal juice, bile, and pancreatic juice, allowing these fluids to neutralize acid and digest nutrients more effectively; (2) to churn chyme and bring it into contact with the mucosa for contact digestion and nutrient absorption; and (3) to move residue toward the large intestine.

Segmentation is a movement in which stationary ringlike constrictions appear at several places along the intestine and then relax as new constrictions form elsewhere (fig. 25.26a). This is the most common type of intestinal contraction. Its effect is to knead or churn the contents. Pacemaker cells of the muscularis externa set the rhythm of segmentation, with contractions about 12 times per minute in the duodenum and 8 to 9 times per minute in the ileum. Since the contractions are less frequent distally, segmentation causes slow progression

of the chyme toward the colon. The intensity (but not frequency) of contractions is modified by nervous and hormonal influences.

When most nutrients have been absorbed and little remains but undigested residue, segmentation declines and peristalsis begins. A peristaltic wave begins in the duodenum, travels 10 to 70 cm, and dies out, only to be followed by another wave that begins a little farther down the tract than the first one did (fig. 25.26b). These successive, overlapping waves of contraction are called a **migrating motor complex**. They milk the chyme toward the colon over a period of about 2 hours. A second complex then expels residue and bacteria from the small intestine, thereby helping to limit bacterial colonization. Refilling of the stomach at the next meal suppresses peristalsis and reactivates segmentation.

The ileocecal valve is usually closed. Food in the stomach, however, triggers both the release of gastrin and the **gastroileal reflex**, both of which enhance segmentation in the ileum and relax the valve. As the cecum fills with residue, the pressure pinches the valve shut and prevents the reflux of cecal contents into the ileum.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

18. What three structures increase the absorptive surface area of the small intestine?
19. Sketch a villus and label its epithelium, brush border, lamina propria, blood capillaries, and lacteal.
20. Distinguish between segmentation and the migrating motor complex of the small intestine. How do these differ in function?

(a) Segmentation

(b) Peristalsis

FIGURE 25.26 Contractions of the Small Intestine. (a) Segmentation, in which circular constrictions of the intestine cut into the contents, churning and mixing them. (b) The migrating motor complex of peristalsis, in which successive waves of peristalsis overlap each other. Each wave travels partway down the intestine and milks the contents toward the colon.

25.6 Chemical Digestion and Absorption

Objectives

When you have completed this section, you should be able to

- describe how each major class of nutrients is chemically digested, name the enzymes involved, and discuss the functional differences among these enzymes; and
- describe how each type of nutrient is absorbed by the small intestine.

Chemical digestion and nutrient absorption are essentially finished by the time food residue leaves the small intestine and enters the cecum. But before going on to the functions of the large intestine, we trace each major class of nutrients—especially carbohydrates, proteins, and fats—from the mouth through the small intestine to see how it is chemically degraded and absorbed.

Carbohydrates

Most digestible dietary carbohydrate is starch. Cellulose is indigestible and is not considered here, although its importance as dietary fiber is discussed in chapter 26. The amount of glycogen in the diet is negligible, but it is digested in the same manner as starch.

Carbohydrate Digestion

Starch is digested first to oligosaccharides up to eight glucose residues long, then into the disaccharide maltose, and finally to glucose, which is absorbed by the small intestine. The process begins in the mouth, where salivary amylase hydrolyzes starch into oligosaccharides. Salivary amylase functions best at pH 6.8 to 7.0, typical of the oral cavity. It is quickly denatured upon contact with stomach acid, but it can digest starch for as long as 1 to 2 hours in the stomach as long as it is in the middle of a food mass and escapes contact with the acid. Amylase therefore works longer when the meal is larger, especially in the fundus, where gastric motility is weakest and a food bolus takes longer to break up. As acid, pepsin, and the churning contractions of the stomach break up the bolus, amylase is denatured; it does not function at a pH any lower than 4.5. Being a protein, amylase is then digested by pepsin along with the dietary proteins.

About 50% of the dietary starch is digested before it reaches the small intestine. Its digestion resumes in the small intestine when the chyme mixes with pancreatic amylase (fig. 25.27). Starch is entirely converted to oligosaccharides and maltose within 10 minutes. Its digestion

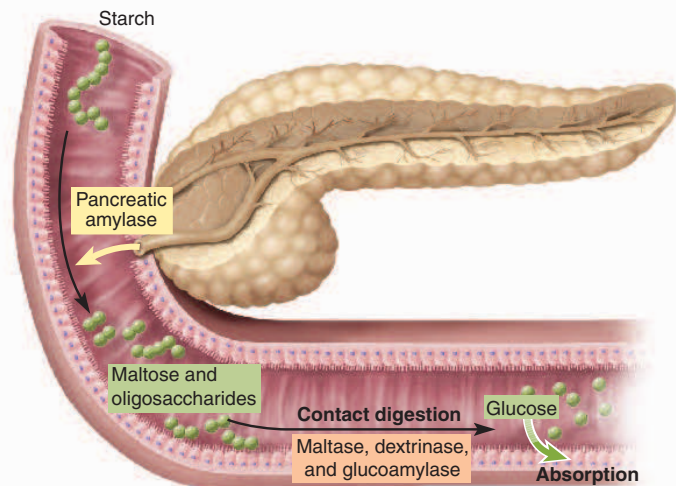

FIGURE 25.27 Starch Digestion in the Small Intestine.

Pancreatic amylase digests starch into maltose and small oligosaccharides. Brush border enzymes (maltase, dextrinase, and glucoamylase) digest these to glucose, which is absorbed by the epithelial cells.

is completed as the chyme contacts the brush border of the absorptive cells. Two brush border enzymes, **dextrinase** and **glucoamylase**, hydrolyze oligosaccharides that are three or more residues long. The third, **maltase**, hydrolyzes maltose to glucose.

Maltose is also present in some foods, but the major dietary disaccharides are sucrose (cane sugar) and lactose (milk sugar). They are digested by the brush border enzymes **sucrase** and **lactase**, respectively, and the resulting monosaccharides (glucose and fructose from the former; glucose and galactose from the latter) are immediately absorbed. In most of the world population, however, lactase production ceases or declines to a low level after age 4 and lactose becomes indigestible (see Insight 25.4).

Carbohydrate Absorption

The plasma membrane of the absorptive cells has transport proteins that absorb monosaccharides as soon as the brush border enzymes release them (fig. 25.28). About 80% of the absorbed sugar is glucose, which is taken up by a sodium–glucose transport protein (SGLT) like that of the kidney tubules (see p. 921). The glucose is subsequently transported out the base of the cell into the extracellular fluid (ECF). Sugar entering the ECF increases its osmolarity, and this draws water osmotically from the lumen of the intestine, through the now leaky tight junctions between the epithelial cells. Water carries more glucose and other nutrients with it by *solvent drag*, much as it does in the kidney. After a high-carbohydrate meal, solvent drag absorbs two to three times as much glucose as the SGLT.

INSIGHT 25.4 Clinical Application

Lactose Intolerance

Humans are a strange species. Unique among mammals, we go on drinking milk in adulthood, and moreover, we drink the milk of other species! This odd habit is largely limited, however, to people of western and northern Europe, a few pastoral tribes of Africa, and their descendants in the Americas and elsewhere. They have an ancestral history of milking domestic animals, a practice that goes back about 10,000 years and has coincided with the continued production of lactase into adulthood.

People without lactase have *lactose intolerance*. If they consume milk, lactose passes undigested into the large intestine, increases the osmolarity of the intestinal contents, and causes colonic water retention and diarrhea. In addition, lactose fermentation by intestinal bacteria produces gas, resulting in painful cramps and flatulence.

Lactose intolerance occurs in about 15% of American whites; 90% of American blacks, who are predominantly descended from nonpastoral African tribes; 70% or more of Mediterraneans; and nearly all people of Asian descent, including those of us descended from the native migrants into North, Central, and South America. People with lactose intolerance can consume products such as yogurt and cheese, in which bacteria have broken down the lactose, and they can digest milk and ice cream with the aid of lactase drops or tablets.

The SGLT also absorbs galactose, whereas fructose is absorbed by facilitated diffusion using a separate carrier that does not depend on Na⁺. Inside the epithelial cell, most fructose is converted to glucose. Glucose, galactose, and the small amount of remaining fructose are then transported out the base of the cell by facilitated diffusion and are absorbed by the blood capillaries of the villus. The hepatic portal system delivers them to the liver; chapter 26 follows the fate of these sugars from there.

Proteins

The amino acids absorbed by the small intestine come from three sources: (1) dietary proteins, (2) digestive enzymes digested by each other, and (3) sloughed epithelial cells digested by these enzymes. The endogenous amino acids from the last two sources total about 30 g/day, compared with about 44 to 60 g/day from the diet.

Enzymes that digest proteins are called **proteases (peptidases)**. They are absent from the saliva but begin work in the stomach. Here, pepsin hydrolyzes any peptide bond between tyrosine and phenylalanine, thereby digesting 10% to 15% of the dietary protein into shorter polypeptides and a small amount of free amino acids (fig. 25.29). Pepsin has an optimal pH of 1.5 to 3.5; thus it is inactivated when it passes into the duodenum and mixes with the alkaline pancreatic juice (pH 8).

FIGURE 25.28 Monosaccharide Absorption by the Small Intestine. Glucose and galactose are absorbed by the SGLT cotransporter in the apical membrane of the absorptive cell (right). Glucose is also absorbed along with water through the paracellular route (between cells) by solvent drag. Fructose is absorbed separately by facilitated diffusion. Most fructose is converted to glucose within the epithelial cell. The monosaccharides pass through the basal membrane of the cell by facilitated diffusion (left) and are then absorbed by the blood capillaries of the villus.

In the small intestine, the pancreatic enzymes trypsin and chymotrypsin take over protein digestion by hydrolyzing polypeptides into even shorter oligopeptides. Finally, these are taken apart one amino acid at a time by three more enzymes: (1) **carboxypeptidase** removes amino acids from the -COOH end of the chain; (2) **aminopeptidase** removes them from the -NH₂ end; and (3) **dipeptidase** splits dipeptides in the middle and releases the last two free amino acids. The last two of these are brush border enzymes, whereas carboxypeptidase is a pancreatic secretion.

Amino acid absorption is similar to that of monosaccharides. Enterocytes have several sodium-dependent amino acid cotransporters for different classes of amino acids. Dipeptides and tripeptides can also be absorbed, but they are hydrolyzed within the epithelial cells before their amino acids are released to the bloodstream. At the basal surfaces of the cells, amino acids behave like the monosaccharides discussed previously—they leave the cell by facilitated diffusion, enter the capillaries of the villus, and are carried away in the hepatic portal circulation.

The absorptive cells of infants can take up intact proteins by pinocytosis and release them to the blood by exocytosis. This allows IgA from breast milk to pass into an infant's bloodstream and confer passive immunity from mother to infant. It has the disadvantage, however, that intact proteins entering the infant's blood are detected

FIGURE 25.29 Protein Digestion and Absorption.

as foreign antigens and sometimes trigger food allergies. As the intestine matures, its ability to pinocytose protein declines but never completely ceases.

Lipids

The hydrophobic quality of lipids makes their digestion and absorption more complicated than that of carbohydrates and proteins (fig. 25.30). Fats are digested by enzymes called **lipases**. *Lingual lipase*, secreted by the intrinsic salivary glands of the tongue, digests a small amount of fat while food is still in the mouth, but becomes even more active at the acidic pH of the stomach. Here it is joined by *gastric lipase*, which makes a much larger contribution to preduodenal fat digestion. About 10% to 15% of dietary fat is digested before the chyme passes on to the duodenum.

Most fat digestion occurs in the small intestine through the action of *pancreatic lipase*. As chyme enters the duodenum, its fat is in large globules exposed to lipase only at their surfaces. Fat digestion would be rather slow and inefficient if it remained this way. Instead, it is broken up into smaller **emulsification droplets** by certain components of the bile—lecithin and bile acids. These agents have hydrophobic regions attracted to the surface of a fat globule and hydrophilic regions attracted to the surrounding water. The agitation produced by intestinal segmentation breaks the fat up into droplets as small as 1 μm in diameter, and a coating of lecithin and bile acids keeps it broken up, exposing far more of its surface to enzymatic action.

There is enough pancreatic lipase in the small intestine after a meal to digest the average daily fat intake in as little as 1 or 2 minutes. When lipase acts on a triglyceride, it removes the first and third fatty acids from the glycerol backbone and usually leaves the middle one. The products of lipase action are therefore two free fatty acids (FFAs) and a monoglyceride.

The absorption of these products and other lipids depends on minute droplets in the bile called **micelles**³⁰ (my-SELLS). Micelles, made in the liver, consist of 20 to 40 bile acid molecules aggregated with their hydrophilic side groups facing outward and their hydrophobic steroid rings facing inward. Bile phospholipids and cholesterol diffuse into the center of the micelle to form its core. The micelles pass down the bile duct into the duodenum, where they absorb fat-soluble vitamins, more cholesterol, and the FFAs and monoglycerides produced by fat digestion. Because of their charged, hydrophilic surfaces, micelles remain suspended in water more easily than free lipids do. They transport lipids to the surfaces of the intestinal absorptive cells, where the lipids leave the micelles and diffuse through the plasma membrane into the cells. The micelles are

reused, picking up another cargo of lipids and ferrying them to the absorptive cells. Without micelles, the small intestine absorbs only about 40% to 50% of the dietary fat and almost no cholesterol.

Within the intestinal cell, the FFAs and monoglycerides are transported into the smooth endoplasmic reticulum and resynthesized into triglycerides. The Golgi complex combines these with a small amount of cholesterol and coats the complex with a film of phospholipids and protein, forming droplets about 60 to 750 nm in diameter called **chylomicrons**³¹ (KY-lo-MY-crons). It packages chylomicrons into secretory vesicles that migrate to the basal surface of the cell and release their contents into the core of the villus. Although some FFAs enter the blood capillaries, chylomicrons are too large to penetrate the endothelium. They are taken up by the more porous lacteal into the lymph. The white, fatty intestinal lymph (*chyle*) flows through larger and larger lymphatic vessels of the mesenteries, eventually passing through the cisterna chyli (see fig. 21.1, p. 817) to the thoracic duct, then entering the bloodstream at the left subclavian vein. The further fate of dietary fat is described in chapter 26.

Think About It

Explain why the right lymphatic duct does not contribute any dietary fat to the bloodstream.

Nucleic Acids

The nucleic acids, DNA and RNA, are present in much smaller quantities than the polymers discussed previously. The **nucleases** (ribonuclease and deoxyribonuclease) of pancreatic juice hydrolyze these to their constituent nucleotides. **Nucleosidases** and **phosphatases** of the brush border then decompose the nucleotides into phosphate ions, ribose (from RNA) or deoxyribose (from DNA), and nitrogenous bases. These products are transported across the intestinal epithelium by membrane carriers and enter the capillary blood of the villus.

Vitamins

Vitamins are absorbed unchanged. The fat-soluble vitamins A, D, E, and K are absorbed with other lipids as just described. Therefore, if they are ingested without fat-containing food, they are not absorbed at all but are passed in the feces and wasted. Water-soluble vitamins (the B complex and vitamin C) are absorbed by simple diffusion, with the exception of vitamin B₁₂. This is an unusually large molecule that can only be absorbed if it binds to intrinsic factor from the stomach. The B₁₂-intrinsic factor complex then binds to receptors on absorptive cells of the distal ileum, where it is taken up by receptor-mediated endocytosis.

³⁰mic = grain, crumb + elle = little

³¹chyl = juice + micr = small

FIGURE 25.30 Fat Digestion and Absorption.

Minerals

Minerals (electrolytes) are absorbed along the entire length of the small intestine. Sodium ions are cotransported with sugars and amino acids. Chloride ions are actively transported in the distal ileum by a pump that exchanges them for bicarbonate ions, thus reversing the chloride–bicarbonate exchange that occurs in the stomach. Potassium ions are absorbed by simple diffusion. The K^+ concentration of the chyme rises as water is absorbed from it, creating a gradient favorable to K^+ absorption. In diarrhea, when water absorption is hindered, potassium ions remain in the intestine and pass with the feces; therefore, chronic diarrhea can lead to hypokalemia.

Iron and calcium are unusual in that they are absorbed in proportion to the body's need, whereas other minerals are absorbed at fairly constant rates regardless of need, leaving it to the kidneys to excrete any excess. Iron absorption is stimulated by the liver hormone hepcidin (see p. 656). The absorptive cells bind ferrous ions (Fe^{2+}) and internalize them by active transport; they are unable to absorb ferric ions (Fe^{3+}), but stomach acid (HCl) reduces most ferric ions to absorbable ferrous ions. Fe^{2+} is transported to the basal surface of the cell and there taken up by the extracellular protein *transferrin*. The transferrin–iron complex diffuses into the blood and is carried to such places as the bone marrow for hemoglobin synthesis, muscular tissue for myoglobin synthesis, and the liver for storage (see fig. 18.7, p. 692). Excess dietary iron, if absorbed, binds irreversibly to ferritin in the epithelial cell and is held there until that cell sloughs off and passes in the feces.

Think About It

Young adult women have four times as many iron transport proteins in the intestinal mucosa as men have. Can you explain this?

Calcium is absorbed throughout the intestine but by different mechanisms—some by active transport in the duodenum and much larger amounts by diffusion between epithelial cells in the jejunum and ileum. In the duodenum, Ca^{2+} enters the absorptive cells through calcium channels in the apical cell membrane. Once inside the cell, it binds to a protein called *calbindin*. This keeps the intracellular concentration of free calcium low, thus maintaining the gradient that favors calcium uptake by the cell. What free calcium there is in the cytoplasm is then pumped out the basal side of the cell by active transport, using a protein called *calcium-ATPase* as well as a *$Na^+ - Ca^{2+}$ antiport*. From there, it enters the blood capillaries of the villus.

Parathyroid hormone is secreted in response to a drop in blood calcium level. It stimulates the kidneys to synthesize vitamin D from the precursors made by the epidermis and liver (see p. 231). Vitamin D then affects

the absorptive cells of the duodenum in three ways: it increases the number of calcium channels in the apical membrane, the amount of calbindin in the cytoplasm, and the number of calcium–ATPase pumps in the basal membrane. Thus, it increases absorption of dietary calcium and raises the level of calcium in the blood. Vitamin D has no effect on the paracellular diffusion of calcium in the jejunum and ileum, where most calcium is absorbed.

Water

The digestive system is one of several systems involved in water balance. The digestive tract receives about 9 L of water per day—0.7 L in food, 1.6 L in drink, and 6.7 L in the gastrointestinal secretions: saliva, gastric juice, bile, pancreatic juice, and intestinal juice. About 8 L of this is absorbed by the small intestine and 0.8 L by the large intestine, leaving 0.2 L voided in the daily fecal output. Water is absorbed by osmosis, following the absorption of salts and organic nutrients that create an osmotic gradient from the intestinal lumen to the ECF.

Diarrhea occurs when the large intestine absorbs too little water. This occurs when the intestine is irritated by bacteria and feces pass through too quickly for adequate reabsorption, or when the feces contain abnormally high concentrations of a solute such as lactose that opposes osmotic absorption of water. *Constipation* occurs when fecal movement is slow, too much water is reabsorbed, and the feces become hardened. This can result from lack of dietary fiber, lack of exercise, emotional upset, or long-term laxative abuse.

Think About It

Magnesium sulfate (*epsom salt*) is poorly absorbed by the intestines. In light of this, explain why it has a laxative effect.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- What three classes of nutrients are most abundant? What are the end products of enzymatic digestion of each?
- What two digestive enzymes occur in the saliva? Why is one of these more active in the stomach than in the mouth?
- Name as many enzymes of the intestinal brush border as you can, and identify the substrate or function of each.
- Explain the distinctions between an emulsification droplet, a micelle, and a chylomicron.
- What happens to digestive enzymes after they have done their job? What happens to dead epithelial cells that slough off the gastrointestinal mucosa? Explain.

25.7 The Large Intestine

Objectives

When you have completed this section, you should be able to

- describe the gross anatomy of the large intestine;
- contrast the mucosa of the colon with that of the small intestine;
- state the physiological significance of intestinal bacteria;
- discuss the types of contractions that occur in the colon; and
- explain the neurological control of defecation.

The large intestine (fig. 25.31) receives about 500 mL of indigestible food residue per day, reduces it to about 150 mL of feces by absorbing water and salts, and eliminates the feces by defecation.

Gross Anatomy

The large intestine measures about 1.5 m (5 feet) long and 6.5 cm (2.5 in.) in diameter in the cadaver. It begins with the **cecum**,³² a blind pouch in the lower right abdominal quadrant inferior to the ileocecal valve. Attached to the lower end of the cecum is the **appendix**, a blind tube 2 to 7 cm long. The appendix is densely populated with lymphocytes and is a significant source of immune cells.

The **colon** is that part of the large intestine between the ileocecal junction and rectum (not including the cecum, rectum, or anal canal). It is divided into the ascending, transverse, descending, and sigmoid regions. The **ascending colon** begins at the ileocecal valve and passes up the right side of the abdominal cavity. It makes a 90° turn at the **right colic (hepatic) flexure**, near the right lobe of the liver, and becomes the **transverse colon**. This passes horizontally across the upper abdominal cavity and turns 90° downward at the **left colic (splenic) flexure** near the spleen. Here it becomes the **descending colon**, which passes down the left side of the abdominal cavity. Ascending, transverse, and descending colons thus form a squarish, three-sided frame around the small intestine.

The pelvic cavity is narrower than the abdominal cavity, so at the pelvic inlet, the colon turns medially and downward, forming a roughly S-shaped portion called the **sigmoid**³³ **colon**. (Visual examination of this region is

performed with an instrument called a *sigmoidoscope*.) In the pelvic cavity, the large intestine continues as the **rectum**,³⁴ about 15 cm long. Despite its name, the rectum is not quite straight but has three lateral curves as well as an anteroposterior curve. It has three infoldings called **transverse rectal folds (rectal valves)**, which enable it to retain feces while passing gas.

The final 3 cm of the large intestine is the **anal canal** (fig. 25.31b), which passes through the levator ani muscle of the pelvic floor and terminates at the anus. Here, the mucosa forms longitudinal ridges called **anal columns** with depressions between them called **anal sinuses**. As feces pass through the canal, they press against the sinuses and cause them to exude extra mucus and lubricate the canal during defecation. Large **hemorrhoidal veins** form superficial plexuses in the anal columns and around the orifice. Unlike veins in the limbs, they lack valves and are particularly subject to distension and venous pooling. *Hemorrhoids* are permanently distended veins that protrude into the anal canal or form bulges external to the anus.

The muscularis externa of the colon is unusual. Although it completely encircles the colon just as it does the small intestine, its longitudinal fibers are especially concentrated in three thickened, ribbonlike strips. Each strip is called a **taenia coli** (TEE-nee-ah CO-lye) (plural, *taeniae coli*). The muscle tone of the taeniae coli contracts the colon lengthwise and causes its wall to bulge, forming pouches called **haustra**³⁵ (HAW-stra; singular, *hastrum*). In the rectum and anal canal, however, the longitudinal muscle forms a continuous sheet and haustra are absent. The anus, like the urethra, is regulated by two sphincters: an **internal anal sphincter** composed of smooth muscle of the muscularis externa and an **external anal sphincter** composed of skeletal muscle of the pelvic diaphragm.

The ascending and descending colon are retroperitoneal, whereas the transverse and sigmoid colon are covered with serosa and anchored to the posterior abdominal wall by the mesocolon. The serosa of these regions often has **omental (epiploic)**³⁶ **appendages**, clublike fatty pouches of peritoneum of unknown function.

Microscopic Anatomy

The mucosa of the large intestine has a simple columnar epithelium in all regions except the lower half of the anal canal, where it has a nonkeratinized stratified squamous epithelium. The latter provides more resistance to the abrasion caused by the passage of feces. There are no circular folds or villi in the large intestine, but there are

³²cec = blind

³³sigm = sigma or S + oid = resembling

Which anal sphincter is controlled by the autonomic nervous system? Which is controlled by the somatic nervous system? Explain the basis for your answers.

intestinal crypts. They are deeper than in the small intestine and have a greater density of goblet cells; mucus is their only significant secretion. The lamina propria and submucosa have an abundance of lymphatic tissue, providing protection from the bacteria that densely populate the large intestine.

Bacterial Flora and Intestinal Gas

The large intestine harbors about 800 species of bacteria collectively called the **bacterial flora**.³⁷ We have a mutually beneficial relationship with many of these. We provide them with room and board, while they provide us with nutrients from our food that we are not equipped to extract on our own. For example, they digest cellulose, pectin, and other plant polysaccharides for which we have no digestive enzymes, and we absorb the resulting sugars. Thus we get more nutrition from our food because of these bacteria than we would get without them. Indeed, one person may get more calories than another from the same amount of food because of differences in their bacterial populations. Some bacteria also synthesize B vitamins and vitamin K, which are absorbed by the colon. This vitamin K is especially important because the diet alone usually does not provide enough to ensure adequate blood clotting.

One of the less desirable and sometimes embarrassing products of these bacteria is intestinal gas. The large intestine contains about 7 to 10 L of gas, expelling about 500 mL/day as **flatus** and reabsorbing the rest. Most of this is swallowed air that has worked its way through the digestive tract, but the bacterial flora add to it. Painful cramping can result when undigested nutrients pass into the colon and furnish an abnormal substrate for bacterial action—for example, in lactose intolerance. Flatus is composed of nitrogen (N₂), carbon dioxide (CO₂), hydrogen (H₂), methane (CH₄), hydrogen sulfide (H₂S), and two amines: indole and skatole. Indole, skatole, and H₂S produce the odor of flatus and feces, whereas the others are odorless. The hydrogen gas is combustible and has been known to explode during the use of electrical cauterization in surgery.

Absorption and Motility

The large intestine takes about 12 to 24 hours to reduce the residue of a meal to feces. It does not chemically change the residue but reabsorbs water and electrolytes (especially NaCl) from it. The feces consist of about

75% water and 25% solids. The solids are about 30% bacteria, 30% undigested dietary fiber, 10% to 20% fat, and smaller amounts of protein, sloughed epithelial cells, salts, mucus, and other digestive secretions. The fat is not from the diet but from broken-down epithelial cells and bacteria.

The most common type of colonic motility is a type of segmentation called **haustral contractions**, which occur about every 30 minutes. Distension of a haustrum with feces stimulates it to contract. This churns and mixes the residue, promotes water and salt absorption, and passes the residue distally to another haustrum. Stronger contractions called **mass movements** occur one to three times a day, last about 15 minutes, and move residue for several centimeters at a time. They are often triggered by the **gastrocolic** and **duodenocolic reflexes**, in which filling of the stomach and duodenum stimulates motility of the colon. Mass movements occur especially in the transverse to sigmoid colon, and often within an hour after breakfast.

Defecation

Stretching of the rectum stimulates the defecation reflexes, which account for the urge to defecate that is often felt soon after a meal. The predictability of this response is useful in house training pets and toilet training children. The process involves two reflexes:

1. The **intrinsic defecation reflex**. This reflex operates entirely within the myenteric nerve plexus. Stretch signals travel through the plexus to the muscularis of the descending and sigmoid colon and the rectum. This activates a peristaltic wave that drives feces downward, and it relaxes the internal anal sphincter. This reflex is relatively weak, however, and usually requires the cooperative action of the following reflex.
2. The **parasympathetic defecation reflex**. This is a spinal reflex. Its principal events (fig. 25.32) are that stretch signals are transmitted to the spinal cord, and motor signals return by way of the pelvic nerves to intensify peristalsis in the descending and sigmoid colon and rectum and to relax the internal anal sphincter.

These reflexes are involuntary and are the sole means of controlling defecation in infants and some people with transecting spinal cord injuries. However, the external anal sphincter, like the external urethral sphincter controlling urination, is under voluntary control, enabling one to limit defecation to appropriate circumstances. Defecation normally occurs only when this sphincter is

³⁷flora = flowers, plants

- 1 Feces stretch the rectum and stimulate stretch receptors, which transmit signals to the spinal cord.
- 2 A spinal reflex stimulates contraction of the rectum.
- 3 The spinal reflex also relaxes the internal anal sphincter.
- 4 Impulses from the brain prevent untimely defecation by keeping the external anal sphincter contracted. Defecation occurs only if this sphincter also relaxes.

voluntarily relaxed. Defecation is also aided by the voluntary Valsalva maneuver, in which a breath hold and contraction of the abdominal muscles increase abdominal pressure, compress the rectum, and squeeze the feces from it. This maneuver can also initiate the defecation reflex by forcing feces from the descending colon into the rectum.

If the defecation urge is suppressed, contractions cease in a few minutes and the rectum relaxes. The defecation reflexes reoccur a few hours later or when another mass movement propels more feces into the rectum.

The effects of aging on the digestive system are discussed on page 1144. Table 25.3 lists and describes some common digestive disorders.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

26. How does the mucosa of the large intestine differ from that of the small intestine? How does the muscularis externa differ?
27. Name and briefly describe two types of contractions that occur in the colon and nowhere else in the alimentary canal.
28. Describe the reflexes that cause defecation in an infant. Describe the additional neural controls that function following toilet-training.

FIGURE 25.32 Neural Control of Defecation.

TABLE 25.3 Some Digestive System Diseases

Acute Pancreatitis	Severe pancreatic inflammation perhaps caused by trauma leading to leakage of pancreatic enzymes into parenchyma, where they digest tissue and cause inflammation and hemorrhage.
Appendicitis	Inflammation of the appendix, with swelling, pain, and sometimes gangrene, perforation, and peritonitis.
Ascites	Accumulation of serous fluid in the peritoneal cavity, often causing extreme distension of the abdomen. Most often caused by cirrhosis of the liver (see Insight 26.3, p. 1036) and frequently associated with alcoholism. The diseased liver “weeps” fluid into the abdomen. About 25% of people who develop ascites as a consequence of cirrhosis die within 1 year.
Cancers	Digestive system is subject to cancer especially of the esophagus, stomach, colon, liver, and pancreas, with colon and pancreatic cancer being among the leading causes of cancer death in the United States.
Crohn Disease	Inflammation of small and large intestines, similar to ulcerative colitis. Produces granular lesions and fibrosis of intestine, diarrhea, and lower abdominal pain. Often hereditary.
Diverticulitis	Presence of inflamed herniations (outpocketings, diverticula) of the colon, associated especially with low-fiber diets. Diverticula may rupture, leading to peritonitis.
Dysphagia	Difficulty swallowing. Can result from esophageal obstructions (tumors, constrictions) or impaired peristalsis (due to neuromuscular disorders).
Gluten-sensitive enteropathy	Formerly called <i>sprue</i> or <i>celiac disease</i> . Atrophy of intestinal villi triggered in genetically susceptible individuals by <i>gluten</i> , the protein component of cereal grains. Onset is usually in infancy or early childhood. Results in severe malabsorption of most nutrients, causing watery or fatty diarrhea, abdominal pain, diminished growth, and multiple problems tied to nutritional deficiencies. Treatable with intensive dietary management.
Hiatal hernia	Protrusion of part of the stomach into the thoracic cavity, where the negative thoracic pressure may cause it to balloon. Often causes gastroesophageal reflux (especially when a person is supine) and esophagitis (inflammation of the esophagus).
Ulcerative colitis	Chronic inflammation resulting in ulceration of the large intestine, especially the sigmoid colon and rectum. Tends to be hereditary but exact causes are not well known.

INSIGHT 25.5 Medical History**The Man with a Hole in His Stomach**

Perhaps the most famous episode in the history of digestive physiology began in 1822 on Mackinac Island between Lake Michigan and Lake Huron. Alexis St. Martin, a 28-year-old Canadian voyageur (fig. 25.33), was standing outside a trading post when he was accidentally hit by a shotgun blast from 3 feet away. An Army doctor stationed at Fort Mackinac, William Beaumont, was summoned to examine St. Martin. As Beaumont later wrote, “a portion of the lung as large as a turkey’s egg” protruded through St. Martin’s lacerated and burnt flesh. Below that was a portion of the stomach with a puncture in it “large enough to receive my forefinger.” Beaumont did his best to pick out bone fragments and dress the wound, though he did not expect St. Martin to survive.

Surprisingly, he lived. Over a period of months the wound extruded pieces of bone, cartilage, gunshot, and gun wadding. As the wound healed, a fistula (hole) remained in the stomach, so large that Beaumont had to cover it with a compress to prevent food from coming out. A fold of tissue later grew over the fistula, but it was easily opened. A year later, St. Martin was still feeble. Town authorities decided they could no longer support him on public funds and wanted to ship him 1,500 miles to his home. Beaumont, however, was imbued with a passionate sense of destiny. Very little was known about digestion, and he saw the accident as a unique opportunity to learn. He took St. Martin in at his personal expense and performed 238 experiments on him over several years. Beaumont had never attended medical school and had little idea how scientists work, yet he proved to be an astute experimenter. Under crude frontier conditions and with almost no equipment, he discovered many of the basic facts of gastric physiology discussed in this chapter.

“I can look directly into the cavity of the stomach, observe its motion, and almost see the process of digestion,” Beaumont wrote. “I can pour in water with a funnel and put in food with a spoon, and draw them out again with a siphon.” He put pieces of meat on a string into the stomach and removed them hourly for examination. He sent vials of gastric juice to the leading chemists of America and Europe, who could do little but report that it contained hydrochloric acid. He proved that digestion required HCl and could even occur outside the stomach, but he found that HCl alone did not digest meat; gastric juice must contain some other digestive ingredient. Theodor Schwann, one of the founders of the cell theory, identified that ingredient as pepsin. Beaumont also demonstrated that gastric juice is secreted only in response to food; it did not accumulate between meals as previously thought. He disproved the idea that hunger is caused by the walls of the empty stomach rubbing against each other.

For his part, St. Martin felt helpless and humiliated by Beaumont’s experiments. The fur trappers taunted him as “the

man with a hole in his stomach,” and he longed to return to his work in the wilderness. He had a wife and daughter in Canada whom he rarely got to see, and he ran away repeatedly to join them. He was once gone for 4 years before poverty made him yield to Beaumont’s financial enticement to come back. Beaumont despised St. Martin’s drunkenness and profanity and was quite insensitive to his embarrassment and discomfort over the experiments. Yet St. Martin’s temper enabled Beaumont to make the first direct observations of the relationship between emotion and digestion. When St. Martin was particularly distressed, Beaumont noted little digestion occurring—as we now know, the sympathetic nervous system inhibits digestive activity.

Beaumont published a book in 1833 that laid the foundation for modern gastric physiology and dietetics. It was enthusiastically received by the medical community and had no equal until Russian physiologist Ivan Pavlov (1849–1936) performed his celebrated experiments on digestion in animals. Building on the methods pioneered by Beaumont, Pavlov received the 1904 Nobel Prize for Physiology or Medicine.

In 1853, Beaumont slipped on some ice, suffered a blow to the base of his skull, and died a few weeks later. St. Martin continued to tour medical schools and submit to experiments by other physiologists, whose conclusions were often less correct than Beaumont’s. Some, for example, attributed chemical digestion to lactic acid instead of hydrochloric acid. St. Martin lived in wretched poverty in a tiny shack with his wife and several children, and died 28 years after Beaumont. By then he was senile and believed he had been to Paris, where Beaumont had often promised to take him.

William Beaumont (1785–1853)

Alexis St. Martin (1794–1880)

FIGURE 25.33 Doctor and Patient in a Pioneering Study of Digestion.

CONNECTIVE ISSUES

Interactions Between the DIGESTIVE SYSTEM and Other Organ Systems

■ indicates ways in which this system affects other systems

■ indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

Skin helps synthesize calcitriol, needed for calcium absorption by small intestine

SKELETAL SYSTEM

Small intestine adjusts calcium absorption in proportion to the needs of the skeletal system

Provides protective enclosure for some digestive organs, support for the teeth, and movements of mastication

MUSCULAR SYSTEM

Liver disposes of lactic acid generated by muscles

Essential for chewing, swallowing, and defecation; muscles protect lower GI organs

NERVOUS SYSTEM

Enteric and autonomic nervous systems regulate GI motility and secretion; somatic nervous system controls chewing, swallowing, and defecation; sense organs involved in food selection; hypothalamus contains centers for hunger, thirst, and satiety

ENDOCRINE SYSTEM

Liver degrades hormones; enteroendocrine cells produce many hormones

Hormones regulate GI motility, secretion, and processing of nutrients

CIRCULATORY SYSTEM

GI tract absorbs fluid needed to maintain blood volume; liver degrades heme from dead RBCs, secretes clotting factors, albumin, and other plasma proteins, and regulates blood glucose and iron levels

ALL SYSTEMS

The digestive system provides all other systems with nutrients in a form usable for cellular metabolism and building of tissues

CIRCULATORY SYSTEM (cont.)

Blood transports hormones that regulate GI activity; absorbs and distributes nutrients; vasomotion alters capillary filtration and salivation

LYMPHATIC/IMMUNE SYSTEM

GI mucosa is a site of lymphocyte production; acid, lysozyme, and other digestive enzymes provide nonspecific defense against pathogens; infant intestine absorbs maternal IgA to confer passive immunity on infant

Lymphatic capillaries (lacteals) absorb digested lipids; immune cells protect GI tract from infection

RESPIRATORY SYSTEM

Pressure of digestive organs against diaphragm aids in expiration when abdominal muscles contract

Provides O₂, removes CO₂; Valsalva maneuver aids defecation

URINARY SYSTEM

Intestines complement kidneys in water and electrolyte reabsorption; liver synthesizes urea and kidneys excrete it

Excretes bile pigments and other products of liver metabolism; completes the synthesis of calcitriol, needed for intestinal absorption of calcium and phosphorus

REPRODUCTIVE SYSTEM

Provides nutrients for fetal growth

Developing fetus crowds digestive organs; may cause constipation and heartburn during pregnancy

CHAPTER REVIEW

Review of Key Concepts

25.1 General Anatomy and Digestive Processes (p. 966)

- The digestive system processes food, extracts nutrients, and eliminates the residue. It does this in five stages: ingestion, digestion (mechanical and chemical), absorption, compaction, and defecation.
 - The *digestive tract* is essentially a tube consisting of the mouth, pharynx, esophagus, stomach, and small and large intestines. The *accessory organs* are the teeth, tongue, salivary glands, liver, gallbladder, and pancreas.
 - In most areas, the wall of the digestive tract consists of an inner *mucosa*, a *submucosa*, a *muscularis externa*, and an outer *serosa*. In some areas, a connective tissue *adventitia* replaces the serosa.
 - The *enteric nervous system* regulates much of digestive activity and consists of two neural networks in the wall of the digestive tract: the *submucosal plexus* and the *myenteric plexus*.
 - In the abdominal cavity, the *dorsal mesentery* suspends the digestive tract from the body wall, wraps around it to form the serosa, and in some places continues as a *ventral mesentery*. The ventral mesentery includes the *greater* and *lesser omenta* and the *mesocolon*.
 - Digestive tract motility and secretion are regulated by hormones such as *gastrin* and *secretin*, paracrines such as *histamine* and *prostaglandins*, *short (myenteric) reflexes*, and *long (vagovagal) reflexes*.
- Mastication breaks food into pieces small enough to be swallowed and exposes more food surface to the action of digestive enzymes, making digestion more efficient.
 - Saliva moistens the mouth, digests starch and fat, cleanses the teeth, inhibits bacterial growth, dissolves taste molecules, and binds food into a soft *bolus* to facilitate swallowing. It contains amylase, lipase, mucus, lysozyme, IgA, and electrolytes.
 - Salivation is controlled by *salivatory nuclei* in the medulla oblongata and pons and occurs in response to the thought, odor, sight, taste, or oral feel of food.
 - The pharynx is a muscular funnel in the throat where the respiratory and digestive tracts meet. Its wall contains three sets of *pharyngeal constrictor* muscles that aid in swallowing.
 - The esophagus extends from the pharynx to the *cardiac orifice* of the stomach. It is lined with a nonkeratinized stratified squamous epithelium, has a mixture of skeletal muscle (dominating the upper esophagus) and smooth muscle (dominating the lower), and is lubricated by mucous *esophageal glands* in the submucosa.
 - Deglutition* (swallowing) requires the coordinated action of numerous muscles and is integrated by the *swallowing center* of the medulla oblongata. It entails a *buccal phase* involving the tongue and a *pharyngeal-esophageal phase* involving the palate, infrahyoid muscles, and *muscularis externa* of the esophagus, among other structures.
 - Food and drink normally drop into the stomach by gravity alone, but esophageal peristalsis, mediated by the myenteric nerve plexus, can help drive food to the stomach.
- The stomach wall is marked by *gastric pits*, with two or three tubular glands opening into the bottom of each pit. Most of the stomach has digestive *gastric glands*, whereas the cardiac and pyloric regions have mucous *cardiac glands* and *pyloric glands*. These various glands contain *mucous*, *regenerative*, *parietal*, *chief*, and *enteroendocrine cells*.
 - The stomach mechanically breaks up food, begins the chemical digestion of proteins, and converts ingested food to soupy *chyme*.
 - Gastric juice* consists mainly of water, HCl, and pepsin.
 - The parietal cells secrete HCl, which activates pepsin, promotes the action of lingual lipase, breaks up ingested plant and animal tissues, converts dietary Fe^{3+} into absorbable Fe^{2+} , and destroys most ingested pathogens.
 - The parietal cells also secrete *intrinsic factor*, which is required for vitamin B_{12} absorption. This is the only function of the stomach that is indispensable to life. Without intrinsic factor, a vitamin B_{12} deficiency occurs and leads to pernicious anemia.
 - The chief cells secrete *pepsinogen* (a precursor of the enzyme pepsin) and the fat-digesting enzyme *gastric lipase*.
 - Enteroendocrine cells of the stomach secrete several chemical messengers, including a variety of *gut-brain peptides*, which coordinate different regions of the digestive tract with each other.
 - Movements of the stomach begin with the *receptive-relaxation response* as it accommodates swallowed food, and progress to peristaltic waves that mix and break up the contents. Peristalsis drives the semidigested food, or *chyme*, a little at a time through the pylorus into the duodenum.
 - The stomach digests some protein and lesser amounts of fat and carbohydrate. It absorbs some drugs, but no significant nutrients.

25.2 The Mouth Through Esophagus (p. 970)

- The mouth (oral cavity) serves for ingestion, sensory responses to food, mastication, chemical digestion, deglutition, speech, and respiration.
- The mouth extends from the oral fissure anteriorly to the fauces posteriorly. Its anatomical elements include the lips, cheeks, tongue, hard and soft palates, teeth, and intrinsic salivary glands. It also receives saliva from three pairs of extrinsic salivary glands: the *parotid*, *sublingual*, and *submandibular glands*.

25.3 The Stomach (p. 977)

- The stomach is primarily a food-storage organ, with a capacity of 4 L. It extends from the cardiac orifice proximally to the pylorus distally.

1010 PART FOUR Regulation and Maintenance

11. The stomach is protected from its own acid and enzymes by its mucous coat, tight junctions between the epithelial cells, and rapid epithelial cell replacement.
12. In the *cephalic phase* of gastric activity, mental and sensory stimuli lead to stimulation of gastric secretion and motility through the vagus nerves.
13. In the *gastric phase*, swallowed food and semidigested protein stimulate gastric activity through short and long reflexes. The neurotransmitter acetylcholine, the paracrine secretion histamine, and the hormone gastrin stimulate the secretion of HCl, intrinsic factor, and pepsinogen in this phase.
14. In the *intestinal phase*, chyme in the duodenum stimulates hormonal and nervous reflexes that initially stimulate the stomach, but soon activate an *enterogastric reflex* that inhibits it. Duodenal enteroendocrine cells secrete *secretin* and *cholecystokinin*, which suppress gastric activity so that the stomach does not load chyme into the duodenum too rapidly.

25.4 The Liver, Gallbladder, and Pancreas (p. 986)

1. The liver is the body's largest gland. It has four conspicuous lobes, each composed of innumerable microscopic, cylindrical *lobules* of liver cells (*hepatocytes*). The hepatocytes add some substances to the blood and remove others from it as the blood filters through the *hepatic sinusoids* between them.
2. Bile, secreted by the liver, fills the *bile duct* and *gallbladder*. The gallbladder concentrates the bile.
3. Bile is composed of water, minerals, cholesterol, fats, phospholipids, bile pigments, and bile acids. Most of these are body wastes. Bile pigments cause the brown color of the feces.
4. Bile acids and lecithin aid fat digestion; this is the liver's only digestive role.
5. The pancreas is a flattened retroperitoneal organ posterior to the greater curvature of the stomach. It is composed mostly of exocrine tissue that secretes *pancreatic juice* into the duodenum. It also contains endocrine pancreatic islets that secrete insulin and glucagon.
6. Pancreatic juice contains sodium bicarbonate, which neutralizes stomach acid, and several digestive enzymes or enzyme precursors (*zymogens*). The

pancreatic enzymes secreted in active form are *pancreatic amylase* (which digests starch), *pancreatic lipase* (which digests fat), *ribonuclease* (which digests RNA), and *deoxyribonuclease* (which digests DNA). Those secreted as zymogens and activated in the small intestine are *trypsin*, *chymotrypsin*, and *carboxypeptidase*, all of which digest proteins.

7. Bile and pancreatic juice are secreted in response to acetylcholine, cholecystokinin, and secretin.

25.5 The Small Intestine (p. 992)

1. The small intestine begins at the pylorus (gateway from the stomach) and ends at the ileocecal junction (gateway to the large intestine). It consists of the *duodenum* (25 cm), *jejunum* (1.0–1.7 m), and *ileum* (1.6–2.7 m).
2. To carry out its digestive and nutrient-absorbing roles, the small intestine has a very large internal surface area stemming from its great length and three kinds of mucosal elaborations: the *circular folds*, *villi*, and *microvilli*.
3. Villi are covered with an epithelium of absorptive cells and goblet cells. Each villus contains a lipid-collecting lymphatic capillary called the *lacteal*. Glandular *intestinal crypts* open onto the floor of the intestine between the villi. The crypt epithelium is composed of absorptive and goblet cells, stem cells, and bacterium-fighting *Paneth cells*.
4. The enzymes that carry out intestinal digestion occur mostly in the brush borders of the absorptive cells and in the pancreatic juice.
5. Movements of the small intestine include chopping *segmentation* contractions and overlapping waves of peristalsis called the *migrating motor complex*.

25.6 Chemical Digestion and Absorption (p. 996)

1. Salivary amylase begins digesting starch in the mouth and continues in the stomach until a food bolus breaks up and exposes the amylase to hydrochloric acid. Starch digestion resumes in the small intestine by the action of pancreatic amylase, which breaks it down into oligosaccharides and maltose.
2. The brush border enzymes *dextrinase*, *glucoamylase*, and *maltase*

finish digesting the breakdown products of starch, while *sucrase* and *lactase* break down the disaccharides sucrose and lactose.

3. The resulting monosaccharides (glucose, galactose, and fructose) are absorbed by the sodium–glucose transport protein, by a fructose carrier, and by solvent drag, then pass into the blood capillaries of the villus.
4. Protein digestion begins with the action of pepsin in the stomach and is continued by trypsin and chymotrypsin in the small intestine. The resulting small peptides are disassembled one amino acid at a time by *carboxypeptidase*, *aminopeptidase*, and *dipeptidase*. The last two of these are brush border enzymes and thus carry out *contact digestion*.
5. The amino acids are absorbed by sodium-dependent cotransport proteins, then pass into the blood capillaries of the villus.
6. Fat digestion is begun by lingual lipase in the saliva and continued by gastric lipase in the stomach, but most fat is digested by pancreatic lipase in the small intestine.
7. In the duodenum, bile acids and lecithin help break fat into *emulsification droplets*, exposing more surface area to the action of lipase. Lipase hydrolyzes triglycerides into free fatty acids and monoglycerides.
8. *Micelles* in the bile collect these breakdown products, along with cholesterol and fat-soluble vitamins, and deliver them to the surface of the intestinal absorptive cells, which absorb the lipids.
9. The absorptive cells resynthesize triglycerides and package them, with cholesterol, into droplets called *chylomicrons*, coated with phospholipid and protein.
10. Chylomicrons are secreted from the basal surface of the absorptive cells and taken into the lacteal in the villus. They enter the bloodstream at the left subclavian vein, where intestinal lymph empties into the blood.
11. Dietary DNA and RNA are hydrolyzed into nucleotides by deoxyribonuclease and ribonuclease. Brush border *nucleosidases* and *phosphatases* then decompose these into ribose, deoxyribose, phosphate, and nitrogenous bases, which are absorbed into the blood capillaries of the villus.

12. Vitamins are not digested, but are absorbed unchanged. Fat-soluble vitamins are absorbed with other dietary lipids; most water-soluble vitamins by simple diffusion; and vitamin B₁₂ binds to intrinsic factor and is then absorbed by receptor-mediated endocytosis.
13. Minerals are absorbed by cotransport with sugars and amino acids (Na⁺), by active transport (Cl⁻, Fe²⁺), and by simple diffusion (K⁺, Ca²⁺). Iron absorption is regulated by the hormone hepcidin and calcium absorption by parathyroid hormone and vitamin D.
14. Water is absorbed by osmosis, following an osmotic gradient created by the absorption of salts and organic nutrients.

25.7 The Large Intestine (p. 1002)

1. The large intestine is about 1.5 m long and consists of the *cecum*; the *ascending*, *transverse*, *descending*, and *sigmoid colon*; *rectum*; and *anal canal*. The anal canal has an involuntary *internal anal sphincter* of smooth muscle and a voluntary *external anal sphincter* of skeletal muscle.
2. The large intestine absorbs water and salts from the indigestible food residue and reduces the residue to feces.
3. Movements of the large intestine include frequent *haustral contractions* that move the feces only a short distance distally, and one to three daily *mass movements* that move the feces several centimeters.

4. Stretching of the rectum triggers the *intrinsic defecation reflex*, mediated by the myenteric nerve plexus. This reflex drives feces downward and relaxes the internal anal sphincter. A stronger *parasympathetic defecation reflex* involves a reflex arc through the spinal cord and parasympathetic fibers of the pelvic nerve.
5. These reflexes tend to cause defecation, although in individuals with bowel control, voluntary control of the external anal sphincter permits or prohibits defecation at will.

Testing Your Recall

1. Which of the following enzymes acts in the stomach?
 - a. chymotrypsin
 - b. lingual lipase
 - c. carboxypeptidase
 - d. enterokinase
 - e. dextrinase
2. Which of the following enzymes does *not* digest any nutrients?
 - a. chymotrypsin
 - b. lingual lipase
 - c. carboxypeptidase
 - d. enterokinase
 - e. dextrinase
3. Which of the following is *not* an enzyme?
 - a. chymotrypsin
 - b. enterokinase
 - c. secretin
 - d. pepsin
 - e. nucleosidase
4. The substance in question 3 that is *not* an enzyme is
 - a. a zymogen.
 - b. a nutrient.
 - c. an emulsifier.
 - d. a neurotransmitter.
 - e. a hormone.
5. The lacteals absorb
 - a. chylomicrons.
 - b. micelles.
 - c. emulsification droplets.
 - d. amino acids.
 - e. monosaccharides.
6. All of the following contribute to the absorptive surface area of the small intestine *except*
 - a. its length.
 - b. the brush border.
 - c. haustra.
 - d. circular folds.
 - e. villi.
7. Which of the following is a periodontal tissue?
 - a. the gingiva
 - b. the enamel
 - c. the cementum
 - d. the pulp
 - e. the dentin
8. Anatomically, the _____ of the stomach most closely resemble the _____ of the small intestine.
 - a. gastric pits, intestinal crypts
 - b. pyloric glands, intestinal crypts
 - c. rugae, Peyer patches
 - d. parietal cells, goblet cells
 - e. gastric glands, duodenal glands
9. Which of the following cells secrete digestive enzymes?
 - a. chief cells
 - b. mucous neck cells
 - c. parietal cells
 - d. goblet cells
 - e. enteroendocrine cells
10. What phase of gastric regulation includes inhibition by the enterogastric reflex?
 - a. the intestinal phase
 - b. the gastric phase
 - c. the buccal phase
 - d. the cephalic phase
 - e. the pharyngo–esophageal phase
11. Cusps are a feature of the _____ surfaces of the molars and premolars.
12. The acidity of the stomach halts the action of _____ but promotes the action of _____, both of which are salivary enzymes.
13. The _____ salivary gland is named for its proximity to the ear.
14. The submucosal and myenteric plexuses collectively constitute the _____ nervous system.
15. Nervous stimulation of gastrointestinal activity is mediated mainly through the parasympathetic fibers of the _____ nerves.
16. Food in the stomach causes G cells to secrete _____, which in turn stimulates the secretion of HCl and pepsinogen.
17. Hepatic macrophages occur in blood-filled spaces of the liver called _____.

1012 PART FOUR Regulation and Maintenance

18. The brush border enzyme that finishes the job of starch digestion, producing glucose, is called _____. Its substrate is _____.
19. Fats are taken into the lymphatic capillaries as droplets called _____.
20. Within the absorptive cells of the small intestine, ferritin binds the nutrient _____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Fat is not digested until it reaches the duodenum.
- A tooth is composed mostly of enamel.
- Hepatocytes secrete bile into the hepatic sinusoids.
- Cholecystokinin stimulates the release of bile into the duodenum.
- Peristalsis is controlled by the myenteric nerve plexus.
- Pepsinogen, trypsinogen, and procarboxypeptidase are enzymatically inactive zymogens.
- The absorption of dietary iron depends on intrinsic factor.
- Filling of the stomach stimulates contractions of the colon.
- The duodenum secretes a hormone that inhibits contractions of the stomach.
- Tight junctions of the small intestine prevent anything from leaking between the epithelial cells.

Answers in appendix B

Testing Your Comprehension

- On Monday, David has a waffle with syrup for breakfast at 7:00, and by 10:30 he feels hungry again. On Tuesday, he has bacon and eggs and feels satisfied until his noon lunch hour approaches. Assuming an equal quantity of food on both days and all other factors to be equal, explain this difference.
- Which of these do you think would have the most severe effect on digestion: surgical removal of the stomach, gallbladder, or pancreas? Explain.
- What do carboxypeptidase and aminopeptidase have in common? Identify as many differences between them as you can.
- What do micelles and chylomicrons have in common? Identify as many differences between them as you can.
- Explain why most dietary lipids must be absorbed by the lacteals rather than by the blood capillaries of a villus.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Metabolism, catabolism, and anabolism (p. 67)
- Oxidation and reduction (p. 67)
- Saturated and unsaturated fats (p. 72)
- Metabolic pathways (p. 80)
- Structure and functions of ATP (p. 80)
- Receptor-mediated endocytosis (p. 106)
- Insulin and glucagon (p. 654)

Nutrition is the starting point and basis for all human form and function. From the time a single-celled, fertilized egg divides in two, nutrition provides the matter needed for cell division, growth, and development. It is the source of fuel that provides the energy for all biological work and of the raw materials for replacement of worn-out biomolecules and cells. The fact that it provides only the *raw* materials means, further, that chemical change—metabolism—lies at the foundation of form and function. In chapter 25, we saw how the digestive system breaks nutrients down into usable form and absorbs them into the blood and lymph. We now consider these nutrients in more depth, follow their fate after absorption, and explore related issues of metabolism and body heat.

animal is undernourished until it loses much of its weight and then allowed to feed at will, it increases its intake and again returns quickly to its former weight.

In humans, the set point varies greatly from person to person, and body weight results from a combination of hereditary and environmental influences. From studies of identical twins and other people, it appears that about 30% to 50% of the variation in human weight is due to heredity, and the rest to environmental factors such as eating and exercise habits.

Appetite

The struggle for weight control often seems to be a struggle against the appetite. Since the early 1990s, physiologists have discovered a still-growing list of peptide hormones and regulatory pathways that control short- and long-term appetite and body weight. Some of the hormones have been called *gut-brain peptides* because they act as chemical signals from the gastrointestinal tract to the brain. Only a few will be described here, but these suffice to give some idea of regulatory mechanisms known to date and where a great deal of research is currently focused.

Short-Term Regulators of Appetite

The following three peptides work over periods of minutes to hours, making one feel hungry and begin eating, then to feel satiated and end a meal:

- describe some factors that regulate hunger and satiety;
 - define *nutrient* and list the six major categories of nutrients;
 - state the function of each class of macronutrients, the approximate amounts required in the diet, and some major dietary sources of each;
 - name the blood lipoproteins, state their functions, and describe how they differ from each other; and
 - name the major vitamins and minerals required by the body and the general functions they serve.
- **Ghrelin.**¹ This is secreted by parietal cells in the fundus of the stomach, especially when the stomach is empty. It produces the sensation of hunger and stimulates the hypothalamus to secrete growth hormone-releasing hormone, thus priming the body to take best advantage of the nutrients about to be absorbed. Within an hour after eating, ghrelin secretion ceases.
 - **Peptide YY (PYY).** This is a member of a family of hormones related to *neuropeptide Y (NPY)*. It is secreted by enteroendocrine cells in the ileum and colon, but they sense that food has arrived even as it enters the stomach. They secrete PYY long before the chyme reaches the ileum, and in quantities proportional to the calories consumed. The primary effect of PYY is to signal satiety and terminate eating. Thus ghrelin is one of the signals that begins a meal, and PYY is one of the signals that ends it. PYY remains elevated well after a meal. It acts as an *ileal brake* that prevents the stomach from emptying too quickly; thus it prolongs the sense of satiety.
 - **Cholecystokinin (CCK).** As we saw in chapter 25, CCK is secreted by enteroendocrine cells in the duodenum and jejunum. It stimulates the secretion of

26.1 Nutrition

Objectives

When you have completed this section, you should be able to

Body Weight and Energy Balance

The subject of nutrition quickly brings to mind the subject of body weight and the popular desire to control it. Weight is determined by the body's energy balance—if energy intake and output are equal, body weight is stable. We gain weight if intake exceeds output and lose weight if output exceeds intake. Although weight is determined by this ratio, it usually remains quite stable over many years' time and seems to have a homeostatic set point. This has been experimentally demonstrated in animals. If an animal is force-fed until it becomes obese and then allowed to feed at will, it voluntarily reduces its intake and quickly returns to its former weight. Similarly, if an

¹Named partly from *ghre* = growth, and partly as an acronym derived from growth hormone-releasing hormone

bile and pancreatic enzymes, but also stimulates the brain and sensory fibers of the vagus nerves, producing an appetite-suppressing effect. Thus it joins PYY as a signal to stop eating.

Long-Term Regulators of Appetite

Other peptides regulate appetite, metabolic rate, and body weight over the longer term, thus governing one's average rate of caloric intake and energy expenditure over periods of weeks to years. The following two members of this group work as "adiposity signals," informing the brain of how much adipose tissue the body has and activating mechanisms for adding or reducing fat.

- **Leptin.**² Leptin is secreted by adipocytes throughout the body. Its level is proportional to one's fat stores, so this is the brain's primary way of knowing how much body fat we have. Animals with a leptin deficiency or a defect in leptin receptors exhibit *hyperphagia* (overeating) and extreme obesity. With few exceptions, however, obese humans are not leptin-deficient or aided by leptin injections. More commonly, it seems that obesity is linked to unresponsiveness to leptin—a receptor defect rather than a hormone deficiency. Adipose tissue is increasingly seen as an important source of multiple hormones that influence the body's energy balance.
- **Insulin.** As we saw in chapter 17, insulin is secreted by the pancreatic beta cells. It stimulates glucose and amino acid uptake and promotes glycogen and fat synthesis. But it also has receptors in the brain and functions, like leptin, as an index of the body's fat stores. It has a weaker effect on appetite than leptin does, however.

An important brain center for appetite regulation is the **arcuate nucleus** of the hypothalamus. All five of the aforementioned peptides have receptors in the arcuate nucleus, although they act on other target cells in the body as well. The arcuate nucleus has two neural networks involved in hunger. One group secretes **neuropeptide Y (NPY)**, itself a potent appetite stimulant. The other secretes **melanocortin**, which inhibits eating. Ghrelin stimulates NPY secretion, whereas insulin, PYY, and leptin inhibit it. Leptin also stimulates melanocortin secretion (fig. 26.1) and inhibits the secretion of appetite stimulants called *endocannabinoids*, named for their resemblance to the tetrahydrocannabinol (THC) of marijuana.

Think About It

Suppose leptin or CCK could be economically produced and packaged as tablets to be taken orally. Would this be an effective diet drug? Why or why not?

INSIGHT 26.1 Clinical Application

Obesity

Obesity is clinically defined as a weight more than 20% above the recommended norm for one's age, sex, and height. In the United States, about 30% of the population is obese and another 35% is overweight; there has lately been an alarming increase in the number of children who are morbidly obese by the age of 10. You can judge whether you are overweight or obese by calculating your *body mass index (BMI)*. If *W* is your weight in kilograms and *H* is your height in meters, $BMI = W/H^2$. (Appendix D provides English-metric conversion factors.) A BMI of 20 to 25 kg/m² is considered to be optimal for most people. A BMI over 27 kg/m² is considered overweight, and above 30 kg/m² is considered obese.

Excess weight shortens life expectancy and increases a person's risk of atherosclerosis, hypertension, diabetes mellitus, joint pain and degeneration, kidney stones, and gallstones; cancer of the breast, uterus, and liver in women; and cancer of the colon, rectum, and prostate gland in men. Excess thoracic fat impairs breathing and results in increased blood Pco₂, sleepiness, and reduced vitality. Obesity is also a significant impediment to successful surgery.

Heredity plays as much role in obesity as in height, and even more than in many other disorders generally acknowledged to be hereditary. However, a predisposition to obesity is often greatly worsened by overfeeding in infancy and childhood. Consumption of excess calories in childhood causes adipocytes to increase in size and number. In adulthood, adipocytes do not multiply except in some extreme weight gains; their number remains constant while weight gains and losses result from changes in cell size (cellular hypertrophy).

As so many dieters learn, it is very difficult to substantially reduce one's adult weight. Most diets are unsuccessful over the long run as dieters lose and regain the same weight over and over. From an evolutionary standpoint, this is not surprising. The body's appetite- and weight-regulating mechanisms have evolved more to limit weight loss than weight gain, for a scarcity of food was surely a more common problem than a food surplus for our prehistoric ancestors. Were it not for the mechanisms that thwart weight loss, our ancestors might not have made it through the lean eons and we might not be here; but now that we are surrounded with a glut of tempting food, these survival mechanisms have become mechanisms of pathology.

Understandably, pharmaceutical companies are keenly interested in developing effective weight-control drugs. There could be an enormous profit, for example, in a drug that could inhibit ghrelin signaling or enhance or mimic leptin or melanocortin signaling. Such efforts have so far met with little success, but clearly a prerequisite to drug development is a better understanding of appetite-regulating peptides and their receptors. This subject is generating a prolific literature, and undoubtedly much more will be known about it before this chapter even gets to the printing press.

²lept = thin

FIGURE 26.1 Gut-Brain Peptides in Appetite Regulation. Tissues and organs at the bottom of the figure are sources of peptides that stimulate or inhibit appetite-regulating neurons in the arcuate nucleus of the hypothalamus. Depending on the balance of stimulation and inhibition, those neurons secrete NPY or melanocortin to create a conscious sensation of hunger or satiety, respectively. (CCK = cholecystokinin; NPY = neuropeptide Y; PYY = peptide YY)

Gut-brain peptides certainly are not the whole story behind appetite regulation. Hunger is also stimulated partly by gastric peristalsis. Mild **hunger contractions** begin soon after the stomach is emptied and increase in intensity over a period of hours. They can become quite a painful and powerful incentive to eat, yet they do not affect the amount of food consumed—this remains much

the same even when nervous connections to the stomach and intestines are severed to cut off all conscious perception of hunger contractions. Food intake is terminated not only by PYY and CCK, but also in ways similar to the way that water intake slakes the thirst (see p. 945). Merely chewing and swallowing food briefly satisfy the appetite, even if the food is removed through an esophageal fistula

(opening) before reaching the stomach. Inflating the stomach with a balloon inhibits hunger even in an animal that has not actually swallowed any food. Satiation produced by these mechanisms, however, is very short-lived. Lasting satiety depends on the absorption of nutrients into the blood.

Appetite is not merely a question of *how much* but also *what kind* of food is consumed. Even animals shift their diets from one kind of food to another, apparently because some foods provide nutrients that others do not. In humans, different neurotransmitters also seem to govern the appetite for different classes of nutrients. For example, *norepinephrine* stimulates the appetite for carbohydrates, *galanin* for fatty foods, and *endorphins* for protein.

Calories

One calorie is the amount of heat that will raise the temperature of 1 g of water 1°C. One thousand calories is called a Calorie (capital *C*) in dietetics and a **kilocalorie (kcal)** in biochemistry. The relevance of calories to physiology is that they are a measure of the capacity to do biological work.

Nearly all dietary calories come from carbohydrates, proteins, and fats. Carbohydrates and proteins yield about 4 kcal/g when they are completely oxidized, and fats yield about 9 kcal/g. Alcohol (7.1 kcal/g) and sugary foods can promote malnutrition by providing “empty calories”—blunting the appetite for foods with greater nutrient diversity (see Insight 26.4, p. 1041). By suppressing the appetite but failing to provide other nutrients the body requires, they can contribute to malnutrition. In sound nutrition, the body’s energy needs are met by more complex foods

that simultaneously meet the need for proteins, lipids, vitamins, and other nutrients.

When a chemical is described as **fuel** in this chapter, we mean it is oxidized solely or primarily to extract energy from it. The extracted energy is usually used to make adenosine triphosphate (ATP), which then transfers the energy to other physiological processes (see fig. 2.30, p. 81).

Nutrients

A **nutrient** is any ingested chemical that is used for growth, repair, or maintenance of the body. Nutrients fall into six major classes: water, carbohydrates, lipids, proteins, minerals, and vitamins (table 26.1). Water, carbohydrates, lipids, and proteins are considered **macronutrients** because they must be consumed in relatively large quantities. Minerals and vitamins are called **micronutrients** because only small quantities are required.

Recommended daily allowances (RDAs) of nutrients were first developed in 1943 by the National Research Council and National Academy of Sciences; they have been revised several times since. An RDA is a liberal but safe estimate of the daily intake that would meet the nutritional needs of most healthy people. Consuming less than the RDA of a nutrient does not necessarily mean you will be malnourished, but the probability of malnutrition increases in proportion to the amount of the deficit and how long it lasts.

Many nutrients can be synthesized by the body when they are unavailable from the diet. The body is incapable, however, of synthesizing minerals, most vitamins, eight of the amino acids, and one to three of the fatty acids. These are called **essential nutrients** because it is essential that they be included in the diet.

TABLE 26.1 Nutrient Classes and Their Principal Functions

Nutrient	Daily Requirement	Representative Functions
Water	2.5 L	Solvent; coolant; reactant or product in many metabolic reactions (especially hydrolysis and condensation); dilutes and eliminates metabolic wastes; supports blood volume and pressure
Carbohydrates	125–175 g	Fuel; a component of nucleic acids, ATP and other nucleotides, glycoproteins, and glycolipids
Lipids	80–100 g	Fuel; plasma membrane structure; myelin sheaths of nerve fibers; hormones; eicosanoids; bile acids; insulation; protective padding around organs; absorption of fat-soluble vitamins; vitamin D synthesis; some blood-clotting factors
Proteins	44–60 g	Muscle contraction; ciliary and flagellar motility; structure of cellular membranes and extracellular material; enzymes; major component of connective tissues; transport of plasma lipids; some hormones; oxygen binding and transport pigments; blood-clotting factors; blood viscosity and osmolarity; antibodies; immune recognition; neuromodulators; buffers; emergency fuel
Minerals	0.05–3,300 mg	Structure of bones and teeth; component of some structural proteins, hormones, ATP, phospholipids, and other chemicals; cofactors for many enzymes; electrolytes; oxygen transport by hemoglobin and myoglobin; buffers; stomach acid; osmolarity of body fluids
Vitamins	0.002–60 mg	Coenzymes for many metabolic pathways; antioxidants; component of visual pigment; one hormone (vitamin D)

Carbohydrates

A well-nourished adult has about 440 g of carbohydrate in the body, most of it in three places: about 325 g of muscle glycogen, 90 to 100 g of liver glycogen, and 15 to 20 g of blood glucose.

Sugars function as a structural component of other molecules including nucleic acids, glycoproteins, glycolipids, ATP, and related nucleotides (GTP, cAMP, etc.), and they can be converted to amino acids and fats. Most of the body's carbohydrate, however, serves as fuel—an easily oxidized source of chemical energy. Most cells meet their energy needs from a combination of carbohydrates and fats, but some cells, such as neurons and erythrocytes, depend almost exclusively on carbohydrates. Even a brief period of **hypoglycemia**³ (deficiency of blood glucose) causes nervous system disturbances felt as weakness or dizziness.

Blood glucose concentration is therefore carefully regulated, mainly through the interplay of insulin and glucagon (see chapter 17 and later in this chapter). Among other effects, these hormones regulate the balance between glycogen and free blood glucose. If blood glucose concentration drops too low, the body draws on its stores of glycogen to meet its energy needs. If glycogen stores are depleted, physical endurance is greatly reduced. Thus, it is important to consume enough carbohydrate to ensure that the body maintains adequate stores of glycogen for periods of exercise and fasting (including sleep).

Carbohydrate intake also influences the metabolism of other nutrients. Fat is oxidized as fuel when glucose and glycogen levels are too low to meet our energy needs, and conversely, excess carbohydrate is converted to fat. This is why the consumption of starchy and sugary foods has a pronounced effect on body weight. It is unwise, however, to try to “burn off fat” by excessively reducing carbohydrate intake. As shown later in this chapter, the complete and efficient oxidation of fats depends on adequate carbohydrate intake and the presence of certain intermediates of carbohydrate metabolism. If these are lacking, fats are incompletely oxidized to ketone bodies, which may cause metabolic acidosis.

Requirements

Because carbohydrates are rapidly oxidized, they are required in greater amounts than any other nutrient. The RDA is 125 to 175 g. The brain alone consumes about 120 g of glucose per day. Most Americans get about 40% to 50% of their calories from carbohydrates, but highly active people should get up to 60%.

Carbohydrate consumption in the United States has become excessive over the past century because of a combination of fondness for sweets, increased use of sugar in processed foods, and reduced physical activity (see Insight 26.2). A century ago, Americans consumed an

average of 1.8 kg (4 lb) of sugar per year. Now, with sucrose and high-fructose corn syrup so widely used in foods and beverages, the average American ingests 200 to 300 g of carbohydrate per day and the equivalent of 27 kg (60 lb) of table sugar and 21 kg (46 lb) of corn syrup per year. A single nondiet soft drink contains 38 to 43 g (about 8 teaspoons) of sugar per 355 mL (12 oz) serving.

Dietary carbohydrates come in three principal forms: monosaccharides, disaccharides, and polysaccharides (complex carbohydrates). The only nutritionally significant polysaccharide is starch. Although glycogen is a polysaccharide, only trivial amounts of it are present in cooked meats. Cellulose, another polysaccharide, is not considered a nutrient because it is not digested and never enters the human tissues. Its importance as dietary fiber, however, is discussed shortly.

The three major dietary disaccharides are sucrose, lactose, and maltose. The monosaccharides—glucose, galactose, and fructose—arise mainly from the digestion of starch and disaccharides. The small intestine and liver convert fructose and galactose to glucose, so ultimately all carbohydrate digestion generates glucose. Outside of the hepatic portal system, glucose is the only monosaccharide present in the blood in significant quantity; thus it is known as *blood sugar*. Its concentration is normally maintained at 70 to 110 mg/dL in peripheral venous blood.

Think About It

Glucose concentration is about 15 to 30 mg/dL higher in arterial blood than in most venous blood. Explain why.

Ideally, most carbohydrate intake should be in the form of complex carbohydrates, primarily starch. This is partly because foods that provide starch also usually provide other nutrients. Simple sugars not only provide empty calories but also promote tooth decay. A typical American, however, now obtains only 50% of his or her carbohydrates from starch and the other 50% from sucrose and corn syrup.

INSIGHT 26.2 Evolutionary Medicine

Evolution of the Sweet Tooth

Our craving for sugar doubtlessly originated in our prehistoric ancestors. Not only did they have to work much harder to survive than we do, but high-calorie foods were scarce and people were at constant risk of starvation. Those who were highly motivated to seek and consume sugary, high-calorie foods passed their “sweet tooth” on to us, their descendants—along with a similarly adaptive appetite for other rare but vital nutrients, namely fat and salt. The tastes that were essential to our ancestors' survival can now be a disadvantage in a culture where salty, fatty, and sugary foods are all too easy to obtain and the food industry eagerly capitalizes on these tastes.

³hypo = below normal + glyc = sugar + emia = blood condition

Dietary Sources

Nearly all dietary carbohydrates come from plants—particularly grains, legumes, fruits, and root vegetables. Sucrose is refined from sugarcane and sugar beets. Fructose is present in fruits and corn syrup. Maltose is present in some foods such as germinating cereal grains. Lactose is the most abundant solute in cow's milk (about 4.6% lactose by weight).

Fiber

Dietary fiber refers to all fibrous materials of plant and animal origin that resist digestion. Most is plant matter—the carbohydrates cellulose and pectin and such noncarbohydrates as gums and lignin. Although it is not a nutrient, fiber is an essential component of the diet. The recommended daily allowance is about 30 g, but average intake varies greatly from country to country—from 40 to 150 g/day in India and Africa to only 12 g/day in the United States.

Water-soluble fiber includes pectin and certain other carbohydrates found in oats, beans, peas, carrots, brown rice, and fruits. It reduces blood cholesterol and low-density lipoprotein (LDL) levels (see Insight 19.5, p. 750).

Water-insoluble fiber includes cellulose, hemicellulose, and lignin. It apparently has no effect on cholesterol or LDL levels, but it absorbs water and swells, thereby softening the stool and increasing its bulk by 40% to 100%. This effect stretches the colon and stimulates peristalsis, thereby quickening the passage of feces. In doing so, water-insoluble fiber reduces the risk of constipation and diverticulitis (see table 25.3, p. 1006).

Contrary to previous popular and scientific belief, dietary fiber has no clear effect on the incidence of colorectal cancer. Excessive fiber can actually have a deleterious effect by interfering with the absorption of iron, calcium, magnesium, phosphorus, and some trace elements.

Lipids

The reference male and female are, respectively, about 15% and 25% fat by weight. Fat accounts for most of the body's stored energy. Lesser amounts of phospholipid, cholesterol, and other lipids also play vital structural and physiological roles.

A well-nourished adult meets 80% to 90% of his or her resting energy needs from fat. Fat is superior to carbohydrates for energy storage for two reasons: (1) carbohydrates are hydrophilic, absorb water, and thus expand and occupy more space in the tissues. Fat, however, is hydrophobic, contains almost no water, and is a more compact energy storage substance. (2) Fat is less oxidized than carbohydrate and contains over twice as much energy (9 kcal/g of fat compared with 4 kcal/g of carbohydrate). A man's typical fat reserves contain enough energy for 119 hours of running, whereas his carbohydrate stores would suffice for only 1.6 hours.

Fat has **glucose-sparing** and **protein-sparing effects**—as long as enough fat is available to meet the energy needs of the tissues, protein is not catabolized for fuel and glucose is spared for consumption by cells that cannot use fat, such as neurons.

Vitamins A, D, E, and K are fat-soluble vitamins, which depend on dietary fat for their absorption by the intestine. People who ingest less than 20 g of fat per day are at risk of vitamin deficiency because there is not enough fat in the intestine to transport these vitamins into the body tissues.

Phospholipids and cholesterol are major structural components of plasma membranes and myelin. Cholesterol is also important as a precursor of steroid hormones, bile acids, and vitamin D. Thromboplastin, an essential blood-clotting factor, is a lipoprotein. Two fatty acids—arachidonic acid and linoleic acid—are precursors of prostaglandins and other eicosanoids.

In addition to its metabolic and structural roles, fat has important protective and insulating functions described under adipose tissue in chapter 5.

Requirements

Fat should account for no more than 30% of your daily caloric intake; no more than 10% of your fat intake should be saturated fat; and average cholesterol intake should not exceed 300 mg/day (one egg yolk contains about 240 mg). A typical American consumes 30 to 150 g of fat per day, obtains 40% to 50% of his or her calories from fat, and ingests twice as much cholesterol as the recommended limit.

Most fatty acids can be synthesized by the body. **Essential fatty acids** are those we cannot synthesize and therefore must obtain from the diet. These include linoleic acid and possibly linolenic and arachidonic acids; there are differences of opinion about the body's ability to synthesize the last two. As long as 1% to 2% of the total energy intake comes from linoleic acid, people show no signs of essential fatty acid deficiency. In the typical Western diet, linoleic acid provides about 6% of the energy.

Sources

Saturated fats are predominantly of animal origin. They occur in meat, egg yolks, and dairy products but also in some plant products such as coconut and palm oils (common in nondairy coffee creamers and other products). Processed foods such as hydrogenated oils and vegetable shortening are also high in saturated fat, which is therefore abundant in many baked goods. Unsaturated fats predominate in nuts, seeds, and most vegetable oils. The essential fatty acids are amply provided by the vegetable oils in mayonnaise, salad dressings, and margarine and by whole grains and vegetables. Excessive consumption of saturated and unsaturated fats is a risk

factor for diabetes mellitus, cardiovascular disease, and breast and colon cancer.

The richest source of cholesterol is egg yolks, but it is also prevalent in milk products; shellfish (especially shrimp); organ meats such as kidneys, liver, and brains; and other mammalian meat. Cholesterol does not occur in foods of plant origin. However, the serum cholesterol level is strongly influenced by the types and quantity of fatty acids in the diet. This relationship is explained in the next section.

Cholesterol and Serum Lipoproteins

Lipids are an important part of the diet and must be transported to all cells of the body, yet they are hydrophobic and do not dissolve in the aqueous blood plasma. This problem is overcome by complexes called **lipoproteins**—tiny droplets with a core of cholesterol and triglycerides and a coating of proteins and phospholipids. The coating not only enables the lipids to remain suspended in the blood, but also serves as a recognition marker for cells that absorb them. The complexes are often referred to as *serum lipoproteins* because their concentrations are expressed in terms of a volume of blood serum, not whole blood.

Lipoproteins are classified into four major categories (and some lesser ones) by their density: **chylomicrons**, **high-density lipoproteins (HDLs)**, **low-density lipoproteins (LDLs)**, and **very-low-density lipoproteins (VLDLs)** (fig. 26.2a). The higher the proportion of protein to lipid, the higher the density. These particles also differ considerably in size: chylomicrons range widely from 75 to 1,200 nm in diameter, but the others diminish in size from VLDLs (30–80 nm), to LDLs (18–25 nm), to HDLs (5–12 nm). Their most important differences, however, are in composition and function. Figure 26.2b shows the three primary pathways by which they are made and processed.

Chylomicrons form in the absorptive cells of the small intestine and then pass into the lymphatic system and ultimately the bloodstream (see p. 1000). Endothelial cells of the blood capillaries have a surface enzyme called **lipoprotein lipase** that hydrolyzes chylomicron triglycerides into monoglycerides and free fatty acids (FFAs). These products can then pass through the capillary walls into adipocytes, where they are resynthesized into storage triglycerides. Some FFAs, however, remain in the blood plasma bound to albumin. The remainder of a chylomicron after the triglycerides have been extracted, called a *chylomicron remnant*, is removed and degraded by the liver.

VLDLs, produced by the liver, transport lipids to the adipose tissue for storage. When their triglycerides are removed in the adipose tissue, the VLDLs become LDLs and contain mostly cholesterol. Cells that need cholesterol (usually for membrane structure or steroid hormone synthesis) absorb LDLs by receptor-mediated endocytosis,

digest them with lysosomal enzymes, and release the cholesterol for intracellular use.

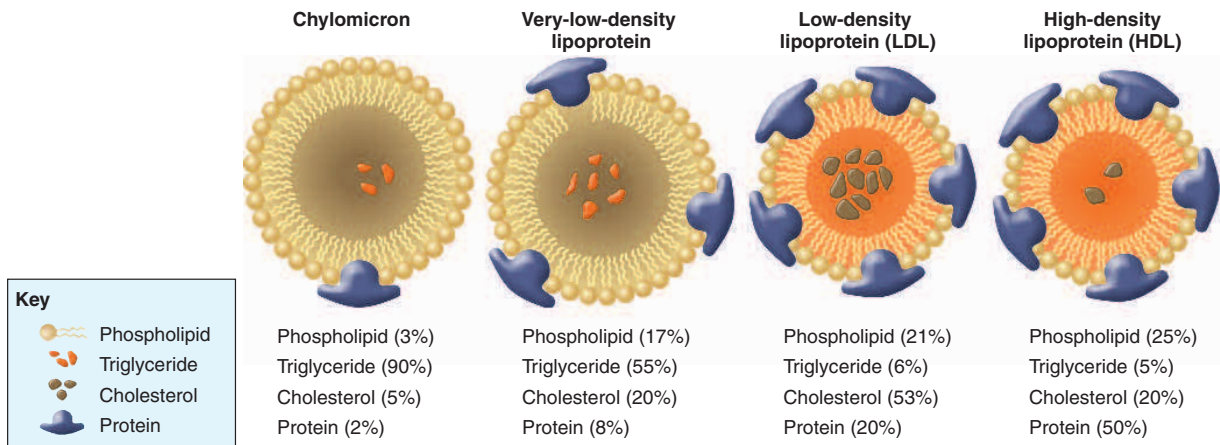

HDL production begins in the liver, which produces an empty, collapsed protein shell. This shell travels in the blood and picks up cholesterol and phospholipids from other organs. The next time it circulates through the liver, the liver removes the cholesterol and eliminates it in the bile as either cholesterol or bile acids. HDLs are therefore a vehicle for removing excess cholesterol from the body.

It is desirable to maintain a total plasma cholesterol concentration of 200 mg/dL or less. From 200 to 239 mg/dL is considered borderline high, and levels over 240 mg/dL are pathological.

Most of the body's cholesterol is endogenous (internally synthesized) rather than dietary, and the body compensates for variations in dietary intake. High intake steps down cholesterol synthesis by the liver, whereas a low dietary intake steps it up. Thus, lowering dietary cholesterol reduces the serum cholesterol level by no more than 5%. More important is the fact that certain saturated fatty acids (SFAs) raise serum cholesterol level. For example, palmitic acid, a 16-carbon SFA, raises serum cholesterol by blocking its uptake by the tissues (yet stearic acid, an 18-carbon SFA, does not raise the cholesterol level). Some food advertising is deceptive on this point. It may truthfully advertise a food as being cholesterol-free, but neglect to mention that it contains SFAs that may raise the consumer's cholesterol level anyway. A moderate reduction of saturated fatty acid intake can lower blood cholesterol by 15% to 20%—considerably more effective than reducing dietary cholesterol per se.

Vigorous exercise also lowers blood cholesterol levels. The mechanism is somewhat roundabout: Exercise reduces the sensitivity of the right atrium of the heart to blood pressure, so the heart secretes less atrial natriuretic peptide. Consequently, the kidneys excrete less sodium and water, and the blood volume rises. This dilutes the lipoproteins in the blood, and the adipocytes compensate by producing more lipoprotein lipase. The adipocytes therefore consume more blood triglycerides. This shrinks the VLDL particles, which shed some of their cholesterol in the process, and HDLs pick up this free cholesterol for removal by the liver.

Blood cholesterol is not the only important measure of healthy lipid concentrations, however. A high LDL concentration is a warning sign because, as you can see from the function of LDLs described previously, it signifies a high rate of cholesterol deposition in the arteries. LDLs are elevated not only by saturated fats but also by cigarette smoking, coffee, and stress. A high proportion of HDL, on the other hand, is beneficial because it indicates that cholesterol is being removed from the arteries and transported to the liver for disposal. Thus it is desirable to increase your ratio of HDL to LDL. This is best done with a diet low in calories and saturated fats and is promoted by regular aerobic exercise.

(a) Lipoprotein types

(b) Lipoprotein-processing pathways

FIGURE 26.2 Lipoprotein Processing. (a) The four types of serum lipoproteins. (b) The three pathways of lipoprotein processing.

Why is a high HDL:LDL ratio healthier than a high LDL:HDL ratio?

Proteins

Protein constitutes about 12% to 15% of the body's mass; 65% of it is in the skeletal muscles. Proteins are responsible for muscle contraction and the motility of cilia and flagella. They are a major structural component of all cellular membranes, with multiple important roles such as membrane receptors, pumps, ion channels, and cell-identity markers. Fibrous proteins such as collagen, elastin, and keratin

make up much of the structure of bone, cartilage, tendons, ligaments, skin, hair, and nails. Globular proteins include antibodies, hormones, neuromodulators, hemoglobin, myoglobin, and about 2,000 enzymes that control nearly every aspect of cellular metabolism. They also include the albumin and other plasma proteins that maintain blood viscosity and osmolarity and transport lipids and some other plasma solutes. Proteins buffer the pH of body fluids and

contribute to the resting membrane potentials of all cells. No other class of biomolecules has such a broad variety of functions.

Requirements

For persons of average weight, the RDA of protein is 44 to 60 g, depending on age and sex. Multiplying your weight in pounds by 0.37 or your weight in kilograms by 0.8 gives an estimate of your RDA of protein in grams. A higher intake is recommended, however, under conditions of stress, infection, injury, and pregnancy. Infants and children require more protein than adults relative to body weight. Excessive protein intake, however, overloads the kidneys with nitrogenous waste and can cause renal damage. This is a risk in certain high-protein fad diets.

Total protein intake is not the only significant measure of dietary adequacy. The nutritional value of a protein depends on whether it supplies the right amino acids in the proportions needed for human proteins. Adults can synthesize 12 of the 20 amino acids from other organic compounds when they are not available from the diet, but there are 8 **essential amino acids** that we cannot synthesize: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. (Infants also require histidine.) In addition, 2 amino acids can only be synthesized from essential amino acids: cysteine from methionine and tyrosine from phenylalanine. The other 10 (9 in infants) are called **inessential amino acids**—not because the body does not require them but because it can synthesize its own when the diet does not supply them.

Cells do not store surplus amino acids for later use. When a protein is to be synthesized, all of the amino acids necessary must be present at once, and if even one is missing, the protein cannot be made. High-quality **complete proteins** are those that provide all of the essential amino acids in the necessary proportions for human tissue growth, maintenance, and nitrogen balance. Lower-quality **incomplete proteins** lack one or more essential amino acids. For example, cereals are low in lysine, and legumes are low in methionine.

Protein quality is also determined by **net protein utilization**—the percentage of the amino acids in a protein that the human body uses. We typically use 70% to 90% of animal protein but only 40% to 70% of plant protein. It therefore takes a larger serving of plant protein than animal protein to meet our needs—for example, we need 400 g (about 14 oz) of rice and beans to provide as much usable protein as 115 g (about 4 oz) of hamburger. However, reducing meat intake and increasing plant intake have advantages. Among other considerations, plant foods provide more vitamins, minerals, and fiber; less saturated fat; no cholesterol; and less pesticide. In an increasingly crowded world, it must also be borne in

mind that it requires far more land to produce meat than to produce food crops.

Dietary Sources

The animal proteins of meat, eggs, and dairy products closely match human proteins in amino acid composition. Thus, animal products provide high-quality complete protein, whereas plant proteins are incomplete. Nevertheless, this does not mean that your dietary protein *must* come from meat; indeed, about two-thirds of the world's population receives adequate protein nutrition from diets containing very little meat. We can combine plant foods so that one provides what another lacks—beans and rice, for example, are a complementary combination of legume and cereal. Beans provide the isoleucine and lysine lacking in grains, while rice provides the tryptophan and cysteine lacking in beans.

Nitrogen Balance

Proteins are our chief dietary source of nitrogen. **Nitrogen balance** is a state in which the rate of nitrogen ingestion equals the rate of excretion (chiefly as nitrogenous wastes). Growing children exhibit a state of **positive nitrogen balance** because they ingest more than they excrete, thus retaining protein for tissue growth. Pregnant women and athletes in resistance training also show positive nitrogen balance. When excretion exceeds ingestion, a person is in a state of **negative nitrogen balance**. This indicates that body proteins are being broken down and used as fuel. Proteins of the muscles and liver are more easily broken down than others; therefore, negative nitrogen balance tends to be associated with muscle atrophy. Negative nitrogen balance may occur if carbohydrate and fat intake are insufficient to meet the need for energy. Carbohydrates and fats are said to have a protein-sparing effect because they prevent protein catabolism when present in sufficient amounts to meet one's energy needs.

Nitrogen balance is affected by some hormones. Growth hormone and sex steroids promote protein synthesis and positive nitrogen balance during childhood, adolescence, and pregnancy. Glucocorticoids, on the other hand, promote protein catabolism and negative nitrogen balance in states of stress.

Think About It

Would you expect a person recovering from a long infectious disease to be in a state of positive or negative nitrogen balance? Why?

Minerals and Vitamins

Minerals are inorganic elements that plants extract from soil or water and introduce into the food web. Vitamins are small dietary organic compounds that are necessary to metabolism. Neither is used as fuel, but both are

essential to our ability to use other nutrients. With the exception of a few vitamins, these nutrients cannot be synthesized by the body and must be included in the diet. They are, however, required in relatively small quantities. Mineral RDAs range from 0.05 mg of chromium and selenium to 1,200 mg of calcium and phosphorus. Vitamin RDAs range from about 0.002 mg of vitamin B₁₂ to 60 mg of vitamin C. Despite the small quantities involved, minerals and vitamins have very potent effects on physiology. Indeed, excessive amounts are toxic and potentially lethal.

Minerals

Minerals constitute about 4% of the body mass, with three-quarters of this being the calcium and phosphorus in the bones and teeth. Phosphorus is also a key structural component of phospholipids, ATP, cAMP, GTP, and creatine phosphate and is the basis of the phosphate buffer system (see chapter 24). Calcium, iron, magnesium, and manganese function as cofactors for enzymes. Iron is essential to the oxygen-carrying capacity of hemoglobin and myoglobin. Chlorine is a component of stomach acid (HCl). Many mineral salts function as electrolytes and govern the function of nerve and muscle cells, osmotically regulate the content and distribution of water in the body, and maintain blood volume.

Table 26.2 summarizes adult mineral requirements and dietary sources. Broadly speaking, the best sources of minerals are vegetables, legumes, milk, eggs, fish, shellfish, and some other meats. Cereal grains are a relatively poor source, but processed cereals may be mineral-fortified.

Sodium chloride has been both a prized commodity and a curse. Animal tissues contain relatively large amounts of salt, and carnivores rarely lack ample salt in their diets. Plants, however, are relatively poor in salt, so herbivores often must supplement their diet by ingesting salt from the soil. As humans developed agriculture and became more dependent on plants, they also became increasingly dependent on supplemental salt. Salt has often been used as a form of payment for goods and services—the word *salary* comes from *sal* (salt). Our fondness for salt and high sensitivity to it undoubtedly stem from its physiological importance and its scarcity in a largely vegetarian diet.

Now, however, this fondness has become a bane. The recommended sodium intake is 1.1 g/day, but a typical American diet contains about 4.5 g/day. This is due not just to the use of table salt but more significantly to the large amounts of salt in processed foods, much of it “disguised” in soy sauce, MSG (monosodium glutamate), baking soda, and baking powder. In some areas of Japan, salt intake averages 27 g/day and most people die before age 70 of stroke and other complications of hypertension.

Hypertension is a leading cause of death among American blacks, who have twice the risk of hypertension

TABLE 26.2

Mineral Requirements and Some Dietary Sources

Mineral	RDA (mg)	Some Dietary Sources*
<i>Major minerals</i>		
Calcium	1,200	Milk, fish, shellfish, greens, tofu, orange juice
Phosphorus	1,200	Red meat, poultry, fish, eggs, milk, legumes, whole grains, nuts
Sodium	1,500	Table salt, processed foods; usually present in excess
Chloride	2,300	Table salt, some vegetables; usually present in excess
Magnesium	280–350	Milk, greens, whole grains, nuts, legumes, chocolate
Potassium	4,700	Red meat, poultry, fish, cereals, spinach, squash, bananas, apricots
Sulfur	Unknown	Meats, milk, eggs, legumes; almost any proteins
<i>Trace minerals</i>		
Zinc	12–15	Red meat, seafood, cereals, wheat germ, legumes, nuts, yeast
Iron	10–15	Red meat, liver, shellfish, eggs, dried fruits, nuts, legumes, molasses
Manganese	2.5–5.0	Greens, fruits, legumes, whole grains, nuts
Copper	1.5–3.0	Red meat, liver, shellfish, legumes, whole grains, nuts, cocoa
Fluoride	1.5–4.0	Fluoridated water and toothpaste, tea, seafood, seaweed
Iodine	0.15	Marine fish, fish oils, shellfish, iodized salt
Molybdenum	0.07–0.25	Beans, whole grains, nuts
Chromium	0.05–0.25	Meats, liver, cheese, eggs, whole grains, yeast, wine
Selenium	0.05–0.07	Red meats, organ meats, fish, shellfish, eggs, cereals
Cobalt	Unknown	Red meat, poultry, fish, liver, milk

*“Red meat” refers to mammalian muscle such as beef and pork. “Organ meat” refers to brain, pancreas, heart, kidney, etc. Liver is specified separately and refers to beef, pork, and chicken livers, which are similar for most nutrients.

and 10 times the risk of dying from it that American whites have. The reason for this is not excessive salt intake, but rather that people of West African descent have kidneys with an especially strong tendency to retain salt.

Vitamins

Vitamins were originally named with letters in the order of their discovery, but they also have chemically descriptive names such as ascorbic acid (vitamin C) and riboflavin (vitamin B₂). Most vitamins must be obtained from the diet (table 26.3), but the body synthesizes some of them from precursors called *provitamins*—niacin from the amino acid tryptophan, vitamin D from cholesterol, and vitamin A from carotene, which is abundantly present in carrots, squash, and other yellow vegetables and fruits. Vitamin K, pantothenic acid, biotin, and folic acid are produced by the bacteria of the large intestine. The feces contain more biotin than food does.

Vitamins are classified as water-soluble or fat-soluble. **Water-soluble vitamins** are absorbed with water from the small intestine, dissolve freely in the body fluids, and are quickly excreted by the kidneys. They cannot be stored in the body and therefore seldom accumulate to excess. The water-soluble vitamins are ascorbic acid (vitamin C) and the B vitamins. Ascorbic acid promotes hemoglobin

synthesis, collagen synthesis, and sound connective tissue structure, and it is an antioxidant that scavenges free radicals and possibly reduces the risk of cancer. The B vitamins function as coenzymes or parts of coenzyme molecules; they assist enzymes by transferring electrons from one metabolic reaction to another, making it possible for enzymes to catalyze these reactions. Some of their functions arise later in this chapter as we consider carbohydrate metabolism.

Fat-soluble vitamins are incorporated into lipid micelles in the small intestine and absorbed with dietary lipids. They are more varied in function than water-soluble vitamins. Vitamin A is a component of the visual pigments and promotes proteoglycan synthesis and epithelial maintenance. Vitamin D promotes calcium absorption and bone mineralization. Vitamin K is essential to prothrombin synthesis and blood clotting. Vitamins A and E are antioxidants, like ascorbic acid.

It is common knowledge that various diseases result from vitamin deficiencies, but it is less commonly known that **hypervitaminosis** (vitamin excess) also causes disease. A *deficiency* of vitamin A, for example, can result in night blindness, dry skin and hair, a dry conjunctiva and cloudy cornea, and increased incidence of urinary, digestive, and respiratory infections. This is

TABLE 26.3 Vitamin Requirements and Some Dietary Sources

Vitamin	RDA (mg)	Some Dietary Sources*
<i>Water-soluble vitamins</i>		
Ascorbic acid (C)	60	Citrus fruits, strawberries, tomatoes, greens, cabbage, cauliflower, broccoli, brussels sprouts
B complex		
Thiamine (B ₁)	1.5	Red meat, organ meats, liver, eggs, greens, asparagus, legumes, whole grains, seeds, yeast
Riboflavin (B ₂)	1.7	Widely distributed, and deficiencies are rare; all types of meat, milk, eggs, greens, whole grains, apricots, legumes, mushrooms, yeast
Pyridoxine (B ₆)	2.0	Red meat, organ meats, fish, liver, greens, apricots, legumes, whole grains, seeds
Cobalamin (B ₁₂)	0.002	Red meat, organ meats, liver, shellfish, eggs, milk; absent from food plants
Niacin (nicotinic acid)	19	Readily synthesized from tryptophan, which is present in any diet with adequate protein; red meat, organ meats, liver, poultry, fish, apricots, legumes, whole grains, mushrooms
Pantothenic acid	4-7	Widely distributed, and deficiencies are rare; red meat, organ meats, liver, eggs, green and yellow vegetables, legumes, whole grains, mushrooms, yeast
Folic acid (folacin)	0.2	Eggs, liver, greens, citrus fruits, legumes, whole grains, seeds
Biotin	0.03-0.10	Red meat, organ meats, liver, eggs, cheese, cabbage, cauliflower, bananas, legumes, nuts
<i>Fat-soluble vitamins</i>		
Retinol (A)	1.0	Fish oils, eggs, cheese, milk, greens, other green and yellow vegetables and fruits, margarine
Calcitriol (D)	0.01	Formed by exposure of skin to sunlight; fish, fish oils, milk
α-tocopherol (E)	10	Fish oils, greens, seeds, wheat germ, vegetable oils, margarine, nuts
Phylloquinone (K)	0.08	Most of the RDA is met by synthesis by intestinal bacteria; liver, greens, cabbage, cauliflower

*See footnote in table 26.2.

the world's most common vitamin deficiency. An *excess* of vitamin A, however, may cause anorexia, nausea and vomiting, headache, pain and fragility of the bones, hair loss, an enlarged liver and spleen, and birth defects. Vitamins B₆, C, D, and E have also been implicated in toxic hypervitaminosis.

Some people take *megavitamins*—doses 10 to 1,000 times the RDA—thinking that they will improve athletic performance. Since vitamins are not burned as fuel, and small amounts fully meet the body's metabolic needs, there is no evidence that vitamin supplements improve performance except when used to correct a dietary deficiency. Megadoses of fat-soluble vitamins can be especially harmful.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Name two hormones that regulate short-term hunger and satiety. How does leptin differ from these in its effects?
2. Explain the following statement: Cellulose is an important part of a healthy diet but it is not a nutrient.
3. What class of nutrients provides most of the calories in the diet? What class of nutrients provides the body's major reserves of stored energy?
4. Contrast the functions of VLDLs, LDLs, and HDLs. Explain how this is related to the fact that a high blood HDL level is desirable, but a high VLDL-LDL level is undesirable.
5. Why do some proteins have more nutritional value than others?

26.2 Carbohydrate Metabolism

Objectives

When you have completed this section, you should be able to

- describe the principal reactants and products of each major step of glucose oxidation;
- contrast the functions and products of anaerobic fermentation and aerobic respiration;
- explain where and how cells produce ATP; and
- describe the production, function, and use of glycogen.

Most dietary carbohydrate is burned as fuel within a few hours of absorption. Although three monosaccharides are absorbed from digested food—glucose, galactose, and fructose—the last two are quickly converted to glucose, and all oxidative carbohydrate consumption is essentially

a matter of glucose catabolism. The overall reaction for this is

The function of this reaction is not to produce carbon dioxide and water but to transfer energy from glucose to ATP.

Along the pathway of glucose oxidation are several links through which other nutrients—especially fats and amino acids—can also be oxidized as fuel. Carbohydrate catabolism therefore provides a central vantage point from which we can view the catabolism of all fuels and the generation of ATP.

Glucose Catabolism

If the preceding reaction were carried out in a single step, it would generate a short, intense burst of heat—like the burning of paper, which has the same chemical equation. Not only would this be useless to the body's metabolism, it would kill the cells. In the body, however, the process is carried out in a series of small steps, each controlled by a separate enzyme. Energy is released in small manageable amounts, and as much as possible is transferred to ATP. The rest is released as heat.

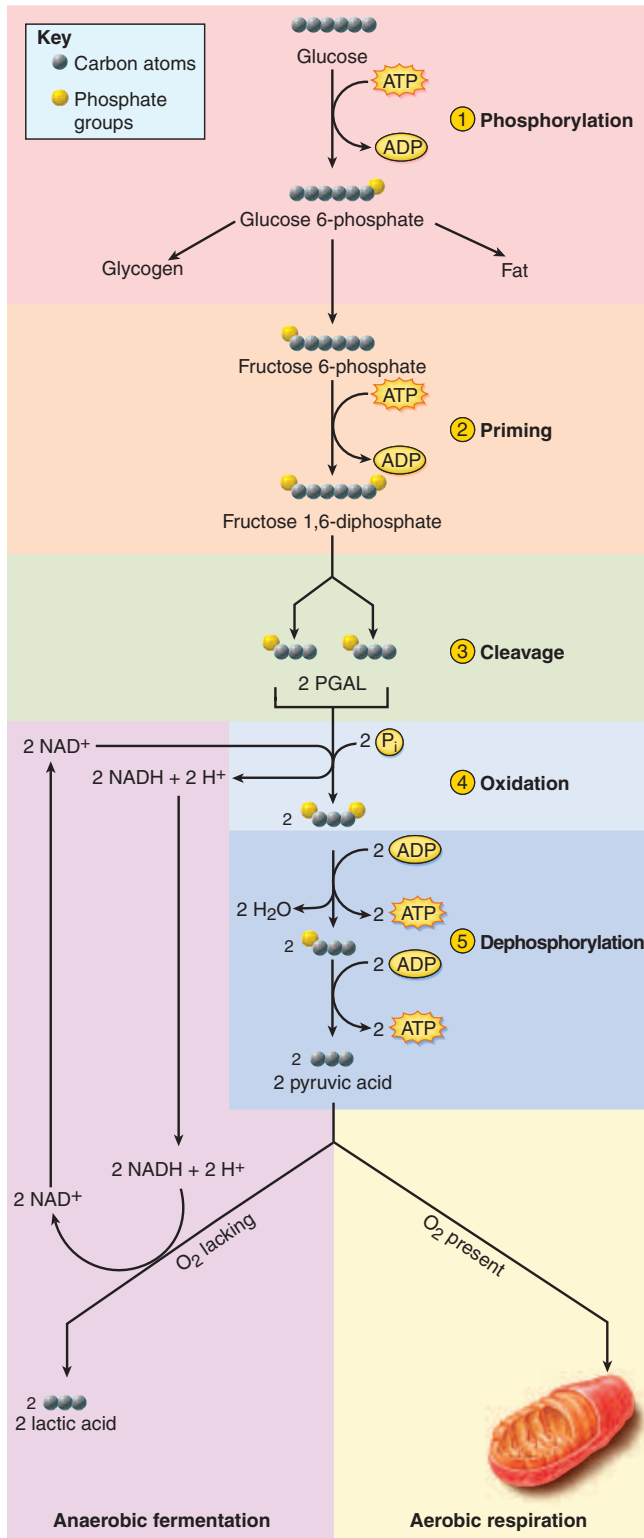

There are three major pathways of glucose catabolism:

1. **glycolysis**, which splits a glucose molecule into two molecules of pyruvic acid;
2. **anaerobic fermentation**, which occurs in the absence of oxygen and reduces pyruvic acid to lactic acid; and
3. **aerobic respiration**, which occurs in the presence of oxygen and oxidizes pyruvic acid to carbon dioxide and water.

You may find it helpful to review figure 2.31 (see p. 82) for a broad overview of these processes and their relationship to ATP production. Figures 26.3 to 26.6 examine these processes in closer detail; the first two of these are labeled with numbers that correspond to the reaction steps to follow.

Coenzymes are vitally important to these reactions. Enzymes remove electrons (as hydrogen atoms) from the intermediate compounds of these pathways, but they do not bind them. Instead, they transfer the hydrogen atoms to coenzymes, and the coenzymes donate them to other compounds later in one of the reaction pathways. Thus the enzymes of glucose catabolism cannot function without their coenzymes.

The two coenzymes of special importance to glucose catabolism are **NAD⁺** (nicotinamide adenine dinucleotide) and **FAD** (flavin adenine dinucleotide). Both are derived from B vitamins: NAD⁺ from niacin and FAD from riboflavin. Hydrogen atoms are removed from metabolic intermediates in pairs—that is, two protons and two electrons (2 H⁺ and 2 e⁻) at a time—and transferred to a coenzyme.

This produces a reduced coenzyme with a higher free energy content than it had before the reaction. Coenzymes thus become the temporary carriers of the energy extracted from glucose metabolites. The reactions for this are

and

FAD binds two protons and two electrons to become FADH₂. NAD⁺, however, binds the two electrons but only one of the protons to become NADH. The other proton remains a free hydrogen ion, H⁺ (or H₃O⁺, but it is represented in this chapter as H⁺).

Glycolysis

Upon entering a cell, glucose begins a series of conversions called glycolysis⁴ (fig. 26.3):

1 Phosphorylation. The enzyme *hexokinase* transfers an inorganic phosphate group (Pi) from ATP to glucose, producing glucose 6-phosphate (G6P). This has two effects:

- It keeps the intracellular concentration of glucose low, maintaining a concentration gradient that favors the continued diffusion of more glucose into the cell.
- Phosphorylated compounds cannot pass through the plasma membrane, so this prevents the sugar from leaving the cell. In most cells, step 1 is irreversible because they lack the enzyme to convert G6P back to glucose. The few exceptions are cells that must be able to release free glucose to the blood: absorptive cells of the small intestine, proximal convoluted tubule cells in the kidney, and liver cells.

G6P is a versatile molecule that can be converted to fat or amino acids, polymerized to form glycogen for storage, or further oxidized to extract its energy. For now, we are mainly concerned with its further oxidation (glycolysis), the general effect of which

⁴glyco = sugar + lysis = splitting

FIGURE 26.3 Glycolysis and Anaerobic Fermentation. Numbered reaction steps are explained in the text.

At what point would this reaction stop, and what reaction intermediate would accumulate, if NAD⁺ was unavailable to the cell? What process replenishes the NAD⁺ supply?

is to split G6P (a six-carbon sugar, C₆) into two three-carbon (C₃) molecules of **pyruvic acid** (pyruvate). Continue tracing these steps in figure 26.3 as you read.

- ② **Priming.** G6P is rearranged (isomerized) to form fructose 6-phosphate, which is phosphorylated again to form fructose 1,6-diphosphate. This “primes” the process by providing activation energy, somewhat like the heat of a match used to light a fireplace. Two molecules of ATP have already been consumed, but just as a fire gives back more heat than it takes to start it, aerobic respiration eventually gives back far more ATP than it takes to prime glycolysis.
- ③ **Cleavage.** The “lysis” part of glycolysis occurs when fructose 1,6-diphosphate splits into two three-carbon (C₃) molecules. Through a slight rearrangement of one of them (not shown in the figure), this generates two molecules of **PGAL (phosphoglyceraldehyde, also called glyceraldehyde 3-phosphate)**.
- ④ **Oxidation.** Each PGAL molecule is then oxidized by removing a pair of hydrogen atoms. The electrons and one proton are picked up by NAD⁺ and the other proton is released into the cytosol, yielding NADH + H⁺. At this step, a phosphate (P_i) group is also added to each of the C₃ fragments. Unlike the earlier steps, this P_i is not supplied by ATP but comes from the cell’s pool of free phosphate ions.
- ⑤ **Dephosphorylation.** In the next two steps, phosphate groups are taken from the glycolysis intermediates and transferred to ADP, converting it to ATP. The C₃ compound becomes pyruvic acid.

The end products of glycolysis are therefore

Note that 4 ATP are actually produced (step 5), but 2 ATP were consumed to initiate glycolysis (steps 1 and 2), so the net gain is 2 ATP per glucose. Some of the energy originally in the glucose is contained in this ATP, some is in the NADH, and some is lost as heat. Most of the energy, however, remains in the pyruvic acid.

Anaerobic Fermentation

The fate of pyruvic acid depends on whether or not oxygen is available. In an exercising muscle, the demand for ATP may exceed the supply of oxygen. The only ATP the cells can make under these circumstances is the 2 ATP produced by glycolysis. Cells without mitochondria, such as erythrocytes, are also restricted to making ATP by this method.

But glycolysis would quickly come to a halt if the reaction stopped at pyruvic acid. Why? Because it would

use up the supply of NAD⁺, which is needed to accept electrons at step 4 and keep glycolysis going. NAD⁺ must be replenished.

In the absence of oxygen, a cell resorts to a one-step reaction called anaerobic fermentation. (This is often inaccurately called *anaerobic respiration*, but strictly speaking, human cells do not carry out anaerobic respiration; that is a process found only in certain bacteria.) In this pathway, NADH donates a pair of electrons to pyruvic acid, thus reducing it to **lactic acid** and regenerating NAD⁺.

Think About It

Does lactic acid have more free energy than pyruvic acid or less? Explain.

Lactic acid leaves the cells that generate it and travels by way of the bloodstream to the liver. When oxygen becomes available again, the liver oxidizes lactic acid back to pyruvic acid, which can then enter the aerobic pathway described shortly. The oxygen required to do this is part of the *oxygen debt* created by exercising skeletal muscles (see p. 427). The liver can also convert lactic acid back to G6P and can do either of two things with that: (1) polymerize it to form glycogen for storage or (2) remove the phosphate group and release free glucose into the blood.

Although anaerobic fermentation keeps glycolysis running a little longer, it has some drawbacks. One is that it is wasteful, because most of the energy of glucose is still in the lactic acid and has contributed no useful work. The other is that lactic acid is toxic and contributes to muscle fatigue.

Skeletal muscle is relatively tolerant of anaerobic fermentation, and cardiac muscle is less so. The brain employs almost no anaerobic fermentation. During birth, when the infant’s blood supply is cut off, almost every organ of its body switches to anaerobic fermentation; thus they do not compete with the brain for the limited supply of oxygen.

Aerobic Respiration

Most ATP is generated in the mitochondria, which require oxygen as the final electron acceptor. In the presence of oxygen, pyruvic acid enters the mitochondria and is oxidized by aerobic respiration. This occurs in two principal steps:

- a group of reactions we will call the **matrix reactions**, because their controlling enzymes are in the fluid of the mitochondrial matrix; and
- reactions we will call the **membrane reactions**, because their controlling enzymes are bound to the membranes of the mitochondrial cristae.

The Matrix Reactions

The matrix reactions are shown in figure 26.4, where the reaction steps are numbered to resume where figure 26.3 ended. Most of the matrix reactions constitute a series called the **citric acid (Krebs⁵) cycle**. Preceding this, however, are three steps that prepare pyruvic acid to enter the cycle and thus link glycolysis to it.

- 6 Pyruvic acid is *decarboxylated*; that is, CO_2 is removed and pyruvic acid, a C_3 compound, becomes a C_2 compound.
- 7 NAD^+ removes hydrogen atoms from the C_2 compound (an oxidation reaction) and converts it to an **acetyl group (acetic acid)**.
- 8 The acetyl group binds to coenzyme A, a derivative of pantothenic acid (a B vitamin). The result is **acetyl-coenzyme A (acetyl-CoA)**. At this stage, the C_2 remnant of the original glucose molecule is ready to enter the citric acid cycle.
- 9 At the beginning of the citric acid cycle, CoA hands off the acetyl (C_2) group to a C_4 compound, **oxaloacetic acid**. This produces the C_6 compound **citric acid**, for which the cycle is named.
- 10 Water is removed and the citric acid molecule is reorganized, but still retains its six carbon atoms.
- 11 Hydrogen atoms are removed and accepted by NAD^+ .
- 12 Another CO_2 is removed and the substrate becomes a five-carbon chain.
- 13–14 Steps 11 and 12 are essentially repeated, generating another free CO_2 molecule and leaving a four-carbon chain. No more carbon atoms are removed beyond this point; the substrate remains a series of C_4 compounds from here back to the start of the cycle. The three carbon atoms of pyruvic acid have all been removed as CO_2 at steps 6, 12, and 14. These *decarboxylation reactions* are the source of most of the CO_2 in your breath.
- 15 Some of the energy in the C_4 substrate goes to phosphorylate guanosine diphosphate (GDP) and convert it to guanosine triphosphate (GTP), a molecule similar to ATP. GTP quickly transfers the P_i group to ADP to make ATP. Coenzyme A participates again in this step but is not shown in the figure.
- 16 Two hydrogen atoms are removed and accepted by the coenzyme FAD.
- 17 Water is added.
- 18 Two final hydrogen atoms are removed and transferred to NAD^+ . This reaction generates oxaloacetic acid, which is available to start the cycle all over again.

FIGURE 26.4 The Mitochondrial Matrix Reactions. Numbered reaction steps are explained in the text.

⁵Sir Hans Krebs (1900–1981), German biochemist

It is important to remember that for every glucose molecule that entered glycolysis, all of these matrix reactions occur twice (once for each pyruvic acid). The matrix reactions can be summarized:

There is nothing left of the organic matter of the glucose; its carbon atoms have all been carried away as CO_2 . Although still more of its energy is lost as heat along the way, some is stored in the additional 2 ATP, and most of it, by far, is in the reduced coenzymes—8 NADH and 2 FADH_2 molecules generated by the matrix reactions and 2 NADH generated by glycolysis. These must be oxidized to extract the energy from them.

The citric acid cycle not only oxidizes glucose metabolites but is also a pathway and a source of intermediates for the synthesis of fats and nonessential amino acids. The connections between the citric acid cycle and the metabolism of other nutrients are discussed later.

The Membrane Reactions

The membrane reactions have two purposes: (1) to further oxidize NADH and FADH_2 and transfer their energy to

FIGURE 26.5 The Mitochondrial Electron-Transport Chain. Transport molecules are grouped into three enzyme complexes, each of which acts as a proton pump. Molecules at the upper left of the figure have a relatively high free energy content, and molecules at the lower right are relatively low in energy.

What two molecules import energy into this reaction chain, supplying the energy that becomes stored in ATP?

ATP and (2) to regenerate NAD^+ and FAD and make them available again to earlier reaction steps. The membrane reactions are carried out by a series of compounds called the **mitochondrial electron-transport chain** (fig. 26.5). Most members of the chain are bound to the inner mitochondrial membrane. They are arranged in a precise order that enables each one to receive a pair of electrons from the member on one side of it (or, in two cases, from NADH and FADH_2) and pass these electrons along to the member on the other side—like a row of people passing along a hot potato. By the time the “potato” reaches the last member in the chain, it is relatively “cool”—its energy has been used to make ATP.

The members of this transport chain are as follows:

- **Flavin mononucleotide (FMN)**, a derivative of riboflavin similar to FAD, bound to a membrane protein. FMN accepts electrons from NADH.
- **Iron–sulfur (Fe-S) centers**, complexes of iron and sulfur atoms bound to membrane proteins.
- **Coenzyme Q (CoQ)**, which accepts electrons from FADH_2 . Unlike the other members, this is a relatively small, mobile molecule that moves about in the membrane.
- **Copper (Cu) ions** bound to two membrane proteins.
- **Cytochromes**,⁶ five enzymes with iron cofactors, so named because they are brightly colored in pure form. In order of participation in the chain, they are cytochromes *b*, *c*₁, *c*, *a*, and *a*₃.

Electron Transport Figure 26.5 shows the order in which electrons are passed along the chain. Hydrogen atoms are split apart as they transfer from coenzymes to the chain. The protons are pumped into the intermembrane space (fig. 26.6), and the electrons travel in pairs ($2 e^-$) along the transport chain. Each electron carrier in the chain becomes reduced when it receives an electron pair and oxidized again when it passes the electrons along to the next carrier. Energy is liberated at each transfer.

The final electron acceptor in the chain is oxygen. Each oxygen atom (half of an O_2 molecule) accepts two electrons ($2 e^-$) from cytochrome *a*₃ and two protons (2 H^+) from the mitochondrial matrix. The result is a molecule of water:

This is the body’s primary source of *metabolic water*—water synthesized in

⁶cyto = cell + chrom = color

1030 PART FOUR Regulation and Maintenance

the body rather than ingested in food and drink. This reaction also explains why the body requires oxygen. Without it, this reaction stops and, like a traffic jam, stops all the other processes leading to it. As a result, a cell produces too little ATP to sustain life, and death ensues within a few minutes.

The Chemiosmotic Mechanism Of primary importance is what happens to the energy liberated by the electrons as they pass along the chain. Some of it is unavoidably lost as heat, but some of it drives the **respiratory enzyme complexes**. The first complex includes FMN and five or more Fe-S centers; the second complex includes cytochromes *b* and *c₁* and an Fe-S center; and the third complex includes two copper centers and cytochromes *a* and *a₃*. Each complex collectively acts as a **proton pump** that removes H⁺ from the mitochondrial matrix and pumps it into the space between the inner and outer mitochondrial membranes (fig. 26.6). Coenzyme Q is a shuttle that transfers electrons

from the first pump to the second, and cytochrome *c* shuttles electrons from the second pump to the third.

These pumps create a very high H⁺ concentration (low pH) and positive charge between the membranes compared with a low H⁺ concentration and negative charge in the mitochondrial matrix. That is, they create a steep electrochemical gradient across the inner mitochondrial membrane. If the inner membrane were freely permeable to H⁺, these ions would have a strong tendency to diffuse down this gradient and back into the matrix.

The inner membrane, however, is permeable to H⁺ only through specific channel proteins called **ATP synthase** (separate from the electron-transport system). As H⁺ flows through these channels, it creates an electrical current (which, you may recall, is simply moving charged particles). ATP synthase harnesses the energy of this current to drive ATP synthesis. This process is called the **chemiosmotic⁷ mechanism**, which suggests the “push” created by the electrochemical H⁺ gradient.

⁷chemi = chemical + osmo = push

FIGURE 26.6 The Chemiosmotic Mechanism of ATP Synthesis. Each enzyme complex pumps hydrogen ions into the space between the mitochondrial membranes. These hydrogen ions diffuse back into the matrix by way of ATP synthase, which taps their energy to synthesize ATP.

Overview of ATP Production

NADH releases its electron pairs (as hydrogen atoms) to FMN in the first proton pump of the electron-transport system. From there to the end of the chain, this generates enough energy to synthesize 3 ATP molecules per electron pair. FADH₂ releases its electron pairs to coenzyme Q, the shuttle between the first and second proton pumps. Therefore, it enters the chain at a point beyond the first pump and does not contribute energy to that pump. Each FADH₂ contributes enough energy to synthesize 2 ATP.

With that in mind, we can draw up an energy balance sheet to see how much ATP is produced by the complete aerobic oxidation of glucose to CO₂ and H₂O and where the ATP comes from; see also figure 26.7. This summary refers back to the reaction steps 1 to 18 in figures 26.3 and 26.4. For each glucose molecule, there are

10 NADH produced at steps 4, 7, 11, 13, and 18
 × 3 ATP per NADH produced by the electron-transport chain

30 ATP generated by NADH

Plus: 2 FADH₂ produced at step 16
 × 2 ATP per FADH₂ produced by the electron-transport chain

= **4 ATP** generated by FADH₂

Plus: **2 ATP** net amount generated by glycolysis (step 5 offset by step 2)

2 ATP generated by the matrix reactions (step 15)

Total: **38 ATP** per glucose

This should be viewed as a theoretical maximum. There is some uncertainty about how much H⁺ must be pumped between the mitochondrial membranes to generate 1 ATP, and some of the energy from the H⁺ current is consumed by pumping ATP from the mitochondrial matrix into the cytosol and exchanging it for more raw materials (ADP and P_i) pumped from the cytosol into the mitochondria.

Furthermore, the NADH generated by glycolysis cannot enter the mitochondria and donate its electrons directly to the electron-transport chain. In liver, kidney, and myocardial cells, NADH passes its electrons to *malate*, a “shuttle” molecule that delivers the electrons to the beginning of the electron-transport chain. In this case, each NADH yields enough energy to generate 3 ATP. In skeletal muscle and brain cells, however, the glycolytic NADH transfers its electrons to *glycerol phosphate*, a different shuttle that donates the electrons farther down the electron-transport chain and results in the production of only 2 ATP. Therefore, the amount of ATP produced per NADH differs from one cell type to another and is still unknown for others.

But if we assume the maximum ATP yield, every mole (180 g) of glucose releases enough energy to synthesize

FIGURE 26.7 Summary of the Sources of ATP Generated by the Complete Oxidation of Glucose.

38 moles of ATP. Glucose has an energy content of 686 kcal/mole and ATP has 7.3 kcal/mole (277.4 kcal in 38 moles). This means that aerobic respiration has an **efficiency** (a ratio of energy output to input) of up to 277.4/686 kcal = 40%. The other 60% (408.6 kcal) is body heat.

The pathways of glucose catabolism are summarized in table 26.4. The aerobic respiration of glucose can be represented in the summary equation:

Glycogen Metabolism

ATP is quickly used after it is synthesized—it is an *energy-transfer* molecule, not an *energy-storage* molecule. Therefore, if the body has an ample amount of ATP and there is still more glucose in the blood, it does not produce and store excess ATP but converts the glucose to other compounds better suited for energy storage—namely, glycogen and fat. Fat synthesis is considered later. Here we consider the synthesis and use of glycogen. The average adult body contains about 400 to 450 g of glycogen: nearly one-quarter of it in the liver, three-quarters of it in the skeletal muscles, and small amounts in cardiac muscle and other tissues.

TABLE 26.4 Pathways of Glucose Catabolism

Stage	Principal Reactants	Principal Products	Purpose
Glycolysis	Glucose, 2 ADP, 2 P _i , 2 NAD ⁺	2 pyruvic acid, 2 ATP, 2 NADH, 2 H ₂ O	Reorganizes glucose and splits it in two in preparation for further oxidation by the mitochondria; sole source of ATP in anaerobic conditions
Anaerobic fermentation	2 pyruvic acid, 2 NADH	2 lactic acid, 2 NAD ⁺	Regenerates NAD ⁺ so glycolysis can continue to function (and generate ATP) in the absence of oxygen
Aerobic respiration			
Matrix reactions	2 pyruvic acid, 8 NAD ⁺ , 2 FAD, 2 ADP, 2 P _i , 8 H ₂ O	6 CO ₂ , 8 NADH, 2 FADH ₂ , 2 ATP, 2 H ₂ O	Remove electrons from pyruvic acid and transfer them to coenzymes NAD ⁺ and FAD; produce some ATP
Membrane reactions	10 NADH, 2 FADH ₂ , 6 O ₂	32–34 ATP, 12 H ₂ O	Finish oxidation and produce most of the ATP of cellular respiration

Glycogenesis, the synthesis of glycogen, is stimulated by insulin. Glucose 6-phosphate (G6P) is isomerized to glucose 1-phosphate (G1P). The enzyme *glycogen synthase* then cleaves off the phosphate group and attaches the glucose to a growing polysaccharide chain.

Glycogenolysis, the hydrolysis of glycogen, releases glucose between meals when new glucose is not being ingested. The process is stimulated by glucagon and epinephrine. The enzyme *glycogen phosphorylase* begins by phosphorylating a glucose residue and splitting it off the glycogen molecule as G1P. This is isomerized to G6P, which can then enter the pathway of glycolysis.

G6P usually cannot leave the cells that produce it. Liver cells, however, have an enzyme called *glucose 6-phosphatase*, which removes the phosphate group and produces free glucose. This can diffuse out of the cell into the blood, where it is available to any cells in the body. Although muscle cells cannot directly release glucose into the blood, they contribute indirectly to blood glucose concentration because they release pyruvic and lactic acids, which are converted to glucose by the liver.

Gluconeogenesis⁸ is the synthesis of glucose from noncarbohydrates such as glycerol and amino acids. It occurs chiefly in the liver, but after several weeks of fasting, the kidneys also undertake this process and eventually produce just as much glucose as the liver does.

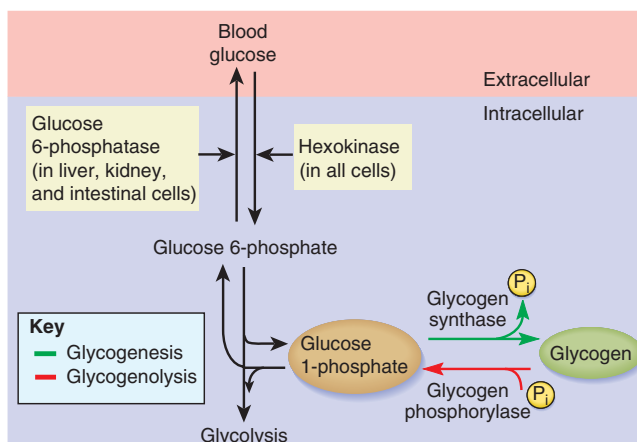

The processes described here are summarized in figure 26.8, and the distinctions among those similar terms are summarized in table 26.5.

⁸ *gluco* = sugar, *glucose* + *neo* = new + *genesis* = production of

FIGURE 26.8 Major Pathways of Glucose Storage and Use. In most cells, the glucose 1-phosphate generated by glycogenolysis can undergo only glycolysis. In liver, kidney, and intestinal cells, it can be converted back to free glucose and released into circulation.

TABLE 26.5 Some Terminology Related to Glucose and Glycogen Metabolism

<i>Anabolic (synthesis) reactions</i>	
Glycogenesis	The synthesis of glycogen by polymerizing glucose
Gluconeogenesis	The synthesis of glucose from noncarbohydrates such as glycerol and amino acids
<i>Catabolic (breakdown) reactions</i>	
Glycolysis	The splitting of glucose into two molecules of pyruvic acid in preparation for anaerobic fermentation or aerobic respiration
Glycogenolysis	The hydrolysis of glycogen to release free glucose or glucose 1-phosphate

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Identify the reaction steps in figures 26.3 and 26.4 at which vitamins are needed for glucose catabolism.
- In the laboratory, glucose can be oxidized in a single step to CO_2 and H_2O . Why is it done in so many little steps in cells?
- Explain the origin of the word glycolysis and why this is an appropriate name for the function of that reaction pathway.
- What are two advantages of aerobic respiration over anaerobic fermentation?
- What important enzyme is found in the inner mitochondrial membrane other than those of the electron-transport chain? Explain how its function depends on the electron-transport chain.
- Describe how the liver responds to (a) an excess and (b) a deficiency of blood glucose.

26.3 Lipid and Protein Metabolism

Objectives

When you have completed this section, you should be able to

- describe the processes of lipid catabolism and anabolism;
- describe the processes of protein catabolism and anabolism; and
- explain the metabolic source of ammonia and how the body disposes of it.

In the foregoing discussion, glycolysis and the mitochondrial reactions were treated from the standpoint of carbohydrate oxidation. These pathways also serve for the oxidation of proteins and lipids as fuel and as a source of metabolic intermediates that can be used for protein and lipid synthesis. Here we examine these related metabolic pathways.

Lipids

Triglycerides are stored primarily in the body's adipocytes, where a given molecule remains for about 2 to 3 weeks. Although the total amount of stored triglyceride remains quite constant, there is a continual turnover as lipids are released, transported in the blood, and either oxidized for energy or redeposited in other adipocytes. Synthesizing fats from other types of molecules is called **lipogenesis**, and breaking down fat for fuel is called **lipolysis** (lih-POL-ih-sis).

Lipogenesis

It is common knowledge that a diet high in sugars causes us to put on fat and gain weight. Lipogenesis employs compounds such as sugars and amino acids to synthesize glycerol and fatty acids, the triglyceride precursors. PGAL, one of the intermediates of glucose oxidation, can be converted to glycerol. As glucose and amino acids enter the citric acid cycle by way of acetyl-CoA, the acetyl-CoA can also be diverted to make fatty acids. The glycerol and fatty acids can then be condensed to form a triglyceride, which can be stored in the adipose tissue or converted to other lipids. These pathways are summarized in figure 26.9.

Lipolysis

Lipolysis, also shown in figure 26.9, begins with the hydrolysis of a triglyceride into glycerol and fatty acids—a process stimulated by epinephrine, norepinephrine, glucocorticoids, thyroid hormone, and growth hormone. The glycerol and fatty acids are further oxidized by separate pathways. Glycerol is easily converted to PGAL and thus enters the pathway of glycolysis. It generates only half as much ATP as glucose, however, because it is a C_3 compound compared with glucose (C_6); thus, it leads to the production of only half as much pyruvic acid.

The fatty acid component is catabolized in the mitochondrial matrix by a process called **beta oxidation**, which removes two carbon atoms at a time. The resulting

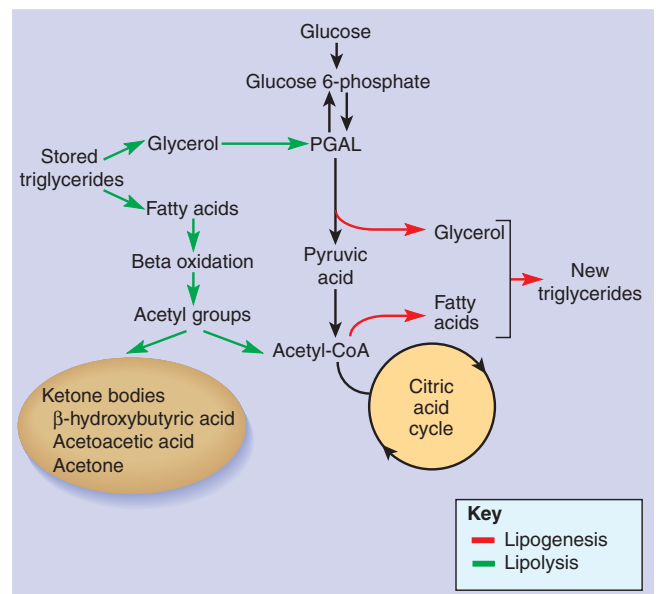

FIGURE 26.9 Pathways of Lipolysis and Lipogenesis in Relation to Glycolysis and the Citric Acid Cycle.

Name the acid-base imbalance that results from the accumulation of the ketone bodies shown in the oval.

acetyl (C_2) groups are bonded to coenzyme A to make acetyl-CoA—the entry point into the citric acid cycle. A fatty acid of 16 carbon atoms can yield 129 molecules of ATP—obviously a much richer source of energy than a glucose molecule, and remember that each fat molecule generates three fatty acids.

Excess acetyl groups can be metabolized by the liver in a process called **ketogenesis**. Two acetyl groups are condensed to form acetoacetic acid, and some of this is further converted to β -hydroxybutyric acid and acetone. These three products are the *ketone bodies*. Some cells convert acetoacetic acid back to acetyl-CoA and thus feed the C_2 fragments into the citric acid cycle to extract their energy. When the body is rapidly oxidizing fats, however, excess ketone bodies accumulate. This causes the ketoacidosis typical of type 1 diabetes mellitus, in which cells must oxidize fats because they cannot absorb glucose.

Acetyl-CoA cannot go backward up the glycolytic pathway and produce glucose, because this pathway is irreversible past the point of pyruvic acid. Although glycerol can be used for gluconeogenesis, fatty acids cannot.

It was mentioned earlier that fats cannot be completely oxidized when there is not enough carbohydrate in the diet. This is because the mitochondrial reactions cannot proceed without oxaloacetic acid as a “pickup molecule” in the citric acid cycle. When carbohydrate is unavailable, oxaloacetic acid is converted to glucose and becomes unavailable to the citric acid cycle. Fat oxidation then produces excess ketones, leading to elevated blood ketones (*ketosis*) and potentially to a resulting pH imbalance (*ketoacidosis*). Ketosis is a serious risk of extreme low-carbohydrate diets.

Proteins

About 100 g of tissue protein breaks down each day into free amino acids. These combine with the amino acids from the diet to form an **amino acid pool** that cells can draw upon to make new proteins. The fastest rate of tissue protein turnover is in the intestinal mucosa, where epithelial cells are replaced at a very high rate. Dead cells are digested along with the food and thus contribute to the amino acid pool. Of all the amino acid absorbed by the pool, about 50% is from the diet, 25% from dead epithelial cells, and 25% from enzymes that have digested each other.

Some amino acids in the pool can be converted to others. Free amino acids also can be converted to glucose and fat or directly used as fuel. Such conversions involve three processes: (1) **deamination**, the removal of an amino group ($-NH_2$); (2) **amination**, the addition of $-NH_2$; or (3) **transamination**, the transfer of $-NH_2$ from one molecule to another. The following discussion shows how these processes are involved in amino acid metabolism.

Use as Fuel

The first step in using amino acids as fuel is to deaminate them. After the $-NH_2$ group is removed, the remainder of the molecule is called a *keto acid*. Depending on which amino acid is involved, the resulting keto acid may be converted to pyruvic acid, acetyl-CoA, or one of the acids of the citric acid cycle (fig. 26.10). It is important to note that some of these reactions are reversible. When there is a deficiency of amino acids in the body, citric acid cycle intermediates can be aminated and converted to amino acids, which are then available for protein synthesis. In gluconeogenesis, keto acids are used to synthesize glucose, essentially through a reversal of the glycolysis reactions.

Transamination, Ammonia, and Urea

When an amino acid is deaminated, its amino group is transferred to a citric acid cycle intermediate, α -ketoglutaric

FIGURE 26.10 Pathways of Amino Acid Metabolism in Relation to Glycolysis and the Citric Acid Cycle.

Find a pathway for gluconeogenesis in this diagram.

acid, converting it to glutamic acid. Such transamination reactions are the route by which several amino acids enter the citric acid cycle.

Glutamic acid can travel from any of the body's cells to the liver. Here its $-NH_2$ group is removed, converting it back to α -ketoglutaric acid. The $-NH_2$ becomes ammonia (NH_3), which is extremely toxic to cells and cannot be allowed to accumulate. In a pathway called the **urea cycle**, the liver quickly combines ammonia with carbon dioxide to produce a less toxic waste, urea. Urea is then excreted in the urine as one of the body's nitrogenous wastes. Other nitrogenous wastes and their sources are described in chapter 23 (see p. 906). When a diseased liver cannot carry out the urea cycle, NH_3 accumulates in the blood and death from *hepatic coma* may ensue within a few days.

Protein Synthesis

Protein synthesis, described in detail in chapter 4, is a complex process involving DNA, mRNA, tRNA, ribosomes, and often the rough ER. It is stimulated by growth hormone, thyroid hormones, and insulin, and it requires a supply of all the amino acids necessary for a particular protein. The liver can make many of these amino acids from other amino acids or from citric acid cycle intermediates by transamination reactions. The essential amino acids, however, must be obtained from the diet.

Liver Functions in Metabolism

You may have noticed that the liver plays a wide variety of roles in the processes discussed in this chapter—especially carbohydrate, lipid, and protein metabolism. Although it is connected to the digestive tract and generally regarded as a digestive gland, the overwhelming majority of its functions are nondigestive (table 26.6). Except for phagocytosis, all of these are performed by the cuboidal hepatocytes described in chapter 25. Such functional diversity is remarkable in light of the uniform structure of these cells. Because of the numerous critical functions performed by the liver, degenerative liver diseases such as hepatitis, cirrhosis, and liver cancer are especially life-threatening (see Insight 26.3).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Which of the processes in table 26.5 is most comparable to lipogenesis? Which is most comparable to lipolysis? Explain.
- When fats are converted to glucose, only the glycerol component is used in this way, not the fatty acid. Explain why, and state what happens to the fatty acids.
- What metabolic process produces ammonia? How does the body dispose of ammonia?

TABLE 26.6 Functions of the Liver

Carbohydrate metabolism

Converts dietary fructose and galactose to glucose. Stabilizes blood glucose concentration by storing excess glucose as glycogen (glycogenesis), releasing glucose from glycogen when needed (glycogenolysis), and synthesizing glucose from fats and amino acids (gluconeogenesis) when glucose demand exceeds glycogen reserves. Receives lactic acid generated by anaerobic fermentation in skeletal muscle and other tissues and converts it back to pyruvic acid or glucose 6-phosphate.

Lipid metabolism

Degrades chylomicron remnants. Carries out most of the body's lipogenesis (fat synthesis) and synthesizes cholesterol and phospholipids; produces VLDLs to transport lipids to adipose tissue and other tissues for storage or use; and stores fat in its own cells. Carries out most beta oxidation of fatty acids; produces ketone bodies from excess acetyl-CoA. Produces HDL shells, which pick up excess cholesterol from other tissues and return it to the liver; excretes the excess cholesterol in bile.

Protein and amino acid metabolism

Carries out most deamination and transamination of amino acids. Removes $-NH_2$ from glutamic acid and converts the resulting ammonia to urea by means of the urea cycle. Synthesizes nonessential amino acids by transamination reactions.

Synthesis of plasma proteins

Synthesizes nearly all the proteins of blood plasma, including albumin, alpha and beta globulins, fibrinogen, prothrombin, and several other clotting factors. (Does not synthesize plasma enzymes or gamma globulins.)

Vitamin and mineral metabolism

Converts vitamin D_3 to calcitriol, a step in the synthesis of calcitriol; stores a 3- to 4-month supply of vitamin D. Stores a 10-month supply of vitamin A and enough vitamin B_{12} to last one to several years. Secretes hepcidin to regulate iron absorption; stores iron in ferritin and releases it as needed. Excretes excess calcium by way of the bile.

Digestion

Synthesizes bile acids and lecithin, which emulsify fat and promote its digestion; produces micelles, which aid in absorption of dietary lipids.

Disposal of drugs, toxins, and hormones

Detoxifies alcohol, antibiotics, and many other drugs. Metabolizes bilirubin from RBC breakdown and excretes it as bile pigments. Deactivates thyroxine and steroid hormones and excretes them or converts them to a form more easily excreted by the kidneys.

Phagocytosis

Macrophages cleanse blood of bacteria and other foreign matter.

INSIGHT 26.3 Clinical Application**Hepatitis and Cirrhosis**

Hepatitis, inflammation of the liver, is usually caused by one of the five strains of hepatitis viruses. They differ in mode of transmission, severity of the resulting illness, affected age groups, and the best strategies for prevention. Hepatitis A is common and mild. Over 45% of people in urban areas of the United States have had it. It spreads rapidly in such settings as day-care centers and residential institutions for psychiatric patients, and it can be acquired by eating uncooked seafood such as oysters. Hepatitis B and C are far more serious. Both are transmitted sexually and through blood and other body fluids; the incidence of hepatitis C has surpassed AIDS as a sexually transmitted disease. Initial signs and symptoms of hepatitis include fatigue, malaise, nausea, vomiting, and weight loss. The liver becomes enlarged and tender. Jaundice, or yellowing of the skin, tends to follow as hepatocytes are destroyed, bile passages are blocked, and bile pigments accumulate in the blood. Hepatitis A causes up to 6 months

of illness, but most people recover and then have permanent immunity to it. Hepatitis B and C, however, often lead to chronic hepatitis, which can progress to cirrhosis or liver cancer. More liver transplants are necessitated by hepatitis C than by any other cause.

Cirrhosis is an irreversible inflammatory liver disease. It develops slowly over a period of years, but has a high mortality rate and is one of the leading causes of death in the United States. It is characterized by a disorganized liver histology in which regions of scar tissue alternate with nodules of regenerating cells, giving the liver a lumpy or knobby appearance and hardened texture. As in hepatitis, blockage of the bile passages results in jaundice. Protein synthesis declines as the liver deteriorates, leading to ascites, impaired blood clotting, and other cardiovascular effects (see Insight 26.4). Obstruction of the hepatic circulation by scar tissue leads to *angiogenesis*, the growth of new blood vessels to bypass the liver. Deprived of blood, the condition of the liver worsens, with increasing necrosis and, often, liver failure. Most cases of cirrhosis result from alcohol abuse, but hepatitis, gallstones, pancreatic inflammation, and other conditions can also bring it about. The prognosis for recovery is often poor.

26.4 Metabolic States and Metabolic Rate

Objectives

When you have completed this section, you should be able to

- define the absorptive and postabsorptive states;
- explain what happens to carbohydrates, fats, and proteins in each of these states;
- describe the hormonal and nervous regulation of each state;
- define *metabolic rate* and *basal metabolic rate*; and
- describe some factors that alter the metabolic rate.

Your metabolism changes from hour to hour depending on how long it has been since your last meal. For about 4 hours during and after a meal, you are in the **absorptive (fed) state**. This is a time in which nutrients are being absorbed and may be used immediately to meet energy and other needs. The **postabsorptive (fasting) state** prevails in the late morning, late afternoon, and overnight. During this time, the stomach and small intestine are empty and the body's energy needs are met from stored fuels. The two states are compared in table 26.7 and explained in the following discussion.

The Absorptive State

In the absorptive state, blood glucose is readily available for ATP synthesis. It serves as the primary fuel and spares the body from having to draw on stored fuels. The status of major nutrient classes during this phase is as follows:

- **Carbohydrates.** Absorbed sugars are transported by the hepatic portal system to the liver. Most glucose passes through the liver and becomes available to cells everywhere in the body. Glucose in excess of immediate need, however, is absorbed by the liver and may be converted to glycogen or fat. Most fat synthesized in the liver is released into the circulation; its further fate is comparable to that of dietary fats, discussed next.
- **Fats.** Fats enter the lymph as chylomicrons and initially bypass the liver. As described earlier, lipoprotein lipase removes fats from the chylomicrons for uptake by the tissues, especially adipose and muscular tissue. The liver disposes of the chylomicron remnants. Fats are the primary energy substrate for hepatocytes, adipocytes, and muscle cells.
- **Amino acids.** Amino acids, like sugars, circulate first to the liver. Most pass through and become available to other cells for protein synthesis. Some, however, are removed by the liver and have one of the following fates: (1) to be used for protein synthesis; (2) to be deaminated and used as fuel for ATP synthesis; or (3) to be deaminated and used for fatty acid synthesis.

TABLE 26.7 Major Aspects of the Absorptive and Postabsorptive States

	Absorptive	Postabsorptive
<i>Regulatory hormones</i>	Principally insulin Also gastrin, secretin, CCK, GIP	Principally glucagon Also epinephrine, growth hormone
<i>Carbohydrate metabolism</i>	Blood glucose rising Glucose uptake Glucose stored by glycogenesis Gluconeogenesis suppressed	Blood glucose falling Glucose released by glycogenolysis Gluconeogenesis stimulated
<i>Lipid metabolism</i>	Lipogenesis occurring Lipid uptake from chylomicrons Lipid storage in fat and muscle	Lipolysis occurring Fatty acids oxidized for fuel Glycerol used for gluconeogenesis
<i>Protein metabolism</i>	Amino acid uptake, protein synthesis Excess amino acids burned as fuel	Amino acids oxidized if glycogen and fat stores are inadequate for energy needs

Regulation of the Absorptive State

The absorptive state is regulated largely by insulin, which is secreted in response to elevated blood glucose and amino acid levels and to the intestinal hormones gastrin, secretin, cholecystokinin, and glucose-dependent insulinotropic peptide (GIP). Insulin regulates the rate of glucose uptake by nearly all cells except neurons, kidney cells, and erythrocytes, which have independent rates of uptake. With those exceptions, insulin has the following effects on its target cells:

- Within minutes, it increases the cellular uptake of glucose by as much as 20-fold. As cells absorb glucose, the blood glucose concentration falls.
- It stimulates glucose oxidation, glycogenesis, and lipogenesis.
- It inhibits gluconeogenesis, which makes sense because blood glucose concentration is already high and there is no immediate need for more.
- It stimulates the active transport of amino acids into cells and promotes protein synthesis.
- It acts on the brain as an adiposity signal, an index of the body's fat stores.

Following a high-protein, low-carbohydrate meal, it may seem that the amino acids would stimulate insulin secretion, insulin would accelerate both amino acid and glucose uptake, and since there was relatively little glucose in the ingested food, this would create a risk of hypoglycemia. In actuality, this is prevented by the fact that a high amino acid level stimulates the secretion of *both* insulin and glucagon. Glucagon, you may recall, is an insulin antagonist (see p. 654). It supports an adequate level of blood glucose to meet the needs of the brain.

The Postabsorptive State

The essence of the postabsorptive state is to homeostatically regulate blood glucose concentration within about 90 to 100 mg/dL. This is especially critical to the brain, which cannot use alternative energy substrates except in cases of prolonged fasting. The postabsorptive status of major nutrients is as follows:

- **Carbohydrates.** Glucose is drawn from the body's glycogen reserves (glycogenolysis) or synthesized from other compounds (gluconeogenesis). The liver usually stores enough glycogen after a meal to support 4 hours of postabsorptive metabolism before significant gluconeogenesis occurs.
- **Fats.** Adipocytes and hepatocytes hydrolyze fats and convert the glycerol to glucose. Free fatty acids (FFAs) cannot be converted to glucose, but they can favorably affect blood glucose concentration. As the liver oxidizes them to ketone bodies, other cells absorb and use these, or use FFAs directly, as their source of energy. By switching from glucose to fatty acid catabolism, they leave glucose for use by the brain (the glucose-sparing effect). After 4 to 5 days of fasting, the brain begins to use ketone bodies as supplemental fuel.
- **Proteins.** If glycogen and fat reserves are depleted, the body begins to use proteins as fuel. Some proteins are more resistant to catabolism than others. Collagen is almost never broken down for fuel, but muscle protein goes quickly. The extreme wasting away seen in cancer and some other chronic diseases, resulting from a loss of appetite (anorexia) as well as altered metabolism, is called **cachexia**⁹ (ka-KEX-ee-ah).

⁹cac = bad + exia = body condition

Regulation of the Postabsorptive State

Postabsorptive metabolism is more complex than the absorptive state. It is regulated mainly by the sympathetic nervous system and glucagon, but several other hormones are involved. As blood glucose level drops, insulin secretion declines and the pancreatic alpha cells secrete glucagon. Glucagon promotes glycogenolysis and gluconeogenesis, raising the blood glucose level, and it promotes lipolysis and a rise in FFA levels. Thus it makes both glucose and lipids available for fuel.

The sympathoadrenal system also promotes glycogenolysis and lipolysis, especially under conditions of injury, fear, anger, and other forms of stress. Adipose tissue is richly innervated by the sympathetic nervous system, while adipocytes, hepatocytes, and muscle cells also respond to epinephrine from the adrenal medulla. In circumstances where there is likely to be tissue injury and a need for repair, the sympathoadrenal system therefore mobilizes stored energy reserves and makes them available to meet the demands of tissue repair. Stress also stimulates the release of cortisol, which promotes fat and protein catabolism and gluconeogenesis (see p. 669).

Growth hormone is secreted in response to a rapid drop in blood glucose level and in conditions of prolonged fasting. It opposes insulin and raises blood glucose concentration.

Metabolic Rate

Metabolic rate means the amount of energy liberated in the body per unit of time, expressed in such terms as kcal/h or kcal/day. Metabolic rate can be measured directly by putting a person in a **calorimeter**, a closed chamber with water-filled walls that absorb the heat given off by the body. The rate of energy release is measured from the temperature change of the water. Metabolic rate can also be measured indirectly with a spirometer, an apparatus described in chapter 22 that can be used to measure the amount of oxygen a person consumes. For every liter of oxygen, approximately 4.82 kcal of energy is released from organic nutrients. This is only an estimate, because the number of kilocalories per liter of oxygen varies slightly with the type of nutrients the person is oxidizing at the time of measurement.

Metabolic rate depends on physical activity, mental state, absorptive or postabsorptive status, thyroid hormone and other hormones, and other factors. The **basal metabolic rate (BMR)** is a baseline or standard of comparison that minimizes the effects of such variables. It is the metabolic rate when one is awake but relaxed, in a room at comfortable temperature, in a postabsorptive state 12 to 14 hours after the last meal. It is not the minimum metabolic rate needed to sustain life, however. When one is asleep, the metabolic rate is slightly lower than the BMR. **Total metabolic rate (TMR)** is the sum of BMR and energy expenditure for voluntary activities, especially muscular contractions.

The BMR of an average adult is about 2,000 kcal/day for a male and slightly less for a female. Roughly speaking, one must therefore consume at least 2,000 kcal/day to fuel essential metabolic tasks—active transport, muscle tone, brain activity, cardiac and respiratory rhythms, renal function, and other essential processes. Even a relatively sedentary lifestyle requires another 500 kcal/day to support a low level of physical activity, and someone who does hard physical labor may require as much as 5,000 kcal/day.

Aside from physical activity, some factors that raise the TMR and caloric requirements include pregnancy, anxiety (which stimulates epinephrine release and muscle tension), fever (TMR rises about 14% for each 1°C of body temperature), eating (TMR rises after a meal), and the catecholamine and thyroid hormones. TMR is relatively high in children and declines with age. Therefore, as we reach middle age we often find ourselves gaining weight with no apparent change in food intake.

Some factors that lower TMR include apathy, depression, and prolonged starvation. In weight-loss diets, loss is often rapid at first and then goes more slowly. This is partly because the initial loss is largely water and partly because the TMR drops over time, fewer dietary calories are “burned off,” and there is more lipogenesis even with the same caloric intake. As one reduces food intake, the body reduces its metabolic rate to conserve body mass—thus making weight loss all the more difficult.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Define the absorptive and postabsorptive states. In which state is the body storing excess fuel? In which state is it drawing from these stored fuel reserves?
- What hormone primarily regulates the absorptive state, and what are the major effects of this hormone?
- Explain why triglycerides have a glucose-sparing effect.
- List a variety of factors and conditions that raise a person's total metabolic rate above basal metabolic rate.

26.5 Body Heat and Thermoregulation

Objectives

When you have completed this section, you should be able to

- identify the principal sources of body heat;
- describe some factors that cause variations in body temperature;

- define and contrast the different forms of heat loss;
- describe how the hypothalamus monitors and controls body temperature; and
- describe conditions in which the body temperature is excessively high or low.

The enzymes that control our metabolism depend on an optimal, stable working temperature. In order to maintain this, heat loss from the body must be matched by heat generation. An excessively low body temperature, called **hypothermia**, can slow down the metabolism to the point that it cannot sustain life. Conversely, an excessively high body temperature, called **hyperthermia**, can make some metabolic pathways race ahead of others and disrupt their coordination to the point that this, too, can lead to death. **Thermoregulation**, the balance between heat production and loss, is therefore a critically important aspect of homeostasis.

Body Temperature

“Normal” body temperature depends on when, where, and in whom it is measured. Body temperature fluctuates about 1°C (1.8°F) in a 24-hour cycle. It tends to be lowest in the early morning and highest in the late afternoon. Temperature also varies from one place in the body to another.

The most important body temperature is the **core temperature**—the temperature of organs in the cranial, thoracic, and abdominal cavities. Rectal temperature is relatively easy to measure and gives an estimate of core temperature: usually 37.2° to 37.6°C (99.0°–99.7°F). It may be as high as 38.5°C (101°F) in active children and some adults.

Shell temperature is the temperature closer to the surface, especially skin and oral temperature. Here, heat is lost from the body and temperatures are slightly lower than rectal temperature. Adult oral temperature is typically 36.6° to 37.0°C (97.9°–98.6°F) but may be as high as 40°C (104°F) during hard exercise. Shell temperature fluctuates as a result of processes that serve to maintain a stable core temperature.

Heat Production and Loss

Most body heat comes from exergonic (energy-releasing) chemical reactions such as nutrient oxidation and ATP use. A little heat is generated by joint friction, blood flow, and other movements. At rest, most heat is generated by the brain, heart, liver, and endocrine glands; the skeletal muscles contribute about 20% to 30% of the total resting heat. Increased muscle tone or exercise greatly increases heat generation in the muscles, however; in vigorous exercise, they produce 30 to 40 times as much heat as the rest of the body.

The body loses heat in three ways: radiation, conduction, and evaporation:

1. **Radiation** is the emission of infrared (IR) rays by moving molecules. In essence, heat means molecular motion, and all molecular motion produces IR rays. When IR rays are absorbed by an object, they increase its molecular motion and raise its temperature. Therefore, IR radiation removes heat from its source and adds heat to anything that absorbs it. The heat lamps used in bathrooms and restaurants work on this principle. Our bodies continually receive IR from the objects around us and give off IR to our surroundings. Since we are usually warmer than the objects around us, we usually lose more heat this way than we gain.
2. **Conduction** is the transfer of kinetic energy from molecule to molecule as they collide with one another. The warmth of your body thereby adds to the molecular motion and temperature of the clothes you wear, the chair you sit in, and the air around you. Conductive heat loss is aided by **convection**, the motion of a fluid due to uneven heating. Air is a fluid that becomes less dense and rises as it is heated. Thus warm air rises from the body and is replaced by cooler air from below. The same is true of water—for example, when you swim in a lake or take a cool bath. You can easily see convection when you heat water in a clear container. Convection of the air around the human body can be seen by a technique called schlieren photography (fig. 26.11). Convection is not a separate category of heat loss in itself, but increases the rate of conductive heat loss.
3. **Evaporation** is the change from a liquid to a gaseous state. The cohesion of water molecules hampers their vibratory movement in response to heat input. If the temperature of water is raised sufficiently, however, its molecular motion becomes great enough for molecules to break free and evaporate. Evaporation of water thus carries a substantial amount of heat with it (0.58 kcal/g). This is the significance of perspiration. Sweat wets the skin surface and its evaporation carries heat away. In extreme conditions, the body can lose 2 L or more of sweat per hour and dissipate up to 600 kcal of heat per hour by evaporative loss. Evaporative heat loss is increased by moving air, as you can readily feel when you are sweaty and stand in front of a fan. The rapid movement of heat-laden air away from the body (**forced convection**) accelerates heat removal, so a breeze or a fan enhances heat loss by conduction and evaporation. It has no effect on radiation.

The relative amounts of heat lost by different methods depend on prevailing conditions. A nude body at an air temperature of 21°C (70°F) loses about 60% of its heat by radiation, 18% by conduction, and 22% by evaporation.

FIGURE 26.11 Heat Loss from the Body. (a) Heat transfers from the body to surrounding air molecules by conduction. Warm air then rises from the body by convection, carrying heat away. Cool air replaces this warm air from below. (b) Schlieren photograph of the column of warm air rising from the body.

If air temperature is higher than skin temperature, evaporation becomes the only means of heat loss because radiation and conduction add more heat to the body than they remove from it. Hot, humid weather hinders even evaporative cooling because there is less of a humidity gradient from skin to air. Such conditions increase the risk of heat-stroke (discussed shortly).

Thermoregulation

Thermoregulation is achieved through several negative feedback loops. The preoptic area of the hypothalamus (anterior to the optic chiasm) functions as a **hypothalamic thermostat**. It monitors the temperature of the blood and receives signals also from **peripheral thermoreceptors** located mainly in the skin. In turn, it sends appropriate signals either to the **heat-loss center**, a nucleus still farther anterior in the hypothalamus, or to the **heat-promoting center**, a more posterior nucleus near the mammillary bodies of the brain.

When the heat-loss center senses that the blood temperature is too high, it activates heat-losing mechanisms. The first and simplest of these is cutaneous vasodilation, which increases blood flow close to the body surface and thus promotes heat loss. If this fails to restore normal temperature, the heat-loss center triggers sweating. It also inhibits the heat-promoting center.

When the heat-promoting center senses that the blood temperature is too low, it activates mechanisms to conserve body heat or generate more. By way of the sympathetic nervous system, it causes cutaneous vasoconstriction. Warm blood is then retained deeper in the body and less heat is lost through the skin. The sympathetic nervous system in other mammals also stimulates the piloerector muscles, which make the hair stand on end. This traps an insulating blanket of still air near the skin. The human sympathetic nervous system attempts to do this as well, but since our body hair is so scanty, the only noticeable effect of this is goose bumps.

If dermal vasoconstriction cannot restore or maintain normal core temperature, the body resorts to **shivering thermogenesis**. If you leave a warm house on a cold day, you may notice that your muscles become tense, sometimes even painfully taut, and you begin to shiver. Shivering involves a spinal reflex that causes tiny alternating contractions in antagonistic muscle pairs. Every muscle contraction releases heat from ATP, and shivering can increase the body's heat production as much as fourfold.

Nonshivering thermogenesis is a more long-term mechanism for generating heat, used especially in the colder seasons of the year. The sympathetic nervous system and thyroid hormone stimulate an increase in metabolic rate, which can rise as much as 30% after several weeks of cold weather. More nutrients are burned as fuel, we consume more calories to “stoke the furnace,” and consequently, we have greater appetites in the winter than in the summer. Infants can generate heat by breaking down *brown fat*, a tissue in which lipolysis is not linked to ATP synthesis, so all the energy released from the fat is in the form of heat.

In addition to these physiological mechanisms, and of even greater importance, humans and other animals practice **behavioral thermoregulation**—behaviors that raise or lower the body's heat gains and losses. Just getting out of

the sun greatly cuts down heat gain by radiation, for example, and shedding heavy clothing or kicking off a blanket at night helps to cool the body.

In summary, you can see that thermoregulation is a function of multiple organs: the brain, autonomic nerves, thyroid gland, skin, blood vessels, and skeletal muscles.

Disturbances of Thermoregulation

Chapter 21 described the mechanism of fever and its importance in combating infection. Fever is a normal protective mechanism that should be allowed to run its course if it is not excessively high. A body temperature above 42° to 43°C (108°–110°F), however, can be very dangerous. The high temperature elevates the metabolic rate and the body generates heat faster than its heat-losing mechanisms can disperse it. Therefore, the elevated metabolic rate increases the fever and the fever increases the metabolic rate in a dangerous positive feedback loop. At a core body temperature of 44° to 45°C (111°–113°F), metabolic dysfunction and neurological damage can be fatal.

Exposure to excessive heat causes heat cramps, heat exhaustion, and heatstroke. **Heat cramps** are painful muscle spasms that result from excessive electrolyte loss in the sweat. They occur especially when a person begins to relax after strenuous exertion and heavy sweating. **Heat exhaustion** results from more severe water and electrolyte loss and is characterized by hypotension, dizziness, vomiting, and sometimes fainting. Prolonged heat waves, especially if accompanied by high humidity, bring on many deaths from **heatstroke (sunstroke)**. The body gains heat by radiation and conduction, but the humidity retards evaporative cooling. Heatstroke is clinically

defined as a state in which the core body temperature is over 40°C (104°F); the skin is hot and dry; and the subject exhibits nervous system dysfunctions such as delirium, convulsions, or coma. It is also accompanied by tachycardia, hyperventilation, inflammation, and multiorgan dysfunction; it is often fatal.

Hypothermia can result from exposure to cold weather or immersion in icy water. It, too, entails life-threatening positive feedback loops. If the core temperature falls below 33°C (91°F), the metabolic rate drops so low that heat production cannot keep pace with heat loss, and the temperature falls even more. Death from cardiac fibrillation may occur below 32°C (90°F), but some people survive body temperatures as low as 29°C (84°F) in a state of suspended animation. A body temperature below 24°C (75°F) is usually fatal. It is dangerous to give alcohol to someone in a state of hypothermia; the chemical “burn” produces an illusion of warmth, but alcohol actually accelerates heat loss by dilating cutaneous blood vessels.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

19. What is the primary source of body heat? What are some lesser sources?
20. What mechanisms of heat loss are aided by convection?
21. Describe the major heat-promoting and heat-losing mechanisms of the body.
22. Describe the positive feedback loops that can cause death from hyperthermia and hypothermia.

INSIGHT 26.4 Clinical Application

Alcohol and Alcoholism

Alcohol not only is a popular mind-altering drug but also is regarded in many cultures as a food staple. As a source of empty calories, an addictive drug, and a toxin, it can have a broad spectrum of adverse effects on the body.

Absorption and Metabolism

Alcohol is rapidly absorbed from the digestive tract—about 20% of it in the stomach and 80% in the proximal small intestine. Carbonation, as in beer and sparkling wines, increases its rate of absorption, whereas food reduces its absorption by delaying gastric emptying so the alcohol takes longer to reach its place of maximum absorption. Alcohol is soluble in both water and fat, so it is rapidly distributed to all body tissues and easily crosses the blood-brain barrier to exert its intoxicating effects on the brain.

Alcohol is detoxified by the hepatic enzyme *alcohol dehydrogenase*, which oxidizes it to acetaldehyde. This enters the citric acid cycle and is oxidized to CO₂ and H₂O. The average

adult male can clear the blood of about 10 mL of 100% (200 proof) alcohol per hour—the amount in about 30 mL (1 oz) of whiskey or 355 mL (12 oz) of beer. Women have less alcohol dehydrogenase and clear alcohol from the bloodstream more slowly. They are also more vulnerable to alcohol-related illnesses such as cirrhosis of the liver.

Tolerance to alcohol, the ability to “hold your liquor,” results from two factors: behavioral modification, such as giving in less readily to lowered inhibitions, and increased levels of alcohol dehydrogenase in response to routine alcohol consumption. Alcohol dehydrogenase also deactivates other drugs, and drug dosages must be adjusted to compensate for this when treating alcoholics for other diseases.

Physiological Effects

Nervous System Alcohol is a depressant that inhibits the release of norepinephrine and disrupts the function of GABA receptors. In low doses, it depresses inhibitory synapses and creates sensations of confidence, euphoria, and giddiness. As the dosage rises, however, the breakdown products of ethanol enhance the diffusion of K⁺ out of neurons, hyperpolarizing them and making them less responsive to neurotransmitters. Thus, the

timing and coordination of communication between neurons are impaired, resulting in such symptoms of intoxication as slurred speech, poor coordination, and slower reaction time. These symptoms begin to become significant at a blood alcohol level of 80 to 100 mg/dL—the legal criterion of intoxication in many states. Above 400 mg/dL, alcohol can so disrupt the electrophysiology of neurons as to induce coma and death.

Liver The liver's role in metabolizing alcohol makes it especially susceptible to long-term toxic effects. Heavy drinking stresses the liver with a high load of acetaldehyde and acetate; this depletes its oxidizing agents and reduces its ability to catabolize these intermediates as well as fatty acids. Alcoholism often produces a greatly enlarged and fatty liver for multiple reasons: the calories provided by alcohol make it unnecessary to burn fat as fuel, fatty acids are poorly oxidized, and acetaldehyde is converted to new fatty acids. Acetaldehyde also causes inflammation of the liver and pancreas (*hepatitis* and *pancreatitis*), leading to disruption of digestive function. Acetaldehyde and other toxic intermediates destroy hepatocytes faster than they can be regenerated, leading to cirrhosis (see Insight 26.3). Many symptoms of alcoholism stem from deterioration of liver functions. Hepatic coma may occur as the liver becomes unable to produce urea, thus allowing ammonia to accumulate in the blood. Jaundice results from the liver's inability to excrete bilirubin.

Circulatory System Deteriorating liver functions exert several effects on the blood and cardiovascular system. Blood clotting is impaired because the liver cannot synthesize clotting factors adequately. Edema results from inadequate synthesis of blood albumin. Cirrhosis obstructs the hepatic portal blood circulation. Portal hypertension results, and combined with hypoproteinemia, this causes the liver and other organs to “weep” serous fluid into the peritoneal cavity. This leads to *ascites*¹⁰ (ah-SY-teez)—swelling of the abdomen with as much as several liters of serous fluid. The combination of hypertension and impaired clotting often leads to hemorrhaging. *Hematemesis*,¹¹ the vomiting of blood, may occur as enlarged veins of the esophagus hemorrhage. Alcohol abuse also destroys myocardial tissue, reduces contractility of the heart, and causes cardiac arrhythmia.

Digestive System and Nutrition Alcohol breaks down the protective mucous barrier of the stomach and the tight junctions between its epithelial cells. Thus, it may cause gastritis and bleeding. Alcohol is commonly believed to be a factor in peptic ulcers, but there is little concrete evidence of this. Heavy drinking, especially in combination with smoking, increases the incidence of esophageal cancer. Malnutrition is a typical complication of alcoholism, partly because the empty calories of alcohol suppress the appetite for more nutritious foods. The

average American gets about 4.5% of his or her calories from alcohol (more when nondrinkers are excluded), but heavy drinkers may obtain half or more of their calories from alcohol and have less appetite for foods that would meet their other nutritional requirements. In addition, acetaldehyde interferes with vitamin absorption and use. Thiamine deficiency is common in alcoholism, and thiamine is routinely given to alcoholics in treatment.

Addiction

Alcohol is the most widely available addictive drug in America. In many respects it is almost identical to barbiturates in its toxic effects, its potential for tolerance and dependence, and the risk of overdose. The difference is that obtaining barbiturates usually requires a prescription, while obtaining alcohol requires, at most, proof of age.

Alcoholism is defined by a combination of criteria, including the pathological changes just described; physiological tolerance of high concentrations; impaired physiological, psychological, and social functionality; and withdrawal symptoms occurring when intake is reduced or stopped. Heavy drinking followed by a period of abstinence—for example, when a patient is admitted to the hospital and cannot get access to alcohol—may trigger *delirium tremens* (*DT*), characterized by restlessness, insomnia, confusion, irritability, tremors, incoherent speech, hallucinations, convulsions, and coma. *DT* has a 5% to 15% mortality rate.

Most alcoholism (type I) sets in after age 25 and is usually associated with stress or peer pressure. These influences lead to increased drinking, which can start a vicious cycle of illness, reduced job performance, family and social problems, arrest, and other stresses leading to still more drinking. A smaller number of alcoholics have type II alcoholism, which is at least partially hereditary. Most people with type II alcoholism are men who become addicted before age 25, especially the sons of other type II alcoholics. Type II alcoholics show abnormally rapid increases in blood acetaldehyde levels when they drink, and they have unusual brain waves (EEGs) even when not drinking. Children of alcoholics have a higher than average incidence of becoming alcoholic even when raised by nonalcoholic foster parents. It is by no means inevitable that such people will become alcoholics, but stress or peer pressure can trigger alcoholism more easily in those who are genetically predisposed to it.

Alcoholism is treated primarily through behavior modification—abstinence, peer support, avoidance or correction of the stresses that encourage drinking, and sometimes psychotherapy. The drug disulfiram (Antabuse) is used to support behavior modification programs. It inhibits the breakdown of acetaldehyde and thus heightens its short-term toxic effects. A person who takes Antabuse and drinks alcohol experiences headache, vomiting, tachycardia, chest pain, and hyperventilation and is less likely to look upon alcohol as a means of pleasure or escape.

¹¹*hemat* = blood + *emesis* = vomiting

CHAPTER REVIEW

Review of Key Concepts

26.1 Nutrition (p. 1014)

- Body weight is stable when average daily energy intake and output are equal. Weight appears to have a homeostatic set point determined partly by heredity. About 30% to 50% of the difference in weight between people is due to heredity and the rest to eating and exercise habits and other environmental variables.
- Appetite is regulated in part by several *gut-brain peptides* that act as chemical signals from the gastrointestinal tract to the brain.
- Ghrelin* stimulates an immediate sensation of hunger and induces eating. *Peptide YY* and *cholecystokinin* create a feeling of satiety and terminate eating.
- Leptin* and *insulin* are adiposity signals that inform the brain of how much adipose tissue one has, and regulate long-term food intake, energy consumption, and body weight.
- Many of the gut-brain peptides act through the *arcuate nucleus* of the hypothalamus, which responds to them by secreting the appetite stimulant *neuropeptide Y* or the appetite suppressant *melanocortin*.
- Hunger contractions of the stomach also motivate eating, and chewing and swallowing alone produce a degree of very short-term reduction of hunger.
- Some hormones stimulate cravings for specific categories of nutrients, such as *norepinephrine* for carbohydrates, *galanin* for fats, and *endorphins* for protein.
- Dietary Calories (kilocalories) come predominantly from carbohydrates, fats, and proteins. “Empty calories” are calories gained from foods such as sugar and alcohol that provide little or no other nutrition.
- Nutrients* are ingested chemicals that provide material for growth, repair, and maintenance of the body. Dietary substances that never become part of the body’s tissues (for example, fiber) are not considered nutrients but are nevertheless important components of a healthy diet. Some nutrients (water, minerals, vitamins) require no digestion and yield no calories.
- Water, carbohydrates, lipids, and proteins are required in relatively large amounts and are thus called *macronutrients*. Minerals and vitamins are needed in small amounts and are thus called *micronutrients*.
- Essential nutrients* must be included in the diet because the body cannot synthesize them from other chemicals.
- Carbohydrates are used as fuel and as structural components of many biological molecules.
- In the body, the carbohydrate fuels are blood glucose and liver and muscle glycogen. The balance between stored glycogen and glucose is regulated by insulin and glucagon.
- Starch is the most quantitatively significant digestible dietary carbohydrate, but significant quantities of lactose, sucrose, and fructose are ingested, especially in processed foods with added sweeteners.
- Dietary fiber includes cellulose, pectin, gums, and lignin. Fiber promotes intestinal motility, and water-soluble fiber (pectin) lowers the levels of blood cholesterol and harmful low-density lipoproteins (LDLs).
- Fat contains most of the body’s stored energy. Being less oxidized than carbohydrates, fats contain more than twice as many calories per gram as carbohydrates do. Being hydrophobic, they serve as an energy-storage medium that is relatively free of water bulk.
- The use of fats for fuel spares glucose and proteins for use by other tissues or for other purposes.
- Other lipids important in human metabolism and structure include phospholipids, cholesterol, fat-soluble vitamins, prostaglandins, and eicosanoids.
- Essential fatty acids—linoleic and possibly linolenic and arachidonic acids—must be included in the diet because the body cannot synthesize them.
- Lipids are transported in the blood as *lipoproteins*—droplets of cholesterol and triglycerides coated with proteins and phospholipids. The types of lipoproteins are *chylomicrons*, which are formed in the small intestine and transport dietary lipids throughout the body; *very-low-density lipoproteins (VLDLs)*, which transport lipids from the liver to the adipose tissue; *low-density lipoproteins (LDLs)*, which are the remainders of the VLDLs after triglycerides are removed, and which transport cholesterol to cells that need it; and *high-density lipoproteins (HDLs)*, which transport excess cholesterol back to the liver for disposal.
- An excessive LDL concentration indicates a heightened risk of cardiovascular disease, while a high HDL concentration is beneficial to cardiovascular health.
- Protein typically constitutes 12% to 15% of the body mass and performs a wider variety of structural and physiological roles than any other class of biological molecules.
- The nutritional value of a protein depends on whether it provides the right proportions of the various amino acids, especially the eight *essential amino acids*. *Complete proteins* supply all the essential amino acids in the proportions needed for the human body. The body makes more efficient use of animal proteins than of plant proteins.
- Nitrogen balance* is a state in which average daily nitrogen intake and output are equal. A greater intake than output (*positive nitrogen balance*) is typical of childhood, pregnancy, resistance training, and other states of tissue growth. Greater output than intake (*negative nitrogen balance*) is typical in stress, muscle atrophy, and malnutrition.
- Minerals* are inorganic elements acquired from the soil by way of plants. Calcium and phosphorus are the body’s most abundant minerals; sodium is a close third. Several

others are present in relatively small quantities but are vitally important.

26. *Vitamins* are small organic molecules that are not used for fuel (caloric content), but are necessary to metabolism. They act as coenzymes, antioxidants, and components of visual pigments, and play other roles.
27. Vitamin C and the B vitamins are the *water-soluble vitamins*; vitamins A, D, E, and K are the *fat-soluble vitamins*.
28. Vitamin deficiencies cause a variety of illnesses, although vitamin excesses (*hypervitaminosis*) can also be quite harmful.

26.2 Carbohydrate Metabolism (p. 1025)

1. The complete oxidation of glucose has the equation $C_6H_{12}O_6 + 6 O_2 \rightarrow 6 CO_2 + 6 H_2O$.
2. The coenzymes NAD^+ and FAD are especially important in transferring electrons from one metabolic pathway to another in this process.
3. Glucose oxidation begins with a pathway called *glycolysis*, which splits glucose into two pyruvic acid molecules and has a net yield of 2 ATP per glucose.
4. In the absence of oxygen, pyruvic acid is reduced to lactic acid in a one-step reaction called *anaerobic fermentation*. The primary purpose of this is to regenerate NAD^+ , which is needed to keep glycolysis running and producing ATP.
5. In the presence of oxygen, pyruvic acid enters a pathway called *aerobic respiration*, which produces much more ATP and has end products (CO_2 and H_2O) that are less toxic than lactic acid. Aerobic respiration occurs in the mitochondria.
6. The first principal group of reactions in aerobic respiration are the *matrix reactions*, mainly the *citric acid cycle*. This cycle breaks pyruvic acid down to CO_2 , generates 2 ATP per glucose, and most importantly, generates 8 $NADH$ and 2 $FADH_2$.
7. The final reactions of aerobic respiration are the *membrane reactions*, which occur on the inner mitochondrial membrane. Enzymes and other electron carriers here transport electrons from $NADH$ and $FADH_2$ to oxygen, producing water as an end product. More importantly, the

energy from these electron transfers drives *proton pumps*, which create a steep H^+ gradient between the mitochondrial membranes. This gradient drives a *chemiosmotic mechanism* by which *ATP synthase* generates ATP.

8. Glycolysis and aerobic respiration collectively produce up to 38 ATP per glucose, with the number varying slightly from one tissue type to another.
9. Glucose in excess of the body's immediate needs can be converted to fat or polymerized and stored as glycogen. *Glycogenesis* is the synthesis of glycogen. *Glycogenolysis* is the hydrolysis of glycogen to release glucose. *Gluconeogenesis* is the synthesis of glucose from glycerol (derived from fats) or amino acids.

26.3 Lipid and Protein Metabolism (p. 1033)

1. Adipocytes store and release most of the body's fat (triglycerides).
2. *Lipogenesis* is the synthesis of fats from precursors such as sugars and amino acids.
3. *Lipolysis* is the breakdown of fats, starting with hydrolysis and continuing with oxidation of the fatty acids and glycerol. Fatty acids are degraded by the process of *beta oxidation*. Oxidation of a typical fatty acid can yield 129 ATP—much more than glucose oxidation.
4. Incomplete fatty acid oxidation produces acidic *ketone bodies*, a process called *ketogenesis*. Ketone bodies can be used as fuel but an excess can cause dangerous ketoacidosis, as it does in diabetes mellitus.
5. Proteins turn over at an average rate of about 100 g/day, with especially high turnover in the intestinal mucosa.
6. Free amino acids in the *amino acid pool* can be used to synthesize new proteins, converted to glucose or fat, or oxidized as fuel.
7. Amino acid catabolism entails *deamination*, the removal of the amino group. The amino group eventually becomes ammonia (NH_3). The liver combines ammonia and CO_2 to produce urea, which is a less toxic waste product than ammonia and the most abundant nitrogenous waste in the blood and urine.

8. Although associated with the digestive tract, the liver carries out mainly nondigestive functions, including many aspects of carbohydrate, lipid, and protein metabolism.

26.4 Metabolic States and Metabolic Rate (p. 1036)

1. The *absorptive state* lasts about 4 hours after a meal. During this time, nutrients are absorbed from the intestine and may be used immediately. Glucose level is high and excess glucose is stored as glycogen or converted to fat.
2. The absorptive state is regulated mainly by insulin, which promotes glucose uptake and oxidation, glycogenesis, and lipogenesis; promotes protein synthesis; and inhibits gluconeogenesis.
3. The *postabsorptive state* prevails between meals and overnight, when the stomach and small intestine are empty and the body uses stored fuels. Glycogenolysis and gluconeogenesis maintain the blood glucose level during this state. Fatty acids derived from lipolysis are used as fuel by many cells.
4. The postabsorptive state is regulated by multiple hormones. Glucagon, epinephrine, and norepinephrine promote lipolysis and glycogenolysis; cortisol promotes fat and protein catabolism; cortisol and glucagon promote gluconeogenesis; and growth hormone raises blood glucose by antagonizing insulin.
5. *Metabolic rate* is the amount of energy released in the body in a given time, such as kcal/day. It varies according to metabolic state and physical, mental, and hormonal conditions. *Basal metabolic rate (BMR)* is a standard of reference based on a comfortable, resting, awake, postabsorptive state. *Total metabolic rate* is a higher nonresting rate that takes muscular activity into account.
6. BMR is about 2,000 kcal/day. A low level of physical activity increases the daily energy need to about 2,500 kcal/day, and hard physical labor can increase it to as much as 5,000 kcal/day. Metabolic rate also varies with age, sex, mental state, stress, and health or illness.

26.5 Body Heat and Thermoregulation (p. 1038)

- Thermoregulation* is the homeostatic control of body temperature. Excessively high or low body temperatures (*hyperthermia* and *hypothermia*) can be fatal.
- Core temperature* can be estimated from rectal temperature and is usually 37.2° to 37.6°C. Shell temperature, usually estimated from oral temperature, is usually 36.6° to 37.0°C.
- Body heat is generated mainly by exergonic chemical reactions, especially in the brain, heart, liver, and endocrine glands at rest and in the skeletal muscles during activity.
- The body loses heat by radiation, conduction, and evaporation.
- The *hypothalamic thermostat* monitors blood temperature and receives signals from peripheral thermoreceptors in the skin.
- To rid the body of excess heat, the thermostat sends signals to a hypothalamic *heat-loss center*, which triggers cutaneous vasodilation and sweating.
- To generate and retain heat, the thermostat sends signals to a hypothalamic *heat-promoting center*, which triggers shivering and cutaneous vasoconstriction.
- Heat can also be produced by *non-shivering thermogenesis*, in which the metabolic rate is increased and releases more heat from organic fuels.
- Behavioral thermoregulation* includes behaviors that adjust body temperature, such as adding or removing clothes, or getting into the shade or sun.
- Heat cramps*, *heat exhaustion*, and *heatstroke* are three effects of hyperthermia. Heatstroke often progresses to fatal multiorgan dysfunction. Hypothermia may be fatal if the core temperature reaches 32°C or lower.

Testing Your Recall

- _____ are not used as fuel and are required in relatively small quantities.
 - Micronutrients
 - Macronutrients
 - Essential nutrients
 - Proteins
 - Lipids
- The only significant digestible polysaccharide in the diet is
 - glycogen.
 - cellulose.
 - starch.
 - maltose.
 - fiber.
- Which of the following stores the greatest amount of energy for the smallest amount of space in the body?
 - glucose
 - triglycerides
 - glycogen
 - proteins
 - vitamins
- The lipoproteins that remove cholesterol from the tissues are
 - chylomicrons.
 - lipoprotein lipases.
 - VLDLs.
 - LDLs.
 - HDLs.
- Which of the following is most likely to make you hungry?
 - leptin
 - ghrelin
 - cholecystokinin
 - peptide YY
 - melanocortin
- The primary function of B-complex vitamins is to act as
 - structural components of cells.
 - sources of energy.
 - components of pigments.
 - antioxidants.
 - coenzymes.
- FAD is reduced to FADH₂ in
 - glycolysis.
 - anaerobic fermentation.
 - the citric acid cycle.
 - the electron-transport chain.
 - beta oxidation of lipids.
- The primary, direct benefit of anaerobic fermentation is to
 - regenerate NAD⁺.
 - produce FADH₂.
 - produce lactic acid.
 - dispose of pyruvic acid.
 - produce more ATP than glycolysis does.
- Which of these occurs in the mitochondrial matrix?
 - glycolysis
 - chemiosmosis
 - the cytochrome reactions
 - the citric acid cycle
 - anaerobic fermentation
- When the body emits more infrared energy than it absorbs, it is losing heat by
 - convection.
 - forced convection.
 - conduction.
 - radiation.
 - evaporation.
- A/an _____ protein lacks one or more essential amino acids.
- In the postabsorptive state, glycogen is hydrolyzed to liberate glucose. This process is called _____.
- Synthesis of glucose from amino acids or triglycerides is called _____.
- The major nitrogenous waste resulting from protein catabolism is _____.
- The organ that synthesizes the nitrogenous waste in question 14 is the _____.
- The absorptive state is regulated mainly by the hormone _____.
- The temperature of organs in the body cavities is called _____.
- The appetite hormones ghrelin, leptin, CCK, and others act on part of the hypothalamus called the _____ nucleus.
- The brightly colored, iron-containing, electron-transfer molecules of the inner mitochondrial membrane are called _____.
- The flow of H⁺ from the intermembrane space to the mitochondrial matrix creates an electrical current used by the enzyme _____ to make _____.

True or False

Determine which five of the following statements are false, and briefly explain why.

- Ghrelin and leptin are two hormones that stimulate the appetite.
- Water is a nutrient, but oxygen and cellulose are not.
- An extremely low-fat diet can cause vitamin-deficiency diseases.
- Most of the body's cholesterol comes from the diet.
- There is no harm in maximizing one's daily protein intake.
- Aerobic respiration produces more ATP than anaerobic fermentation.
- Reactions occurring on the mitochondrial inner membrane produce more ATP than glycolysis and the matrix reactions combined.
- Gluconeogenesis occurs especially in the absorptive state during and shortly after a meal.
- Brown fat generates more ATP than white fat and is therefore especially important for thermoregulation.
- At a comfortable air temperature, the body loses more heat as infrared radiation than by any other means.

Answers in appendix B

Testing Your Comprehension

- Cyanide blocks the transfer of electrons from cytochrome a_3 to oxygen. In light of this, explain why it causes sudden death. Also explain whether cyanide poisoning could be treated by giving a patient supplemental oxygen, and justify your answer.
- Chapter 17 defines and describes some hormone actions that are synergistic and antagonistic. Identify some synergistic and antagonistic hormone interactions in the postabsorptive state of metabolism.
- Mrs. Jones, a 42-year-old, complains that, "Everything I eat goes to fat. But my husband and my son eat twice as much as I do, and they're both as skinny as can be." How would you explain this to her?
- A television advertisement proclaims, "Feeling tired? Need more energy? Order your supply of Zippy Megavitamins and feel better fast!" Your friend Cathy is about to send in her order, and you try to talk her out of wasting her money. Summarize the argument you would use.
- Explain why a patient whose liver has been extensively damaged by hepatitis could show elevated concentrations of thyroid hormone and bilirubin in the blood.

27.5 Clinical Application: Sexually Transmitted Diseases 1071

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Chromosome structure (p. 128)
- Stages of mitosis (p. 141)
- The karyotype (p. 142)
- Muscles of the pelvic floor (p. 347)
- Hypothalamic releasing hormones (p. 644)
- Pituitary gonadotropins (p. 645)
- Negative feedback inhibition of the pituitary (p. 647)
- Androgens (p. 653)

From all we have learned of the structure and function of the human body, it seems a wonder that it works at all! The fact is, however, that even with modern medicine we cannot keep it working forever. The body suffers various degenerative changes as we age, and eventually our time is up and we must say good-bye. Yet our genes live on in new containers—our offspring. The production of offspring is the subject of these last three chapters. In this chapter, we examine some general aspects of human reproductive biology and then focus on the role of the male in reproduction. Chapter 28 focuses on the female and chapter 29 on the embryonic development of humans and on changes at the other end of the life span—the changes of old age.

27.1 Sexual Reproduction and Development

Objectives

When you have completed this section, you should be able to

- identify the most fundamental biological distinction between male and female;
- define *primary sex organs*, *secondary sex organs*, and *secondary sex characteristics*;
- explain the role of the sex chromosomes in determining sex;
- explain how the Y chromosome determines the response of the fetal gonad to prenatal hormones;
- identify which of the male and female external genitalia are homologous to each other; and
- describe the descent of the gonads and explain why it is important.

The Two Sexes

The essence of sexual reproduction is that it is biparental—the offspring receive genes from two parents and therefore are not genetically identical to either one. To achieve this, the parents must produce **gametes**¹ (sex cells) that meet and combine their genes in a **zygote**² (fertilized egg).

The gametes must have two properties for reproduction to be successful: motility so they can achieve contact, and nutrients for the developing embryo. A single cell cannot perform both of these roles optimally, because to contain ample nutrients means to be relatively large and heavy, and this is inconsistent with the need for motility. Therefore, these tasks are usually apportioned to two kinds of gametes. The small motile one—little more than DNA with a propeller—is the **sperm (spermatozoon)**, and the large nutrient-laden one is the **egg (ovum)**.

In any sexually reproducing species, by definition, an individual that produces eggs is female and one that produces sperm is male. These criteria are not always that simple, as we see in certain abnormalities in sexual development. Genetically, however, any human with a Y sex chromosome is classified as male and anyone lacking a Y is classified as female.

In mammals, the female is also the parent that provides a sheltered internal environment for the development and prenatal nutrition of the embryo. For fertilization and development to occur in the female, the male must have a copulatory organ, the penis, for introducing his gametes into the female reproductive tract, and the female must have a copulatory organ, the vagina, for receiving the sperm. This is the most obvious difference between the sexes, but appearances can be deceiving (see fig. 17.30, p. 674 and Insight 27.1).

Overview of the Reproductive System

The **reproductive system** in the male serves to produce sperm and introduce them into the female body. The female reproductive system produces eggs, receives the sperm, provides for the union of these gametes, harbors the fetus, gives birth, and nourishes the offspring.

The reproductive system consists of primary and secondary sex organs. The **primary sex organs**, or **gonads**,³ are organs that produce the gametes—**testes** of the male and **ovaries** of the female. The **secondary sex organs** are organs other than gonads that are necessary for reproduction. In the male, they constitute a system of ducts, glands, and the penis, concerned with the storage, survival, and conveyance of sperm. In the female, they include the uterine tubes, uterus, and vagina, concerned with uniting the sperm and egg and harboring the developing fetus.

According to location, the reproductive organs are classified as **external** and **internal genitalia** (table 27.1). The external genitalia are located in the perineum (see fig. 27.6). Most of them are externally visible, except for the accessory glands of the female perineum. The internal genitalia are located mainly in the pelvic cavity, except for the male testes and some associated ducts contained in the scrotum.

¹gam = marriage, union

²zygo = yoke, union

³gon = seed

INSIGHT 27.1 Clinical Application

Androgen-Insensitivity Syndrome

Occasionally, a girl shows all the usual changes of puberty except that she fails to menstruate. Physical examination shows the presence of testes in the abdomen and a karyotype reveals that she has the XY chromosomes of a male. The testes produce normal male levels of testosterone, but the target cells lack receptors for it. This is called *androgen-insensitivity syndrome (AIS)*, or *testicular feminization*.

The external genitals develop female anatomy as if no testosterone were present. At puberty, breasts and other feminine secondary sex characteristics develop (fig. 27.1) because the testes secrete small amounts of estrogen and there is no overriding influence of testosterone. However, there is no uterus or menstruation. If the abdominal testes are not removed, the person has a high risk of testicular cancer.

FIGURE 27.1 Androgen-Insensitivity Syndrome. These siblings are genetically male (XY). Testes are present and secrete testosterone, but the target cells lack receptors for it, so testosterone cannot exert its masculinizing effects. The external genitalia and secondary sex characteristics are feminine, but there are no ovaries, uterus, or vagina.

◀ *In what way is androgen-insensitivity syndrome similar to type 2 diabetes mellitus?*

TABLE 27.1

The External and Internal Genitalia

External Genitalia	Internal Genitalia
Male	
Penis	Testes (singular, testis)
Scrotum	Epididymides (s., epididymis)
	Ductus deferentes (s., ductus deferens)
	Seminal vesicles
	Prostate
	Bulbourethral glands
Female	
Mons pubis	Ovaries
Labia majora (s., labium majus)	Uterine tubes
Labia minora (s., labium minus)	Uterus
Clitoris	Vagina
Vaginal orifice	
Vestibular bulbs	
Vestibular glands	
Paraurethral glands	

Secondary sex characteristics are features that further distinguish the sexes and play a role in mate attraction. They typically appear only as an animal approaches sexual maturity (during adolescence in humans). From the call of a bullfrog to the tail of a peacock, these are well known in the animal kingdom. In humans, the physical attributes that contribute to mate attraction are so culturally conditioned that it is more difficult to identify what secondary sex characteristics are biologically fundamental. Generally accepted as such in both sexes are the pubic and axillary hair and their associated scent glands, and the pitch of the voice. Other traits commonly regarded as male secondary sex characteristics are the facial hair, relatively coarse and visible hair on the torso and limbs, and the relatively muscular physique. In females, they include the distribution of body fat, enlargement of the breasts (independently of lactation), and relatively hairless appearance of the skin.

Chromosomal Sex Determination

What determines whether a zygote develops into a male or female? The distinction begins with the combination of sex chromosomes bequeathed to the zygote. Most of our cells have 23 pairs of chromosomes: 22 pairs of *autosomes* and 1 pair of *sex chromosomes* (see fig. 4.17, p. 143). A sex chromosome can be either a large X chromosome or a small Y chromosome. Every egg contains an X chromosome, but

FIGURE 27.2 Chromosomal Sex Determination. All eggs carry the X chromosome. The sex of a child is determined by whether the egg is fertilized by an X-bearing sperm or a Y-bearing sperm.

half of the sperm carry an X and the other half carry a Y. If an egg is fertilized with an X-bearing sperm, it produces an XX zygote that is destined to become a female. If it is fertilized with a Y-bearing sperm, it produces an XY zygote destined to become a male. Thus, the sex of a child is determined at conception (fertilization), and not by the mother's egg but by the sperm that fertilizes it (fig. 27.2).

Prenatal Hormones and Sexual Differentiation

Sex determination does not end with fertilization, however. It requires an interaction between genetics and the hormones produced by the mother and fetus. Just as we have seen with other hormones (see chapter 17), those involved here require specific receptors on their target cells to exert an effect.

Up to a point, a fetus is sexually undifferentiated, or “noncommittal” as to which sex it will become. Its gonads begin to develop at 5 to 6 weeks as *gonadal ridges*, each lying alongside a primitive kidney, the *mesonephros*, which later degenerates. Adjacent to each gonadal ridge are two ducts: the **mesonephric**⁴ (MEZ-oh-NEF-ric) (**wolffian**⁵) **duct**, which originally serves the mesonephros, and the **paramesonephric**⁶ (**müllerian**⁷) **duct**. In males, the mesonephric ducts develop into the reproductive tract and the paramesonephric ducts degenerate. In females, the opposite occurs (fig. 27.3).

But why? The Y chromosome has a gene called **SRY** (sex-determining region of the Y) that codes for a protein called **testis-determining factor (TDF)**. TDF then interacts with genes on some of the other chromosomes, including

a gene on the X chromosome for androgen receptors and genes that initiate the development of male anatomy. By 8 to 9 weeks, the male gonadal ridge has become a rudimentary testis that begins to secrete testosterone. Testosterone stimulates the mesonephric duct on its own side to develop into the system of male reproductive ducts. By this time, the testis also secretes a hormone called **müllerian-inhibiting factor (MIF)** that causes atrophy of the paramesonephric (müllerian) duct on that side. Even an adult male, however, retains a tiny Y-shaped vestige of the paramesonephric ducts, like a vestigial uterus and uterine tubes, in the area of the prostatic urethra.

It may seem as if androgens should induce the formation of a male reproductive tract and estrogens induce a female reproductive tract. However, the estrogen level is always high during pregnancy, so if this mechanism were the case, it would feminize all fetuses. Thus, the development of a female results from the absence of androgens, not the presence of estrogens.

Development of the External Genitalia

You perhaps regard the external genitals as the most definitive characteristics of a male or female, yet there is more similarity between the sexes than most people realize. In the embryo, the genitals begin developing from identical structures in both sexes. By 6 weeks, the embryo has the following (fig. 27.4):

- a **genital tubercle**, an anterior bud destined to become the head (glans) of the penis or clitoris;
- **urogenital folds**, a pair of medial tissue folds slightly posterior to the genital tubercle; and
- **labioscrotal folds**, a larger pair of tissue folds lateral to the urogenital folds.

By the end of week 9, the fetus begins to show sexual differentiation, and either male or female genitalia are distinctly formed by the end of week 12. In the female, the three structures just listed become the clitoral glans, labia minora, and labia majora, respectively; all of these are more fully described in chapter 28. In the male, the genital tubercle elongates to form the *phallus*; the urogenital folds fuse to enclose the urethra, joining the phallus to form the penis; and the labioscrotal folds fuse to form the scrotum, a sac that will later contain the testes.

Male and female organs that develop from the same embryonic structure are said to be **homologous**. Thus, the penis is homologous to the clitoris and the scrotum is homologous to the labia majora. This becomes strikingly evident in some abnormalities of sexual development. In the presence of excess androgen, the clitoris may become greatly enlarged and resemble a small penis. In other cases, the ovaries descend into the labia majora as if they were testes descending into a scrotum. Such abnormalities sometimes result in mistaken identification of the sex of an infant at birth.

⁷Johannes P. Müller (1801–58), German physician

FIGURE 27.3 Embryonic Development of the Male and Female Reproductive Tracts. Note that the male tract develops from the mesonephric duct and the female tract from the paramesonephric duct; the other duct in each sex degenerates.

Descent of the Gonads

Both male and female gonads initially develop high in the abdominal cavity, near the kidneys, and migrate into the pelvic cavity (ovaries) or scrotum (testes). In the

embryo, a connective tissue cord called the *gubernaculum*⁸ (GOO-bur-NACK-you-lum) extends from the gonad to the floor of the abdominopelvic cavity. As the male

⁸*gubern* = rudder, to guide

FIGURE 27.4 Development of the External Genitalia. By 6 weeks, the embryo has three primordial structures—the genital tubercle, urogenital folds, and labioscrotal folds—which will become the male or female genitalia. At 8 weeks, these structures have grown but the sexes are still indistinguishable. Slight sexual differentiation is noticeable at 10 weeks, and the sexes are fully distinguishable by 12 weeks. Matching colors identify homologous structures of the male and female.

FIGURE 27.5 Descent of the Testis. Note that the testis and spermatic ducts are retroperitoneal. An extension of the peritoneum called the *vaginal process* passes through the inguinal canal and becomes the *tunica vaginalis*.

Why is this structure of male anatomy called the *tunica vaginalis*?

gubernaculum continues to grow, it passes between the internal and external abdominal oblique muscles and into the scrotal swelling. Independently of the migration of the testis, the peritoneum also develops a fold that extends into the scrotum as the *vaginal process*.⁹ The gubernaculum and vaginal process create a path of low resistance through the groin, anterior to the pubic symphysis, called the **inguinal canal**—the most common site of herniation in boys and men (*inguinal hernia*; see Insight 10.2, p. 349).

The **descent of the testes** (fig. 27.5) begins as early as week 6. The superior part of the embryonic gonad degenerates and its inferior part migrates downward, guided by the gubernaculum. In the seventh month, the testes abruptly pass through the inguinal canals into the scrotum. As they descend, they are accompanied by ever-elongating testicular arteries and veins and by lymphatic vessels, nerves, spermatic ducts, and extensions of the internal abdominal oblique muscle. The vaginal process becomes separated from the peritoneal cavity and persists as a sac, the *tunica vaginalis*, enfolding the anterior and lateral sides of the testis.

The actual mechanism of descent remains obscure, although multiple hypotheses have been offered. Testosterone stimulates descent, but it is unknown how. The reason this descent is necessary, however, will be explained in the next section.

About 3% of boys are born with undescended testes, or **cryptorchidism**.¹⁰ In most such cases, the testes descend within the first year of infancy, but if they do not, the condition can usually be corrected with a testosterone injection or a fairly simple surgery to dilate the inguinal canals and draw the testes into the scrotum. Uncorrected cryptorchidism, however, leads inevitably to sterility and sometimes to testicular cancer.

The ovaries also descend, but to a much lesser extent. A gubernaculum extends from the inferior pole of the ovary to the labioscrotal fold. The ovaries eventually lodge just inferior to the brim of the lesser pelvis. The gubernaculum becomes a pair of ligaments that support the ovary and uterus.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Define gonad and gamete. Explain the relationship between the terms.
2. Define male, female, sperm, and egg.
3. What are mesonephric and paramesonephric ducts? What factors determine which one develops and which one regresses in the fetus?
4. What male structure develops from the genital tubercle and urogenital folds? What develops from the labioscrotal folds?
5. Describe the pathway taken during descent of the male gonad.

27.2 Male Reproductive Anatomy

Objectives

When you have completed this section, you should be able to

- describe the anatomy of the scrotum, testes, and penis;
- describe the pathway taken by a sperm cell from its formation to its ejaculation, naming all the passages it travels; and
- state the names, locations, and functions of the male accessory reproductive glands.

⁹vagin = sheath

¹⁰crypto = hidden + orchid = testis + ism = condition

FIGURE 27.6 The Male Perineum.

We will survey the male reproductive system beginning with the scrotum and testes, continuing through the spermatic ducts and accessory glands associated with them, and ending with the penis—thus taking anatomy in the order of sperm formation, transport, and emission.

The Scrotum

The scrotum and penis constitute the external genitalia of the male and occupy the **perineum** (PERR-ih-NEE-um). This is a diamond-shaped area between the thighs bordered by the pubic symphysis, ischial tuberosities, and coccyx (fig. 27.6).

The **scrotum**¹¹ is a pendulous pouch of skin, muscle, and fibrous connective tissue, containing the testes (fig. 27.7). The left testis is usually suspended lower than the right so the two are not compressed against each other between the thighs. The skin of the scrotum has sebaceous glands, sparse hair, rich sensory innervation, and somewhat darker pigmentation than skin elsewhere. The scrotum is divided into right and left compartments by an internal **median septum**, which protects each testis from infections of the

¹¹scrotum = bag

FIGURE 27.7 The Scrotum and Spermatic Cord.

other one. The location of the septum is externally marked by a seam called the **perineal raphe**¹² (RAY-fee), which also extends anteriorly along the ventral side of the penis and posteriorly as far as the margin of the anus (fig. 27.6).

Posteriorly, the scrotum contains the **spermatic cord**, a bundle of fibrous connective tissue containing the *ductus deferens* (a sperm duct), blood and lymphatic vessels, and testicular nerves. It passes upward behind and superior to the testis, where it is easily palpated through the skin of the scrotum. It continues across the anterior side of the pubis and into a 4-cm-long **inguinal canal**, which leads through the muscles of the groin and emerges into the pelvic cavity. The inferior entrance into the inguinal canal is called the *external inguinal ring*, and its superior exit into the pelvic cavity is the *internal inguinal ring*.

The original reason that a scrotum evolved is a subject of debate among reproductive biologists. For whatever reason human testes reside in the scrotum, however, they have adapted to this cooler environment and cannot produce sperm at the core body temperature of 37°C; they must be held at about 35°C. The scrotum has three mechanisms for regulating the temperature of the testes:

1. The **cremaster**¹³ **muscle**—strips of the internal abdominal oblique muscle that enmesh the spermatic cord. When it is cold, the cremaster contracts and draws the testes closer to the body to keep them warm. When it is warm, the cremaster relaxes and the testes are suspended farther from the body.
2. The **dartos**¹⁴ **muscle**—a subcutaneous layer of smooth muscle. It, too, contracts when it is cold, and the scrotum becomes taut and wrinkled. The tautness of the scrotum helps to hold the testes snugly against the warm body and it reduces the surface area of the scrotum, thus reducing heat loss.
3. The **pampiniform**¹⁵ **plexus**—an extensive network of veins from the testis that surround the testicular artery in the spermatic cord. As they pass through the inguinal canal, these veins converge to form the testicular vein, which emerges from the canal into the pelvic cavity. Without the pampiniform plexus, warm arterial blood would heat the testis and inhibit sperm production. The pampiniform plexus, however, prevents this by acting as a *countercurrent heat exchanger* (fig. 27.8). Imagine that a house had uninsulated hot and cold water pipes running close to each other. Much of the heat from the hot water pipe would be absorbed by the cold water pipe next to it—especially if the water flowed in opposite directions so the cold water carried the heat away. In the spermatic cord, such a mechanism removes heat from the descending arterial blood, so by the time it reaches

FIGURE 27.8 The Countercurrent Heat Exchanger. Warm blood flowing down the testicular artery loses some of its heat to the cooler blood flowing in the opposite direction through the pampiniform plexus of veins (represented as a single vessel for simplicity). Arterial blood is about 2°C cooler by the time it reaches the testis.

the testis this blood is 1.5° to 2.5°C cooler than the core body temperature.

The Testes

The testes (testicles) are combined endocrine and exocrine glands that produce sex hormones and sperm. Each testis is oval and slightly flattened, about 4 cm long, 3 cm from anterior to posterior, and 2.5 cm wide (fig. 27.9a). Its anterior and lateral surfaces are covered by the tunica vaginalis. The testis itself has a white fibrous capsule called the **tunica albuginea**¹⁶ (TOO-nih-ca AL-byu-JIN-ee-uh). Connective tissue septa extend from the capsule into the parenchyma, dividing it into 250 to 300 wedge-shaped lobules. Each lobule contains one to three **seminiferous**¹⁷ (SEM-ih-NIF-er-us) **tubules**—slender ducts up to 70 cm long in which the sperm are produced. Between the seminiferous tubules are clusters of **interstitial (Leydig)**¹⁸ **cells**, the source of testosterone.

A seminiferous tubule has a narrow lumen lined by a thick **germinal epithelium** (fig. 27.10). The epithelium

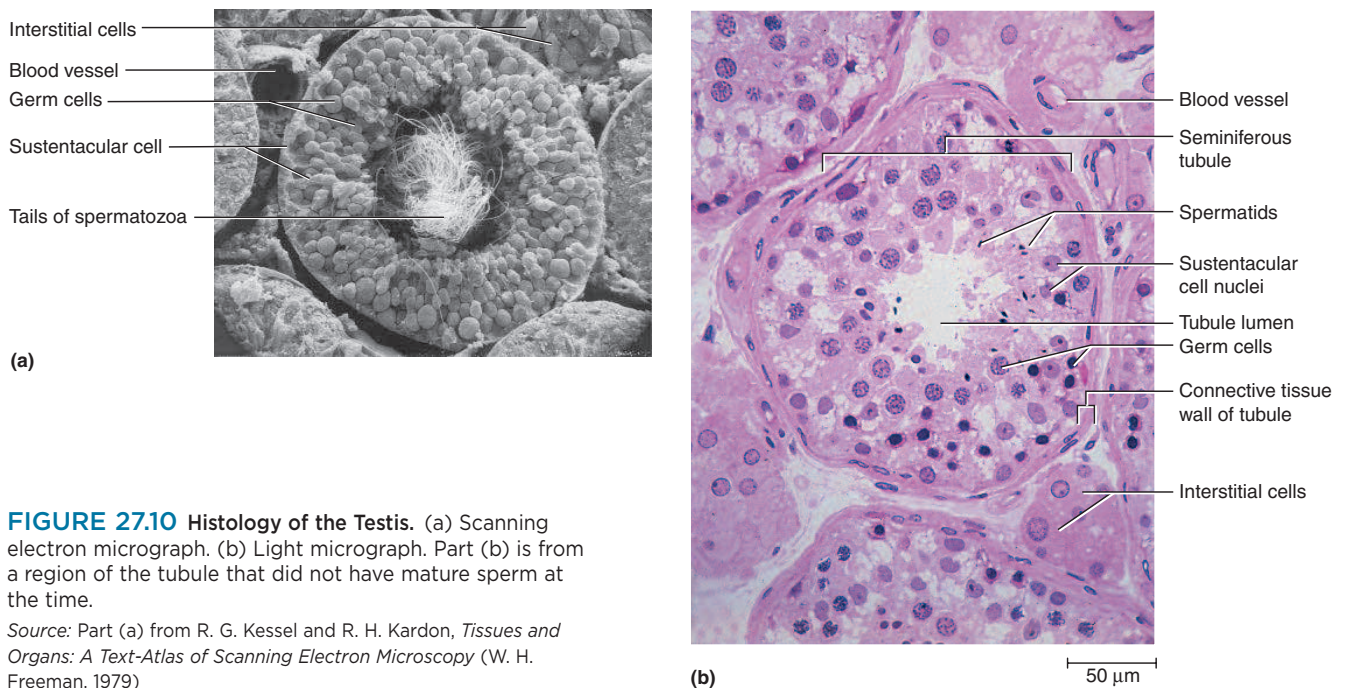

FIGURE 27.10 Histology of the Testis. (a) Scanning electron micrograph. (b) Light micrograph. Part (b) is from a region of the tubule that did not have mature sperm at the time.

Source: Part (a) from R. G. Kessel and R. H. Kardon, *Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy* (W. H. Freeman, 1979)

consists of several layers of **germ cells** in the process of becoming sperm, and a much smaller number of tall **sustentacular**¹⁹ (**Sertoli**²⁰) **cells**, which protect the germ cells and promote their development. The germ cells depend on the sustentacular cells for nutrients, waste removal, growth factors, and other needs. The sustentacular cells also secrete a hormone, *inhibin*, which regulates the rate of sperm production, as we will see later.

A sustentacular cell is shaped a little like a tree trunk whose roots spread out over the basement membrane, forming the boundary of the tubule, and whose thick trunk reaches to the tubule lumen. Tight junctions between adjacent sustentacular cells form a **blood–testis barrier (BTB)**, which prevents antibodies and other large molecules in the blood and intercellular fluid from getting to the germ cells. This is important because the germ cells, being genetically different from other cells of the body, would otherwise be attacked by the immune system. Some cases of sterility occur when the BTB fails to form adequately in adolescence and the immune system produces autoantibodies against the germ cells.

Think About It

Would you expect to find blood capillaries in the walls of the seminiferous tubules? Why or why not?

The seminiferous tubules lead into a network called the **rete**²¹ (REE-tee) **testis**, embedded in the capsule on the posterior side of the testis. Sperm partially mature in the rete. They are moved along by the flow of fluid secreted by the sustentacular cells and by the cilia on some rete cells. Sperm do not swim while they are in the male reproductive tract.

Each testis is supplied by a **testicular artery** that arises from the abdominal aorta just below the renal artery. This is a very long, slender artery that winds its way down the posterior abdominal wall before passing through the inguinal canal into the scrotum (see fig. 27.7). Its blood pressure is very low, and indeed this is one of the few arteries to have no pulse. Consequently, blood flow to the testes is quite meager and the testes receive a poor oxygen supply. In response to this, the sperm develop unusually large mitochondria, which may precondition them for survival in the hypoxic environment of the female reproductive tract.

Blood leaves the testis by way of the pampiniform plexus of veins. As these veins pass through the inguinal canal, they converge and form the **testicular vein**. The right testicular vein drains into the inferior vena cava and the left one drains into the left renal vein. Lymphatic

vessels also drain each testis. They travel through the inguinal canal with the veins and lead to lymph nodes adjacent to the lower aorta. Lymph from the penis and scrotum, however, travels to lymph nodes adjacent to the iliac arteries and veins and in the inguinal region.

Testicular nerves lead to the gonads from spinal cord segments T10 and T11. They are mixed sensory and motor nerves containing predominantly sympathetic but also some parasympathetic fibers. The sensory fibers are concerned primarily with pain and the autonomic fibers are predominantly vasomotor, for regulation of blood flow.

The Spermatic Ducts

After leaving the testis, the sperm travel through a series of *spermatic ducts* to reach the urethra (fig. 27.11). These include the following:

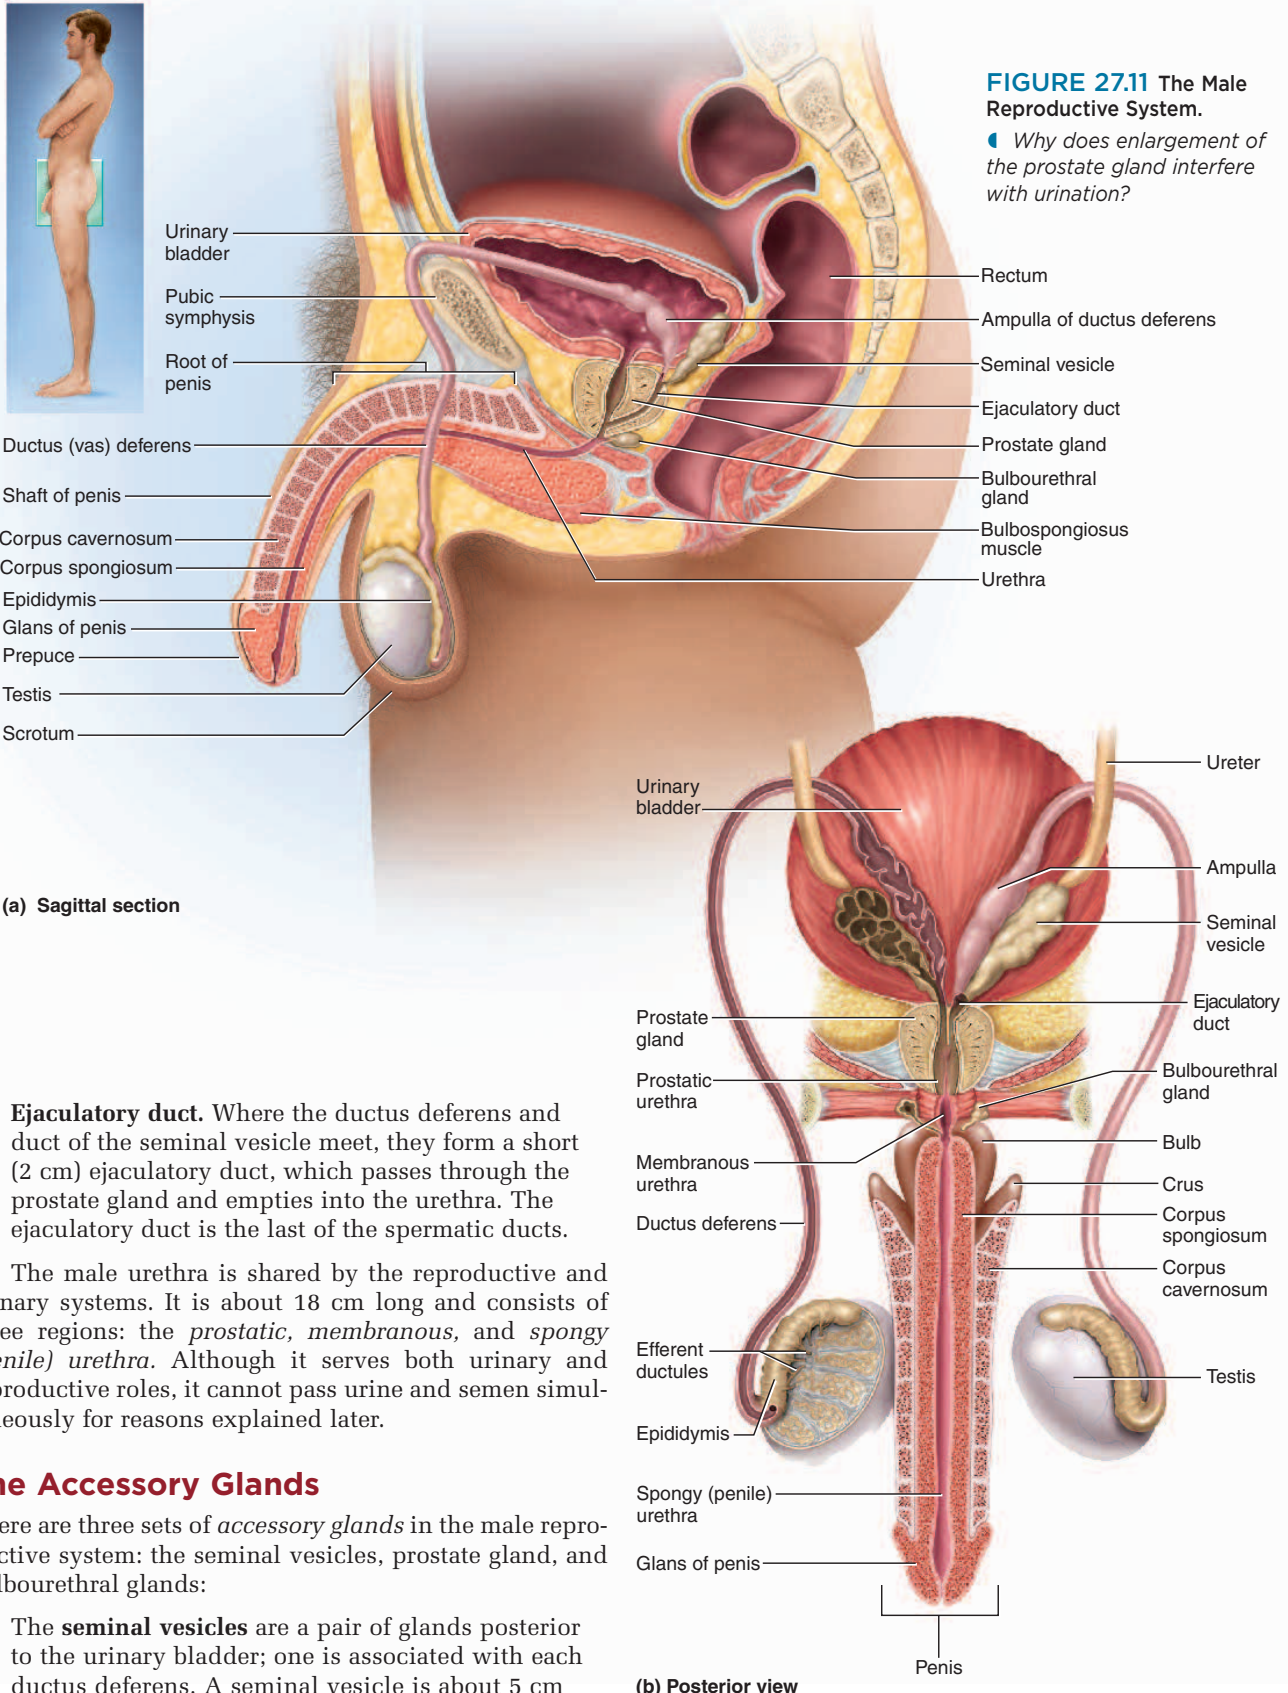

- **Efferent ductules.** About 12 small efferent ductules arise from the posterior side of the testis and carry sperm to the epididymis. They have clusters of ciliated cells that help drive the sperm along.
- **Duct of the epididymis.** The **epididymis**²² (EP-ih-DID-ih-miss; plural, *epididymides*) is a site of sperm maturation and storage. It adheres to the posterior side of the testis (see fig. 27.9); measures about 7.5 cm long; and consists of a clublike *head* at the superior end, a long middle *body*, and a slender *tail* at its inferior end. It contains a single coiled duct, about 6 m (18 feet) long, embedded in connective tissue. This duct reabsorbs about 90% of the fluid secreted by the testis. Sperm are physiologically immature when they leave the testis but mature as they travel through the head and body of the epididymis. In 20 days or so, they reach the tail. They are stored here and in the adjacent portion of the ductus deferens. Stored sperm remain fertile for 40 to 60 days, but if they become too old without being ejaculated, they disintegrate and the epididymis reabsorbs them.
- **Ductus (vas) deferens.** The duct of the epididymis straightens out at the tail, turns 180°, and becomes the ductus deferens. This is a muscular tube about 45 cm long and 2.5 mm in diameter. It passes upward through the spermatic cord and inguinal canal and enters the pelvic cavity. There, it turns medially and approaches the urinary bladder. After passing between the bladder and ureter, the duct turns downward behind the bladder and widens into a terminal **ampulla**. The ductus deferens ends by uniting with the duct of the seminal vesicle, a gland considered later. The duct has a very narrow lumen and a thick wall of smooth muscle well innervated by sympathetic nerve fibers.

¹⁹sustentacul = support

²⁰Enrico Sertoli (1842–1910), Italian histologist

²¹rete = network

²²epi = upon + didym = twins, testes

- **Ejaculatory duct.** Where the ductus deferens and duct of the seminal vesicle meet, they form a short (2 cm) ejaculatory duct, which passes through the prostate gland and empties into the urethra. The ejaculatory duct is the last of the spermatic ducts.

The male urethra is shared by the reproductive and urinary systems. It is about 18 cm long and consists of three regions: the *prostatic*, *membranous*, and *spongy (penile) urethra*. Although it serves both urinary and reproductive roles, it cannot pass urine and semen simultaneously for reasons explained later.

The Accessory Glands

There are three sets of *accessory glands* in the male reproductive system: the seminal vesicles, prostate gland, and bulbourethral glands:

1. The **seminal vesicles** are a pair of glands posterior to the urinary bladder; one is associated with each ductus deferens. A seminal vesicle is about 5 cm

long, with approximately the dimensions of the little finger. It has a connective tissue capsule and underlying layer of smooth muscle. The secretory portion is a very convoluted duct with numerous branches that form a complex labyrinth. The duct empties into the ejaculatory duct. The yellowish secretion of the seminal vesicles constitutes about 60% of the semen; its composition and functions are discussed later.

2. The **prostate**²³ (PROSS-tate) **gland** surrounds the urethra and ejaculatory ducts immediately inferior to the urinary bladder (see Insight 27.2). It measures about 2 by 4 by 3 cm and is an aggregate of 30 to 50 compound tubuloacinar glands enclosed in a single fibrous capsule. These glands empty through about 20 pores in the urethral wall. The stroma of the prostate consists of connective tissue and smooth muscle, like that of the seminal vesicles. The thin, milky secretion of the prostate constitutes about 30% of the semen. Its functions, too, are considered later.

3. The **bulbourethral (Cowper)**²⁴ **glands** are named for their position near a dilated bulb at the inner end of the penis and their association with the urethra. They are brownish, spherical glands about 1 cm in diameter, with a 2.5 cm duct to the urethra. During sexual arousal, they produce a clear slippery fluid that lubricates the head of the penis in preparation for intercourse. Perhaps more important, though, it protects the sperm by neutralizing the acidity of residual urine in the urethra.

The Penis

The **penis**²⁵ serves to deposit semen in the vagina. Half of it is an internal **root** and half is the externally visible **shaft** and **glans**²⁶ (figs. 27.11 and 27.12). The external portion is about 8 to 10 cm (3–4 in.) long and 3 cm in diameter when flaccid (nonerect); the typical dimensions of an erect penis are 13 to 18 cm (5–7 in.) long and 4 cm in diameter. The glans is the expanded head at the distal end of the penis with the external urethral orifice at its tip.

²³pro = before + stat = to stand; commonly misspelled and mispronounced "prostrate"

²⁴William Cowper (1666–1709), British anatomist

²⁵penis = tail

²⁶glans = acorn

FIGURE 27.12 Anatomy of the Penis. (a) Superficial dissection of shaft, lateral view. (b) Cross section at midshaft.

What is the functional benefit of the corpus spongiosum not having a tunica albuginea?

INSIGHT 27.2 Clinical Application**Prostate Diseases**

The prostate gland weighs about 20 g by age 20, remains at that weight until age 45 or so, and then begins to grow slowly again. By age 70, over 90% of men show some degree of *benign prostatic hyperplasia (BPH)*—noncancerous enlargement of the gland. The major complication of this is that it compresses the urethra, obstructs the flow of urine, and may promote bladder and kidney infections.

Prostate cancer is the second most common cancer in men (after lung cancer); it affects about 9% of men over the age of 50. Prostate tumors tend to form near the periphery of the gland, where they do not obstruct urine flow; therefore, they often go unnoticed until they cause pain. Prostate cancer often metastasizes to nearby lymph nodes and then to the lungs and other organs. It is more common among American blacks than whites and very uncommon among Japanese.

The position of the prostate immediately anterior to the rectum allows it to be palpated through the rectal wall to check for tumors. This procedure is called *digital rectal examination (DRE)*. Prostate cancer can also be diagnosed from elevated levels of *serine protease* (also known as *prostate-specific antigen, PSA*) and *acid phosphatase* (another prostatic enzyme) in the blood. Up to 80% of men with prostate cancer survive when it is detected and treated early, but only 10% to 50% survive if it spreads beyond the prostatic capsule.

Directional terminology may be a little confusing in the penis, because the *dorsal* side is the one that faces anteriorly, at least when the penis is flaccid, whereas the *ventral* side of the penis faces posteriorly. This is because in most mammals, the penis is horizontal, held against the abdomen by skin, and points anteriorly. The urethra passes through its lower, more obviously ventral, half. Directional terminology in the human penis follows the same convention as for other mammals, even though our bipedal posture and more pendulous penis changes these anatomical relationships.

The skin is loosely attached to the penile shaft, allowing for expansion during erection. It continues over the glans as the **prepuce**, or foreskin, which is often removed by circumcision. A ventral fold of tissue called the **frenulum** attaches the skin to the glans. The skin of the glans itself is thinner and firmly attached to the underlying erectile tissue. The glans and facing surface of the prepuce have sebaceous glands that produce a waxy secretion called **smegma**.²⁷

The penis consists mainly of three cylindrical bodies called **erectile tissues**, which fill with blood during sexual arousal and account for its enlargement and erection. A single erectile body, the **corpus spongiosum**, passes along the ventral side of the penis and encloses the penile ure-

thra. It expands at the distal end to fill the entire glans. Proximal to the glans, the dorsal side of the penis has a **corpus cavernosum** (plural, *corpora cavernosa*) on each side. Each is ensheathed in a fibrous **tunica albuginea**, and they are separated from each other by a **median septum**. (Note that the testes also have a tunica albuginea and the scrotum also has a median septum.)

All three cylinders of erectile tissue are spongy in appearance and contain numerous tiny blood sinuses called **lacunae**. The partitions between lacunae, called **trabeculae**, are composed of connective tissue and smooth **trabecular muscle**. In the flaccid penis, trabecular muscle tone collapses the lacunae, which appear as tiny slits in the tissue.

At the body surface, the penis turns 90° posteriorly and continues inward as the root. The corpus spongiosum terminates internally as a dilated **bulb**, which is ensheathed in the bulbospongiosus muscle and attached to the lower surface of the perineal membrane within the urogenital triangle (see p. 348). The corpora cavernosa diverge like the arms of a Y. Each arm, called a **crus** (pronounced “cruss”; plural, *crura*), attaches the penis to the pubic arch (ischiopubic ramus) and perineal membrane on its respective side. Each crus is enveloped by an ischiocavernosus muscle. The innervation and blood supply to the penis are discussed later in connection with the mechanism of erection.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- State the names and locations of two muscles that help regulate the temperature of the testes.
- Name three types of cells in the testes, and describe their locations and functions.
- Name all the ducts that the sperm follow, in order, from the time they form in the testis to the time of ejaculation.
- Describe the locations and functions of the seminal vesicles, prostate, and bulbourethral glands.
- Name the erectile tissues of the penis, and describe their locations relative to each other.

27.3 Puberty and Climacteric**Objectives**

When you have completed this section, you should be able to

- describe the hormonal control of puberty;
- describe the resulting changes in the male body; and
- define and describe male climacteric and the effect of aging on male reproductive function.

²⁷smegma = unguent, ointment, soap

FIGURE 27.13 Hormonal Relationships Between the Hypothalamus, Pituitary Gland, and Testis.

Unlike any other organ system, the reproductive system remains dormant for several years after birth. Around age 10 to 12 in most boys and 8 to 10 in most girls, however, a surge of pituitary gonadotropins awakens the reproductive system and begins preparing it for adult reproductive function. This is the onset of puberty.

Definitions of *adolescence* and *puberty* vary. This book uses **adolescence**²⁸ to mean the period from the onset of gonadotropin secretion and reproductive development until a person attains full adult height. **Puberty**²⁹ is the first few years of adolescence, until the first menstrual period in girls or the first ejaculation of viable sperm in boys. In North America, this is typically attained around age 12 in girls and age 13 in boys.

Endocrine Control of Puberty

The testes secrete substantial amounts of testosterone in the first trimester (3 months) of fetal development. Even in the first few months of infancy, testosterone levels are about as high as they are in midpuberty, but then the testes become dormant for the rest of infancy and childhood. From puberty through adulthood, reproductive function is regulated by hormonal links between the hypothalamus, pituitary gland, and gonads (fig. 27.13).

As the hypothalamus matures, it begins producing **gonadotropin-releasing hormone (GnRH)**, which travels by way of the hypophyseal portal system to the anterior lobe of the pituitary. Here it stimulates cells called *gonadotropes* to secrete **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**, two *gonadotropins* that stimulate different cells in the testis.

²⁸*adolesc* = to grow up

²⁹*puber* = grown up

LH stimulates the interstitial cells of the testes to secrete androgens, mainly testosterone. In the male, LH is sometimes called *interstitial cell-stimulating hormone (ICSH)*. FSH stimulates the sustentacular cells to secrete a protein called **androgen-binding protein (ABP)** into the lumen of the seminiferous tubules. ABP raises the testosterone level in the tubules and epididymis by binding and accumulating the hormone. Without FSH and ABP, testosterone has no effect on the testes. Germ cells have no androgen receptors and do not respond to it.

Many of the physiological processes of puberty go unnoticed at first, but in time, the androgens produce many conspicuous effects on the body:

- They stimulate growth of the sex organs. The first visible sign of puberty is usually enlargement of the testes and scrotum around age 13. The penis continues to grow for about 2 more years after the testes attain their mature size. Internally, the ducts and accessory glands also enlarge.
- Testosterone stimulates a burst of generalized body growth—the limb bones elongate rapidly, a boy grows taller, and he develops more muscle mass. The larynx also enlarges, deepening the voice and making the thyroid cartilage more prominent on the front of the neck. Even erythropoiesis is accelerated, resulting in a higher RBC count and hematocrit in males than in females. Along with all this growth, the basal metabolic rate increases, accompanied by an increase in appetite.
- One of the androgens, dihydrotestosterone (DHT), stimulates development of the pubic hair, axillary hair, and later the facial hair. The skin becomes darker and thicker and secretes more sebum, which often leads to acne; acne patients have 2 to 20 times the normal level of DHT in their skin. The apocrine scent glands of the perineal, axillary, and beard areas develop in conjunction with the hair in those regions.
- The accumulation of testosterone by ABP leads to the onset and rising rate of sperm production. If testosterone secretion ceases, the sperm count and semen volume decline rapidly and a male becomes sterile.
- Testosterone inhibits GnRH secretion by the hypothalamus and GnRH sensitivity of the pituitary. Consequently, FSH and LH secretion are held in check. Over the course of puberty, however, the pituitary becomes less sensitive to this negative feedback and secretes increasing amounts of gonadotropins, resulting in a rising level of androgens.
- Testosterone also stimulates the brain and awakens the **libido** (sex drive)—although, perhaps surprisingly, the neurons convert it to estrogen (a supposedly “female” sex hormone), which is what

directly affects the behavior. With increasing libido and sensitivity to stimulation, erections occur frequently and ejaculation often occurs during sleep (nocturnal emissions, or “wet dreams”).

Throughout adulthood, testosterone sustains the male reproductive tract, sperm production, and libido.

The body can modulate FSH secretion and sperm production without having to reduce LH and testosterone secretion. The mechanism for this is a hormone called **inhibin**, secreted by the sustentacular cells of the seminiferous tubules. Inhibin selectively suppresses FSH output from the pituitary. When the sperm count drops below 20 million sperm/mL, however, inhibin secretion drops and FSH secretion rises.

Think About It

If a male animal is castrated, would you expect FSH and LH levels to rise, fall, or be unaffected. Why?

Aging and Sexual Function

Testosterone secretion peaks at about 7 mg/day at age 20, then declines steadily to as little as one-fifth of this level by age 80. There is a corresponding decline in the number and secretory activity of the interstitial cells (the source of testosterone) and sustentacular cells (the source of inhibin). As testosterone and inhibin levels decline, so does feedback inhibition of the pituitary. Consequently, FSH and LH levels rise significantly after age 50 and produce changes called **male climacteric** or **andropause**. Most men pass through climacteric with little or no effect, but in a few cases there are mood changes, hot flashes, and illusions of suffocation—symptoms similar to those of menopause in women. Despite references to “male menopause,” the term *menopause* refers to the cessation of menstruation and therefore makes no sense in the context of male physiology.

About 20% of men in their 60s and 50% of men in their 80s experience *erectile dysfunction* (impotence), the frequent inability to produce or maintain an erection sufficient for intercourse (see table 27.2). Erectile dysfunction (ED) and declining sexual activity can have a major impact on older people’s perception of the quality of life. Over 90% of men with ED, however, remain able to ejaculate.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

11. State the source, target organ, and effect of GnRH.
12. Identify the target cells and effects of FSH and LH.
13. Explain how testicular hormones affect the secretion of FSH and LH.
14. Describe the major effects of androgens on the body.
15. Define male climacteric.

27.4 Sperm and Semen

Objectives

When you have completed this section, you should be able to

- describe the stages of meiosis and contrast meiosis with mitosis;
- describe the sequence of cell types in spermatogenesis, and relate these to the stages of meiosis;
- describe the role of the sustentacular cell in spermatogenesis;
- describe or draw and label a sperm cell; and
- describe the composition of semen and functions of its components.

Spermatogenesis is the process of sperm production. It occurs in the seminiferous tubules and involves three principal events: (1) remodeling of a relatively large germ cell into small, mobile cells with flagella; (2) reduction of the chromosome number by one-half; and (3) a shuffling of the genes so that each chromosome of the sperm carries new gene combinations that did not exist in the chromosomes of the parents. This ensures genetic variety in the offspring. The genetic recombination and reduction in chromosome number are achieved through a form of cell division called **meiosis**, which produces four daughter cells that subsequently differentiate into sperm.

Meiosis

In nearly all living organisms except bacteria, there are two forms of cell division: mitosis and meiosis. Mitosis, described in chapter 4, is the basis for division of the single-celled fertilized egg, growth of an embryo, and all postnatal growth and tissue repair. It is essentially the splitting of a cell with a distribution of chromosomes that results in two genetically identical daughter cells. It consists of four stages: prophase, metaphase, anaphase, and telophase.

You may find it beneficial to review figure 4.16 (p. 141) because of the important similarities and differences between mitosis and meiosis. There are three important differences:

1. In mitosis, each double-stranded chromosome divides into two single-stranded ones, but each daughter cell still has 46 chromosomes (23 pairs). Meiosis, by contrast, reduces the chromosome number by half. The parent cell is **diploid (2n)**, meaning it has 46 chromosomes in 23 homologous pairs (see fig. 4.17, p. 143), whereas the daughter cells are **haploid (n)**, with 23 unpaired chromosomes.
2. In mitosis, the chromosomes do not change their genetic makeup. In an early stage of meiosis, however, the chromosomes of each homologous pair join and exchange portions of their DNA. This creates new combinations of genes, so the chromosomes we pass to our offspring are not the same ones that we inherited from our parents.
3. In mitosis, each parent cell produces only two daughter cells. In meiosis, it produces four. In the male, four sperm therefore develop from each original germ cell. The situation is somewhat different in the female (see chapter 28).

Why use such a relatively complicated process for gametogenesis? Why not use mitosis, as we do for all other cell replication in the body? The answer is that sexual reproduction is, by definition, biparental. If we are going to combine gametes from two parents to make a child, there must be a mechanism for keeping the chromosome number constant from generation to generation. Mitosis would produce eggs and sperm with 46 chromosomes each. If these gametes combined, the zygote and the next generation would have 92 chromosomes per cell, the generation after that would have 184, and so forth. To prevent the chromosome number from doubling in every generation, the number is reduced by half during gametogenesis. Meiosis³⁰ is sometimes called *reduction division* for this reason.

The stages of meiosis are fundamentally the same in both sexes. Briefly, it consists of two cell divisions in succession and occurs in the following phases: prophase I, metaphase I, anaphase I, telophase I, interkinesis, prophase II, metaphase II, anaphase II, and telophase II. These events are detailed in figure 27.14, but let us note some of its unique and important aspects.

In prophase I, each pair of homologous chromosomes line up side by side and form a **tetrad** (*tetra* denoting the four chromatids). One chromosome of each tetrad is from the individual's father (the paternal chromosome) and the other is from the mother (the maternal chromosome). The paternal and maternal chromosomes exchange segments of DNA in a process called **crossing-over**. This creates new combinations of genes and thus contributes to genetic variety in the offspring.

After crossing-over, the chromosomes line up at the midline of the cell in metaphase I, they separate at anaphase I, and the cell divides in two at telophase I. This looks superficially like mitosis, but there is an important difference: The centromeres do not divide and the chromatids do not separate from each other at anaphase I; rather, each homologous chromosome parts company with its twin. Therefore, at the conclusion of meiosis I, each chromosome is still double-stranded, but each daughter cell has only 23 chromosomes—it has become haploid.

³⁰meio = less, fewer

FIGURE 27.14 Meiosis. For simplicity, the cell is shown with only two pairs of homologous chromosomes. Human cells begin meiosis with 23 pairs.

Although we pass the same genes to our offspring as we inherit from our parents, we do not pass on the same chromosomes. What process in this figure accounts for the latter fact?

FIGURE 27.15 Spermatogenesis. $2n$ indicates diploid cells and n indicates haploid cells. The process proceeds from the bottom of the figure to the top. The daughter cells from secondary spermatocytes through spermatids remain connected by slender cytoplasmic processes until spermiogenesis is complete and individual spermatozoa are released. See text for explanation of steps 1 to 5.

❗ Why must the primary spermatocyte move through the blood-testis barrier before undergoing meiosis?

Meiosis II is more like mitosis—the chromosomes line up on the cell equator again at metaphase II, the centromeres divide, and each chromosome separates into two chromatids. These chromatids are drawn to opposite poles of the cell at anaphase II. At the end of meiosis II, there are four haploid cells, each containing 23 single-stranded chromosomes. Fertilization combines 23 chromosomes from the father with 23 chromosomes from the mother and reestablishes the diploid number of 46 in the zygote.

Spermatogenesis

Now we will relate meiosis to sperm production (fig. 27.15). The first stem cells specifically destined to become sperm are **primordial germ cells**. Like the first blood cells, these form in the yolk sac, a membrane associated with the developing embryo. In the fifth to sixth week of development, they crawl into the embryo itself and colonize the gonadal ridges. Here they become stem cells called **spermatogonia**. They remain dormant through childhood, lying along the periphery of the seminiferous tubule near the basement membrane, outside the blood-testis barrier (BTB).

At puberty, testosterone secretion rises, reactivates the spermatogonia, and brings on spermatogenesis. The essential steps of spermatogenesis are as follows, numbered to match figure 27.15.

- ❶ Spermatogonia divide by mitosis. One daughter cell from each division remains near the tubule wall as a stem cell called a *type A spermatogonium*. Type A spermatogonia serve as a lifetime supply of stem cells, so men normally remain fertile throughout old age. The other daughter cell, called a *type B spermatogonium*, migrates slightly away from the wall on its way to producing sperm.
- ❷ The type B spermatogonium enlarges and becomes a **primary spermatocyte**. Since this cell is about to undergo meiosis and become genetically different from other cells of the body, it must be protected from the immune system. Ahead of the primary spermatocyte, the tight junction between two sustentacular cells is dismantled, while a new tight junction forms behind the spermatocyte. The spermatocyte moves toward the lumen, like an astronaut passing through the double-door airlock of a spaceship, and is now protected by the BTB closing behind it.

FIGURE 27.16 Spermiogenesis. In this process, the spermatids discard excess cytoplasm, grow tails, and become spermatozoa.

FIGURE 27.17 The Mature Spermatozoon. (a) Head and part of the tail of a spermatozoon (TEM). (b) Sperm structure.

- ③ Now safely isolated from blood-borne antibodies, the primary spermatocyte undergoes meiosis I, which gives rise to two equal-size, haploid and genetically unique **secondary spermatocytes**.
- ④ Each secondary spermatocyte undergoes meiosis II, dividing into two **spermatids**—a total of four for each spermatogonium.
- ⑤ A spermatid divides no further, but undergoes a transformation called **spermiogenesis**, in which it differentiates into a single spermatozoon (fig. 27.16). The spermatid sprouts a tail (flagellum) and discards most of its cytoplasm, making the sperm a light-weight, mobile, self-propelled cell. It will not move under its own power, however, until ejaculation.

Each stage of this process is a little closer to the lumen than the earlier stages. All stages on the luminal side of the BTB are bound to the sustentacular cells by tight junctions and gap junctions, and are closely enveloped in tendrils of the sustentacular cells. Throughout their meiotic divisions, the daughter cells never completely separate, but remain connected to each other by cytoplasmic bridges. Eventually, however, the mature sperm separate from each other, depart from their supportive sustentacular cells, and are washed down the tubule by a slow flow of fluid. It takes about 74 days for a type B spermatogonium to become mature spermatozoa. A young man produces about 300,000 sperm per minute, or 400 million per day.

The Spermatozoon

The spermatozoon has two parts: a pear-shaped head and a long tail (fig. 27.17). The **head**, about 4 to 5 μm long and 3 μm wide at its broadest part, contains three structures: a nucleus, acrosome, and flagellar basal body. The most important of these is the nucleus, which fills most of the head and contains a haploid set of condensed, genetically inactive chromosomes. The **acrosome**³¹ is a lysosome in the form of a thin cap covering the apical half of the nucleus. It contains enzymes that are later used to penetrate the egg if the sperm is successful. The basal body of the tail flagellum is nestled in an indentation at the basal end of the nucleus.

The **tail** is divided into three regions called the **midpiece**, **principal piece**, and **endpiece**. The **midpiece**, a cylinder about 5 to 9 μm long and half as wide as the head, is the thickest part. It contains numerous large mitochondria that coil tightly around the axoneme of the flagellum. They produce the ATP needed for the beating of the tail when the sperm migrates up the female reproductive tract. The **principal piece**, 40 to 45 μm long, constitutes most of the tail and consists of the axoneme surrounded by a sheath of supportive

³¹acro = tip, peak + some = body

fibers. The **endpiece**, 4 to 5 μm long, consists of the axoneme only and is the narrowest part of the sperm.

Semen

The fluid expelled during orgasm is called **semen**³² (seminal fluid). A typical ejaculation discharges 2 to 5 mL of semen, composed of about 10% sperm and spermatic duct secretions, 30% prostatic fluid, 60% seminal vesicle fluid, and a trace of bulbourethral fluid. Most of the sperm emerge in the first one or two jets of semen. The semen usually has a **sperm count** of 50 to 120 million sperm/mL. A sperm count any lower than 20 to 25 million sperm/mL is usually associated with **infertility** (sterility), the inability to fertilize an egg (see table 27.2). The prostate and seminal vesicles contribute the following constituents to the semen:

1. The prostate produces a thin, milky white fluid containing calcium, citrate, and phosphate ions, a clotting enzyme, and a protein-hydrolyzing enzyme called *serine protease* (prostate-specific antigen, PSA; see Insight 27.2).
2. The seminal vesicles contribute a viscous yellowish fluid. This is the last component of the semen to emerge, and it flushes any remaining sperm from the urethra. This fluid contains fructose and other carbohydrates, citrate, prostaglandins (discovered in and named for the bovine prostate, but more abundant in the seminal vesicle fluid), and a protein called *prosemínogelin*.

A well-known property of semen is its stickiness, an adaptation that promotes fertilization. It arises when the clotting enzyme from the prostate activates prosemínogelin, converting it to a sticky fibrinlike protein, **semínogelin**. Semínogelin entangles the sperm, sticks to the walls of the inner vagina and cervix, and ensures that the semen does not simply drain back out of the vagina. It may also promote the uptake of sperm-laden clots of semen into the uterus. Twenty to 30 minutes after ejaculation, the **serine protease** of the prostatic fluid breaks down semínogelin and liquifies the semen. The sperm now become very active, thrashing with their tails and crawling up the mucosa of the vagina and uterus. The prostaglandins of the semen may thin the mucus in the *cervical canal* of the female (see chapter 28), making it easier for sperm to migrate from the vagina into the uterus, and they may stimulate peristaltic waves in the uterus and uterine tubes that help to spread semen through the female reproductive tract.

Two requirements must be met for sperm motility: an elevated pH and an energy source. The pH of the vagina is about 3.5 to 4.0, and the male spermatic ducts are also quite acidic. The sperm remain still at such low pHs. But the prostatic fluid buffers the vaginal and

INSIGHT 27.3 Clinical Application

Reproductive Effects of Pollution

In recent decades, wildlife biologists have noticed increasing numbers of male birds, fish, and alligators with a variety of abnormalities in reproductive development. These deformities have been attributed to chemical pollutants called *endocrine disruptors* or *estrogen mimics*. Evidence is mounting that humans, too, are showing declining fertility and increasing anatomical abnormalities because of pollutants in water, meat, vegetables, and even breast milk and the uterine environment.

Over the last several decades, there has been an alarming increase in the incidence of cryptorchidism and hypospadias (a condition in which the urethra opens on the ventral side of the penis instead of at the tip). The rate of testicular cancer has more than tripled in that time. Data on 15,000 men from several countries show a sharp drop in average sperm count—from 113 million/mL in 1940 to only 66 million/mL in 1990. Total sperm production decreased even more, because the average volume of semen per ejaculate has dropped 19% over this period.

The pollutants implicated in this trend include a wide array of common herbicides, insecticides, industrial chemicals, and breakdown products of materials ranging from plastics to dishwashing detergents. Some authorities think these chemicals act by mimicking estrogens or blocking the action of testosterone by binding to its receptors. Other scientists, however, question the data and feel the issue may be overstated. While the debate continues, the U.S. Environmental Protection Agency is screening thousands of industrial chemicals for endocrine effects.

seminal acidity, raising the pH to about 7.5 and activating the sperm. The sperm must synthesize a lot of ATP to power their movements. They get the energy for this from the fructose and other sugars contributed by the seminal vesicles.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. Name the stages of spermatogenesis from spermatogonium to spermatozoon. How do they differ in the number of chromosomes per cell and chromatids per chromosome?
17. Describe the two major parts of a spermatozoon and state what organelles or cytoskeletal components are contained in each.
18. List the major contributions of the seminal vesicles and prostate gland to the semen, and state the functions of these components.

³²semen = seed

27.5 Male Sexual Response

Objectives

When you have completed this section, you should be able to

- describe the blood and nerve supply to the penis; and
- explain how these govern erection and ejaculation.

The physiology of sexual intercourse was unexplored territory before the 1950s because of repressive attitudes toward the subject. British psychologist Havelock Ellis (1859–1939) suffered severe professional sanctions merely for surveying people on their sexual behavior. In the 1950s, William Masters and Virginia Johnson daringly launched the first physiological studies of sexual response in the laboratory. In 1966, they published *Human Sexual Response*, which detailed measurements and observations on more than 10,000 sexual acts by nearly 700 volunteer men and women. Masters and Johnson then turned their attention to disorders of sexual function and pioneered modern therapy for sexual dysfunctions. They divided intercourse into four recognizable phases, which they called excitement, plateau, orgasm, and resolution. The following discussion is organized around this model, although other authorities have modified it or proposed alternatives. Sexual intercourse is also known as **coitus**, **coition**,³³ or **copulation**.³⁴

Anatomical Foundations

To understand male sexual function, we must give closer attention to the blood circulation and nerve supply to the penis.

Each internal iliac artery gives rise to an **internal pudendal (penile) artery**, which enters the root of the penis and divides in two. One branch, the **dorsal artery**, travels dorsally along the penis not far beneath the skin (see fig. 27.12), supplying blood to the skin, fascia, and corpus spongiosum. The other branch, the **deep artery**, travels through the core of the corpus cavernosum and gives off smaller **helicine**³⁵ **arteries**, which penetrate the trabeculae and empty into the lacunae. When the deep artery dilates, the lacunae fill with blood and the penis becomes erect. When the penis is flaccid, most of its blood supply comes from the dorsal arteries. There are numerous anastomoses between the dorsal and deep arteries, so neither of them is the exclusive source of blood to any one erectile tissue. A median **deep dorsal vein** drains blood from the penis. It runs between the two

dorsal arteries beneath the deep fascia and empties into a plexus of prostatic veins.

The penis is richly innervated by sensory and motor nerve fibers. The glans has an abundance of tactile, pressure, and temperature receptors, especially on its proximal margin and frenulum. They lead by way of a pair of prominent **dorsal nerves** of the penis to the **internal pudendal nerves**, then via the sacral plexus to segments S2 to S4 of the spinal cord. Sensory fibers of the shaft, scrotum, perineum, and elsewhere are also highly important to erotic stimulation.

Both autonomic and somatic motor fibers carry impulses from integrating centers in the spinal cord to the penis and other pelvic organs. Sympathetic fibers arise from levels T12 to L2, pass through the hypogastric and pelvic plexuses, and innervate the penile arteries, trabecular muscle, spermatic ducts, and accessory glands. They dilate the penile arteries and can induce erection even when the sacral region of the spinal cord is damaged. They also initiate erection in response to input to the special senses and to sexual thoughts.

Parasympathetic fibers extend from segments S2 to S4 of the spinal cord through the pudendal nerves to the arteries of the penis. They are involved in an autonomic reflex arc that causes erection in response to direct stimulation of the penis and perineal region.

Excitement and Plateau

The **excitement phase** is characterized by **vasocongestion** (swelling of the genitals with blood); **myotonia** (muscle tension); and increases in heart rate, blood pressure, and pulmonary ventilation (fig. 27.18). The bulbourethral glands secrete their fluid during this phase. The excitement phase can be initiated by a broad spectrum of erotic stimuli—sights, sounds, aromas, touch—and even by dreams or thoughts. Conversely, emotions can inhibit sexual response and make it difficult to function when a person is anxious, stressed, or preoccupied with other thoughts.

The most obvious manifestation of male sexual excitement is **erection** of the penis, which makes entry of the vagina possible. Erection is an autonomic reflex mediated predominantly by parasympathetic nerve fibers that travel alongside the deep and helicine arteries of the penis. These fibers trigger the secretion of nitric oxide (NO), which leads to the relaxation of the deep arteries and lacunae (see Insight 27.4). Whether this is enough to cause erection, or whether it is also necessary to block the outflow of blood from the penis, is still debated. According to one hypothesis, as lacunae near the deep arteries fill with blood, they compress lacunae closer to the periphery of the erectile tissue. This is where blood leaves the erectile tissues, so the compression of the peripheral lacunae helps retain blood in the penis. Their compression is aided by the fact that each corpus cavernosum is

³³*coit* = to come together

³⁴*copul* = link, bond

³⁵*helic* = coil, helix

FIGURE 27.18 Neural Control of Male Sexual Response.

INSIGHT 27.4 Clinical Application**Treating Erectile Dysfunction**

Among the most lucrative drugs developed in the last 15 years are the popular treatments for erectile dysfunction: sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis). The basis for developing them was a seemingly unrelated discovery: the role of nitric oxide in cell signaling. When sexual stimulation triggers NO secretion, NO activates the enzyme guanylate cyclase. Guanylate cyclase produces cyclic guanosine monophosphate (cGMP). cGMP then relaxes the smooth muscle of the deep arteries and lacunae of the corpora cavernosa, increasing blood flow into these erectile tissues and bringing about an erection (fig. 27.19).

The erection subsides when cGMP is broken down by the enzyme *phosphodiesterase type 5 (PDE5)*. The problem for many men and their partners is that it subsides too soon, and the solution is to prevent cGMP from breaking down so fast. The aforementioned drugs are in a family called *phosphodiesterase inhibitors*. By slowing down the action of PDE5, they prolong the life of cGMP and the duration of the erection.

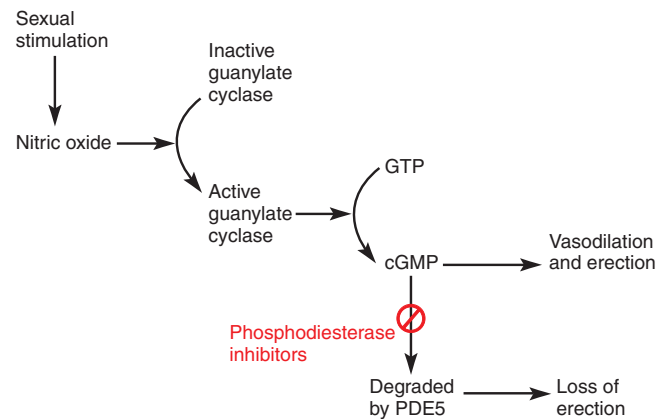

FIGURE 27.19 The Action of Viagra and Other Phosphodiesterase Inhibitors.

wrapped in a tunica albuginea, which fits over the erectile tissue like a tight fibrous sleeve and contributes to its tension and firmness. In addition, the bulbospongiosus and ischiocavernosus muscles aid in erection by compressing the root of the penis and forcing blood forward into the shaft.

As the corpora cavernosa expand, the penis becomes enlarged, rigid, and elevated to an angle conducive to entry of the vagina. Once **intromission** (entry) is achieved, the tactile and pressure sensations produced by vaginal massaging of the penis further accentuate the erection reflex.

The corpus spongiosum has neither a central artery nor a tunica albuginea. It swells and becomes more visible as a cordlike ridge along the ventral surface of the penis, but it does not become nearly as engorged and hardened as the corpora cavernosa. Vasocongestion is not limited to the penis; the testes also become as much as 50% larger during excitement.

In the **plateau phase**, variables such as respiratory rate, heart rate, and blood pressure are sustained at a high level, or rise slightly, for a few seconds to a few minutes before orgasm. This phase may be marked by increased vasocongestion and myotonia.

Think About It

Why is it important that the corpus spongiosum not become as engorged and rigid as the corpora cavernosa?

Orgasm and Ejaculation

The **orgasm**,³⁶ or **climax**, is a short but intense reaction that lasts 3 to 15 seconds and usually is marked by the discharge of semen. The heart rate increases to as high as 180 beats/min, blood pressure rises proportionately, and the respiratory rate becomes as high as 40 breaths/min. From the standpoint of producing offspring, the most significant aspect of male orgasm is the **ejaculation**³⁷ of semen into the vagina.

Ejaculation occurs in two stages called emission and expulsion. In **emission**, the sympathetic nervous system stimulates peristalsis in the smooth muscle of the ductus deferens, which propels sperm from the tail of the epididymis, along the ductus, and into the ampulla. Contractions of the ampulla propel the sperm into the prostatic urethra, and contractions of smooth muscle in the prostate gland force prostatic fluid into the urethra. Secretions of the seminal vesicles join the semen soon after the prostatic secretion. The contractions and seminal flow of this phase create an urgent sensation that ejaculation is inevitable.

Semen in the urethra activates somatic and sympathetic reflexes that result in its **expulsion**. Sensory signals travel to the spinal cord via the internal pudendal nerve and reach an integrating center in the upper lumbar region. Sympathetic nerve fibers carry motor signals from

³⁶orgasm = swelling

³⁷e = ex = out + jacul = to throw

here out to the prostate gland and seminal vesicles, causing the smooth muscle in their walls to express more fluid into the urethra. The sympathetic reflex also constricts the internal urethral sphincter so urine cannot enter the urethra and semen cannot enter the bladder.

Somatic motor signals leave the third and fourth sacral segments of the cord and travel to the bulbospongiosus, ischiocavernosus, and levator ani muscles. The bulbospongiosus, which envelops the root of the penis (see fig. 10.20a), undergoes five or six strong, spasmodic contractions that compress the urethra and forcibly expel the semen. Most sperm are ejected in the first milliliter of semen, mixed primarily with prostatic fluid. The seminal vesicle secretion follows and flushes most remaining sperm from the ejaculatory ducts and urethra. Some sperm may seep from the penis prior to ejaculation, and pregnancy can therefore result from genital contact even without orgasm.

Orgasm is accompanied by an intense feeling of release from tension. Ejaculation and orgasm are not the same. Although they usually occur together, it is possible to have all of the sensations of orgasm without ejaculating, and ejaculation occasionally occurs with little or no sensation of orgasm.

Resolution

Immediately following orgasm comes the **resolution** phase. Discharge of the sympathetic nervous system constricts the internal pudendal artery and reduces the flow of blood into the penis. It also causes contraction of the trabecular muscles, which squeeze blood from the lacunae of the erectile tissues. The penis may remain semierect long enough to continue intercourse, which may be important to the female's attainment of climax, but gradually the

penis undergoes **detumescence**—it becomes soft and flaccid again. The resolution phase is also a time in which cardiovascular and respiratory functions return to normal. Many people break out in sweat during the resolution phase. In men, resolution is followed by a **refractory period**, lasting anywhere from 10 minutes to a few hours, in which it is usually impossible to attain another erection and orgasm.

Men and women have many similarities and a few significant differences in sexual response. The response cycle of women is described in chapter 28.

Two of the most common concerns related to sex are sexually transmitted diseases (STDs) and contraception. Understanding most contraceptive methods requires a prior understanding of female anatomy and physiology, so contraceptive techniques for both sexes are discussed at the end of the next chapter, while STDs are discussed in this chapter (see Insight 27.5). This is not to imply, of course, that STDs are only a male concern and contraception only a female concern. Reproductive disorders specific to males and females are briefly summarized in tables 27.2 and 28.5, respectively. The effects of aging on the reproductive system are described in chapter 29 (p. 1144).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

19. Explain how penile blood circulation changes during sexual arousal and why the penis becomes enlarged and stiffened.
20. State the roles of the sympathetic, parasympathetic, and somatic nervous systems in male sexual response.

INSIGHT 27.5 Clinical Application

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) have been well known since the writings of Hippocrates. Here we discuss three bacterial STDs—gonorrhea, chlamydia, and syphilis—and three viral STDs—genital herpes, genital warts, and hepatitis. AIDS is discussed in chapter 21.

All of these STDs have an *incubation period* in which the pathogen multiplies without symptoms, and a *communicable period* in which one can transmit the disease to others, even in the absence of symptoms. There are no vaccines for STDs, because the bacteria and viruses live inside host cells and go undetected by the immune system. STDs often cause fetal deformity, stillbirth, and neonatal death (see p. 1136).

Gonorrhea (GON-oh-REE-uh) is caused by the bacterium *Neisseria gonorrhoeae*. Galen, thinking the pus discharged from the penis was semen, named the disease *gonorrhea* (“flow of seed”). Gonorrhea causes abdominal discomfort, genital pain

and discharge, painful urination, and abnormal uterine bleeding, but most infected women are asymptomatic. It can cause scarring of the uterine tubes, resulting in infertility. Gonorrhea is treated with antibiotics.

Nongonococcal urethritis (NGU) is any urethral inflammation caused by agents other than the gonorrhea bacterium. NGU often produces pain or discomfort on urination. The most common bacterial NGU is *chlamydia*, caused by *Chlamydia trachomatis*. Most chlamydia infections are asymptomatic, but they may cause urethral discharge and pain in the testes or pelvic region. Gonorrhea and chlamydia frequently occur together.

Pelvic inflammatory disease (PID) is bacterial infection of the female pelvic organs, usually with *Chlamydia* or *Neisseria*. It often results in sterility and may require surgical removal of infected uterine tubes or other organs. The incidence of PID in the United States has increased from 17,800 cases in 1970 to more than a million cases per year currently. PID is responsible for many cases of ectopic pregnancy (see p. 1123).

Syphilis (SIFF-ih-liss) is caused by a spiral bacterium named *Treponema pallidum*. After an incubation period of 2 to 6 weeks, a small, hard lesion called a *chancre* (SHAN-kur) appears

at the site of infection—usually on the penis of a male but sometimes out of sight in the vagina of a female. It disappears in 4 to 6 weeks, ending the first stage of syphilis and often creating an illusion of recovery. A second stage ensues, however, with a widespread pink rash, other skin eruptions, fever, joint pain, and hair loss. This subsides in 3 to 12 weeks, but symptoms can come and go for up to 5 years. A person is contagious even when symptoms are not present. The disease may progress to a third stage, *tertiary syphilis (neurosyphilis)*, with cardiovascular damage and brain lesions that can cause paralysis and dementia. Syphilis is treatable with antibiotics.

Genital herpes is the most common STD in the United States, with 20 to 40 million infected people. It is usually caused by the *herpes simplex virus type 2 (HSV-2)*. After an incubation period of 4 to 10 days, the virus causes blisters on the penis of the male; on the labia, vagina, or cervix of the female; and sometimes on the thighs and buttocks of either sex. Over 2 to 10 days, these blisters rupture, seep fluid, and begin to form scabs. The initial infection may be painless or may cause intense pain, urethritis, and watery discharge from the penis or vagina. The lesions heal in 2 to 3 weeks and leave no scars.

During this time, however, HSV colonizes sensory nerve and ganglia. Here they can lie dormant for years, later migrating along the nerves and causing epithelial lesions anywhere on the body. The movement from place to place is the basis of the

name *herpes*.³⁸ Most patients have five to seven recurrences, ranging from several years apart to several times a year. An infected person is contagious to a sexual partner when the lesions are present and sometimes even when they are not. HSV may increase the risk of cervical cancer and AIDS.

Genital warts (condylomas) are one of the most rapidly increasing STDs today, with about 6.2 million new cases per year. They are caused by various *human papillomavirus (HPV)* strains. In the male, lesions usually appear on the penis, perineum, or anus; and in the female, they are usually on the cervix, vaginal wall, perineum, or anus. Lesions are sometimes small and almost invisible. HPV has been implicated in cancer of the penis, vagina, cervix, and anus; it is found in about 90% of cervical cancers. About 90% of genital warts, however, involve strains that have not been linked to cancer. Genital warts are sometimes treated with cryosurgery (freezing and excision), laser surgery, or interferon.

Hepatitis B and C are inflammatory liver diseases caused by the hepatitis B and C viruses (HBV, HCV), introduced in Insight 26.3 (p. 1036). Although they can be transmitted by means other than sex, they are becoming increasingly common as STDs. Hepatitis C threatens to become a major epidemic of the twenty-first century. It already far surpasses the prevalence of AIDS and is the leading reason for liver transplants in the United States.

³⁸*herp* = to creep

TABLE 27.2

Some Male Reproductive Disorders

Breast cancer	Accounts for 0.2% of male cancers in the United States; usually seen after age 60 but sometimes in children and adolescents. About 175 females get breast cancer for every male who does so. Usually felt as a lump near the nipple, often with crusting and discharge from nipple. Often quite advanced by the time of diagnosis, with poor prospects for recovery, because of denial and delay in seeking treatment.	
Erectile dysfunction (impotence)	Inability to maintain an erection adequate for vaginal entry in half or more of one's attempts. Can stem from aging and declining testosterone level as well as cardiovascular and neurological diseases, diabetes mellitus, medications, fear of failure, depression, and other causes.	
Hypospadias ³⁹ (HY-po-SPAY-dee-us)	A congenital defect in which the urethra opens on the ventral side or base of the penis rather than at the tip; usually corrected surgically at about 1 year of age.	
Infertility	Inability to fertilize an egg because of a low sperm count (lower than 20 to 25 million/mL), poor sperm motility, or a high percentage of deformed sperm (two heads, defective tails, etc.). May result from malnutrition, gonorrhea and other infections, toxins, or testosterone deficiency.	
Penile cancer	Accounts for 1% of male cancers in the United States; most common in black males ages 50 to 70 and of low income. Most often seen in men with nonretractable foreskins (phimosis) combined with poor penile hygiene; least common in men circumcised at birth.	
Testicular cancer	The most common solid tumor in men 15 to 34 years old, especially white males of middle to upper economic classes. Typically begins as a painless lump or enlargement of the testis. Highly curable if detected early. Men should routinely palpate the testes for normal size and smooth texture.	
Varicocele (VAIR-ih-co-seal)	Abnormal dilation of veins of the spermatic cord, so that they resemble a "bag of worms." Occurs in 10% of males in the United States. Caused by absence or incompetence of venous valves. Reduces testicular blood flow and often causes infertility.	
Disorders described elsewhere		
Androgen-insensitivity syndrome p. 1049	Genital herpes p. 1072	Prostate cancer p. 1060
Benign prostatic hyperplasia p. 1060	Genital warts p. 1072	Syphilis p. 1071
Chlamydia p. 1071	Gonorrhea p. 1071	

³⁹*hypo* = below + *spad* = to draw off (the urine)

CHAPTER REVIEW

Review of Key Concepts

27.1 Sexual Reproduction and Development (p. 1048)

- Sexual reproduction is the production of offspring that combine genes from two parents.
- Sexual reproduction entails the union of two *gametes* to form a *zygote* (fertilized egg). The gametes are a small motile *sperm* produced by the male and a large, immobile, nutrient-laden *egg* produced by the female.
- The *gonads* (testes and ovaries) are the *primary sex organs*. *Secondary sex organs* are other anatomical structures needed to produce offspring, such as the male glands, ducts, and penis and the female uterine tubes, uterus, and vagina. The *external genitalia* are located in the perineum and are mostly visible externally. The *internal genitalia* are mostly in the pelvic cavity.
- Secondary sex characteristics* are features not essential to reproduction but that help to attract mates.
- Human chromosomes include 22 pairs of *autosomes* and 1 pair of *sex chromosomes*. There are two types of sex chromosomes, a large X and a smaller Y chromosome. A person who inherits two X chromosomes is genetically female, and one who inherits an X and a Y is genetically male.
- The Y chromosome bears a gene called *SRY*, which codes for a protein called *testis-determining factor (TDF)*. TDF indirectly causes the fetal gonads to develop into testes. The testes secrete androgens, which stimulate the *mesonephric ducts* to develop into a male reproductive tract, and *müllerian-inhibiting factor*, which stimulates the *paramesonephric ducts* to degenerate.
- In the absence of a Y chromosome, the gonads become ovaries, the mesonephric ducts degenerate, and the paramesonephric ducts develop into a female reproductive tract.
- The external genitalia of both sexes begin as a *genital tubercle*, a pair of *urogenital folds*, and a pair of

labioscrotal folds. The genital tubercle differentiates into the glans of the penis or clitoris; the urogenital folds enclose the urethra of the male or become the labia minora of a female; and the labioscrotal folds become the scrotum of a male or labia majora of a female.

- During male development, the fetal testes follow a cord called the *gubernaculum* through the inguinal canal into the scrotum; this is called *descent of the testes*. The ovaries descend in a similar manner, but only as far as the lesser pelvis.

27.2 Male Reproductive Anatomy (p. 1053)

- The *scrotum* contains the testes and the *spermatic cord*, which is a bundle of connective tissue, testicular blood vessels, and a sperm duct, the *ductus deferens*. The spermatic cord passes up the back of the scrotum and through the inguinal ring into the pelvic cavity.
- Sperm cannot develop at the core body temperature of 37°C. The testes are kept about 2°C cooler than this by three structures in the scrotum: the *cremaster muscle* of the spermatic cord, which relaxes when it is warm and contracts when it is cool, thus lowering or raising the scrotum and testes; the *dartos muscle* in the scrotal wall, which contracts and tautens the scrotum when it is cool; and the *pampiniform plexus* of blood vessels in the spermatic cord, which acts as a *countercurrent heat exchanger* to cool the blood on its way to the testis.
- The testis has a fibrous capsule, the *tunica albuginea*. Fibrous septa divide the interior of the testis into 250 to 300 compartments called *lobules*. Each lobule contains 1 to 3 sperm-producing *seminiferous tubules*. Testosterone-secreting *interstitial cells* lie in clusters between the tubules.
- The epithelium of a seminiferous tubule consists of *germ cells* and *sustentacular cells*. The germ cells

develop into sperm, while the sustentacular cells support and nourish them, form a *blood–testis barrier* between the germ cells and nearest blood supply, and secrete *inhibin*, which regulates the rate of sperm production.

- Each testis is supplied by a long, slender *testicular artery* and drained by veins of the pampiniform plexus, which converge to form the *testicular vein*. It is supplied with *testicular nerves* and lymphatic vessels.
- Spermatic ducts* carry sperm from the testis to the urethra. They include several *efferent ductules* leaving the testis; a single *duct of the epididymis*, a highly coiled structure adhering to the posterior side of the testis; a muscular *ductus deferens* that travels through the spermatic cord into the pelvic cavity; and a short *ejaculatory duct* that carries sperm and seminal vesicle secretions the last 2 cm to the urethra. The urethra completes the path of the sperm to the outside of the body.
- The male has three sets of accessory glands: a pair of *seminal vesicles* posterior to the urinary bladder; a single *prostate gland* inferior to the bladder, enclosing the prostatic urethra; and a pair of small *bulbourethral glands* that secrete into the proximal end of the urethra. The seminal vesicles and prostate secrete most of the semen. The bulbourethral glands produce a small amount of clear slippery fluid that lubricates the urethra and neutralizes its pH.
- The *penis* is divided into an internal *root* and an external *shaft* and *glans*. It is covered with loose skin that extends over the glans as the *prepuce*, or foreskin.
- Internally, the penis consists mainly of three long *erectile tissues*—a pair of dorsal *corpora cavernosa*, which engorge with blood and produce most of the effect of erection, and a single ventral *corpus spongiosum*, which contains the urethra. All three tissues have blood sinuses called *lacunae*

separated by *trabeculae* composed of connective tissue and smooth muscle (*trabecular muscle*).

- At the proximal end of the penis, the corpus spongiosum dilates into a *bulb* that receives the urethra and ducts of the bulbourethral glands, and the corpora cavernosa diverge into a pair of *crura* that anchor the penis to the pubic arch and perineal membrane.

27.3 Puberty and Climacteric (p. 1060)

- Adolescence* is a period from the onset of gonadotropin secretion to the attainment of adulthood. The first few years of adolescence, until ejaculation begins, constitute *puberty*.
- At puberty, the hypothalamus begins secreting *gonadotropin-releasing hormone (GnRH)*, which induces the anterior pituitary to secrete *follicle-stimulating hormone (FSH)* and *luteinizing hormone (LH)*. These hormones stimulate enlargement of the testes, an early sign of puberty.
- LH stimulates the interstitial cells to produce androgens (especially testosterone), and FSH causes the sustentacular cells to produce *androgen-binding protein (ABP)*.
- Testosterone stimulates spermatogenesis; modulates the secretion of GnRH, FSH, and LH; stimulates the development of the secondary sex organs and sex characteristics; stimulates bodily growth and erythropoiesis; and activates sexual interest, or *libido*.
- Inhibin*, secreted by the sustentacular cells, selectively inhibits FSH secretion and sperm production without inhibiting LH and testosterone secretion.
- After age 20, testosterone secretion steadily declines, as do the number and secretory activity of interstitial and sustentacular cells. Declining testosterone and inhibin levels reduce the negative feedback inhibition of the pituitary, which thus secretes elevated levels of FSH and LH. In some men, this results in physiological and mood changes called *male climacteric* (andropause).
- In older age, *erectile dysfunction* becomes common, but the ability to ejaculate remains unaffected in most cases.

27.4 Sperm and Semen (p. 1063)

- Spermatogenesis* is the production of sperm. It employs a form of cell division called *meiosis*, which reduces the chromosome number by half. This prevents a doubling of chromosome number in each generation when egg and sperm combine. Meiosis produces *haploid* gametes with 23 chromosomes each. The union of two such gametes restores the *diploid* number of 46 chromosomes in the zygote.
- Meiosis consists of one cell division with stages called *prophase I*, *metaphase I*, *anaphase I*, and *telophase I*; then an interval called *interkinesis*; then a second cell division consisting of *prophase II*, *metaphase II*, *anaphase II*, and *telophase II*. The ultimate result is four haploid daughter cells.
- Prophase I also involves *crossing-over*, an exchange of genes between an individual's homologous maternal and paternal chromosomes. As a consequence, the chromosomes passed to a child have new genetic combinations not inherited from one's parents.
- Spermatogenesis begins with *primordial germ cells*, which arise in the yolk sac, migrate to the gonads, and become *spermatogonia* by the time a boy is born.
- From puberty to death, primary spermatogonia divide by mitosis into *type A* and *type B* spermatogonia. The latter develop into *primary spermatocytes*, then enter into meiosis and divide into *secondary spermatocytes* and finally *spermatids*.
- In a process called *spermiogenesis*, spermatids shed excess cytoplasm and grow a tail (flagellum), thus becoming sperm.
- The sperm consists of a head containing the nucleus and *acrosome*, and a tail composed of a mitochondria-stuffed *midpiece*, a long *principal piece*, and a short *endpiece*.
- Semen* is a mixture of sperm (10% of the volume) and fluids from the prostate (30%) and seminal vesicles (60%). It contains fructose, *seminogelin*, a clotting enzyme, prostaglandins, and *serine protease*, among other substances.

27.5 Male Sexual Response (p. 1068)

- The penis is supplied by a pair of internal pudendal arteries. One branch of this artery, the *dorsal artery*, travels dorsally under the skin of the penis and the other, the *deep artery*, travels through the corpus cavernosum and supplies blood to the lacunae. The dorsal arteries supply most of the blood when the penis is flaccid, and the deep arteries during erection.
- Nerves of the penis converge on the *dorsal nerve*, which leads via the *internal pudendal nerve* to the sacral plexus and then the spinal cord. The penis receives sympathetic, parasympathetic, and somatic motor nerve fibers.
- The *excitement phase* of male sexual response is marked by vasocongestion of the genitals; myotonia of the skeletal muscles; increases in heart rate, blood pressure, and pulmonary ventilation; secretion by the bulbourethral glands; and erection of the penis.
- Erection occurs when parasympathetic nerve fibers trigger the secretion of nitric oxide, which dilates the deep arteries and lacunae. Blood flow into the erectile tissues engorges the lacunae, causing the penis to enlarge and stiffen.
- The *plateau phase* is marked by elevated but stable or slightly rising heart rate, blood pressure, and respiration, and sometimes increased vasocongestion and myotonia.
- Orgasm (climax)* is marked by a sudden rise in heart rate, blood pressure, and respiration, and usually the ejaculation of semen. Ejaculation occurs in stages: *emission*, the peristaltic propulsion of sperm from the epididymis to the prostatic urethra, where it mixes with the prostatic and seminal vesicle secretions; and *expulsion*, in which five or six spasmodic contractions of the bulbospongiosus muscle compress the urethra and expel the semen from the penis.
- Orgasm is followed by *resolution*, in which physiological values return to normal and the penis undergoes *detumescence*, or loss of engorgement and erection. This is typically followed by a *refractory period* in which it is impossible to attain another erection and orgasm.

Testing Your Recall

- The ductus deferens develops from the ____ of the embryo.
 - mesonephric duct
 - paramesonephric duct
 - phallus
 - labioscrotal folds
 - urogenital folds
- The protein that clots and causes the stickiness of the semen is
 - seminogelin.
 - prostaglandin.
 - fibrin.
 - phosphodiesterase.
 - serine protease.
- The expulsion of semen occurs when the bulbospongiosus muscle is stimulated by
 - somatic efferent neurons.
 - somatic afferent neurons.
 - sympathetic efferent neurons.
 - parasympathetic efferent neurons.
 - prostaglandins.
- Prior to ejaculation, sperm are stored primarily in
 - the seminiferous tubules.
 - the rete testis.
 - the epididymis.
 - the seminal vesicles.
 - the ejaculatory ducts.
- The penis is attached to the pubic arch by crura of
 - the corpora cavernosa.
 - the corpus spongiosum.
 - the perineal membrane.
 - the bulbospongiosus.
 - the ischiocavernosus.
- The first hormone secreted at the onset of puberty is
 - follicle-stimulating hormone.
 - interstitial cell-stimulating hormone.
 - human chorionic gonadotropin.
 - gonadotropin-releasing hormone.
 - testosterone.
- When it is necessary to reduce sperm production without reducing testosterone secretion, the sustentacular cells secrete
 - dihydrotestosterone.
 - androgen-binding protein.
 - LH.
 - FSH.
 - inhibin.
- Four spermatozoa arise from each
 - primordial germ cell.
 - type A spermatogonium.
 - type B spermatogonium.
 - secondary spermatocyte.
 - spermatid.
- The point in meiosis at which sister chromatids separate from each other is
 - prophase I.
 - metaphase I.
 - anaphase I.
 - anaphase II.
 - telophase II.
- Blood is forced out of the penile lacunae by contraction of the ____ muscles.
 - bulbospongiosus
 - ischiocavernosus
 - cremaster
 - trabecular
 - dartos
- Under the influence of androgens, the embryonic ____ duct develops into the male reproductive tract.
- Spermatozoa obtain energy for locomotion from ____ in the semen.
- The ____, a network of veins in the spermatic cord, helps keep the testes cooler than the core body temperature.
- All germ cells beginning with the ____ are genetically different from the rest of the body cells and therefore must be protected by the blood–testis barrier.
- The corpora cavernosa as well as the testes have a fibrous capsule called the ____.
- Over half of the semen consists of secretions from a pair of glands called the ____.
- The blood–testis barrier is formed by tight junctions between the ____ cells.
- The earliest haploid stage of spermatogenesis is the ____.
- Erection of the penis occurs when nitric oxide causes the ____ arteries to dilate.
- A sperm penetrates the egg by means of enzymes in its ____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- The male scrotum is homologous to the female labia majora.
- Sperm cannot develop at the core body temperature.
- Luteinizing hormone stimulates the testes to secrete testosterone.
- The testes and penis are the primary sex organs of the male.
- A high testosterone level makes a fetus develop a male reproductive system, and a high estrogen level makes it develop a female reproductive system.
- Most of the semen is produced by the seminal vesicles.
- The pampiniform plexus serves to keep the testes warm.
- Prior to ejaculation, sperm are stored mainly in the seminal vesicles.
- Male menopause is the cessation of sperm production around the age of 55.
- Erection is caused by parasympathetic stimulation of the penile arteries.

Answers in appendix B

Testing Your Comprehension

1. Explain why testosterone may be considered both an endocrine and a paracrine secretion of the testes. (Review paracrines in chapter 17 if necessary.)
2. A young man is in a motorcycle accident that severs his spinal cord at the neck and leaves him paralyzed from the neck down. When informed of the situation, his wife asks the physician if her husband will be able to have erections and father any children. What should the doctor tell her? Explain your answer.
3. Considering the temperature in the scrotum, would you expect hemoglobin to unload more oxygen to the testes, or less, than it unloads in the warmer internal organs? Why? (*Hint:* See fig. 22.26, p. 894.) How would you expect this fact to influence sperm development?
4. Why is it possible for spermatogonia to be outside the blood–testis barrier, yet necessary for primary spermatocytes and later stages to be within the barrier, isolated from the blood?
5. A 68-year-old man taking medication for hypertension complains to his physician that it has made him impotent. Explain why this could be an effect of antihypertension drugs.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Negative feedback inhibition of the pituitary gland (p. 647)
- Synergistic, permissive, and antagonistic hormone interactions (p. 668)
- Fetal development of the reproductive system (pp. 1050–1051)
- Meiosis and general aspects of gametogenesis (p. 1063)
- General (not sex-specific) aspects of sexual response (p. 1068)

The female reproductive system is more complex than the male's because it serves more purposes. Whereas the male needs only to produce and deliver gametes, the female must do this as well as provide nutrition and safe harbor for fetal development, then give birth and nourish the infant. Furthermore, female reproductive physiology is more conspicuously cyclic, and female hormones are secreted in a more complex sequence compared with the relatively steady, simultaneous secretion of regulatory hormones in the male.

This chapter discusses the anatomy of the female reproductive system; the production of gametes and how it relates to the ovarian and menstrual cycles; the female sexual response; and the physiology of pregnancy, birth, and lactation. Embryonic and fetal development are treated in chapter 29.

28.1 Reproductive Anatomy

Objectives

When you have completed this section, you should be able to

- describe the structure of the ovary;
- trace the female reproductive tract and describe the gross anatomy and histology of each organ;
- identify the ligaments that support the female reproductive organs;
- describe the blood supply to the female reproductive tract;
- identify the external genitalia of the female; and
- describe the structure of the nonlactating breast.

Sexual Differentiation

The female reproductive system (fig. 28.1) is obviously different from that of the male, but as we saw earlier, the two

FIGURE 28.1 The Female Reproductive System.

sexes are indistinguishable for the first 8 to 10 weeks of development (see fig. 27.4, p. 1052). The female reproductive tract develops from the paramesonephric duct not because of the positive action of any hormone, but because of the absence of testosterone and müllerian-inhibiting factor (MIF). Without testosterone, the mesonephric duct degenerates while the genital tubercle becomes the glans of the clitoris, the urogenital folds develop into labia minora, and the labioscrotal folds develop into labia majora. Without MIF, the paramesonephric duct develops into the uterine tubes, uterus, and vagina (see fig. 27.3, p. 1051). This developmental pattern can be disrupted, however, by abnormal hormonal exposure before birth, as happens in adrenogenital syndrome (see fig. 17.30, p. 674).

The Genitalia

The internal genitalia include the ovaries and a duct system that runs from the vicinity of each ovary to the outside of the body—the uterine tubes, uterus, and vagina. The external genitalia include principally the clitoris, labia minora, and labia majora. These occupy the perineum, which is defined by the same skeletal landmarks as in the male (see fig. 27.6, p. 1054). The ovaries are the primary

sex organs, and the other internal and external genitalia are the secondary sex organs.

The Ovaries

The female gonads are the **ovaries**,¹ which produce egg cells (ova) and sex hormones. The ovary is an almond-shaped organ nestled in the *ovarian fossa*, a depression in the posterior pelvic wall. It measures about 3 cm long, 1.5 cm wide, and 1 cm thick. Its capsule, like that of the testis, is called the **tunica albuginea**. The interior of the ovary is indistinctly divided into an outer **cortex**, where the germ cells develop, and a central **medulla** occupied by the major arteries and veins (fig. 28.2).

The ovary lacks ducts comparable to the seminiferous tubules of the testis. Instead, each egg develops in its own fluid-filled, bubblelike **follicle** and is released by *ovulation*, the bursting of the follicle. Figure 28.2 shows several types of follicles that coincide with different stages of egg maturation, as discussed later.

The ovary is held in place by several connective tissue ligaments (fig. 28.3). Its medial pole is attached to the

¹ov = egg + ary = place for

FIGURE 28.2 Structure of the Ovary. Arrows indicate the developmental sequence of the ovarian follicles; the follicles do not migrate around the ovary and not all the follicle types illustrated here are present simultaneously.

FIGURE 28.3 The Female Reproductive Tract and Supportive Ligaments. (a) Posterior view of the reproductive tract. (b) Relationship of the uterine tube and ovary to the supporting ligaments. (c) Anterior view of the major female reproductive organs from a cadaver.

uterus by the **ovarian ligament** and its lateral pole is attached to the pelvic wall by the **suspensory ligament**. The anterior margin of the ovary is anchored by a peritoneal fold called the **mesovarium**.² This ligament extends to a sheet of peritoneum called the *broad ligament*, which flanks the uterus and encloses the uterine tube in its superior margin.

The ovary receives blood from two arteries: the **ovarian branch of the uterine artery**, which passes through the mesovarium and approaches the medial pole of the ovary, and the **ovarian artery**, which passes through the suspensory ligament and approaches the lateral pole. The ovarian artery is the female equivalent of the male testicular artery described in chapter 27, arising high on the aorta and traveling down to the gonad along the posterior body wall. The ovarian and uterine arteries anastomose along the margin of the ovary and give off multiple small arteries that enter the ovary on that side. Ovarian veins, lymphatics, and nerves also travel through the suspensory ligament. The veins and lymphatics follow courses similar to those described for the testes (p. 1057).

The Uterine Tubes

The **uterine tube**, also called the **oviduct** or **fallopian³ tube**, is a canal about 10 cm long from the ovary to the uterus. At the distal (ovarian) end, it flares into a trumpet-shaped **infundibulum⁴** with feathery projections called **fimbriae⁵** (FIM-bree-ee); the middle and longest part of the tube is the **ampulla**; and near the uterus it forms a narrower **isthmus**. The uterine tube is enfolded in the **mesosalpinx⁶** (MEZ-oh-SAL-pinks), which is the superior margin of the broad ligament.

The wall of the uterine tube is well endowed with smooth muscle. Its mucosa is highly folded into longitudinal ridges and has an epithelium of ciliated cells and a smaller number of secretory cells (fig. 28.4). The cilia beat toward the uterus and, with the help of muscular contractions of the tube, convey the egg in that direction.

The Uterus

The **uterus⁷** is a thick muscular chamber that opens into the roof of the vagina and usually tilts forward over the urinary bladder (see fig. 28.1). Its function is to harbor the fetus, provide a source of nutrition, and expel the fetus at the end of its development. It is somewhat pear-shaped, with a broad superior curvature called the **fundus**, a midportion called the **body (corpus)**, and a cylindrical inferior end called the **cervix** (fig. 28.3). The uterus measures about 7 cm from cervix to fundus, 4 cm wide at its

FIGURE 28.4 Epithelial Lining of the Uterine Tube.

Secretory cells are shown in red and green, and cilia of the ciliated cells in yellow (SEM).

◀ *What purpose do these cilia serve?*

broadest point on the fundus, and 2.5 cm thick, but it is somewhat larger in women who have been pregnant.

The lumen of the uterus is roughly triangular, with its two upper corners opening into the uterine tubes. In the nonpregnant uterus, the lumen is not a hollow cavity but rather a *potential space* (see p. 37); the mucous membranes of the opposite walls are pressed against each other with little room between them. The lumen communicates with the vagina by way of a narrow passage through the cervix called the **cervical canal**. The superior opening of this canal into the body of the uterus is the **internal os⁸** (pronounced “oz” or “ose”) and its opening into the vagina is the **external os**. The canal contains **cervical glands** that secrete mucus, thought to prevent the spread of microorganisms from the vagina into the uterus. Near the time of ovulation, the mucus becomes thinner than usual and allows easier passage for sperm.

INSIGHT 28.1 Clinical Application**Pap Smears and Cervical Cancer**

Cervical cancer is common among women between the ages of 30 and 50, especially those who smoke, who began sexual activity at an early age, and who have histories of frequent sexually transmitted diseases or cervical inflammation. It is often caused by the human papillomavirus (HPV), a sexually transmitted pathogen (see p. 1072). Cervical cancer usually begins in the epithelial cells of the lower cervix, develops slowly, and remains a local, easily removed lesion for several years. If the cancerous cells spread to the subepithelial connective tissue, however, the cancer is said to be *invasive* and is much more dangerous and potentially fatal.

The best protection against cervical cancer is early detection by means of a *Pap⁹ smear*—a procedure in which loose cells are removed from the cervix and vagina with a small flat stick and cervical brush, then microscopically examined. The pathologist looks for cells with signs of *dysplasia* (abnormal development) or carcinoma (fig. 28.5). One system of grading Pap smears classifies abnormal results in three grades of *cervical intraepithelial*

neoplasia (CIN). Findings are rated on the following scale, and further vigilance or treatment planned accordingly:

ASCUS—atypical squamous cells of undetermined significance
CIN I—mild dysplasia with cellular changes typically associated with HPV

CIN II—moderate dysplasia with precancerous lesions

CIN III—severe dysplasia, *carcinoma in situ* (preinvasive carcinoma of surface cells)

A rating of ASCUS or CIN I calls for a repeat Pap smear and visual examination of the cervix (*colposcopy*) in 3 to 6 months. CIN II calls for a biopsy, often done with an “electric scalpel” in a procedure called LEEP (loop electrosurgical excision procedure). A cone of tissue is removed to evaluate the depth of invasion by the malignant or premalignant cells. This in itself may be curative if all margins of the specimen are normal, indicating all abnormal cells were removed. CIN III may be cause for *hysterectomy*¹⁰ or radiation therapy.

An average woman is typically advised to have annual Pap smears for 3 years and may then have them less often at the discretion of her physician. Women with any of the risk factors listed may be advised to have more frequent examinations.

FIGURE 28.5 Pap Smears. These are smears of squamous epithelial cells scraped from the cervix. In the malignant (cancerous) cells, note the loss of cell volume and the greatly enlarged nuclei.

Uterine Wall The uterine wall consists of an external serosa called the *perimetrium*, a middle muscular layer called the *myometrium*, and an inner mucosa called the *endometrium*. The **myometrium**¹¹ constitutes most of the wall; it is about 1.25 cm thick in the nonpregnant uterus.

It is composed mainly of bundles of smooth muscle that sweep downward from the fundus and spiral around the body of the uterus. The myometrium is less muscular and more fibrous near the cervix; the cervix itself is almost entirely collagenous. The muscle cells of the myometrium are about 40 μm long immediately after menstruation, but they are twice this long at the middle of the menstrual cycle and 10 times as long in pregnancy. The function of the myometrium is to produce the labor contractions that help to expel the fetus.

⁹George N. Papanicolaou (1883–1962), Greek–American physician and cytologist

¹⁰*hyster* = uterus + *ectomy* = cutting out

¹¹*myo* = muscle + *metr* = uterus

FIGURE 28.6 Histology of the Endometrium.

The inner lining of the uterus, or mucosa, is called the **endometrium**.¹² It has a simple columnar epithelium, compound tubular glands, and a stroma populated by leukocytes, macrophages, and other cells (fig. 28.6). The superficial half to two-thirds of it, called the **stratum functionalis**, is shed in each menstrual period. The deeper layer, called the **stratum basalis**, stays behind and regenerates a new functionalis in the next cycle. When pregnancy occurs, the endometrium is the site of attachment of the embryo and forms the maternal part of the *placenta* from which the fetus is nourished.

Ligaments The uterus is supported by the muscular floor of the pelvic outlet and folds of peritoneum that form supportive ligaments around the organ, as they do for the ovary and uterine tube (see fig. 28.3a). The **broad ligament** has two parts: the *mesosalpinx* mentioned earlier and the *mesometrium* on each side of the uterus. The cervix and superior part of the vagina are supported by **cardinal (lateral cervical) ligaments** extending to the pelvic wall. A pair of **uterosacral ligaments** attach the posterior side of the uterus to the sacrum, and a pair of **round ligaments** arise from the anterior surface of the uterus,

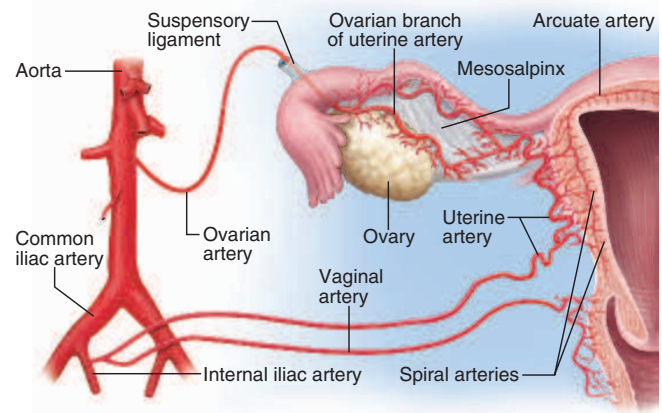

FIGURE 28.7 Blood Supply to the Female Reproductive Tract. The vaginal, uterine, and ovarian arteries are exaggerated in length by the perspective of the drawing, moving the aorta away from the uterus for clarity.

pass through the inguinal canals, and terminate in the labia majora, much like the gubernaculum of the male terminating in the scrotum.

As the peritoneum folds around the various pelvic organs, it creates several dead-end recesses and pouches (extensions of the peritoneal cavity). Two major ones are the *vesicouterine*¹³ *pouch*, which forms the space between the uterus and urinary bladder, and *rectouterine pouch* between the uterus and rectum (see fig. 28.1).

Blood Supply The uterine blood supply is particularly important to the menstrual cycle and pregnancy. A **uterine artery** arises from each internal iliac artery and travels through the broad ligament to the uterus (fig. 28.7). It gives off several branches that penetrate into the myometrium and lead to **arcuate arteries**. Each arcuate artery travels in a circle around the uterus and anastomoses with the arcuate artery on the other side. Along its course, it gives rise to smaller arteries that penetrate the rest of the way through the myometrium, into the endometrium, and produce the **spiral arteries**. The spiral arteries wind tortuously between the endometrial glands toward the surface of the mucosa (see fig. 28.16). They rhythmically constrict and dilate, making the mucosa alternately blanch and flush with blood.

The Vagina

The **vagina**¹⁴ is a tube about 8 to 10 cm long that allows for the discharge of menstrual fluid, receipt of the penis and semen, and birth of a baby. The vaginal wall is thin

¹²endo = inside + metr = uterus

¹³vesico = bladder

¹⁴vagina = sheath

but very distensible. It consists of an outer adventitia, a middle muscularis, and an inner mucosa. The vagina tilts posteriorly between the urethra and rectum; the urethra is bound to its anterior wall. The vagina has no glands, but it is lubricated by the *transudation* (“vaginal sweating”) of serous fluid through its walls and by mucus from the cervical glands above it. The vagina extends slightly beyond the cervix and forms blind-ended spaces called *fornices*¹⁵ (FOR-nih-sees; singular, *fornix*) surrounding it (see figs. 28.1 and 28.3a).

The lower end of the vagina has transverse friction ridges, or **vaginal rugae**, which stimulate the penis and help induce ejaculation. At the vaginal orifice, the mucosa folds inward and forms a membrane, the **hymen**, which stretches across the opening. The hymen has one or more openings to allow menstrual fluid to pass through, but it usually must be ruptured to allow for intercourse. A little bleeding often accompanies the first act of intercourse; however, the hymen is commonly ruptured before then by tampons, medical examinations, or strenuous exercise.

The vaginal epithelium is simple cuboidal in childhood, but the estrogens of puberty transform it into a stratified squamous epithelium. This is an example of *metaplasia*, the transformation of one tissue type to another. The epithelial cells are rich in glycogen. Bacteria ferment this to lactic acid, which produces a low vaginal pH (about 3.5–4.0) that inhibits the growth of pathogens. Recall from chapter 27 that this acidity is neutralized by the semen so it does not harm the sperm. The mucosa also has antigen-presenting **dendritic cells**, which are a route by which HIV from infected semen invades the female body.

Think About It

For what functional reason do you think the vaginal epithelium changes type at puberty? Of all types of epithelium it might become, why stratified squamous?

The External Genitalia

The external genitalia of the female occupy most of the perineum and are collectively called the **vulva**¹⁶ (**pudendum**¹⁷); they include the mons pubis, labia majora and minora, clitoris, vaginal orifice, and accessory glands and erectile tissues (fig. 28.8).

The **mons**¹⁸ **pubis** consists mainly of an anterior mound of adipose tissue overlying the pubic symphysis, bearing most of the pubic hair (see fig. A.5a, p. 33). The **labia majora**¹⁹ (singular, *labium majus*) are a pair of thick folds of skin and adipose tissue inferior to the mons; the slit between them is the *pudendal cleft*. Pubic

FIGURE 28.8 The Female Perineum. (a) Surface anatomy. (b) Subcutaneous structures.

Which of the glands in part (b) is homologous to the male prostate gland?

hair grows on the lateral surfaces of the labia majora at puberty, but the medial surfaces remain hairless. Medial to the labia majora are the much thinner, entirely hairless **labia minora**²⁰ (singular, *labium minus*). The area

¹⁵fornix = arch, vault

¹⁶vulva = covering

¹⁷pudend = shameful

¹⁸mons = mountain

¹⁹labi = lip + major = larger, greater

²⁰minor = smaller, lesser

enclosed by them, called the **vestibule**, contains the urinary and vaginal orifices. At the anterior margin of the vestibule, the labia minora meet and form a hoodlike **prepuce** over the clitoris.

The **clitoris** is structured like the penis in many respects, but has no urinary role. Its function is entirely sensory, serving as the primary center of erotic stimulation. Unlike the penis, it is almost entirely internal, it has no corpus spongiosum, and it does not enclose the urethra. Essentially, it is a pair of corpora cavernosa enclosed in connective tissue. Its head, the **glans**, protrudes slightly from the prepuce. The **body (corpus)** passes internally, inferior to the pubic symphysis (see fig. 28.1). At its internal end, the corpora cavernosa diverge like a Y as a pair of **crura**, which, like those of the penis, attach the clitoris to each side of the pubic arch. The circulation and innervation of the clitoris are much like those of the penis (see p. 1068).

Just deep to the labia majora, a pair of subcutaneous erectile tissues called the **vestibular bulbs** bracket the vagina like parentheses. They become congested with blood during sexual excitement and cause the vagina to tighten somewhat around the penis, enhancing sexual stimulation.

On each side of the vagina is a pea-size **greater vestibular (Bartholin²¹) gland** with a short duct opening into the vestibule or lower vagina (fig. 28.8b). These glands are homologous to the bulbourethral glands of the male. They keep the vulva moist, and during sexual excitement they provide most of the lubrication for intercourse. The vestibule is also lubricated by a number of **lesser vestibular glands**. A pair of mucous **paraurethral (Skene²²) glands**, homologous to the male prostate, open into the vestibule near the external urethral orifice.

The Breasts and Mammary Glands

The **breast** (fig. 28.9) is a mound of tissue overlying the pectoralis major. It enlarges at puberty and remains so for life, but most of this time it contains very little mammary gland. The **mammary gland** develops within the breast during pregnancy, remains active in the lactating breast, and atrophies when a woman ceases to nurse.

The breast has two principal regions: the conical to pendulous **body**, with the nipple at its apex, and an extension toward the armpit called the **axillary tail**. Lymphatics of the axillary tail are especially important as a route of breast cancer metastasis.

The nipple is surrounded by a circular colored zone, the **areola**. Dermal blood capillaries and nerves come closer to the surface here than in the surrounding skin and make the areola more sensitive and more reddish in

color. In pregnancy, the areola and nipple often darken, making them more visible to the indistinct vision of a nursing infant. Sensory nerve fibers of the areola are important in triggering a *milk ejection reflex* when an infant nurses. The areola has sparse hairs and **areolar glands**, visible as small bumps on the surface. These glands are intermediate between sweat glands and mammary glands in their degree of development. When a woman is nursing, secretions of the areolar glands and sebaceous glands protect the areola and nipple from chapping and cracking. The dermis of the areola has smooth muscle fibers that contract in response to cold, touch, and sexual arousal, wrinkling the skin and erecting the nipple.

Internally, the nonlactating breast consists mostly of adipose and collagenous tissue (fig. 28.9b). Breast size is determined by the amount of adipose tissue and has no relationship to the amount of milk the mammary gland can produce. **Suspensory ligaments** attach the breast to the dermis of the overlying skin and to the fascia of the pectoralis major. Although the nonlactating breast contains little glandular tissue, it does have a system of ducts branching through its fibrous stroma and converging on the nipple. When the mammary gland develops during pregnancy, it exhibits 15 to 20 lobes arranged radially around the nipple, separated from each other by stroma. Each lobe is drained by a **lactiferous²³ duct**, which dilates to form a **lactiferous sinus** opening onto the nipple. Lactation and the associated changes in breast structure are described at the end of this chapter.

Breast Cancer

Breast cancer (fig. 28.10) occurs in one out of every eight or nine American women and is one of the leading causes of female mortality. Breast tumors begin with cells of the mammary ducts and may metastasize to other organs by way of the mammary and axillary lymphatics. Signs of breast cancer include a palpable lump (the tumor), puckering of the skin, changes in skin texture, and drainage from the nipple.

Two breast cancer genes were discovered in the 1990s, named *BRCA1* and *BRCA2*, but most breast cancer is nonhereditary. Some breast tumors are stimulated by estrogen. Consequently, breast cancer is more common among women who begin menstruating early in life and who reach menopause relatively late—that is, women who have a long period of fertility and estrogen exposure. Other risk factors include aging, exposure to ionizing radiation and carcinogenic chemicals, excessive alcohol and fat intake, and smoking. Over 70% of cases, however, lack any identifiable risk factors.

The cluster of lobules boxed in part (c) would contain numerous microscopic acini like the one in part (d). Part (d) is not to be construed as an enlargement of the entire boxed area.

• *What is the function of the myoepithelial cells in part (d)?*

FIGURE 28.10 Breast Cancer Screening and Treatment. (a) Radiologic technologist assisting a patient in mammography. (b) Mammogram of a breast with a tumor visible at the arrow (left), compared with the appearance of normal fibrous connective tissue of the breast (right). (c) Patient following mastectomy of the right breast. (d) The same patient following surgical breast reconstruction.

◀ What is the diagnostic benefit of compressing the breast for a mammogram?

The majority of tumors are discovered during breast self-examination (BSE), which should be a monthly routine for all women. *Mammograms* (breast X-rays), however, can detect tumors too small to be noticed by BSE. Although opinions vary, a schedule commonly recommended is to have a baseline mammogram in the late 30s and then have one every 2 years from ages 40 to 49 and every year beginning at age 50.

Treatment of breast cancer is usually by *lumpectomy* (removal of the tumor only) or *simple mastectomy* (removal of the breast tissue only or breast tissue and some axillary lymph nodes). *Radical mastectomy*, rarely done since the 1970s, involves the removal of not only the breast but also the underlying muscle, fascia, and lymph nodes. Although very disfiguring, it proved to be no more effective than simple mastectomy or lumpectomy. Surgery is generally followed by radiation or chemotherapy, and estrogen-sensitive tumors may also be treated with an

estrogen blocker such as tamoxifen. A natural-looking breast can often be reconstructed from skin, fat, and muscle from other parts of the body.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. How do the site of female gamete production and mode of release from the gonad differ from those in the male?
2. How is the structure of the uterine tube mucosa related to its function?
3. Contrast the function of the endometrium with that of the myometrium.
4. List the subcutaneous erectile tissues and glands of the female perineum and state the function of each.

28.2 Puberty and Menopause

Objectives

When you have completed this section, you should be able to

- name the hormones that regulate female reproductive function, and state their roles;
- describe the principal signs of puberty;
- describe the hormonal changes of female climacteric and their effects; and
- define and describe menopause, and distinguish menopause from climacteric.

Puberty and menopause are physiological transitions at the beginning and end of a female's reproductive life.

Puberty

Puberty begins at ages 8 to 10 for most girls in the United States and Europe, but significantly later in many countries. However, a 1997 study of more than 17,000 girls in the United States showed 3% of black girls and 1% of white girls beginning puberty by age 3, and 27% and 7%, respectively, by age 7.

Puberty is triggered by the same hypothalamic and pituitary hormones in girls as it is in boys. Rising levels of gonadotropin-releasing hormone (GnRH) stimulate the anterior lobe of the pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH, especially, stimulates development of the ovarian follicles, which, in turn, secrete estrogens, progesterone, inhibin, and a small amount of androgen. These hormone levels rise gradually from ages 8 to 12 and then more sharply in the early teens. The **estrogens**²⁴ are feminizing hormones with widespread effects on the body. They include *estradiol* (the most abundant), *estriol*, and *estrone*. Most of the visible changes at puberty result from estradiol and androgens.

The earliest noticeable sign of puberty is **thelarche**²⁵ (thee-LAR-kee), the onset of breast development. Estrogen, progesterone, and prolactin initially induce the formation of lobules and ducts in the breast. Duct development is completed under the influence of glucocorticoids and growth hormone, while adipose and fibrous tissue enlarge the breast. Breast development is complete around age 20, but minor changes occur in each menstrual cycle and major changes occur in pregnancy.

Thelarche is soon followed by **pubarche** (pyu-BAR-kee), the appearance of pubic and axillary hair, sebaceous glands, and axillary glands. Androgens from the ovaries

and adrenal cortex stimulate pubarche as well as the libido. Women secrete about 0.5 mg of androgens per day, compared with 6 to 8 mg/day in men.

Next comes **menarche**²⁶ (men-AR-kee), the first menstrual period. In Europe and America, the average age at menarche declined from age 16.5 in 1860 to age 12 in 1997, mostly because of improved nutrition. Menarche cannot occur until a girl has attained about 17% body fat, and adult menstruation generally ceases if a woman drops below 22% fat. This is about the minimum needed to sustain pregnancy and lactation; thus, the body reacts as if to prevent a futile pregnancy when it is too lean.

As explained in chapter 26, the brain can monitor the amount of body fat from the amount of leptin in the blood. In addition to its role in regulating appetite, leptin stimulates gonadotropin secretion. Therefore, if body fat and leptin levels drop too low, gonadotropin secretion declines and a girl's or woman's menstrual cycle may cease. Adolescent girls with very low body fat, such as avid dancers and gymnasts, tend to begin menstruating at a later age than average.

Menarche does not necessarily signify fertility. A girl's first few menstrual cycles are typically *anovulatory* (no egg is ovulated). Most girls begin ovulating regularly about a year after they begin menstruating.

Estradiol stimulates many other changes of puberty. It causes the vaginal metaplasia described earlier. It stimulates growth of the ovaries and secondary sex organs. It stimulates growth hormone secretion and causes a rapid increase in height and widening of the pelvis. Estradiol is largely responsible for the feminine physique because it stimulates fat deposition in the mons pubis, labia majora, hips, thighs, buttocks, and breasts. It makes a girl's skin thicken, but the skin remains thinner, softer, and warmer than in males of corresponding age.

Progesterone²⁷ acts primarily on the uterus, preparing it for possible pregnancy in the second half of each menstrual cycle and playing roles in pregnancy discussed later. Estrogens and progesterone also suppress FSH and LH secretion through negative feedback inhibition of the anterior pituitary. **Inhibin** selectively suppresses FSH secretion.

Thus we see many hormonal similarities in males and females from puberty onward. The sexes differ less in the identity of the hormones that are present than in their relative amounts—high levels of androgens and low levels of estrogens in males and the opposite in females. Another difference is that these hormones are secreted more or less continually and simultaneously in males, whereas in females, secretion is distinctly cyclic and the hormones are secreted in sequence. This will be very apparent as you read about the ovarian and menstrual cycles.

²⁴ *estro* = desire, *frenzy* + *gen* = to produce

²⁵ *thel* = breast, *nipple* + *arche* = beginning

²⁶ *men* = monthly

²⁷ *pro* = favoring + *gest* = pregnancy + *sterone* = steroid hormone

Climacteric and Menopause

Women, like men, go through a midlife change in hormone secretion called the **climacteric**. In women, it is accompanied by **menopause**, the cessation of menstruation (see Insight 28.2).

A female is born with about 2 million eggs in her ovaries, each in its own follicle. The older she gets, the fewer follicles remain. Climacteric begins not at any specific age, but when she has only about 1,000 follicles left. Even the remaining follicles are less responsive to gonadotropins, so they secrete less estrogen and progesterone. Without these steroids, the uterus, vagina, and breasts atrophy. Intercourse may become uncomfortable, and vaginal infections more common, as the vagina becomes thinner, less distensible, and drier. The skin becomes thinner, cholesterol levels rise (increasing the risk of cardiovascular disease), and bone mass declines (increasing the risk of osteoporosis). Blood vessels constrict and dilate in response to shifting hormone balances, and the sudden dilation of cutaneous arteries may cause **hot flashes**—a spreading sense of heat from the abdomen to the thorax, neck, and face. Hot flashes may occur several times a day, sometimes accompanied by headaches resulting from the sudden vasodilation of arteries in the head. In some people, the changing hormonal profile also causes mood changes. Many physicians prescribe hormone replacement therapy (HRT)—low doses of estrogen and progesterone usually taken orally or by a skin patch—to relieve some of these symptoms. The risks and benefits of HRT are still being debated.

Think About It

FSH and LH secretion rise at climacteric and these hormones attain high concentrations in the blood. Explain this using the preceding information and what you know about the pituitary–gonadal relationship.

Menopause is the cessation of menstrual cycles, usually occurring between the ages of 45 and 55. The average age has increased steadily in the last century and is now about 52. It is difficult to precisely establish the time of menopause because the menstrual periods can stop for several months and then begin again. Menopause is generally considered to have occurred when there has been no menstruation for a year or more.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe the similarities and differences between male and female puberty.
- Describe the major changes that occur in female climacteric and the principal cause of these changes.
- What is the difference between climacteric and menopause?

INSIGHT 28.2 Evolutionary Medicine

The Evolution of Menopause

There has been considerable speculation about why women do not remain fertile to the end of their lives, as men do. Some theorists argue that menopause served a biological purpose for our prehistoric foremothers. Human offspring take a long time to rear. Beyond a certain point, the frailties of age make it unlikely that a woman could rear another infant to maturity or even survive the stress of pregnancy. She might do better in the long run to become infertile and finish rearing her last child, or help to rear her grandchildren, instead of having more. In this view, menopause was biologically advantageous for our ancestors—in other words, an evolutionary adaptation.

Others argue against this hypothesis on the grounds that Pleistocene (Ice Age) skeletons indicate that early hominids rarely lived past age 40. If this is true, menopause setting in at 45 to 55 years of age could have served little purpose. In this view, Pleistocene women may indeed have been fertile to the end of their lives; menopause now may be just an artifact of modern nutrition and medicine, which have made it possible for us to live much longer than our ancestors did.

28.3 Oogenesis and the Sexual Cycle

Objectives

When you have completed this section, you should be able to

- describe the process of egg production (oogenesis);
- describe changes in the ovarian follicles (folliculogenesis) in relation to oogenesis;
- describe the hormonal events that regulate the ovarian cycle;
- describe how the uterus changes during the menstrual cycle; and
- construct a chart of the phases of the monthly sexual cycle showing the hormonal, ovarian, and uterine events of each phase.

The reproductive lives of women are conspicuously cyclic. They include the **reproductive cycle**, which encompasses the sequence of events from fertilization to giving birth, and the **sexual cycle**, which encompasses the events that recur every month when pregnancy does not intervene. The sexual cycle, in turn, consists of two interrelated cycles controlled by shifting patterns of hormone secretion: the **ovarian cycle**, consisting of events in the ovaries, and the **menstrual cycle**, consisting of parallel changes in the uterus. In this

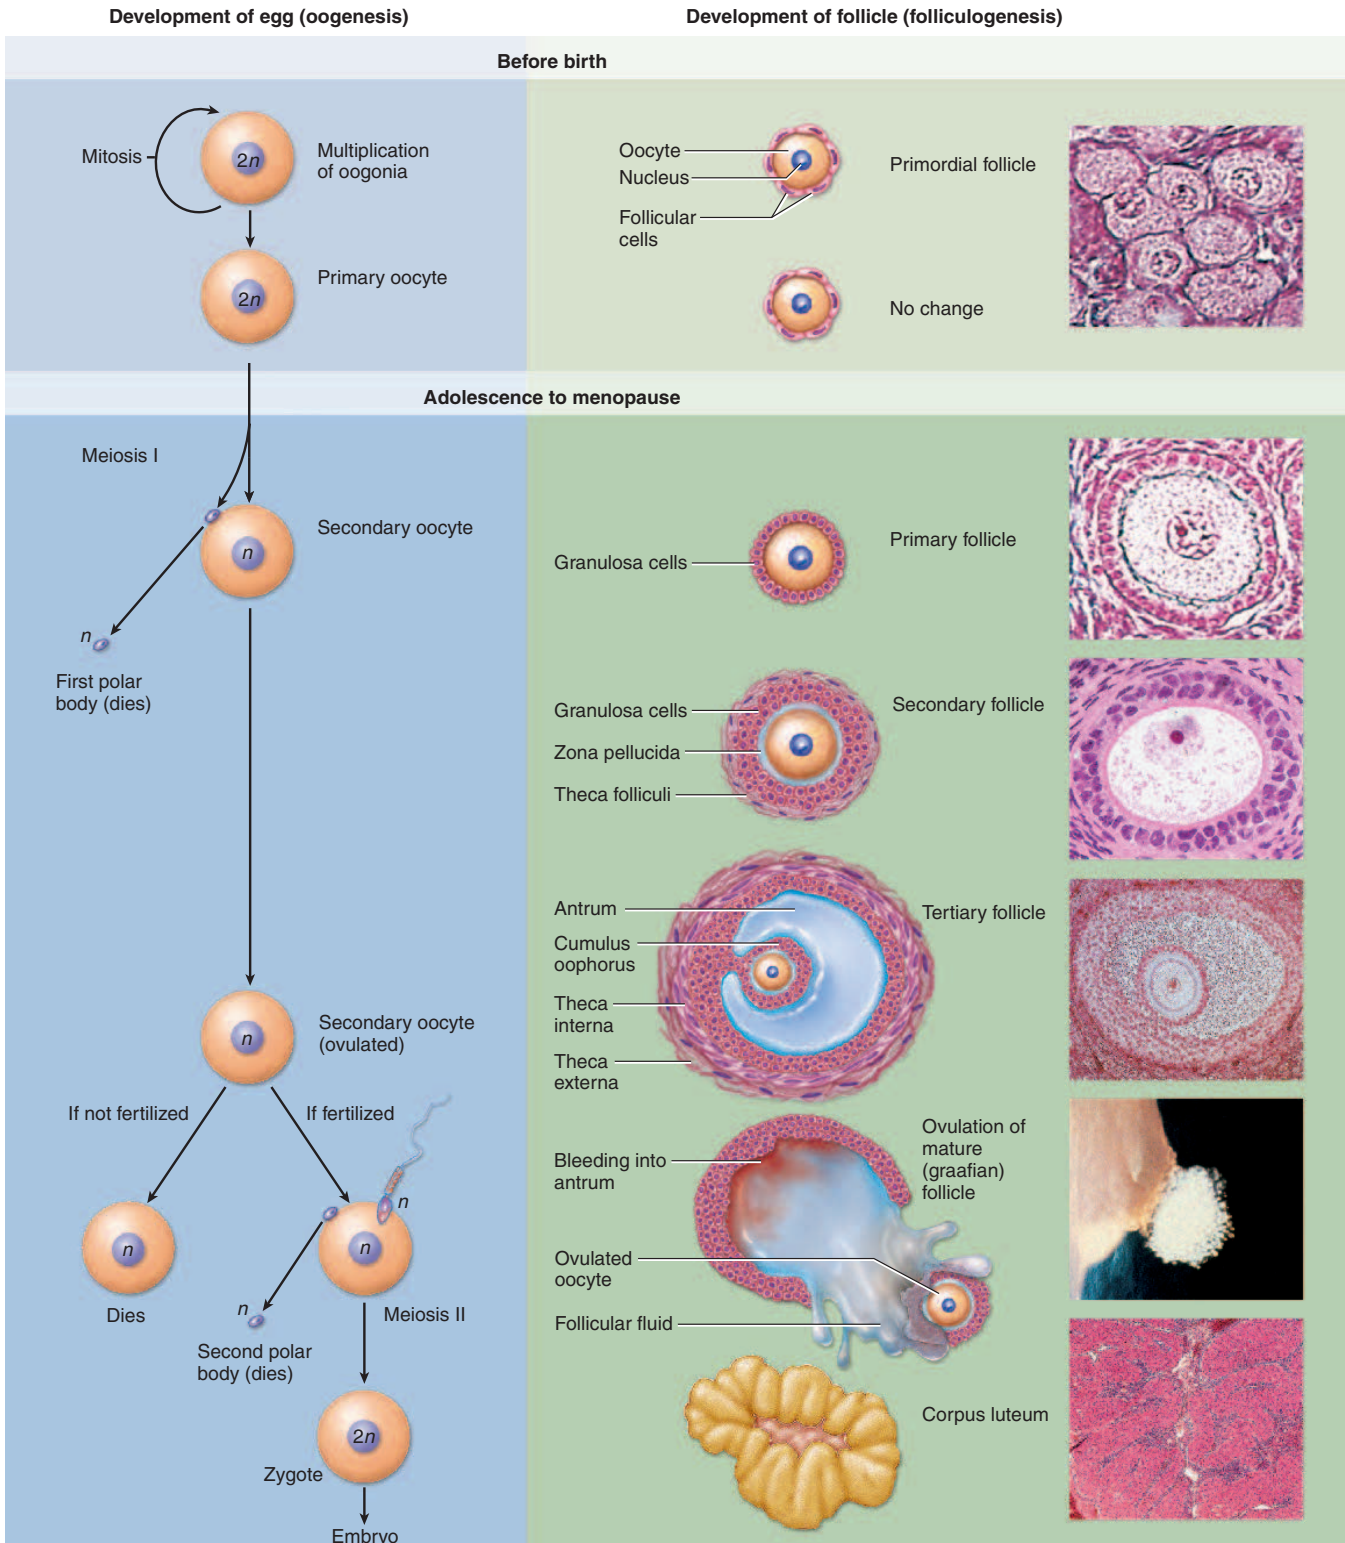

FIGURE 28.11 Oogenesis (Left) and Corresponding Development of the Follicle (Right).

section, we examine the process of egg production and the monthly events of the ovarian and menstrual cycles.

Oogenesis

Egg production is called **oogenesis**²⁸ (OH-oh-JEN-eh-sis) (fig. 28.11). Like spermatogenesis, it produces a haploid gamete by means of meiosis. There are, however, numerous differences between the two. The most obvious, perhaps, is that males produce sperm continually, whereas oogenesis is a distinctly cyclic event that normally releases only one egg per month. Oogenesis is accompanied by cyclic changes in hormone secretion and in the histological structure of the ovaries and uterus; the uterine changes result in the monthly menstrual flow.

The female germ cells arise, like those of the male, from the yolk sac of the embryo. They colonize the gonadal ridges in the first 5 to 6 weeks of development and then differentiate into **oogonia** (OH-oh-GO-nee-uh). Oogonia multiply until the fifth month, reach 6 to 7 million in number, then go into a state of arrested development until shortly before birth. At that time, some of them transform into **primary oocytes** and go as far as early meiosis I. All of them reach this stage by 6 months after birth, and no oogonia remain beyond that time. Any stage from the primary oocyte to the time of fertilization can be called an **egg**, or **ovum**.

Most primary oocytes undergo a process of degeneration called **atresia** (ah-TREE-zhee-uh) before a girl is born. Two million remain at the time of birth; most of those undergo atresia during childhood; and by puberty, only 400,000 remain. This is the female's lifetime supply of gametes, but it is more than ample; even if she ovulated every 28 days from the ages of 14 to 50, she would ovulate only 480 times.

Egg development resumes in adolescence, when FSH stimulates monthly cohorts of oocytes to complete meiosis I. Each oocyte divides into two haploid daughter cells of unequal size and different destinies. In oogenesis, it is important to produce an egg with as much cytoplasm as possible, because if fertilized it must divide repeatedly and

produce numerous daughter cells. Splitting each oocyte into four equal but small parts would run counter to this purpose. Therefore, meiosis I produces a large daughter cell called the **secondary oocyte** and a much smaller one called the **first polar body**. The polar body sometimes undergoes meiosis II, but ultimately disintegrates. It is merely a means of discarding the extra haploid set of chromosomes.

The secondary oocyte proceeds as far as metaphase II, then arrests until after ovulation. If it is not fertilized, it dies and never finishes meiosis. If fertilized, it completes meiosis II and casts off a **second polar body**, which disposes of one chromatid from each chromosome. The chromosomes of the large remaining egg unite with those of the sperm. Further development of the fertilized egg is discussed in chapter 29.

Folliculogenesis

As an egg undergoes oogenesis, the follicle around it undergoes developments called **folliculogenesis**:

1. **Primordial follicles.** A primordial follicle consists of a primary oocyte in early meiosis, surrounded by a single layer of squamous **follicular cells** and a basement membrane separating the follicle from the surrounding stroma of the ovary (fig. 28.12a). The follicular cells are connected to the oocyte surface by fine cytoplasmic processes that allow them to pass nutrients and chemical signals to it. Primordial follicles are concentrated in the cortex of the ovary, close to the capsule. They begin to appear long before a girl is born, as early as 12 weeks of development. They persist into adulthood, with most of them waiting at least 13 years and some as long as 50 years before they develop any further. In the adult ovary, 90% to 95% of the follicles are primordial.
2. **Primary follicles.** These have a larger oocyte and follicular cells that still form only a single layer, but have now grown to a cuboidal shape. Few follicles develop from the primordial to the primary stage before puberty. It is

²⁸oo = egg + genesis = production

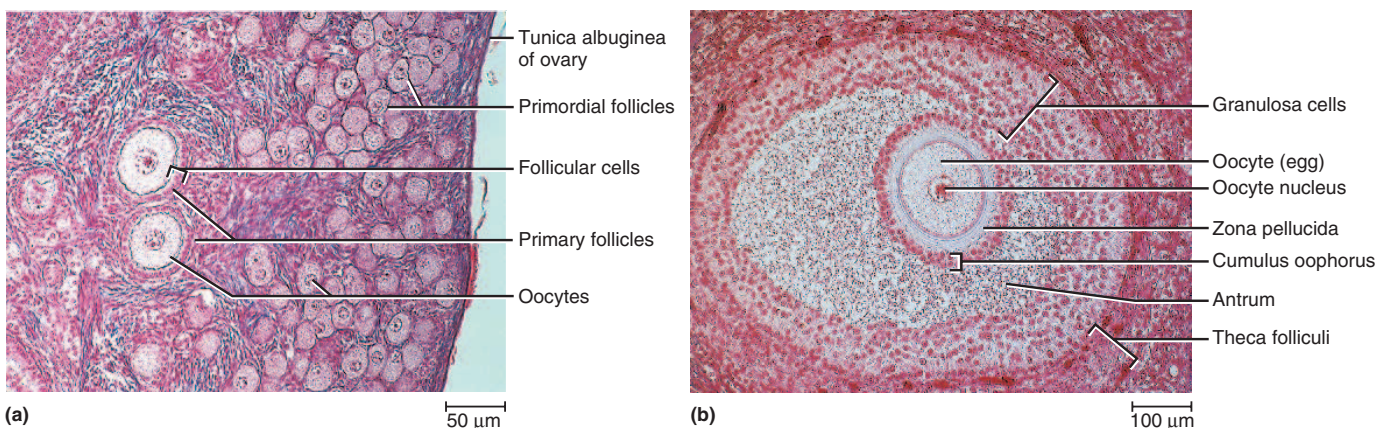

FIGURE 28.12 Ovarian Follicles. (a) Note the very thin layer of squamous cells around the oocyte in a primordial follicle, and the single layer of cuboidal cells in a primary follicle. (b) A mature (graafian) follicle. Just before ovulation, this follicle will grow to as much as 30 mm in diameter.

unknown what activates them to resume development or selects which follicles resume in a given cycle.

- Secondary follicles.** These are distinguished by a still larger oocyte and by follicular cells that have now multiplied and piled atop each other to form two or more layers. The now stratified follicular cells are called **granulosa cells**. They secrete a layer of glycoprotein gel, the **zona pellucida**,²⁹ around the oocyte. The connective tissue around the granulosa cells condenses to form a fibrous husk called the **theca**³⁰ **folliculi** (THEE-ca fol-IC-you-lye).
- Tertiary follicles.** Next, the granulosa cells begin secreting **follicular fluid**, which accumulates in little pools in the follicle wall (see fig. 28.14). The presence of these pools defines the tertiary follicle. As they enlarge, the pools merge and become a single fluid-filled cavity, the **antrum** (fig. 28.12b). Because of this, tertiary and mature follicles are called *antral* follicles, whereas the earlier stages are called *preantral*. On one side of the antrum, a mound of granulosa cells called the **cumulus oophorus**³¹ covers the oocyte and secures it to the follicle wall. The innermost layer of cells in the cumulus, surrounding the zona pellucida and oocyte, is called the **corona radiata**.³² These cells communicate with the oocyte by way of cytoplasmic processes that cross the zona pellucida. This ensures that nothing from the bloodstream can get to the oocyte except by going through the cytoplasm of the corona cells, which form a protective barrier around the egg functionally similar to the blood–testis barrier described in chapter 27. The theca folliculi also continues to differentiate, layering to form an outer fibrous capsule, rich in blood vessels, called the *theca externa*, and an inner cellular, hormone-secreting layer, the *theca interna*. The theca interna produces androgens (androstenedione and testosterone), and the granulosa cells convert them to estradiol.
- Mature (graafian³³) follicles.** Normally only one follicle in each month's cohort becomes a mature follicle, destined to ovulate while the rest degenerate. As the mature follicle approaches ovulation, the cumulus oophorus constricts until the oocyte is attached to the wall by only a narrow stalk of granulosa cells. In the last day or so, the oocyte and cumulus break away and float freely in the antrum.

The Sexual Cycle

The sexual cycle averages 28 days in length, so we will use that as the basis for the timetable described in the following pages. It commonly varies from 20 to 45 days, however, so be

aware that the timetable given in this discussion may differ from person to person and from month to month. As you study this cycle, bear in mind that hormones of the hypothalamus regulate the pituitary gland; pituitary hormones regulate the ovaries; and the ovaries, in turn, secrete hormones that regulate the uterus. That is, the basic hierarchy of control can be represented: hypothalamus → pituitary → ovaries → uterus. However, the ovaries also exert feedback control over the hypothalamus and pituitary.

We begin with a brief preview of the sexual cycle as a whole. It begins with a 2-week *follicular phase*. The first 3 to 5 days are marked by menstruation, in which blood and endometrial tissue are discharged vaginally. The uterus then replaces the lost tissue by mitosis. While this is going on, a cohort of ovarian follicles grows until one of them ovulates around day 14. After ovulation, the remainder of that follicle becomes a body called the *corpus luteum*. Over the next 2 weeks, called the *luteal phase*, the corpus luteum stimulates endometrial secretion, making the endometrium thicken still more. If pregnancy does not occur, the endometrium breaks down again in the last 2 days. As loose tissue and blood accumulate, menstruation begins and the cycle starts over.

The Ovarian Cycle

We can now examine the ovarian cycle in more detail. We will see, in three principal steps, what happens in the ovaries and in their relationship to the hypothalamus and pituitary gland. Much remains unknown about the timing of folliculogenesis. The timetable presented here is one view, but authorities differ in how many weeks or months it takes a selected preantral follicle to reach the point of maturity and ovulation.

- Follicular phase.** The follicular phase of an ovarian cycle extends from the beginning of menstruation until ovulation—that is, from day 1 to day 14 in an average cycle. The portion from the *end* of menstruation until ovulation is also called the *preovulatory phase*. The follicular phase is the most variable part of the cycle, so unfortunately for family planning or pregnancy avoidance, it is seldom possible to reliably predict the date of ovulation.

Preparation for the follicular phase begins almost two months earlier (in the view adopted here). Shortly after ovulation in what we will call cycle 1, a new cohort of preantral follicles descends from the cortex deeper into the ovary and begins to grow. Each follicle develops an antrum, and by late in cycle 2, attains a diameter of about 2 mm. At that time, there is a 5-day *selection window* in which one of them is selected to mature and ovulate in the next cycle. That follicle is called the **dominant follicle**.

This is the state of things going into cycle 3. During the follicular phase, FSH stimulates continued growth of all follicles in the cohort, but of the dominant follicle above all. FSH stimulates the gran-

²⁹zona = zone + pellucid = clear, transparent

³⁰theca = box, case

³²corona = crown + radiata = radiating

³³Reijnier de Graaf (1641–73), Dutch physiologist and histologist

ulosa cells of the antral follicles to secrete estradiol. In response to estradiol, the dominant follicle up-regulates its receptors for FSH, LH, and estradiol itself, thereby becoming increasingly sensitive to these hormones. At the same time, estradiol inhibits the secretion of gonadotropin-releasing hormone (GnRH) by the hypothalamus. The anterior pituitary gland secretes less and less FSH, but an increasing amount of LH. Most antral follicles suffer from the reduced FSH level and degenerate (undergo atresia). The dominant follicle, however, has the richest blood supply and the greatest density of FSH receptors, so it continues to grow, reaching a diameter of about 20 mm by the late follicular phase. It is then regarded as the mature (graafian) follicle.

2. **Ovulation.** Ovulation is the rupture of the mature follicle and the release of its egg and attendant cells, typically around day 14. Dramatic changes over the preceding day signify its imminence. Estradiol stimulates a surge of LH and a lesser spike in FSH secretion by the pituitary (fig. 28.13 and the midpoint of fig. 28.14). LH induces several momentous events. The primary oocyte completes meiosis I, producing a haploid secondary oocyte and the first polar body. Follicular fluid builds rapidly and the follicle swells to as much as 25 mm in diameter—more than twice the usual thickness of the ovary. It looks like a blister on the surface of the ovary. The follicular wall and adjacent ovarian tissue are weakened by inflammation and a proteolytic enzyme. With mounting internal pressure and a weakening wall, the mature follicle approaches rupture.

Meanwhile, the uterine tube prepares to catch the oocyte when it emerges. It swells with edema; its fimbriae envelop and caress the ovary in synchrony with the woman's heartbeat; and its cilia create a gentle current in the nearby peritoneal fluid.

Ovulation itself takes only 2 or 3 min. A nipplelike **stigma** appears on the ovarian surface over the follicle. It seeps follicular fluid for 1 or 2 min, and then the follicle bursts. The remaining fluid oozes out, carrying the oocyte and cumulus oophorus (fig. 28.15). These are normally swept up by the ciliary current and taken into the uterine tube, although many oocytes fall into the pelvic cavity and die.

Think About It

In chapter 17, review the concept of the permissive effect in hormone interactions; explain its relevance to the first 14 days of the ovarian cycle.

3. **Luteal phase.** Days 15 to 28, from just after ovulation to the onset of menstruation, are called the **luteal (postovulatory) phase**. Assuming pregnancy does not occur, the major events of this phase are as follows.

FIGURE 28.13 Control of Ovulation by Pituitary and Ovarian Hormones.

INSIGHT 28.3 Clinical Application

Signs of Ovulation

If a couple is attempting to conceive a child or to avoid pregnancy, it is important to be able to tell when ovulation occurs. The signs are subtle but detectable. For one, the cervical mucus becomes thinner and more stretchy. Also, the resting body temperature (*basal temperature*) rises 0.2° to 0.3°C (0.4°–0.6°F). This is best measured first thing in the morning, before rising from bed; the change can be detected if basal temperatures are recorded for several days before ovulation in order to see the difference. The LH surge that occurs about 24 hours before ovulation can be detected with a home testing kit. Finally, some women experience twinges of ovarian pain known by the German name, *mittelschmerz*,³⁴ which last from a few hours to a day or so at the time of ovulation. The most likely time to become pregnant is within 24 hours after the cervical mucus changes consistency and the basal temperature rises.

When the follicle ruptures, it collapses and bleeds into the antrum. As the clotted blood is slowly absorbed, granulosa and theca interna cells multiply and fill the antrum, and a dense bed of blood capillaries grows amid them. The ovulated follicle has

³⁴*mittel* = in the middle + *schmerz* = pain

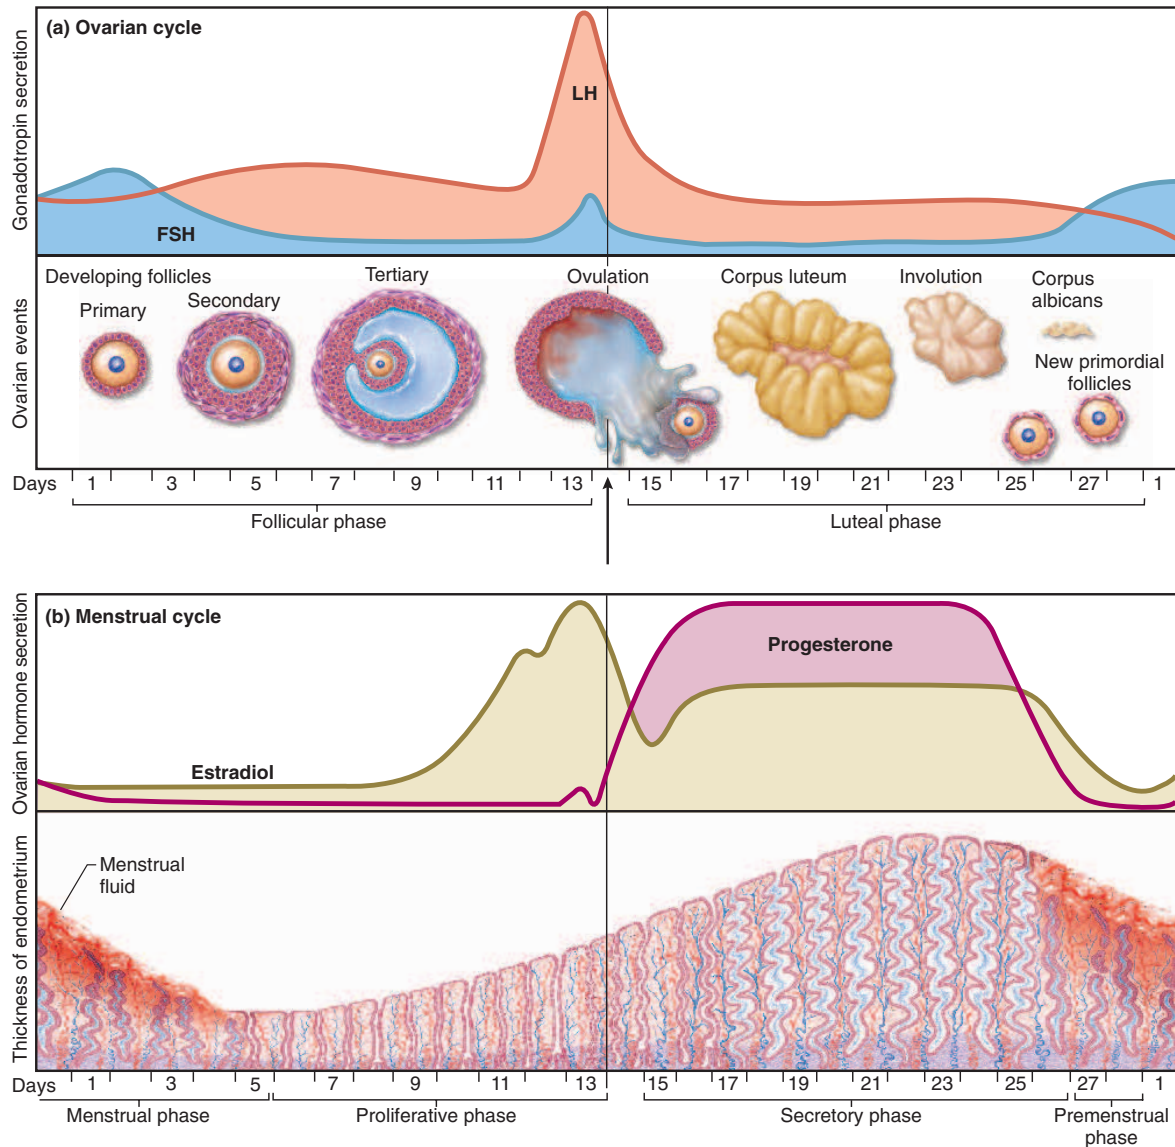

FIGURE 28.14 The Female Sexual Cycle. (a) The ovarian cycle (events in the ovary). (b) The menstrual cycle (events in the uterus). The two hormone levels in part (a) are drawn to the same scale, but those in part (b) are not. The peak progesterone concentration is about 17 times as high as the peak estradiol concentration.

now become a structure called the **corpus luteum**,³⁵ named for a yellow lipid that accumulates in the theca interna cells. These cells are now called **lutein cells**. The transformation from ruptured follicle to corpus luteum is regulated by LH; hence, LH is also called *luteotropic hormone*.

LH stimulates the corpus luteum to continue growing and to secrete rising levels of estradiol and progesterone. The most important aspect of the luteal phase is a 10-fold increase in progesterone level (fig. 28.14).

This hormone has a crucial role in preparing the uterus for the possibility of pregnancy. Notwithstanding its luteinizing role, however, LH secretion declines steadily over the rest of the cycle, as does FSH. This is because the high levels of estradiol and progesterone, along with inhibin from the corpus luteum, have a negative feedback effect on the pituitary. (This fact is the basis for hormonal birth control; see Insight 28.4.)

If pregnancy does not occur, the corpus luteum begins a process of **involution**, or shrinkage, beginning around day 22 (8 days after ovulation). By day 26, involution is complete and the corpus luteum has

³⁵corpus = body + lute = yellow

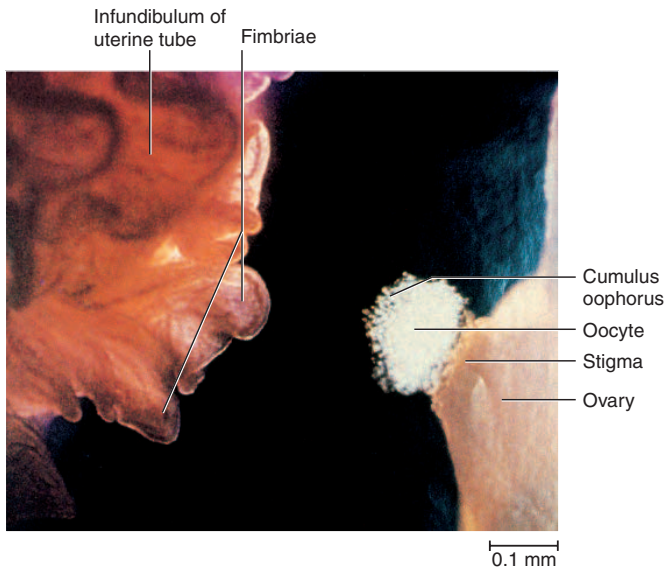

FIGURE 28.15 Endoscopic View of Human Ovulation. The oocyte is shrouded by a blanket of cumulus oophorus cells.

become an inactive bit of scar tissue called the **corpus albicans**.³⁶ With the waning of ovarian steroid secretion, the pituitary is no longer inhibited and FSH levels begin to rise again, ripening a new cohort of follicles.

All of these events repeat themselves every month, but bear in mind that the follicles engaged in each monthly cycle began their development prenatally, as much as 50 years earlier, and the oocyte that ovulates each month may have begun ripening 2 or 4 months earlier, not necessarily in the cycle when it ovulates. Follicle maturation and ovulation normally occur in only one ovary per cycle, and the ovaries usually alternate from month to month. Table 28.1 summarizes the main events of the ovarian cycle and correlates them with events of the menstrual cycle, which we examine next.

The Menstrual Cycle

The menstrual cycle consists of a buildup of the endometrium through most of the sexual cycle, followed by its breakdown and vaginal discharge. The menstrual cycle is divided into a *proliferative phase*, *secretory phase*, *premenstrual phase*, and *menstrual phase* (fig. 28.14).

³⁶corpus = body + alb = white

TABLE 28.1		Phases of the Ovarian Cycle
Days	Phase	Major Features
1-14	Follicular phase	Development of ovarian follicles and secretion primarily of estradiol. Coincides with menstrual and proliferative phases of the menstrual cycle.
	Primordial follicle	Formed prenatally and many persist into adulthood. Consists of an oocyte surrounded by a single layer of squamous follicular cells.
	Primary follicle	Consists of an oocyte surrounded by one layer of cuboidal follicular cells.
	Secondary follicle	Follicular cells stratify, become granulosa cells, and secrete a zona pellucida. Theca folliculi forms around follicle.
	Tertiary follicle	Develops from a secondary follicle in each cycle. Forms an antrum filled with follicular fluid and exhibits a cumulus oophorus, corona radiata, zona pellucida, and bilayered theca.
	Dominant follicle	The tertiary follicle that is destined to ovulate. Present by the end of the menstrual phase. Hormonally dominates the rest of the cycle, while other follicles in the cohort undergo atresia. Secretes mainly estradiol. Coincides with the proliferative phase of the menstrual cycle, in which the uterine endometrium thickens by mitosis.
	Mature (graafian) follicle	The dominant follicle just prior to ovulation. Attains a diameter of 20 to 30 mm and builds to high internal fluid pressure as adjacent ovarian wall weakens.
14	Ovulation	Rupture of mature follicle and release of oocyte.
15-28	Luteal (postovulatory) phase	Dominated by corpus luteum. Coincides with secretory and premenstrual phases of the menstrual cycle.
	Corpus luteum	Develops from ovulated follicle by proliferation of granulosa and theca interna cells. Progesterone stimulates thickening of endometrium by secretion (secretory phase of the menstrual cycle). Begins to involute by day 22 in the absence of pregnancy; involution complete by day 26.
	Corpus albicans	Scar tissue left by involution of corpus luteum; not hormonally active. In the absence of progesterone, endometrium exhibits ischemia, necrosis, and sloughing of tissue. Necrotic endometrial tissue mixes with blood and forms menstrual fluid.

FIGURE 28.16 Endometrial Changes Through the Menstrual Cycle. (a) Late proliferative phase. The endometrium is 2 to 3 mm thick and has relatively straight, narrow endometrial glands. Spiral arteries penetrate upward between the endometrial glands. (b) Secretory phase. The endometrium has thickened to 5 to 6 mm by accumulating glycogen and mucus. The endometrial glands are much wider and more distinctly coiled, showing a zigzag or “sawtooth” appearance in histological sections. (c) Menstrual phase. Ischemic tissue has begun to die and fall away from the uterine wall, with bleeding from broken blood vessels and pooling of blood in the tissue and uterine lumen.

The menstrual phase averages 5 days long, and the first day of noticeable vaginal discharge is defined as day 1 of the sexual cycle. But even though it begins our artificial timetable for the cycle, the reason for menstruation is best understood after you become acquainted with the buildup of endometrial tissue that precedes it. Thus, we begin our survey of the cycle with the proliferative phase.

1. **Proliferative phase.** The layer of endometrial tissue (stratum functionalis) lost in the last menstruation is rebuilt during the **proliferative phase**. At the end of menstruation, around day 5, the endometrium is about 0.5 mm thick and consists only of the stratum basalis. But as a new cohort of follicles develops, they secrete more and more estrogen. Estrogen stimulates mitosis in the stratum basalis and the prolific regrowth of

blood vessels, thus regenerating the functionalis (fig. 28.16a). By day 14, the endometrium is 2 to 3 mm thick. Estrogen also stimulates endometrial cells to produce progesterone receptors, priming them for the progesterone-dominated secretory phase to follow.

2. **Secretory phase.** The endometrium thickens still more during the **secretory phase**, but as a result of secretion and fluid accumulation rather than mitosis. This phase extends from day 15 (after ovulation) to day 26 of a typical cycle. After ovulation, the corpus luteum secretes mainly progesterone. This hormone stimulates the endometrial glands to secrete glycogen. The glands grow wider, longer, and more coiled, and the lamina propria swells with tissue fluid (fig. 28.16b). By the end of this phase, the endometrium is 5 to

6 mm thick—a soft, wet, nutritious bed available for embryonic development in the event of pregnancy.

3. **Premenstrual phase.** The last 2 days or so of the cycle are the **premenstrual phase**, a period of endometrial degeneration. As we have already seen, when there is no pregnancy, the corpus luteum atrophies and the progesterone level falls sharply. The drop in progesterone level triggers spasmodic contractions of the spiral arteries of the endometrium, causing endometrial ischemia (interrupted blood flow). The premenstrual phase is therefore also called the **ischemic** (iss-KEE-mic) **phase**. Ischemia brings on tissue necrosis (and menstrual cramps). As the endometrial glands, stroma, and blood vessels degenerate, pools of blood accumulate in the stratum functionalis. Necrotic endometrium falls away from the uterine wall, mixes with blood and serous fluid in the lumen, and forms the **menstrual fluid** (fig. 28.16c).
4. **Menstrual phase.** When enough menstrual fluid accumulates in the uterus, it begins to be discharged from the vagina for a period called the **menstrual phase (menses)**. The first day of discharge marks day 1 of a new cycle. The average woman expels about 40 mL of blood and 35 mL of serous fluid over a 5-day period. Menstrual fluid contains fibrinolysin, so it does not clot. The vaginal discharge of clotted blood may indicate uterine pathology rather than normal menstruation.

In summary, the ovaries go through a follicular phase characterized by growing follicles; then ovulation; and then a postovulatory (mostly luteal) phase dominated by the corpus luteum. The uterus, in the meantime, goes through a menstrual phase in which it discharges its stratum functionalis; then a proliferative phase in which it replaces that tissue by mitosis; then a secretory phase in which the endometrium thickens by the accumulation of secretions; and finally, a premenstrual (ischemic) phase in which the stratum functionalis breaks down again. The first half of the cycle is governed largely by follicle-stimulating hormone (FSH) from the pituitary gland and estrogen from the ovaries. Ovulation is triggered by luteinizing hormone (LH) from the pituitary, and the second half of the cycle is governed mainly by LH and progesterone, the latter secreted by the ovaries.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

8. Name the sequence of cell types in oogenesis and identify the ways in which oogenesis differs from spermatogenesis.
9. Distinguish between primordial, primary, secondary, and tertiary follicles. Describe the major structures of a mature follicle.
10. Describe what happens in the ovary during the follicular and postovulatory phases.
11. Describe what happens in the uterus during the menstrual, proliferative, secretory, and premenstrual phases.
12. Describe the effects of FSH and LH on the ovary.
13. Describe the effects of estrogen and progesterone on the uterus, hypothalamus, and anterior pituitary.

28.4 Female Sexual Response

Objectives

When you have completed this section, you should be able to

- describe the female sexual response at each phase of intercourse; and
- compare and contrast the female and male responses.

Female sexual response, the physiological changes that occur during intercourse, may be viewed in terms of the four phases identified by Masters and Johnson and discussed in chapter 27: excitement, plateau, orgasm, and resolution (fig. 28.17). The neurological and vascular controls of female sexual response are essentially the same as in the male (pp. 1068–1071) and need not be repeated here. The emphasis here is on ways the female response differs from that of the male.

Excitement and Plateau

Excitement is marked by myotonia, vasocongestion, and increased heart rate, blood pressure, and respiratory rate. Although vasocongestion works by the same mechanism in both sexes, its effects are quite different in females. The labia minora become congested and often protrude beyond the labia majora. The labia majora become reddened and enlarged and then flatten and spread away from the vaginal orifice.

The vaginal wall becomes purple due to hyperemia, and serous fluid called the **vaginal transudate** seeps through the wall into the canal. Along with secretions of the greater vestibular glands, this moistens the vestibule and provides lubrication. The inner end of the vagina dilates and becomes cavernous, while the lower one-third of it constricts to form a narrow passage called the **orgasmic platform**. The narrower canal and the vaginal rugae (friction ridges) enhance stimulation and help induce orgasm in both partners.

The uterus, which normally tilts forward over the urinary bladder, stands more erect during excitement and the cervix withdraws from the vagina. In plateau, the uterus is nearly vertical and extends into the false pelvis. This is called the **tenting effect**.

FIGURE 28.17 Stages of the Female Sexual Response. Anatomy is shown in the supine position.

Although the vagina is the female copulatory organ, the clitoris is more comparable to the penis in structure, physiology, and importance as the primary focus of erotic stimulation. It has a high concentration of sensory nerve endings, which, by contrast, are relatively scanty in the vagina. Recall that the penis and clitoris are homologous structures. Both have a pair of corpora cavernosa with *deep arteries*, and both become engorged by the same mechanism. The glans and shaft of the clitoris swell to two or three times their unstimulated size, but since the clitoris cannot swing upward away from the body like the penis, it tends to withdraw beneath the prepuce. Thrusting of the penis in the vagina tugs on the labia minora and, by extension, pulls on the prepuce

and stimulates the clitoris. The clitoris may also be stimulated by pressure between the pubic symphyses of the partners.

The breasts also become congested and swollen during the excitement phase, and the nipples become erect. Stimulation of the breasts also enhances sexual arousal.

Orgasm

Late in plateau, many women experience involuntary pelvic thrusting, followed by 1 to 2 seconds of “suspension” or “stillness” preceding orgasm. Orgasm is commonly described as an intense sensation spreading from the clitoris through the pelvis, sometimes with pelvic

throbbing and a spreading sense of warmth. The orgasmic platform gives three to five strong contractions about 0.8 seconds apart, while the cervix plunges spasmodically into the vagina and pool of semen, should this be present. The uterus exhibits peristaltic waves of contraction; it is still debated whether or not this helps to draw semen from the vagina. The anal and urethral sphincters constrict, and the paraurethral glands, which are homologous to the prostate, sometimes expel copious fluid similar to prostatic fluid (“female ejaculation”). Tachycardia and hyperventilation occur; the breasts enlarge still more and the areolae often become engorged; and in many women, a reddish, rashlike flush appears on the lower abdomen, chest, neck, and face.

Resolution

During resolution, the uterus drops forward to its resting position. The orgasmic platform quickly relaxes, while the inner end of the vagina returns more slowly to its normal dimensions. The flush disappears quickly and the areolae and nipples undergo rapid detumescence, but it may take 5 to 10 minutes for the breasts to return to their normal size. In many women (and men), there is a postorgasmic outbreak of perspiration. Unlike men, women do not have a refractory period and may quickly experience additional orgasms.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

14. What are the female sources of lubrication in coitus?
15. What female tissues and organs become vasocongested?
16. Describe the actions of the uterus throughout the sexual response cycle.

28.5 Pregnancy and Childbirth

Objectives

When you have completed this section, you should be able to

- list the major hormones that regulate pregnancy and explain their roles;
- describe a woman’s bodily adaptations to pregnancy;
- identify the physical and chemical stimuli that increase uterine contractility in late pregnancy;
- describe the mechanism of labor contractions;
- name and describe the three stages of labor; and
- describe the physiological changes that occur in a woman during the weeks following childbirth.

This section treats pregnancy from the maternal standpoint—that is, adjustments of the woman’s body to pregnancy and the mechanism of childbirth. Development of the fetus is described in chapter 29.

Gestation (pregnancy) lasts an average of 266 days from conception to childbirth, but the gestational calendar is usually measured from the first day of the woman’s last menstrual period (LMP). Thus the birth is predicted to occur 280 days (40 weeks) from the LMP. The duration of pregnancy, called its *term*, is commonly described in 3-month intervals called **trimesters**.

Prenatal Development

A few fundamental facts of fetal development must be introduced as a foundation for understanding maternal physiology. All the products of conception—the embryo or fetus as well as the placenta and membranes associated with it—are collectively called the **conceptus**. The developing individual is a hollow ball called a *blastocyst* for much of the first 2 weeks, an *embryo* from day 16 through week 8, and a *fetus* from the beginning of week 9 until birth. The fetus is attached by way of an *umbilical cord* to a disc-shaped *placenta* on the uterine wall. The placenta provides fetal nutrition and waste disposal, and secretes hormones that regulate pregnancy, mammary development, and fetal development. For the first 6 weeks after birth, the infant is called a *neonate*.³⁷

Hormones of Pregnancy

The hormones with the strongest influences on pregnancy are estrogens, progesterone, human chorionic gonadotropin, and human chorionic somatomammotropin. These are secreted primarily by the placenta, but the corpus luteum is an important source of hormones in the first several weeks. If the corpus luteum is removed before week 7, abortion almost always occurs. From weeks 7 to 17, the corpus luteum degenerates and the placenta takes over its endocrine functions.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (HCG) is secreted by the blastocyst and placenta. Its presence in the urine is the basis of pregnancy tests and can be detected with home testing kits as early as 8 or 9 days after conception. HCG secretion peaks around 10 to 12 weeks and then falls to a relatively low level for the rest of gestation (fig. 28.18). Like LH, it stimulates growth of the corpus luteum, which doubles in size and secretes increasing amounts of progesterone and estrogen. Without HCG, the corpus luteum would atrophy and the uterus would expel the conceptus.

³⁷*neo* = new + *nate* = born, birth

FIGURE 28.18 Hormone Levels over the Course of Pregnancy.

● How does the changing ratio of estradiol to progesterone relate to labor contractions?

Estrogens

Estrogen secretion increases to about 30 times the usual amount by the end of gestation. The corpus luteum is an important source of estrogen for the first 12 weeks; after that, it comes mainly from the placenta. The adrenal glands of the mother and fetus secrete androgens, which the placenta converts to estrogens. The most abundant estrogen of pregnancy is estriol, but its effects are relatively weak; estradiol is less abundant but accounts for most of the estrogenic effects in pregnancy.

Estrogen stimulates tissue growth in the fetus and mother. It causes the mother's uterus and external genitalia to enlarge, the mammary ducts to grow, and the breasts to increase to nearly twice their former size. It makes the pubic symphysis more elastic and the sacroiliac joints more limber, so the pelvis widens during pregnancy and the pelvic outlet expands during childbirth.

Progesterone

The placenta secretes a great deal of progesterone, and early in the pregnancy, so does the corpus luteum. Progesterone and estrogen suppress pituitary secretion of FSH and LH, thereby preventing more follicles from developing during pregnancy. (This is the basis for contraceptive pills and implants; see Insight 28.4, p. 1108.) Progesterone also suppresses uterine contractions so the conceptus is not prematurely expelled. It prevents menstruation and promotes the proliferation of *decidual cells* of the endometrium, on which the blastocyst feeds. Once estrogen has stimulated growth of the mammary ducts, progesterone stimulates development of the secretory acini—another step toward lactation.

Human Chorionic Somatomammotropin

The amount of **human chorionic somatomammotropin (HCS)** secreted in pregnancy is several times that of all the other hormones combined, yet its function is the least understood. The placenta begins secreting HCS around the fifth week and HCS output increases steadily from then until term, in direct proportion to the size of the placenta.

HCS is sometimes called *human placental lactogen* because, in other mammals, it causes mammary development and lactation; however, it does not induce lactation in humans. Its effects seem similar to those of growth hormone, but weaker. It also seems to reduce the mother's insulin sensitivity and glucose usage such that the mother consumes less glucose and leaves more of it for use by the fetus. HCS promotes the release of free fatty acids from the mother's adipose tissue, providing an alternative energy substrate for her cells to use in lieu of glucose.

Other Hormones

Many other hormones induce additional bodily changes in pregnancy (table 28.2). A woman's pituitary gland grows about 50% larger during pregnancy and produces markedly elevated levels of thyrotropin, prolactin, and ACTH. The thyroid gland also becomes about 50% larger under the influence of HCG, pituitary thyrotropin, and *human chorionic thyrotropin* from the placenta. Elevated thyroid hormone secretion increases the metabolic rate of the mother and fetus. The parathyroid glands enlarge and stimulate osteoclast activity, liberating calcium from the mother's bones for fetal use. ACTH stimulates glucocorticoid secretion, which may serve primarily to mobilize amino acids for fetal protein synthesis. Aldosterone secretion rises and promotes fluid retention, contributing to the mother's increased blood volume. The corpus luteum and placenta secrete *relaxin*, which relaxes the pubic symphysis in other animals but does not seem to have this effect in humans. In humans, it synergizes progesterone in stimulating the multiplication of decidual cells in early pregnancy and promotes the growth of blood vessels in the pregnant uterus.

Adjustments to Pregnancy

Pregnancy places considerable stress on a woman's body and requires adjustments in nearly all the organ systems. A few of the major adjustments and effects of pregnancy are described here.

Digestive System, Nutrition, and Metabolism

For many women, one of the first signs of pregnancy is **morning sickness**—nausea, especially after rising from bed—in the first few months of gestation. The cause of morning sickness is unknown. One hypothesis is that it

TABLE 28.2 The Hormones of Pregnancy

Hormone	Effects
Human chorionic gonadotropin (HCG)	Prevents involution of corpus luteum and stimulates its growth and secretory activity; basis of pregnancy tests
Estrogens	Stimulate maternal and fetal tissue growth, including enlargement of uterus and maternal genitalia; stimulate development of mammary ducts; soften pubic symphysis and sacroiliac joints, facilitating pelvic expansion in pregnancy and childbirth; suppress FSH and LH secretion
Progesterone	Suppresses premature uterine contractions; prevents menstruation; stimulates proliferation of decidual cells, which nourish embryo; stimulates development of mammary acini; suppresses FSH and LH secretion
Human chorionic somatomammotropin (HCS)	Weak growth-stimulating effects similar to growth hormone; glucose-sparing effect on mother, making glucose more available to fetus; mobilization of fatty acids as maternal fuel
Pituitary thyrotropin	Stimulates thyroid activity and metabolic rate
Human chorionic thyrotropin	Same effect as pituitary thyrotropin
Parathyroid hormone	Stimulates osteoclasts and mobilizes maternal calcium for fetal use
Adrenocorticotrophic hormone	Stimulates glucocorticoid secretion; thought to mobilize amino acids for fetal protein synthesis
Aldosterone	Causes fluid retention, contributing to increased maternal blood volume
Relaxin	Promotes development of decidual cells and blood vessels in the pregnant uterus

stems from the reduced intestinal motility caused by the steroids of pregnancy. Another is that it is an evolutionary adaptation to protect the fetus from toxins. The fetus is most vulnerable to toxins at the same time that morning sickness peaks. Women with morning sickness tend to prefer bland foods and to avoid spicy and pungent foods, which are highest in compounds that might be toxic to the fetus. In some women, the nausea progresses to vomiting. Occasionally, this is severe enough to require hospitalization (see *hyperemesis gravidarum* in table 28.5).

Constipation and heartburn are common in pregnancy. The former is another result of reduced intestinal motility. The latter is due to the enlarging uterus pressing upward on the stomach, causing the reflux of gastric contents into the esophagus.

The basal metabolic rate rises about 15% in the second half of gestation. Pregnant women often feel overheated because of this and the effort of carrying the extra weight. The appetite may be strongly stimulated, but a pregnant woman needs only 300 extra kcal/day even in the last trimester. Some women overeat, however, and gain as much as 34 kg (75 lb) of weight compared with a healthy average of 11 kg (24 lb). Maternal nutrition should emphasize the quality of food eaten, not quantity.

During the last trimester, the fetus needs more nutrients than the mother's digestive tract can absorb. In preparation for this, the placenta stores nutrients early in gestation and releases them in the final trimester. The demand is especially high for protein, iron, calcium, and phosphates. A pregnant woman needs an extra 600 mg of iron for her own hemopoiesis and 375 mg for the fetus. She is likely to become anemic if she does not ingest enough iron during late pregnancy. Supplemental vitamin K is

often given late in pregnancy to promote prothrombin synthesis in the fetus. In the United States, newborns are routinely given an injection of vitamin K to minimize the risk of neonatal hemorrhage, especially in the brain, caused by the stresses of birth. A vitamin D supplement helps to ensure adequate calcium absorption to meet fetal demands. Supplemental folic acid reduces the risk of neurological disorders in the fetus, such as spina bifida and anencephaly (failure of the cerebrum, cerebellum, and calvaria to develop), but it is effective only if taken habitually prior to conception (see Insight 13.1, p. 485).

Circulatory System

By full term, the placenta requires about 625 mL/min of blood from the mother. The mother's blood volume rises about 30% during pregnancy because of fluid retention and hemopoiesis; she eventually has about 1 to 2 L of extra blood. Cardiac output rises about 30% to 40% above normal by 27 weeks, but for unknown reasons, it falls almost to normal in the last 8 weeks. As the pregnant uterus puts pressure on the large pelvic blood vessels, it interferes with venous return from the legs and pelvic region. This can result in hemorrhoids, varicose veins, and edema of the feet.

Respiratory System

Over the course of the pregnancy, respiratory rate remains constant but the tidal volume and minute ventilation increase about 40%. There are two reasons for this: (1) The oxygen demand rises in proportion to the woman's increased metabolic rate and the increasing needs of the fetus. (2) Progesterone increases the sensitivity of the

woman's respiratory chemoreceptors to carbon dioxide, and ventilation is adjusted to keep her arterial P_{CO_2} lower than normal. Low maternal P_{CO_2} promotes the diffusion of CO_2 from the fetal bloodstream through the placenta and into the maternal blood. As pregnancy progresses, many women feel an increasing "air hunger" (dyspnea) and make more conscious efforts to breathe. This sensation apparently stems from her increased CO_2 sensitivity and, late in pregnancy, pressure on the diaphragm from the growing uterus. In the last month, however, the pelvis usually expands enough for the fetus to drop lower in the abdominopelvic cavity, taking some pressure off the diaphragm and allowing the woman to breathe more easily.

Urinary System

Aldosterone and the steroids of pregnancy promote water and salt retention by the kidneys. Nevertheless, the glomerular filtration rate increases by 50% and urine output is slightly elevated. This enables a woman to dispose of both her own and the fetus's metabolic wastes. As the pregnant uterus compresses the bladder and reduces its capacity, urination becomes more frequent and some women experience uncontrollable leakage of urine (incontinence).

Integumentary System

The skin grows to accommodate expansion of the abdomen and breasts and the added fat deposition in the hips and thighs. Stretching of the dermis often tears the connective tissue and causes *striae*, or *stretch marks*. These appear reddish at first but fade after pregnancy. Melanocyte activity increases in some areas and darkens the areolae and linea alba. The latter often becomes a dark line, the **linea nigra**³⁸ (LIN-ee-uh NY-gruh), from the umbilical to the pubic region. Some women also acquire a temporary blotchy darkening of the skin over the nose and cheeks called the "mask of pregnancy," or **chloasma**³⁹ (clo-AZ-muh), which usually disappears when the pregnancy is over.

Uterine Growth and Weight Gain

The uterus weighs about 50 g when a woman is not pregnant and about 900 g by the end of pregnancy. Its growth is monitored by palpating the fundus, which eventually reaches almost to the xiphoid process (fig. 28.19). Table 28.3 shows the sources of weight gain in a typical healthy pregnancy.

³⁸linea = line + nigra = black
³⁹chlo = green + asma = to be

FIGURE 28.19 The Full-Term Fetus in Vertex Position. Note the displacement and compression of the abdominal viscera.

TABLE 28.3 Distribution of Weight Gain in Pregnancy

Fetus	3 kg (7 lb)
Placenta, fetal membranes, and amniotic fluid	1.8 kg (4 lb)
Blood and tissue fluid	2.7 kg (6 lb)
Fat	1.4 kg (3 lb)
Uterus	0.9 kg (2 lb)
Breasts	0.9 kg (2 lb)
Total	11 kg (24 lb)

Childbirth

In the seventh month of gestation, the fetus normally turns into a head-down *vertex position*. Consequently, most babies are born head first, the head acting as a wedge that widens the mother's cervix, vagina, and vulva during birth. The ancients thought that the fetus kicked against the uterus and pushed itself out head first. The fetus, however, is a rather passive player in its own birth; its expulsion is achieved only by the contractions of the mother's uterine and abdominal muscles. Yet there is evidence that the fetus may play some role in its birth by chemically stimulating labor contractions and perhaps even sending chemical messages that signify when it is developed enough to be born.

Uterine Contractility

Over the course of gestation, the uterus exhibits relatively weak **Braxton Hicks⁴⁰ contractions**. These become stronger in late pregnancy and often send women rushing to the hospital with "false labor." At term, however, these contractions transform suddenly into the more powerful **labor contractions**. True labor contractions mark the onset of **parturition** (PAR-too-RISH-un), the process of giving birth.

Progesterone and estrogen (estradiol) balance may be one factor in this pattern of increasing contractility. Both hormone levels increase over the course of gestation. Progesterone inhibits uterine contractions, but its secretion levels off or declines slightly after 6 months, while estradiol secretion continues to rise (fig. 28.18). Estradiol stimulates uterine contractions and may be a factor in the irritability of the uterus in late pregnancy.

Also, as the pregnancy nears full term, the posterior pituitary releases more oxytocin (OT) and the uterine muscle equips itself with more OT receptors. Oxytocin promotes labor in two ways: (1) it directly stimulates muscle of the myometrium; and (2) it stimu-

lates the fetal membranes to secrete prostaglandins, which are synergists of OT in producing labor contractions. Labor is prolonged if OT or prostaglandins are lacking, and it may be induced or accelerated by giving a vaginal prostaglandin suppository or an intravenous OT "drip."

The conceptus itself may produce chemical stimuli promoting its own birth. Fetal cortisol secretion rises in late pregnancy and may enhance estrogen secretion by the placenta. The fetal pituitary gland also produces oxytocin, which does not enter the maternal circulation but may stimulate the fetal membranes to secrete prostaglandins.

Uterine stretching is also thought to play a role in initiating labor. Stretching any smooth muscle increases its contractility, and movements of the fetus produce the sort of intermittent stretch that is especially stimulatory to the myometrium. Twins are born an average of 19 days earlier than solitary infants, probably because of the greater stretching of the uterus. When a fetus is in the vertex position, its head pushes against the cervix, which is especially sensitive to stretch.

Labor Contractions

Labor contractions begin about 30 minutes apart. As labor progresses, they become more intense and eventually occur every 1 to 3 minutes. It is important that they be intermittent rather than one long, continual contraction. Each contraction sharply reduces maternal blood flow to the placenta, so the uterus must periodically relax to restore flow and oxygen delivery to the fetus. Contractions are strongest in the fundus and body of the uterus and weaker near the cervix, thus pushing the fetus downward.

According to the **positive feedback theory of labor**, labor contractions are induced by stretching of the cervix. This triggers a reflex contraction of the uterine body that pushes the fetus downward and stretches the cervix still more. Thus there is a self-amplifying cycle of stretch and contraction. In addition, cervical stretching induces a neuroendocrine reflex through the spinal cord, hypothalamus, and posterior pituitary. The posterior pituitary releases oxytocin, which is carried in the blood and stimulates the uterine muscle both directly and through the action of prostaglandins. This, too, is a positive feedback cycle: cervical stretching → oxytocin secretion → uterine contraction → cervical stretching (see fig. 1.12, p. 19).

As labor progresses, a woman feels a growing urge to "bear down." A reflex arc extends from the uterus to the spinal cord and back to the skeletal muscles of the abdomen. Contraction of these muscles—partly reflexive and partly voluntary—aids in expelling the fetus, especially when combined with the Valsalva maneuver for increasing intra-abdominal pressure.

⁴⁰John Braxton Hicks (1823–97), British gynecologist

The pain of labor is due at first mainly to ischemia of the myometrium—muscle hurts when deprived of blood, and each labor contraction temporarily restricts uterine circulation. As the fetus enters the vaginal canal, the pain becomes stronger because of stretching of the cervix, vagina, and perineum and sometimes the tearing of vaginal tissue. At this stage, the obstetrician may perform an *episiotomy*—an incision in the vulva to widen the vaginal orifice and prevent random tearing. The pain of human childbirth, compared with the relative ease with which other mammals give birth, is an evolutionary product of two factors: the unusually large brain and head of the human infant, and the narrowing of the pelvic outlet, which helped to adapt hominids to bipedal locomotion (see p. 12).

Stages of Labor

Labor occurs in three stages. The duration of each stage tends to be longer in a **primipara**⁴¹ (a woman giving birth for the first time) than in a **multipara**⁴² (a woman who has previously given birth).

- Dilation (first) stage.** This is the longest stage, lasting 8 to 24 hours in a primipara but as little as a few minutes in a multipara. It is marked by the **dilation** (widening) of the cervical canal and **effacement** (thinning) of the cervix (fig. 28.20a, b). The cervix reaches a maximum diameter of about 10 cm (the diameter of the baby's head). During dilation, the fetal membranes usually rupture and the *amniotic fluid* is discharged (the “breaking of the waters”).
- Expulsion (second) stage.** This stage typically lasts about 30 to 60 minutes in a primipara and as little as 1 minute in a multipara. It begins when the baby's head enters the vagina and lasts until the baby is entirely expelled (fig. 28.20c). The baby is said to be **crowning** when the top of its head is visible, stretching the vulva (fig. 28.21a). Delivery of the head is the most difficult part, with the rest of the body following much more easily. An episiotomy may be performed during this stage. An attendant often uses a suction bulb to remove mucus from the baby's mouth and nose even before it is fully delivered. When the baby is fully expelled, an attendant drains the blood of the placental vein into the baby, clamps the umbilical cord in two places, and cuts the cord between the clamps.
- Placental (third) stage.** The uterus continues to contract after expulsion of the baby. The placenta, however, is a nonmuscular organ that cannot contract, so it buckles away from the uterine wall

(fig. 28.20d). About 350 mL of blood is typically lost at this stage, but contractions of the myometrium compress the blood vessels and prevent more extensive bleeding. The placenta, amnion, and other fetal membranes are expelled by uterine contractions, which may be aided by a gentle pull on the umbilical cord. The membranes (*afterbirth*) must be carefully inspected to be sure everything has been expelled (fig. 28.21c). If any of these structures remain in the uterus, they can cause postpartum hemorrhaging. The umbilical blood vessels are counted because an abnormal number in the cord may indicate cardiovascular abnormalities in the infant.

The Puerperium

The first 6 weeks **postpartum** (after birth) are called the **puerperium**⁴³ (PYU-er-PEER-ee-um), a period in which the mother's anatomy and physiology stabilize and the reproductive organs return nearly to the pregravid state (their condition prior to pregnancy). The shrinkage of the uterus during this period is called **involution**. In a lactating woman, it loses about 50% of its weight in the first week and is nearly at its pregravid weight in 4 weeks. Involution is achieved by **autolysis** (self-digestion) of uterine cells by their own lysosomal enzymes. For about 10 days, this produces a vaginal discharge called **lochia**, which is bloody at first and then turns clear and serous. Breast-feeding promotes involution because (1) it suppresses estrogen secretion, which would otherwise cause the uterus to remain more flaccid; and (2) it stimulates oxytocin secretion, which causes the myometrium to contract and firm up the uterus sooner. It is important for the puerperium to be undisturbed, as emotional upset can inhibit lactation in some women.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- List the roles of HCG, estrogen, progesterone, and HCS in pregnancy.
- What is the role of the corpus luteum in pregnancy? What eventually takes over this role?
- List and briefly explain the special nutritional requirements of pregnancy.
- How much weight does the average woman gain in pregnancy? What contributes to this weight gain other than the fetus?
- Describe the positive feedback theory of labor.
- What major events define the three stages of labor?

⁴¹primi = first + para = birth

⁴²multi = many + para = births

⁴³puer = child + per (from par) = birth

FIGURE 28.20 The Stages of Childbirth.

28.6 Lactation

Objectives

When you have completed this section, you should be able to

- describe development of the breasts in pregnancy;
- describe the shifting hormonal balance that regulates the onset and continuation of lactation;
- describe the mechanism of milk ejection;
- contrast colostrum with breast milk; and
- discuss the benefits of breast-feeding.

Lactation is the synthesis and ejection of milk from the mammary glands. It lasts for as little as a week postpartum in women who do not breast-feed their infants, but it can continue for many years as long as the breast is stimulated by a nursing infant or mechanical device (breast pump). Numerous studies conducted before the widespread marketing of artificial infant formulas suggest that worldwide, women traditionally nursed their infants until a median age of about 2.8 years.

Development of the Mammary Glands in Pregnancy

The high estrogen level in pregnancy causes the ducts of the mammary glands to grow and branch extensively. Growth hormone, insulin, glucocorticoids, and prolactin also contribute to this development. Once the ducts are complete, progesterone stimulates the budding and development of acini at the ends of the ducts. The fully developed mammary gland is of the compound tubuloacinar type. The acini are organized into grapelike clusters (lobules) within each lobe of the breast (see fig. 28.9).

Colostrum and Milk Synthesis

In late pregnancy, the mammary acini and ducts are distended with a secretion called **colostrum**. This is similar to breast milk in protein and lactose content but contains about one-third less fat. It is the infant's only natural source of nutrition for the first 1 to 3 days postpartum. Colostrum has a thin watery consistency and a cloudy yellowish color. The amount of colostrum secreted per day is at most 1% of the amount of milk secreted later, but since infants are born with excess body water and ample fat, they do not require high calorie or fluid intake at first. A major benefit of colostrum is that it contains immunoglobulins, especially IgA. IgA resists digestion and may protect the infant from gastroenteritis. It is also thought to be pinocytosed by the small intestine and to confer wider, systemic immunity to the neonate.

Milk synthesis is promoted by prolactin, a hormone of the anterior pituitary gland. In the nonpregnant state, dopamine (prolactin-inhibiting hormone) from the hypothalamus inhibits prolactin secretion. Prolactin secretion begins 5 weeks into the pregnancy, and by full term it is 10 to 20 times its normal level. Even so, prolactin has little effect on the mammary glands until after birth. While the steroids of pregnancy prepare the mammary glands for lactation, they antagonize prolactin and suppress milk synthesis. When the placenta is discharged at birth, the steroid levels abruptly drop and allow prolactin to have a stronger effect. Milk is synthesized in increasing quantity over the following week. Milk synthesis also requires the action of growth hormone, cortisol, insulin, and parathyroid hormone to mobilize the necessary amino acids, fatty acids, glucose, and calcium.

At the time of birth, baseline prolactin secretion drops to the nonpregnant level. Every time the infant nurses, however, it jumps to 10 to 20 times this level for the next hour and stimulates the synthesis of milk for the next feeding (fig. 28.22). These prolactin surges are accompanied by smaller increases in estrogen and progesterone secretion. If the mother does not nurse or these hormone surges are absent (due to pituitary damage, for example), the mammary glands stop producing milk in about a week. Even if she does nurse, milk production declines after 7 to 9 months.

Only 5% to 10% of women become pregnant again while breast-feeding. Apparently, either prolactin or nerve signals from the breast inhibit GnRH secretion, which, in turn, results in reduced gonadotropin secretion and ovarian cycling. This mechanism may have evolved

FIGURE 28.22 Prolactin Secretion in the Lactating Female. Each time the infant nurses, maternal prolactin secretion surges. This prolactin stimulates synthesis of the milk that will be available at the next feeding.

as a natural means of spacing births, but breast-feeding is not a reliable means of contraception. Even in women who breast-feed, the ovarian cycle sometimes resumes several months postpartum. In those who do not breast-feed, the cycles resume in a few weeks, but for the first 6 months they are usually anovulatory.

Milk Ejection

Milk is continually secreted into the mammary acini, but it does not easily flow into the ducts. Its flow, called **milk ejection (letdown)**, is controlled by a neuroendocrine reflex. The infant's suckling stimulates nerve endings of the nipple and areola, which in turn signal the hypothalamus and posterior pituitary to release oxytocin. Oxytocin stimulates **myoepithelial cells**, which form a basketlike mesh around each gland acinus (see fig. 28.9d). These cells are of epithelial origin, but are packed with actin and contract like smooth muscle to squeeze milk from the acinus into the duct. The infant does not get any milk for the first 30 to 60 seconds of suckling, but milk soon fills the ducts and lactiferous sinuses and is then easily sucked out.

Think About It

When a woman is nursing her baby at one breast, would you expect only that breast, or both breasts, to eject milk? Explain why.

Breast Milk

Table 28.4 compares the composition of colostrum, human milk, and cow's milk. Breast milk changes composition over the first 2 weeks, varies from one time of day to another, and changes even during the course of a single feeding. For example, at the end of a feeding there is less lactose and protein in the milk, but six times as much fat, as there is at the beginning.

Nutrient	Human Colostrum	Human Milk	Cow's Milk
Total protein (g/L)	22.9	10.6	30.9
Lactalbumin (g/L)	—	3.7	25.0
Casein (g/L)	—	3.6	2.3
Immunoglobulins (g/L)	19.4	0.09	0.8
Fat (g/L)	29.5	45.4	38.0
Lactose (g/L)	57	71	47
Calcium (mg/L)	481	344	1370
Phosphorus (mg/L)	157	141	910

*Colostrum data are for the first day postpartum, and human milk data are for "mature milk" at about 15 days postpartum.

Cow's milk is not a good substitute for human milk. It has one-third less lactose but three to five times as much protein and minerals. The excess protein forms a harder curd in the infant's stomach, so cow's milk is not digested and absorbed as efficiently as mother's milk. It also increases the infant's nitrogenous waste excretion, which increases the incidence and severity of diaper rash, particularly as bacteria in the diaper break urea down to ammonia, a skin irritant.

Colostrum and milk have a laxative effect that helps to clear the neonatal intestine of *meconium*, a greenish black, sticky fecal matter composed of bile, epithelial cells, and other wastes that accumulated during fetal development. By clearing bile and bilirubin from the body, breast-feeding also reduces the incidence and degree of jaundice in neonates. Breast milk promotes colonization of the neonatal intestine with beneficial bacteria and continues to supply antibodies that lend protection against infection by pathogenic bacteria. Breast-feeding also tends to promote a closer bond between mother and infant.

A woman nursing one baby eventually produces about 1.5 L of milk per day; women with twins produce more. Lactation places a great metabolic demand on the mother. It is equivalent to losing 50 g of fat, 100 g of lactose (made from her blood glucose), and 2 to 3 g of calcium phosphate per day. A woman is at greater risk of bone loss when breast-feeding than when she is pregnant, because much of the infant's skeleton is still cartilage at birth and becomes mineralized at her expense in the first year postpartum. If a nursing mother does not have enough calcium and vitamin D in her own diet, lactation stimulates parathyroid hormone secretion and osteoclast activity, taking calcium from her bones to supply her baby.

To conclude this chapter, table 28.5 briefly describes some of the common disorders of pregnancy. Other reproductive disorders are discussed elsewhere: cervical cancer in Insight 28.1, breast cancer on page 1085, and sexually transmitted diseases at the end of chapter 27.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Why is little or no milk secreted while a woman is pregnant?
- How does a lactating breast differ from a nonlactating breast in structure? What stimulates these differences to develop during pregnancy?
- What is colostrum and what is its significance?
- How does suckling stimulate milk ejection?
- Why is breast milk superior to cow's milk for an infant?

TABLE 28.5 Some Disorders of Pregnancy

Abruptio placentae ⁴⁴	Premature separation of the placenta from the uterine wall, often associated with preeclampsia or cocaine use. May require birth by cesarean section.
Ectopic ⁴⁵ pregnancy	Implantation of the conceptus anywhere other than the uterus; usually in the uterine tube (tubal pregnancy) but occasionally in the abdominopelvic cavity. See Insight 29.2 for further details.
Gestational diabetes	A form of diabetes mellitus that develops in about 1% to 3% of pregnant women, characterized by insulin insensitivity, hyperglycemia, glycosuria, and a risk of excessive fetal size and birth trauma. Glucose metabolism often returns to normal after delivery of the infant, but 40% to 60% of women with gestational diabetes develop diabetes mellitus within 15 years after the pregnancy.
Hyperemesis gravidarum ⁴⁶	Severe vomiting, dehydration, alkalosis, and weight loss in early pregnancy, often requiring hospitalization to stabilize fluid, electrolyte, and acid-base balance; sometimes associated with liver damage.
Placenta previa ⁴⁷	Blockage of the cervical canal by the placenta, preventing birth of the infant before the placenta separates from the uterus. Requires birth by cesarean section.
Preeclampsia ⁴⁸	Gestational hypertension and proteinuria, often with edema of the face and hands, occurring especially in the third trimester in primiparas. Correlated with abnormal development of placental arteries, ultimately leading to widespread thrombosis and organ dysfunction in the mother. Occurs in 5% to 8% of pregnancies. Sometimes progresses to <i>eclampsia</i> (seizures), which may be fatal to the mother, fetus, or both. <i>Eclampsia</i> may occur <i>postpartum</i> .
Spontaneous abortion	Occurs in 10% to 15% of pregnancies, usually because of fetal deformities or chromosomal abnormalities incompatible with survival, but may also result from maternal abnormalities, infectious disease, and drug abuse.

⁴⁴*ab* = away + *rupt* = to tear + *placentae* = of the placenta⁴⁵*ec* = out of + *top* = place⁴⁶*hyper* = excessive + *emesis* = vomiting + *gravid* = pregnant woman⁴⁷*pre* = before + *via* = the way (obstructing the way)⁴⁸*ec* = forth + *lampsia* = shining**INSIGHT 28.4** Clinical Application**Methods of Contraception**

The term *contraception* is used here to mean any procedure or device intended to prevent pregnancy (the presence of an implanted conceptus in the uterus). This essay describes the most common methods of contraception, some issues involved in choosing among them, and the relative reliability of the various methods. Several of those options are shown in figure 28.23.

Behavioral Methods

Abstinence (refraining from intercourse) is, obviously, a completely reliable method if used consistently. The *rhythm method* (periodic abstinence) is based on avoiding intercourse near the time of expected ovulation. Among typical users, it has a 25% failure rate, partly due to lack of restraint and partly because it is difficult to predict the exact date of ovulation. Intercourse must be avoided for at least 7 days before ovulation so there will be no surviving sperm in the reproductive tract when the egg is ovulated, and for at least 2 days after ovulation so there will be no fertile egg present when sperm are introduced. The rhythm method is valuable, however, for couples who are trying to conceive a child by having intercourse at the time of apparent ovulation.

Withdrawal (*coitus interruptus*) requires the male to withdraw the penis before ejaculation. This often fails because of lack of willpower, because some sperm are present in the

preejaculatory fluid, and because sperm ejaculated anywhere in the female genital region can potentially get into the reproductive tract.

Barrier and Spermicidal Methods

Barrier methods are designed to prevent sperm from getting into or beyond the vagina. They are most effective when used with chemical *spermicides*, available as nonprescription foams, creams, and jellies.

The *male condom* is a sheath of latex, rubber, or animal membrane (lamb intestine) that is unrolled over the erect penis and collects the semen. It is inexpensive, convenient, and very reliable when used carefully. About 25% of American couples who use contraceptives use only condoms, which rank second to birth-control pills in popularity.

The *female condom* is less used. It is a polyurethane sheath with a flexible ring at each end. The inner ring fits over the cervix and the outer ring covers the external genitalia. Male and female condoms are the only contraceptives that also protect against disease transmission. Animal membrane condoms, however, are porous to HIV and hepatitis B viruses and do not afford dependable protection from disease.

The *diaphragm* is a latex or rubber dome that is placed over the cervix to block sperm migration. It requires a physical examination and prescription to ensure proper fit, but is otherwise comparable to the condom in convenience and reliability, provided it is used with a spermicide. Without a spermicide, it is not very effective.

Male condom

Female condom

Diaphragm with contraceptive jelly

Contraceptive foam with vaginal applicator

Birth-control pills

NuvaRing

Intrauterine device (IUD)

FIGURE 28.23 Contraceptive Devices.

The *sponge* is a foam disc inserted before intercourse to cover the cervix. It is impregnated with a spermicide and acts by trapping and killing the sperm. It requires no prescription or fitting. The sponge provides protection for up to 24 hours, and must be left in place for 6 hours after the last act of intercourse.

Contraceptive sponges and other barrier methods date to antiquity. Ancient Egyptians and Greeks used vaginal sponges soaked in lemon juice, which had a mild spermicidal effect. Some Egyptian women used vaginal suppositories made of crocodile dung and honey.

Hormonal Methods

Most hormonal methods of contraception are aimed at preventing ovulation. Efforts to develop a hormonal contraceptive for men have so far been unsuccessful, but are continuing. In women, hormonal contraceptives mimic the negative feedback effect of ovarian hormones, inhibiting FSH and LH secretion so follicles do not mature. For most women, they are highly effective and present minimal complications. Their differences lie largely in method of application and convenience of use and, to some extent in reliability and risk of complications.

The oldest and still the most widely used hormonal method in the United States is the *combined oral contraceptive*, or *birth-control pill*, first approved for use in 1960. “The pill” is composed of estrogen and progestin (a synthetic progesterone-like hormone). It must be taken daily, at the same time of day, for 21 days each cycle. It comes in 28-day packets, marked day by day, with the last 7 pills being a sugar placebo just to keep the user in the habit of taking one every day. The 7-day withdrawal from hormones allows for menstruation. Side effects include an elevated risk of heart attack or stroke in smokers and in women with a history of diabetes, hypertension, or clotting disorders.

Other hormonal methods avoid the need to remember a daily pill. One option is a skin patch marketed as Ortho Evra in the United States, which releases estrogen and progestin transdermally. It is changed at 7-day intervals (three patches per month and 1 week without). The NuvaRing is a soft flexible vaginal ring that releases estrogen and progestin for absorption through the vaginal mucosa. It must be worn continually for 3 weeks and removed for the fourth week of each cycle. Reportedly, it cannot be felt even during intercourse, and there is hope that when more data are in, it will prove even more reliable than the pill. *Medroxyprogesterone* (trade name Depo-Provera) is a progestin administered by injection two to four

times per year. It provides highly reliable, long-term contraception, although in some women it causes headaches, nausea, or weight gain, and fertility may not return immediately when its use is discontinued.

Some drugs can be taken orally after intercourse to prevent implantation of a conceptus. These are called emergency contraceptive pills (ECPs), or “morning-after pills” (trade names Plan B, Levonelle). An ECP is a high dose of estrogen and progestin or a progestin alone. It can be taken within 72 hours after intercourse and induces menstruation within 2 weeks. ECPs work on several fronts: inhibiting ovulation; inhibiting sperm or egg transport in the uterine tube; or preventing implantation. They do not work if a blastocyst is already implanted. ECPs are available without a prescription in some states, but availability has been limited or delayed elsewhere by political controversy.

Mifepristone (Mifeprex, also known as RU-486) is a progesterone antagonist. It is used less as a contraceptive than as an *abortifacient*; in high doses, it induces abortion up to 2 months into pregnancy. But at a dose of 2 mg/day, it prevents ovulation like other steroidal contraceptives, and a single 10-mg dose can also be used as an emergency “morning-after” contraceptive if taken after intercourse but before ovulation.

The Intrauterine Device

The *intrauterine device (IUD)* is a springy plastic device inserted through the cervical canal into the uterus; it can be left in place for 5 to 12 years. It prevents the implantation of a blastocyst in the uterine wall. Some IUDs were removed from the market in the 1980s because they caused serious complications such as uterine perforation, and many other models were removed for fear of legal liability, but at least five models now on the market are deemed safe for long-term use and more effective than oral contraceptives.

Surgical Sterilization

People who are confident that they do not want more children (or any) often elect to be surgically sterilized. This entails the cutting and tying or clamping of the genital ducts, thus blocking the passage of sperm or eggs. Surgical sterilization has the advantage of convenience, since it requires no further attention. Its initial cost is higher, however, and for people who later change their minds, surgical reversal is much more expensive than the original procedure and is often unsuccessful. *Vasectomy* is the severing of the ductus (vas) deferens, done through a small incision in the scrotum. In *tubal ligation*,⁴⁹ the uterine tubes are cut.

⁴⁹*ligat* = to tie

This can be done through small abdominal incisions to admit a cutting instrument and laparoscope (viewing device).

Issues in Choosing a Contraceptive

Many issues enter into the appropriate choice of a contraceptive, including personal preference, pattern of sexual activity, medical history, religious views, convenience, initial and ongoing costs, and disease prevention. For most people, however, the two primary issues are safety and reliability.

The following table shows the expected rates of failure for several types of contraception as reported by the World Health Organization (WHO). Each column shows the number of sexually active women who typically become pregnant within 1 year while they or their partners are using the indicated contraceptives. The lowest rate (perfect use) is for those who use the method correctly and consistently, whereas the higher rate (typical use) is based on random surveys of users and takes human error (lapses and incorrect usage) into account.

We have not considered all the currently available methods of contraception or all the issues important to the choice of a contraceptive. No one contraceptive method can be recommended as best for all people. Further information necessary to a sound choice and proper use of contraceptives should be sought from a health department, college health service, physician, or other such sources.

Failure Rates of Contraceptive Methods

Method	Rate of Failure (Pregnancies per 100 Users)	
	Perfect Use	Typical Use
No protection	85	85
Rhythm method	3–5	25
Withdrawal	4	27
Spermicide alone	18	26
Condom alone (male or female)	2–5	15–21
Diaphragm with spermicide	6	16
Vaginal sponge	9–20	16–32
Birth-control pill, patch, or NuvaRing	0.3–0.5	8
Medroxyprogesterone	0.3	3
Intrauterine device	0.2–0.6	0.2–0.8
Vasectomy	0.10	0.15
Tubal ligation	0.5	0.5

CONNECTIVE ISSUES

Interactions Between the REPRODUCTIVE SYSTEM and Other Organ Systems

■ indicates ways in which this system affects other systems

■ indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

At puberty, androgens stimulate development of body hair and apocrine glands, and increased sebaceous secretion; estrogens stimulate fat deposition and breast development in females; pregnancy may cause pigmentation changes and stretch marks

Sensory stimulation of skin important to sexual arousal; mammary glands nourish infant

SKELETAL SYSTEM

Androgens and estrogens stimulate adolescent skeletal growth and maintain adult bone mass

Encloses and protects pelvic organs; provides minerals for fetal growth and lactation; narrow pelvic outlet makes childbirth difficult

MUSCULAR SYSTEM

Gonadal steroids stimulate muscle growth

Pelvic muscles support reproductive organs, aid in erection and orgasm; abdominal muscles aid in childbirth; cremaster helps to maintain temperature of testes

NERVOUS SYSTEM

Androgens stimulate libido; hormones from gonads and placenta exert negative feedback control on hypothalamus

Hypothalamus regulates gonadotropin secretion; libido and sexual behavior; labor contractions; and lactation

ENDOCRINE SYSTEM

Gonadal and placental hormones exert feedback control on anterior pituitary

Hormones regulate puberty, gametogenesis, libido, pregnancy, lactation, and climacteric

CIRCULATORY SYSTEM

Androgens stimulate erythropoiesis; estrogens may inhibit development of atherosclerosis in females; pregnancy increases blood volume and cause varicose veins

Changes in blood flow produce vasocongestion and erection in sexual arousal; blood distributes sex hormones, transports nutrients to fetus, and removes fetal wastes; pampiniform plexus prevents overheating of testes

LYMPHATIC/IMMUNE SYSTEM

Blood-testis barrier isolates sperm and protects them from immune system; zona pellucida does same in ovary

Immune cells protect reproductive organs; IgA in colostrum and milk confers passive immunity on neonate

RESPIRATORY SYSTEM

Sexual arousal increases pulmonary ventilation; pregnancy increases pulmonary ventilation

Provides O₂, removes CO₂; Valsalva maneuver aids childbirth

URINARY SYSTEM

Sexual arousal constricts internal urinary sphincter; prostatic hyperplasia may impede urine flow; pregnancy crowds urinary bladder and often causes incontinence

Disposes of maternal and fetal wastes; urethra serves as passageway for semen

DIGESTIVE SYSTEM

Fetus crowds digestive organs, contributing to heartburn and constipation

Provides nutrients for gametogenesis and fetal development

CHAPTER REVIEW

Review of Key Concepts

28.1 Reproductive Anatomy (p. 1078)

1. In the female fetus, the absence of testosterone and müllerian inhibiting factor results in the paramesonephric duct developing into the uterine tubes, uterus, and vagina and the external genitalia developing into a clitoris, labia minora, and labia majora.
2. The ovary has a central *medulla*, a surface layer of parenchyma called the *cortex*, and an outer fibrous capsule, the *tunica albuginea*. The ovary is supported by three ligaments and supplied by an ovarian artery, ovarian veins, and ovarian nerves.
3. Each egg develops in its own bubblelike *follicle*. Follicles are located primarily in the cortex.
4. The *uterine (fallopian) tube* is a ciliated duct that extends from the ovary to the uterus.
5. The uterus is a thick muscular chamber superior to the urinary bladder. It consists of an upper *fundus*, middle *corpus* (body), and lower *cervix* (neck), where it meets the vagina.
6. The uterine wall consists of an outer serosa called the *perimetrium*, a thick muscular *myometrium*, and an inner mucosa called the *endometrium*. The endometrium contains numerous tubular glands and is divided into two layers: a thick superficial *stratum functionalis*, which is shed in each menstrual period, and a thinner, deeper *stratum basalis*, which is retained from cycle to cycle.
7. The uterus is anchored by four pairs of ligaments and supplied with blood by a *uterine artery* that arises from each internal iliac artery.
8. The *vagina* tilts posteriorly between the urethra and rectum. It has no glands but is moistened by transudation of serous fluid through the vaginal wall and by mucus from glands in the cervical canal.
9. The *vulva* (pudendum or external genitalia) include the *mons pubis*, *labia majora* and *minora*, *clitoris*, vaginal orifice, accessory glands (*greater* and *lesser vestibular glands* and *paraurethral glands*) and erectile

tissues (*vestibular bulbs*). The urethra also opens into the vulva.

10. The breast is internally divided into lobes, each with a *lactiferous duct* that conveys milk to the nipple. Outside of pregnancy or lactation, the breast contains only small traces of mammary gland.
11. Breast cancer strikes a high percentage of women. Two breast cancer genes are known, although most cases are nonhereditary and have no association with identifiable risk factors.

28.2 Puberty and Menopause (p. 1088)

1. In the United States and Europe, female puberty typically begins around age 9 or 10. Rising GnRH levels trigger the secretion of FSH and LH. In response to FSH, the ovaries secrete estrogens, progesterone, inhibin, and androgens.
2. The earliest visible sign of puberty is breast development, or *thelarche*, which is stimulated by estrogen, progesterone, prolactin, glucocorticoids, and growth hormone.
3. *Pubarche* is the development of pubic and axillary hair, sebaceous glands, and axillary sweat glands. Androgens induce pubarche and activate the female libido.
4. *Menarche* is a girl's first menstrual period, occurring at an average age of 12 in the United States and Europe. The first few menstrual cycles are usually anovulatory; ovulation becomes regular about a year after menarche.
5. The estradiol of puberty induces development of the ovaries and secondary sex organs, has feminizing effects on the external anatomy, and stimulates bone growth. Progesterone acts primarily on the uterus, and inhibin modulates FSH secretion.
6. With age, the number of ovarian follicles declines and with it, the source of estrogen and progesterone. The decline in levels of steroids brings on a transitional period of *climacteric*, lasting a few years and marked by *menopause*, the eventual cessation of ovulation and menstruation.

28.3 Oogenesis and the Sexual Cycle (p. 1089)

1. The *sexual cycle* is the monthly cycle of events that occurs when a woman is not pregnant. It includes the *ovarian cycle* of events in the ovaries and the *menstrual cycle* of events in the uterus.
2. *Oogenesis* is the production of eggs. Unlike spermatogenesis, it occurs in a monthly rhythm and usually produces only one mature gamete (egg) per month.
3. Oogenesis begins with *oogonia*, which multiply until the fifth month of a girl's fetal development. Some of these develop into *primary oocytes* and begin meiosis I before birth. Most primary oocytes undergo *atresia* during fetal life and childhood, leaving about 400,000 at puberty.
4. Starting in adolescence, surviving primary oocytes undergo meiosis I to produce a small *first polar body*, which dies, and a *secondary oocyte*. The secondary oocyte progresses only as far as metaphase II if it is not fertilized. If fertilized, it completes meiosis II, producing a *second polar body*, which also dies, and an ovum that goes on to become the zygote.
5. *Folliculogenesis* is the development of ovarian follicles. The earliest follicle type is the *primordial follicle*—a primary oocyte surrounded by a single layer of squamous follicular cells. This progresses to a *primary follicle* when the follicular cells become cuboidal; a *secondary follicle* when they multiply and become stratified; and a *tertiary follicle* when pools of *follicular fluid* form and merge into a cavity called the *antrum*. Normally, one tertiary follicle each month becomes the *mature follicle* and ovulates.
6. In tertiary and mature follicles, the multilayered follicular cells are called *granulosa cells*. A mound of granulosa cells called the *cumulus oophorus* covers the egg and secures it to the follicle wall. The innermost

layer of cumulus cells is the *corona radiata*. It is separated from the egg by a gelatinous *zona pellucida*. The follicle is enclosed in a two-layered capsule, the *theca folliculi*.

7. The *ovarian cycle*, occurring in the absence of pregnancy, typically lasts about 28 days, with day 1 considered to be the first day of visible menstruation.
8. Soon after ovulation in one ovarian cycle, a new cohort of follicles begins to develop. One of these ovulates about 2 months later. In the *follicular phase* of the cycle in which ovulation will occur, FSH stimulates one follicle of the cohort to become a mature follicle, while the others undergo atresia.
9. The mature follicle ovulates around day 14, primarily under the influence of luteinizing hormone. After releasing its oocyte, it collapses and develops into a *corpus luteum*. The period from ovulation to the end of the cycle (days 15–28) is called the *luteal phase*. The corpus luteum secretes estradiol and progesterone, but in the absence of pregnancy it involutes from days 22 to 26 and is an inactive scar (*corpus albicans*) after day 26.
10. The menstrual cycle is divided into proliferative, secretory, premenstrual, and menstrual phases.
11. The *proliferative phase* (days 6–14) is a period of mitotically rebuilding the stratum functionalis lost in menstruation. It is driven by estrogen from the ovaries.
12. The *secretory phase* (days 15–26) is a period of thickening of the endometrium by secretion of mucus and glycogen under the influence of progesterone from the corpus luteum.
13. The *premenstrual phase* is a period triggered by involution of the corpus luteum and the resulting drop in progesterone secretion. Spasms of the spiral arteries deprive the endometrium of blood flow, resulting in necrosis and sloughing off of the stratum functionalis.
14. The *menstrual phase* begins when enough necrotic tissue and blood have accumulated to produce noticeable vaginal discharge of menstrual fluid.

28.4 Female Sexual Response (p. 1097)

1. Female sexual response occurs in stages similar to that of the male, with the following major differences: In the excitement phase, the labia

majora and minora, the clitoris, and the breasts become vasocongested; secretions of the greater vestibular glands lubricate the vulva; and the vagina is moistened by vaginal transudate. The inner end of the vagina dilates and its lower end constricts to form a narrow passage, the *orgasmic platform*. The uterus rises from its forward-tilted position to a nearly vertical one (the *tenting effect*).

2. In orgasm, the paraurethral glands secrete into the vulva, the orgasmic platform of the vagina constricts repeatedly, and the cervix plunges into the vaginal canal (into the semen if present).
3. In resolution, the uterus returns to its forward tilt, the orgasmic platform relaxes, the breasts become less congested, and there may be an outbreak of perspiration. Unlike men, women lack a refractory period and may experience successive orgasms.

28.5 Pregnancy and Childbirth (p. 1099)

1. *Gestation* lasts an average of 266 days from conception to birth, but birth is predicted to occur about 280 days from the onset of the last menstrual period.
2. All the products of fertilization—the embryo or fetus and the associated membranes—are called the *conceptus*.
3. *Human chorionic gonadotropin (HCG)* stimulates the corpus luteum to grow and secrete estrogen and progesterone.
4. Estrogen from the corpus luteum and later from the placenta stimulates tissue growth in the mother and fetus and softens joints of the mother's pelvic girdle in preparation for giving birth.
5. Progesterone from the corpus luteum and placenta inhibits premature uterine contractions and stimulates the mitosis of uterine *decidual cells* that nourish the early conceptus. Estrogen and progesterone also promote mammary gland development and inhibit the secretion of FSH.
6. *Human chorionic somatomotropin (HCS)* from the placenta mobilizes fatty acids as fuel for the mother while it spares glucose for use by the fetus.
7. Thyroid hormone, parathyroid hormone, glucocorticoids, aldosterone, and relaxin also contribute to the developments of pregnancy (table 28.2).
8. Morning sickness, constipation, and heartburn sometimes accompany pregnancy as steroid hormones inhibit intestinal motility and the growing uterus compresses the digestive organs. The basal metabolic rate rises and one may feel hot as a result. Nutrient intake must increase moderately to meet the needs of the fetus.
9. Blood volume and cardiac output increase in pregnancy. Pressure from the uterus may cause edema, hemorrhoids, or varicose veins.
10. Tidal volume and pulmonary ventilation increase in pregnancy as O₂ demand and CO₂ sensitivity increase, reducing the maternal Pco₂ and promoting diffusion of CO₂ from the fetal to maternal blood. Dyspnea is common but breathing becomes easier late in pregnancy when the fetus drops lower into the pelvic cavity.
11. Glomerular filtration and urine output increase to dispose of both fetal and maternal wastes, but the capacity of the bladder is reduced by pressure from the uterus.
12. The maternal skin grows, especially on the breasts and abdomen; dermal tearing may cause *striae*; and some women exhibit melanization of the skin on the abdomen (*linea nigra*) or face (*chloasma*).
13. In the seventh month, the fetus usually turns into the vertex (head-down) position.
14. Late in pregnancy, the uterus becomes more contractile, sometimes exhibiting *Braxton Hicks contractions* weeks before the true *labor contractions* occur. A rising ratio of estrogen to progesterone may be responsible for this increased contractility late in pregnancy. True labor contractions are stimulated by uterine stretching and oxytocin (OT).
15. According to the positive feedback theory of labor, stretching of the cervix triggers reflex contraction of the uterine body, which pushes the fetus downward and stretches the cervix still more. Cervical stretching also activates a neuroendocrine reflex that results in OT secretion, and OT stimulates more and more intense uterine contractions. The voluntary abdominal muscles also aid in giving birth.
16. The *dilation (first) stage* of labor involves dilation of the cervical canal to a diameter of 10 cm and thinning (*effacement*) of the cervical tissue.

The fetal membranes typically rupture and discharge the *amniotic fluid* during this stage.

17. The *expulsion (second) stage* begins when the baby's head enters the vagina and lasts until the baby is entirely discharged. An attendant usually drains, clamps, and cuts the umbilical cord at the end of this stage.
18. The *placental (third) stage* is the discharge of the placenta, amnion, and other components of the *afterbirth*. The afterbirth is inspected to be sure it has all been discharged and that it shows no abnormalities.
19. The *puerperium* is a period of 6 weeks postpartum marked by *involution* of the uterus and the return of other maternal anatomy and physiology to the pregravid state.

28.6 Lactation (p. 1106)

1. During pregnancy, estrogen, growth hormone, insulin, glucocorticoids, and prolactin stimulate growth and branching of the ducts of the mammary glands. Progesterone then stimulates the development of secretory acini at the ends of the ducts.
2. For 1 to 3 days postpartum, the mammary glands secrete a fluid called *colostrum* rather than milk. Colostrum is higher than milk in protein but lower in fat and lactose. It contains immunoglobulins that give the neonate some immunity to infection.
3. Prolactin is secreted during pregnancy but cannot stimulate milk synthesis until after the placenta is shed. The mammary glands begin releasing milk about 2 or 3 days postpartum.
4. The nursing infant stimulates neuroendocrine reflexes in which the pituitary gland secretes OT and prolactin. OT triggers contraction of *myoepithelial cells* of the acini, making milk flow down the lactiferous ducts to the nipple. Prolactin stimulates synthesis of the milk that will be used for the next feeding.
5. Breast milk changes composition over the first 2 weeks and varies at different times of day and over the course of a single feeding. Most lactose and protein are delivered to the infant at the beginning of a feeding, and most fat at the end.
6. A woman nursing one infant eventually produces about 1.5 L of milk per day at a cost of 50 g of fat, 100 g of lactose, and 2 or 3 g of calcium phosphate. Her diet must compensate for these demands.

Testing Your Recall

1. Of the following organs, the one(s) most comparable to the penis in structure is (are)
 - a. the clitoris.
 - b. the vagina.
 - c. the vestibular bulbs.
 - d. the labia minora.
 - e. the prepuce.
2. The ovaries secrete all of the following *except*
 - a. estrogens.
 - b. progesterone.
 - c. androgens.
 - d. follicle-stimulating hormone.
 - e. inhibin.
3. The first haploid stage in oogenesis is
 - a. the oogonium.
 - b. the primary oocyte.
 - c. the secondary oocyte.
 - d. the second polar body.
 - e. the zygote.
4. The haploid secondary oocyte is shielded from immune attack by
 - a. the zona pellucida.
 - b. the theca folliculi.
 - c. the cumulus oophorus.
 - d. follicular fluid.
 - e. inhibin.
5. The hormone that most directly influences the secretory phase of the menstrual cycle is
 - a. HCG.
 - b. FSH.
 - c. LH.
 - d. estrogen.
 - e. progesterone.
6. The ischemic phase of the uterus results from
 - a. rising progesterone levels.
 - b. falling progesterone levels.
 - c. stimulation by oxytocin.
 - d. stimulation by prostaglandins.
 - e. stimulation by estrogens.
7. Before secreting milk, the mammary glands secrete
 - a. prolactin.
 - b. colostrum.
 - c. lochia.
 - d. meconium.
 - e. chloasma.
8. Few women become pregnant while nursing because _____ inhibits GnRH secretion.
 - a. FSH.
 - b. prolactin.
 - c. prostaglandins.
 - d. oxytocin.
 - e. HCG.
9. Smooth muscle cells of the myometrium and myoepithelial cells of the mammary glands are the target cells for
 - a. prostaglandins.
 - b. LH.
 - c. oxytocin.
 - d. progesterone.
 - e. FSH.
10. Which of these is not true of the luteal phase of the sexual cycle?
 - a. Progesterone level is high.
 - b. The endometrium stores glycogen.
 - c. Ovulation occurs.
 - d. Fertilization may occur.
 - e. The endometrial glands enlarge.
11. Each egg cell develops in its own fluid-filled space called a/an _____.
12. The mucosa of the uterus is called the _____.
13. A girl's first menstrual period is called _____.
14. A yellowish structure called the _____ secretes progesterone during the secretory phase of the menstrual cycle.
15. The layer of cells closest to a mature secondary oocyte is the _____.

16. A tertiary follicle differs from a primary follicle in having a cavity called the _____.
17. Menopause occurs during a midlife period of changing hormone secretion called _____.
18. All the products of fertilization, including the embryo or fetus, the placenta, and the embryonic membranes, are collectively called the _____.
19. The funnel-like distal end of the uterine tube is called the _____ and has feathery processes called _____.
20. Postpartum uterine involution produces a vaginal discharge called _____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. After ovulation, a follicle begins to move down the uterine tube to the uterus.
2. Human chorionic gonadotropin is secreted by the granulosa cells of the follicle.
3. An oocyte never completes meiosis II unless it is fertilized.
4. A slim girl who is active in dance and gymnastics is likely to begin menstruating at a later age than an overweight inactive girl.
5. There are more future egg cells in the ovary at puberty than there are at birth.
6. Women do not lactate while they are pregnant because prolactin is not secreted until after birth.
7. Colostrum contains more protein than milk, but less fat.
8. Several follicles develop in each ovarian cycle even though only one of them usually ovulates.
9. Progesterone inhibits uterine contractions.
10. The entire endometrium is shed in each menstrual period.

Answers in appendix B

Testing Your Comprehension

1. Would you expect puberty to create a state of positive or negative nitrogen balance? Explain. (See chapter 26 for nitrogen balance.)
2. Aspirin and ibuprofen can inhibit the onset of labor and are sometimes used to prevent premature birth. Review your knowledge of these drugs and the mechanism of labor, and explain this effect.
3. At 6 months postpartum, a nursing mother is in an automobile accident that fractures her skull and severs the hypophyseal portal vessels. How would you expect this to affect her milk production? How would you expect it to affect her future ovarian cycles? Explain the difference.
4. If the ovaries are removed in the first 6 weeks of pregnancy, the embryo will be aborted. If they are removed later in pregnancy, the pregnancy can go to a normal full term. Explain the difference.
5. A breast-feeding woman leaves her baby at home and goes shopping. There, she hears another woman's baby crying and notices her blouse becoming wet with a little exuded milk. Explain the physiological link between hearing that sound and the ejection of milk.

29.3 Clinical Application: Neonatal Assessment 1134

29.4 Clinical Application: Reproductive Technology—Making Babies in the Laboratory 1147

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Structure of the spermatozoon (p. 1066)
- Anatomy and histology of the uterus (pp. 1081–1083)
- Stages of oogenesis (pp. 1089–1091)
- Structure of a mature ovarian follicle (p. 1092)

Perhaps the most dramatic, miraculous aspect of human life is the transformation of a one-celled fertilized egg into an independent, fully developed individual. From the beginning of recorded thought, people have pondered how a baby forms in the mother's body and how two parents can produce another human being who, although unique, possesses characteristics of each. In his quest to understand prenatal development, Aristotle dissected bird embryos and established the sequence in which their organs appeared and took shape. He also speculated that the hereditary traits of a child resulted from the mixing of the male's semen with the female's menstrual blood. Misconceptions about human development persisted for many centuries. In the seventeenth century, scientists thought that the features of the infant existed in a preformed state in the egg or the sperm, and simply unfolded and expanded as the embryo developed. Some thought that the head of the sperm had a miniature human curled up in it, while others thought that the miniature person existed in the egg and the sperm were parasites in the semen.

The modern science of **embryology**—the study of prenatal development—was not born until the nineteenth century, largely because darwinism at last gave biologists a systematic framework for asking the right questions and discovering unifying themes in the development of diverse species of animals, including humans. It was in that era, too, that the human egg was first observed. Embryology is now a part of **developmental biology**, a broader science that embraces changes in form and function from fertilized egg through old age. A rapidly expanding area of developmental biology today is the genetic regulation of development. Human development from conception to death is the scope of this chapter.

- describe the major events that transform a fertilized egg into an embryo; and
- describe the implantation of the preembryo in the uterine wall.

Authorities attach different meanings to the word **embryo**. Some use it to denote stages beginning with the fertilized egg or at least with the two-celled stage produced by its first division. Others first apply the word *embryo* to an individual 16 days old, when it consists of three **primary germ layers** called the *ectoderm*, *mesoderm*, and *endoderm*. The events leading up to that stage are called *embryogenesis*, and the first 16 days after fertilization are thus called the *preembryonic stage*. This is the sense in which we will use such terms in this book. We begin with the process in which a sperm locates and fertilizes the egg.

Sperm Migration

If it is to survive, an egg must be fertilized within 12 to 24 hours of ovulation; yet it takes about 72 hours for an egg to reach the uterus. Therefore, in order to fertilize an egg before it dies, sperm must encounter it somewhere in the distal one-third of the uterine tube. The vast majority of sperm never make it that far. Many are destroyed by vaginal acid or drain out of the vagina. Others fail to penetrate the mucus of the cervical canal, and those that do are often destroyed by leukocytes in the uterus. Of those that get past the uterus, probably half go up the wrong uterine tube. Finally, 2,000 to 3,000 spermatozoa reach the vicinity of the egg—not many of the 300 million that were ejaculated.

Sperm migrate mainly by means of the snakelike lashing of their tails as they crawl along the female mucosa, but they are assisted by certain aspects of female physiology. Strands of mucus guide them through the cervical canal. Although female orgasm is not required for fertilization, orgasm does involve uterine contractions that may suck semen from the vagina and spread it throughout the uterus, like hand lotion pressed between your palms. The egg itself may release a chemical that attracts sperm from a short distance; this has been demonstrated for some animals but remains unproven for humans.

Capacitation

Sperm can reach the distal uterine tube within 5 to 10 minutes of ejaculation, but they cannot fertilize an egg for about 10 hours. While migrating, they must undergo a process of **capacitation** that makes it possible to penetrate an egg. In fresh sperm, the plasma membrane is toughened by cholesterol. This prevents the premature release of acrosomal enzymes while sperm are still in the male, and thus avoids wastage of sperm. It also prevents

29.1 Fertilization and the Preembryonic Stage

Objectives

When you have completed this section, you should be able to

- describe the process of sperm migration and fertilization;
- explain how an egg prevents fertilization by more than one sperm;

enzymatic damage to the spermatic ducts. After ejaculation, however, fluids of the female reproductive tract leach cholesterol from the plasma membrane and dilute other inhibitory factors in the semen. The membrane of the sperm head becomes more fragile and more permeable to calcium ions, which diffuse into the sperm and stimulate more powerful lashing of the tail.

Sperm remain viable for up to 6 days after ejaculation, so there is little chance of pregnancy from intercourse occurring more than a week before ovulation. Fertilization also is unlikely if intercourse takes place more than 14 hours after ovulation, because the egg would no longer be viable by the time the sperm became capacitated. For those wishing to conceive a child, the optimal "window of opportunity" is therefore from a few days before ovulation to 14 hours after. Those wishing to avoid pregnancy, however, should allow a wider margin of safety for variations in sperm and egg longevity, capacitation time, and time of ovulation—variations that make the rhythm method of contraception so unreliable.

Fertilization

When the sperm encounters an egg, it undergoes an **acrosomal reaction**—exocytosis of the acrosome, releasing the enzymes needed to penetrate the egg. But the first sperm to reach an egg is not the one to fertilize it. Sperm must first penetrate the granulosa cells and zona pellucida that surround it (fig. 29.1). It may require hundreds of sperm to clear a path for the one that penetrates the egg proper.

Two of the acrosomal enzymes are **hyaluronidase**, which digests the hyaluronic acid that binds granulosa cells together, and **acrosin**, a protease similar to the trypsin of pancreatic juice. When a path has been cleared through the granulosa cells, a sperm binds to the zona pellucida and releases its enzymes, digesting a pathway through the zona until it contacts the egg itself. The sperm head and midpiece enter the egg, but the egg destroys the sperm mitochondria and passes only maternal mitochondria on to the offspring.

FIGURE 29.1 Fertilization and the Slow Block to Polyspermy.

Fertilization combines the haploid (n) set of sperm chromosomes with the haploid set of egg chromosomes, producing a diploid ($2n$) set. Fertilization by two or more sperm, called **polyspermy**, would produce a triploid ($3n$) or larger set of chromosomes and the egg would die. Thus it is important for the egg to prevent this, and it has two mechanisms for doing so: a fast block and slow block to polyspermy. In the **fast block**, binding of the sperm to the egg opens Na^+ channels in the egg membrane. The rapid inflow of Na^+ depolarizes the membrane and inhibits the attachment of any more sperm. The **slow block** involves secretory vesicles called **cortical granules** just beneath the membrane. Sperm penetration releases an inflow of Ca^{2+} ; this, in turn, stimulates a **cortical reaction** in which the cortical granules release their secretion beneath the zona pellucida. The secretion swells with water, pushes any remaining sperm away from the egg, and creates an impenetrable **fertilization membrane** between the egg and the zona pellucida.

Think About It

What similarity can you see between the slow block to polyspermy and the release of acetylcholine from the synaptic vesicles of a neuron? (Compare p. 465.)

Meiosis II

A secondary oocyte begins meiosis II before ovulation and completes it only if fertilized. Through the formation of a second polar body, the fertilized egg discards one chromatid from each chromosome. The sperm and egg nuclei then swell and become **pronuclei**. A mitotic spindle forms between them, each pronucleus ruptures, and the chromosomes of the two gametes mix into a single diploid set (fig. 29.2). The fertilized egg, now called a **zygote**, is ready for its first mitotic division.

As in chapter 28, we will use the term *conceptus* for everything that arises from this zygote—not only the developing individual but also the placenta, umbilical cord, and membranes associated with the embryo and fetus.

Major Stages of Prenatal Development

Clinically, the course of a pregnancy is divided into 3-month intervals called **trimesters**:

1. The **first trimester** extends from fertilization through the first 12 weeks. This is the most precarious stage, for more than half of all embryos

FIGURE 29.2 Migration of the Conceptus. The egg is fertilized in the distal end of the uterine tube, and the preembryo begins cleavage as it migrates to the uterus.

❶ Why can't the egg be fertilized in the uterus?

die in the first trimester. The conceptus is most vulnerable to stress, drugs, and nutritional deficiencies during this time.

- The **second trimester** (weeks 13 through 24) is a period in which the organs complete most of their development. It becomes possible with sonography to see good anatomical detail in the fetus. By the end of this trimester, the fetus looks distinctly human, and with intensive clinical care, infants born at the end of the second trimester have a chance of survival.
- In the **third trimester** (week 25 to birth), the fetus grows rapidly and the organs achieve enough cellular differentiation to support life outside the womb. Some organs, such as the brain, liver, and kidneys, however, require further differentiation after birth to become fully functional. At 35 weeks from fertilization, the fetus typically weighs about 2.5 kg (5.5 lb). It is considered mature at this weight, and usually survives if born early. Most twins are born at about 35 weeks' gestation, and solitary infants at 40 weeks.

From a more biological than clinical standpoint, human development is divided into three stages called the *preembryonic*, *embryonic*, and *fetal stages*. The timetable and landmark events that distinguish these stages are outlined in table 29.1 and described in the following pages. We end this section with the preembryonic stage, in which the fertilized egg divides into hundreds of cells, the cells organize themselves into the primary germ layers, and the conceptus becomes firmly attached to the uterine wall.

The Preembryonic Stage

The **preembryonic stage** comprises the first 16 days of development, culminating in the existence of an embryo. It involves three major processes: cleavage, implantation, and embryogenesis.

Cleavage

Cleavage refers to mitotic divisions that occur in the first 3 days, while the conceptus migrates down the uterine tube (fig. 29.2). The first cleavage occurs about 30 hours after fertilization and produces the first two daughter cells, or **blastomeres**.¹ These divide simultaneously at shorter and shorter time intervals, doubling the number of blastomeres each time. By the time the conceptus arrives in the uterus, about 72 hours after ovulation, it consists of 16 or more cells and somewhat resembles a mulberry—hence it is called a **morula**.² The morula is no larger than the zygote; cleavage merely produces smaller and smaller blastomeres. This increases the ratio of cell surface area to volume, which favors rapid nutrient uptake and waste removal, and it produces a larger number of cells from which to form different embryonic tissues.

The morula lies free in the uterine cavity for 4 to 5 days and divides into 100 cells or so. Meanwhile, the zona pellucida disintegrates and releases the conceptus, which is now at a stage called the **blastocyst**—a hollow sphere with an outer layer of squamous cells called the **trophoblast**,³ an inner cell mass called the **embryoblast**,

¹*blast* = bud, precursor + *mer* = segment, part

²*mor* = mulberry + *ula* = little

³*troph* = food, nourishment

TABLE 29.1 The Stages of Prenatal Development

Stage	Age*	Major Developments and Defining Characteristics
<i>Preembryonic stage</i>		
Zygote	0–30 hours	A single diploid cell formed by the union of egg and sperm
Cleavage	30–72 hours	Mitotic division of the zygote into smaller, identical blastomeres
Morula	3–4 days	A spherical stage consisting of 16 or more blastomeres
Blastocyst	4–16 days	A fluid-filled, spherical stage with an outer mass of trophoblast cells and inner mass of embryoblast cells; becomes implanted in the endometrium; inner cell mass forms an embryonic disc and differentiates into the three primary germ layers
<i>Embryonic stage</i>		
	16 days–8 weeks	A stage in which the primary germ layers differentiate into organs and organ systems; ends when all organ systems are present
<i>Fetal stage</i>		
	8–38 weeks	A stage in which organs grow and mature at a cellular level to the point of being capable of supporting life independently of the mother

*From the time of fertilization

INSIGHT 29.1 Clinical Application**Twins**

There are two ways in which twins are produced (and, by extension, other multiple births). About two-thirds of twins are *dizygotic (DZ)*—produced when two eggs are ovulated and fertilized by separate sperm. They are no more or less genetically similar than any other siblings and may be of different sexes. Multiple ovulation can also result in triplets, quadruplets, or even greater numbers of offspring. DZ twins implant separately on the uterine wall and each forms its own placenta, although their placentas may fuse if they implant close together (fig. 29.3).

Monozygotic (MZ) twins are produced when a single egg is fertilized and the cell mass (embryoblast) later divides into two. MZ twins are genetically identical, or nearly so, and are therefore of the same sex and nearly identical appearance. In most cases, they share the same placenta. Identical triplets and quadruplets occasionally result from the splitting of a single embryoblast.

Reproductive biologists are beginning to question whether MZ twins are truly genetically identical. They have suggested that blastomeres may undergo mutation in the course of DNA replication, and the splitting of the embryoblast may represent an attempt of each cell mass to reject the other one as genetically different and presumably foreign.

FIGURE 29.3 Dizygotic Twins with Separate Placentas.

and an internal cavity called the **blastocoel** (BLAST-oh-seal) (fig. 29.4a). The trophoblast is destined to form part of the placenta and play an important role in nourishment of the embryo, whereas the embryoblast is destined to become the embryo itself.

Implantation

About 6 days after ovulation, the blastocyst attaches to the endometrium, usually on the fundus or the posterior wall of the uterus. The process of attachment, called **implantation**, begins when the blastocyst adheres to the endometrium. The trophoblast cells on this side separate into two layers. In the superficial layer, in contact with the endometrium, the plasma membranes break down and the trophoblast cells fuse into a multinucleate mass called the **syncytiotrophoblast**⁴ (sin-SISH-ee-oh-TRO-fo-blast). (A *syncytium* is any body of protoplasm containing multiple nuclei.) The deep layer, close to the embryoblast, is called the **cytotrophoblast** because it retains individual cells divided by membranes (fig. 29.4b).

The syncytiotrophoblast grows into the uterus like little roots, digesting endometrial cells along the way. The

endometrium reacts to this injury by growing over the blastocyst and eventually covering it, so the conceptus becomes completely buried in endometrial tissue (fig. 29.4c). Implantation takes about a week and is completed about the time the next menstrual period would have occurred if the woman had not become pregnant.

Another role of the trophoblast is to secrete human chorionic gonadotropin (HCG). HCG stimulates the corpus luteum to secrete estrogen and progesterone, and progesterone suppresses menstruation. The level of HCG in the mother's blood rises until the end of the second month. During this time, the trophoblast develops into a membrane called the *chorion*, which takes over the role of the corpus luteum and makes HCG unnecessary. The ovaries then become inactive for the rest of the pregnancy, but estrogen and progesterone levels rise dramatically as they are secreted by the ever-growing chorion (see fig. 28.18, p. 1100).

Embryogenesis

During implantation, the embryoblast undergoes **embryogenesis**—arrangement of the blastomeres into the three primary germ layers: *ectoderm*, *mesoderm*, and *endoderm*. At the beginning of this phase, the embryoblast

⁴syn = together + cyt = cell

FIGURE 29.4 Implantation. (a) Structure of the blastocyst 6 to 7 days after ovulation, when it first adheres to the uterine wall. (b) The progress of implantation about 1 day later. The syncytiotrophoblast has begun growing rootlets, which penetrate the endometrium. (c) By 16 days, the conceptus is completely covered by endometrial tissue. The embryo is now flanked by a yolk sac and amnion and is composed of three primary germ layers.

INSIGHT 29.2 Clinical Application

Ectopic Pregnancy

In about 1 out of 300 pregnancies, the blastocyst implants somewhere other than the uterus, producing an *ectopic*⁵ pregnancy. Most cases are *tubal pregnancies*, implantation in the uterine tube. This usually occurs because the conceptus encounters an obstruction such as a constriction resulting from such causes as earlier pelvic inflammatory disease, tubal surgery, previous ectopic pregnancies, or repeated miscarriages. The uterine tube cannot expand enough to accommodate the growing conceptus for long; if the situation is not detected and treated early, the tube usually ruptures within 12 weeks, potentially with fatal hemorrhaging. Occasionally, a conceptus implants in the abdominopelvic cavity, producing an *abdominal pregnancy*. It can grow anywhere it finds an adequate blood supply—for example, on the broad ligament or the outside of the uterus, colon, or bladder. About 1 pregnancy in 7,000 is abdominal. This is a serious threat to the mother's life and usually requires abortion, but about 9% of abdominal pregnancies result in live birth by cesarean section.

separates slightly from the trophoblast, creating a narrow space between them called the **amniotic cavity**. The embryoblast flattens into an **embryonic disc** composed initially of two layers: the *epiblast* facing the amniotic cavity and the *hypoblast* facing away. Some hypoblast cells multiply and form a membrane called the *yolk sac* enclosing the blastocoel. Now the embryonic disc is flanked by two spaces: the amniotic cavity on one side and the yolk sac on the other.

Meanwhile, the embryonic disc elongates and, around day 15, a thickened cell layer called the **primitive streak** forms along the midline of the epiblast, with a **primitive groove** running down its middle. These events make the embryo bilaterally symmetric and define its future right and left sides, dorsal and ventral surfaces, and cephalic and caudal ends.

The next step is **gastrulation**—multiplying epiblast cells migrate medially toward the primitive groove and down into it (fig. 29.5). They replace the original hypoblast with a layer now called **endoderm**, which will become the inner lining of the digestive tract among other things. A day later, migrating epiblast cells form a

⁵ec = outside + top = place

FIGURE 29.5 Formation of the Primary Germ Layers (Gastrulation). Composite view of the embryonic disc at 15 to 16 days. Epiblast cells migrate over the surface and down into the primitive groove, first replacing the hypoblast cells with endoderm, then filling the space with mesoderm. Upon completion of this process, the uppermost layer is considered ectoderm.

third layer between the first two, called **mesoderm**. Once this is formed, the remaining epiblast is called **ectoderm**. Thus, all three primary germ layers arise from the original epiblast. Some mesoderm overflows the embryonic disc and becomes an extensive *extraembryonic mesoderm*, which contributes to formation of the placenta (fig. 29.4c).

The ectoderm and endoderm are epithelia composed of tightly joined cells, but the mesoderm is a more loosely organized tissue. It later differentiates into a loose fetal connective tissue called **mesenchyme**, which gives rise to such tissues as muscle, bone, and blood. Mesenchyme is composed of a loose network of wispy *mesenchymal cells* embedded in a gelatinous ground substance.

Once the three primary germ layers are formed, embryogenesis is complete and the individual is considered an embryo. It is about 2 mm long and 16 days old at this point.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. How soon can a sperm reach an egg after ejaculation? How soon can it fertilize an egg? What accounts for the difference?
2. Describe two ways a fertilized egg prevents the entry of excess sperm.
3. In the blastocyst, what are the cells called that eventually give rise to the embryo? What are the cells that carry out implantation?
4. What major characteristic distinguishes an embryo from a preembryo?

29.2 The Embryonic and Fetal Stages

Objectives

When you have completed this section, you should be able to

- describe the formation and functions of the placenta;
- explain how the conceptus is nourished before the placenta takes over this function;
- describe the embryonic membranes and their functions;
- identify the major tissues derived from the primary germ layers;
- describe the major events of fetal development; and
- describe the fetal circulatory system.

Sixteen days after conception, the germ layers are present and the **embryonic stage** of development begins. Over the next 6 weeks, a placenta forms on the uterine wall and becomes the embryo's primary means of nutrition, while the germ layers differentiate into organs and organ systems—a process called **organogenesis** (table 29.2). Although these organs are still far from functional, it is their presence at 8 weeks that marks the transition from the embryonic stage to the fetal stage. Here we will see how the embryo becomes a fetus, how the membranes collectively known as the “afterbirth” develop around the fetus, and how the conceptus is nourished throughout its gestation.

Embryonic Folding and Organogenesis

One of the major transformations to occur in the embryonic stage is conversion of the flat embryonic disc of figure 29.4c into a somewhat cylindrical form. This occurs during week 4 as the embryo rapidly grows and folds around a membrane called the yolk sac (fig. 29.6). As the cephalic and caudal ends curve around the ends of the yolk sac, the embryo becomes C-shaped, with the head and tail almost touching. At the same time, the lateral margins of the disc fold around the sides of the yolk sac to form the ventral surface of the embryo. This lateral folding encloses a longitudinal channel, the *primitive gut*, which later becomes the digestive tract.

As a result of embryonic folding, the entire surface is covered with ectoderm, which later produces the epidermis of the skin. In the meantime, the mesoderm splits into two layers. One of them adheres to the ectoderm and the other to the endoderm, thus opening a body cavity between them called the **coelom** (SEE-loam)

TABLE 29.2 Derivatives of the Three Primary Germ Layers	
Layer	Major Derivatives
Ectoderm	Epidermis; hair follicles and piloerector muscles; cutaneous glands; nervous system; adrenal medulla; pineal and pituitary glands; lens, cornea, and intrinsic muscles of the eye; internal and external ear; salivary glands; epithelia of the nasal cavity, oral cavity, and anal canal
Mesoderm	Skeleton; skeletal, cardiac, and most smooth muscle; cartilage; adrenal cortex; middle ear; dermis; blood; blood and lymphatic vessels; bone marrow; lymphoid tissue; epithelium of kidneys, ureters, gonads, and genital ducts; mesothelium of the abdominal and thoracic cavities
Endoderm	Most of the mucosal epithelium of the digestive and respiratory tracts; mucosal epithelium of urinary bladder and parts of urethra; epithelial components of accessory reproductive and digestive glands (except salivary glands); thyroid and parathyroid glands; thymus

FIGURE 29.6 Embryonic Folding. The right-hand figures are cross sections cut about midway along the figures on the left. Part (a) corresponds to figure 29.4c at a slightly later stage of development. Note the general trend for the cephalic and caudal (head and tail) ends of the embryo to curl toward each other (left-hand figures) until the embryo assumes a C shape, and for the flanks of the embryo to fold laterally (right-hand figures), converting the flat embryonic disc into a more cylindrical body and eventually enclosing a body cavity (c).

(fig. 29.6c). The body cavity becomes divided into the thoracic cavity and peritoneal cavity by a wall, the diaphragm. By the end of week 5, the thoracic cavity further subdivides into pleural and pericardial cavities.

Two more especially significant events in organogenesis are the appearance of a **neural tube** (fig. 29.6b), which will later become the brain and spinal cord, and segmentation of the mesoderm into blocks of tissue called **somites** (see fig. 29.11a, b), which will give rise to the vertebral column, trunk muscles, and dermis of the skin.

We cannot delve at greater length into development of all the organ systems, but this description is at least enough to see how some of them begin to form. Some have also been described in earlier chapters. By the end of 8 weeks, all of the organ systems are present, the individual is about 3 cm long, and it is now considered a **fetus** (see fig. 29.11d). The bones have just begun to calcify and the skeletal muscles exhibit spontaneous contractions, although these are too weak to be felt by the mother. The heart, beating since the fourth week, now circulates blood. The heart and liver are very large and form the prominent ventral bulge seen in figure 29.11c. The head is nearly half the total body length.

Think About It

List the four primary tissue types of the adult body (see chapter 5) and identify which of the three primary germ layers of the embryo predominantly gives rise to each.

Embryonic Membranes

Several accessory organs develop alongside the embryo: a *placenta*, *umbilical cord*, and four embryonic membranes called the *amnion*, *yolk sac*, *allantois*, and *chorion* (figs. 29.6 and 29.7). To understand these membranes, it helps to realize that all mammals evolved from egg-laying reptiles. Within the shelled, self-contained egg of a reptile, the embryo rests atop a yolk, which is enclosed in the yolk sac; it floats in a little sea of liquid contained in the amnion; it stores its toxic wastes in the allantois; and to breathe, it has a chorion permeable to gases. All of these membranes persist in mammals, including humans, but are modified in their functions.

The **amnion** is a transparent sac that develops from cells of the epiblast (see figs. 29.4c and 29.5). It grows to completely enclose the embryo and is penetrated only by the umbilical cord. The amnion fills with **amniotic fluid** (see fig. 29.11d), which protects the embryo from trauma, infection, and temperature fluctuations; allows the freedom of movement important to muscle development; enables the embryo to develop symmetrically; prevents

body parts from adhering to each other, such as an arm to the trunk; and stimulates lung development as the fetus “breathes” the fluid. At first, the amniotic fluid forms by filtration of the mother’s blood plasma, but beginning at 8 to 9 weeks, the fetus urinates into the amniotic cavity about once an hour and contributes substantially to the fluid volume. The volume remains stable, however, because the fetus swallows amniotic fluid at a comparable rate. At term, the amnion contains 700 to 1,000 mL of fluid.

The **yolk sac** arises from hypoblast cells opposite the amnion. It is a small sac suspended from the ventral side of the embryo. It contributes to the formation of the digestive tract and produces the first blood cells and future egg or sperm cells.

The **allantois** (ah-LON-toe-iss) begins as an outpocketing of the yolk sac (see fig. 29.4c), but eventually becomes an outgrowth of the caudal end of the gut. It forms the foundation for the umbilical cord and becomes part of the urinary bladder. It can be seen in cross sections cut near the fetal end of a mature umbilical cord.

The **chorion** is the outermost membrane, enclosing all the rest of the membranes and the embryo (fig. 29.7). Initially, it has shaggy outgrowths called **chorionic villi** around its entire surface, but as the pregnancy advances, the villi of the placental region grow and branch while the rest of them degenerate. At the placental attachment, the chorion is then called the *villous chorion*, and the rest is called the *smooth chorion*. The villous chorion forms the fetal portion of the placenta, discussed shortly.

Prenatal Nutrition

Over the course of gestation, the conceptus is nourished in three different, overlapping ways: by *uterine milk*, *trophoblastic nutrition*, and *placental nutrition*.

Uterine milk is a glycogen-rich secretion of the uterine tubes and endometrial glands. The conceptus absorbs this fluids as it travels down the tube and lies free in the uterine cavity before implantation. The accumulating fluid forms the blastocoel in figure 29.4a.

As it implants, the conceptus makes a transition to **trophoblastic nutrition**, in which it consumes so-called **decidual⁶ cells** of the endometrium. Progesterone from the corpus luteum stimulates these cells to proliferate and accumulate a store of glycogen, proteins, and lipids. As the conceptus burrows into the endometrium, the syncytiotrophoblast digests them and supplies the nutrients to the embryoblast. Trophoblastic nutrition is the only mode of nutrition for the first week after implantation. It

⁶decid = falling off

FIGURE 29.7 The Placenta and Embryonic Membranes. (a) Embryo at 4 weeks, enclosed in the amnion and chorion and surrounded by a developing placenta. (b) Fetus at 12 weeks. The placenta is now complete and lies on only one side of the fetus. (c) A portion of the mature placenta and umbilical cord, showing the relationship between fetal and maternal circulation.

FIGURE 29.8 The Timetable of Trophoblastic and Placental Nutrition. Trophoblastic nutrition peaks at 2 weeks and ends by 12 weeks. Placental nutrition begins at 2 weeks and becomes increasingly important until birth, 37 weeks after implantation. The two modes of nutrition overlap up to the eighth week, but the *trophoblast phase* is the period in which most nutrients are supplied by trophoblastic nutrition, and the *placental phase* is the period in which most (eventually all) nutrition comes from the placenta.

❖ At what point do the two modes contribute equally to prenatal nutrition?

remains the dominant source of nutrients through the end of week 8; the period from implantation through week 8 is therefore called the **trophoblastic phase** of the pregnancy. Trophoblastic nutrition wanes as placental nutrition takes over, and ceases entirely by the end of week 12 (fig. 29.8).

In **placental nutrition**, nutrients diffuse from the mother's blood through the placenta into the fetal blood. The **placenta**⁷ is a disc-shaped organ attached to the uterine wall on one side and, on the other side, attached by way of an **umbilical cord** to the fetus (fig. 29.9). When fully developed, it is about 20 cm in diameter, 3 cm thick, and weighs about one-sixth as much as the newborn infant. The surface facing the fetus is smooth and gives rise to the umbilical cord, while the surface attached to the uterine wall is rougher. The uterine surface consists of chorionic villi embedded in the mother's endometrium.

The placenta begins to develop about 11 days after conception, becomes the dominant mode of nutrition around the beginning of week 9, and is the sole mode of nutrition from the end of week 12 until birth. The period from week 9 until birth is called the **placental phase** of the pregnancy.

(a) Fetal side

(b) Maternal (uterine) side

FIGURE 29.9 The Placenta and Umbilical Cord. (a) The fetal side, showing blood vessels, the umbilical cord, and some of the amniotic sac attached to the lower left margin. (b) The maternal (uterine) side, where chorionic villi give the placenta a rougher texture.

Figures 29.4 and 29.7 depict the development of the placenta, or *placentation*. The process begins during implantation, as extensions of the syncytiotrophoblast penetrate more and more deeply into the endometrium, like the roots of a tree penetrating into the nourishing “soil” of the uterus. These roots are the early chorionic villi. As they penetrate uterine blood vessels, they become surrounded by *lacunae*, or endometrial spaces filled with maternal blood (see fig. 29.4c). The lacunae eventually merge to form a single blood-filled cavity, the **placental sinus**. Exposure to maternal blood

⁷placenta = flat cake

stimulates increasingly rapid growth of the villi, which become branched and treelike. Extraembryonic mesoderm grows into the villi and gives rise to the blood vessels that connect to the embryo by way of the umbilical cord.

The umbilical cord contains two **umbilical arteries** and one **umbilical vein**. Pumped by the fetal heart, blood flows into the placenta by way of the umbilical arteries and then returns to the fetus by way of the umbilical vein. The chorionic villi are *filled with* fetal blood and *surrounded by* maternal blood (see fig. 29.7c); the two bloodstreams do not mix unless there is damage to the placental barrier. The barrier, however, is only 3.5 μm thick—half the diameter of a red blood cell. Early in development, the villi have thick membranes that are not very permeable to nutrients and wastes, and their total surface area is relatively small. As the villi grow and branch, their surface area increases and the membranes become thinner and more permeable. This brings about a dramatic increase in *placental conductivity*, the rate at which substances diffuse through the membrane. Materials diffuse from the side of the membrane where they are more concentrated to the side where they are less so. Therefore, oxygen and nutrients pass from the maternal blood to the fetal blood, while fetal wastes pass the other way to be eliminated by the mother. Unfortunately, the placenta is also permeable to nicotine, alcohol, and most other drugs that may be present in the maternal bloodstream.

Table 29.3 summarizes the nutritional, excretory, and other functions of the placenta.

Fetal Development

The fetus is the final stage of prenatal development, from the start of the ninth week until birth. The organs that formed during the embryonic stage now undergo growth and cellular differentiation, acquiring the functional capability to support life outside the mother.

The circulatory system shows the most conspicuous anatomical changes from a prenatal state, dependent on the placenta, to the independent neonatal (newborn) state (fig. 29.10). The unique aspects of fetal circulation are the umbilical–placental circuit and the presence of three circulatory shortcuts called *shunts*. The internal iliac arteries give rise to the umbilical arteries, which pass on either side of the bladder into the umbilical cord. The blood in these arteries is low in oxygen and high in carbon dioxide and other fetal wastes; thus, they are depicted in blue in figure 29.10a. The arterial blood discharges its wastes in the placenta, loads oxygen and nutrients, and returns to the fetus by way of a single umbilical vein, which leads toward the liver. The umbilical vein is depicted in red because of its well-oxygenated blood. Some of this venous blood filters through the liver to

TABLE 29.3

Functions of the Placenta

Nutritional roles	Permits nutrients such as glucose, amino acids, fatty acids, minerals, and vitamins to diffuse from the maternal blood to the fetal blood; stores nutrients such as carbohydrates, protein, iron, and calcium in early pregnancy and releases them to the fetus later, when fetal demand is greater than the mother can absorb from the diet
Excretory roles	Permits nitrogenous wastes such as ammonia, urea, uric acid, and creatinine to diffuse from the fetal blood to the maternal blood
Respiratory roles	Permits O_2 to diffuse from mother to fetus and CO_2 from fetus to mother
Endocrine roles	Secretes estrogens, progesterone, relaxin, human chorionic gonadotropin, and human chorionic somatomammotropin; allows other hormones synthesized by the conceptus to pass into the mother's blood and maternal hormones to pass into the fetal blood
Immune roles	Transfers maternal antibodies (especially IgG) into fetal blood to confer passive immunity on fetus

nourish it. However, the immature liver is not capable of performing many of its postpartum functions, so it does not require a great deal of perfusion before birth. Most of the venous blood therefore bypasses it by way of a shunt called the **ductus venosus**, which leads directly to the inferior vena cava.

In the inferior vena cava, placental blood mixes with venous blood from the fetus's body and flows to the right atrium of the heart. After birth, the right ventricle pumps all of its blood into the lungs, but there is little need for this in the fetus because the lungs are not yet functional. Therefore, most fetal blood bypasses the pulmonary circuit. Some goes directly from the right atrium to the left through the **foramen ovale**, a hole in the interatrial septum. Some also goes into the right ventricle and is pumped into the pulmonary trunk, but most of this is shunted directly into the aorta by way of a short passage called the **ductus arteriosus**. This occurs because the collapsed state of the fetal lungs creates high resistance and blood pressure in the pulmonary circuit, so blood in the pulmonary trunk flows through the ductus into the aorta, where the blood pressure is lower. The lungs receive only a trickle of blood, sufficient to meet their metabolic needs during development.

FIGURE 29.10 Blood Circulation in the Fetus and Newborn. Boldface terms in part (a) indicate the three shunts in the fetal circulation, which allow most blood to bypass the liver and lungs. Boldface terms in part (b) indicate the postpartum vestiges of fetal structures.

Blood leaving the left ventricle enters the general systemic circulation, and some of this returns to the placenta. This circulatory pattern changes dramatically at birth, when the neonate is cut off from the placenta and the lungs expand with air. Those changes will be described later.

Fetal growth is charted by weight and body length (table 29.4). Body length is customarily measured from the crown of the head to the curve of the buttocks in a sitting position (*crown-to-rump length, CRL*), thus excluding the lower limbs. Full-term fetuses have an average CRL of about 36 cm (14 in.) and average weight of about 3.0 to 3.4 kg (6.6–7.5 lb). The fetus gains about 50% of its birth weight in the last 10 weeks.

Additional aspects of embryonic and fetal development are listed in table 29.4 and depicted in figure 29.11.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Distinguish between trophoblastic and placental nutrition.
- Identify the two sources of blood to the placenta. Where do these two bloodstreams come closest to each other? What keeps them separated?
- State the functions of the placenta, amnion, chorion, yolk sac, and allantois.
- What developmental characteristic distinguishes a fetus from an embryo? At what gestational age is this attained?
- Identify the three circulatory shunts of the fetus. Why does the blood take these “shortcuts” before birth?

TABLE 29.4 Major Events of Prenatal Development, with Emphasis on the Fetal Stage

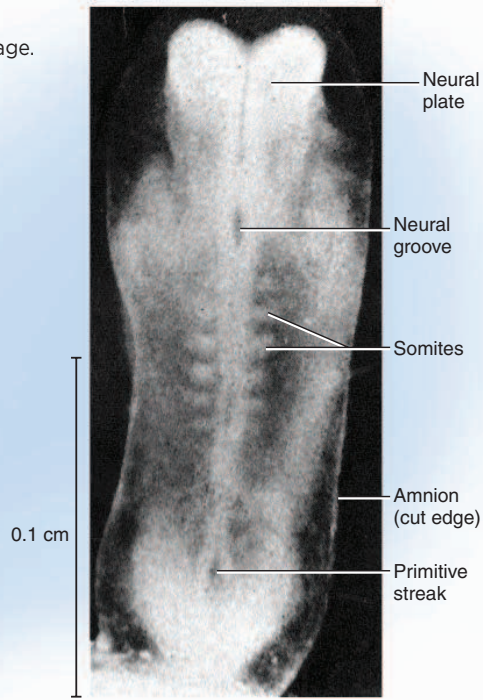

End of Week	Crown-to-Rump Length; Weight	Developmental Events
4	0.6 cm; <1 g	Vertebral column and central nervous system begin to form; limbs represented by small limb buds; heart begins beating around day 22; no visible eyes, nose, or ears
8	3 cm; 1 g	Eyes form, eyelids fused shut; nose flat, nostrils evident but plugged with mucus; head nearly as large as the rest of the body; brain waves detectable; bone calcification begins; limb buds form paddlelike hands and feet with ridges called digital rays , which then separate into distinct fingers and toes; blood cells and major blood vessels form; genitals present but sexes not yet distinguishable
12	9 cm; 45 g	Eyes well developed, facing laterally; eyelids still fused; nose develops bridge; external ears present; limbs well formed, digits exhibit nails; fetus swallows amniotic fluid and produces urine; fetus moves, but too weakly for mother to feel it; liver is prominent and produces bile; palate is fusing; sexes can be distinguished
16	14 cm; 200 g	Eyes face anteriorly, external ears stand out from head, face looks more distinctly human; body larger in proportion to head; skin is bright pink, scalp has hair; joints forming; lips exhibit sucking movements; kidneys well formed; digestive glands forming and meconium ⁸ (fetal feces) accumulating in intestine; heartbeat can be heard with a stethoscope
20	19 cm; 460 g	Body covered with fine hair called lanugo ⁹ and cheeselike sebaceous secretion called vernix caseosa , ¹⁰ which protects it from amniotic fluid; skin bright pink; brown fat forms and will be used for postpartum heat production; fetus is now bent forward into “fetal position” because of crowding; quickening occurs—mother can feel fetal movements
24	23 cm; 820 g	Eyes partially open; skin wrinkled, pink, and translucent; lungs begin producing surfactant; rapid weight gain
28	27 cm; 1,300 g	Eyes fully open; skin wrinkled and red; full head of hair present; eyelashes formed; fetus turns into upside-down vertex position ; testes begin to descend into scrotum; marginally viable if born at 28 weeks
32	30 cm; 2,100 g	Subcutaneous fat deposition gives fetus a more plump, babyish appearance, with lighter, less wrinkled skin; testes descending; twins usually born at this stage
36	34 cm; 2,900 g	More subcutaneous fat deposited, body plump; lanugo is shed; nails extend to fingertips; limbs flexed; firm hand grip
38	36 cm; 3,400 g	Prominent chest, protruding breasts; testes in inguinal canal or scrotum; fingernails extend beyond fingertips

⁸*mecon* = poppy juice, opium; refers to an appearance similar to black tar opium

⁹*lan* = down, wool

¹⁰*vernix* = varnish + *caseo* = cheese

29.3 The Neonate

Objectives

When you have completed this section, you should be able to

- describe how and why the circulatory system changes at birth;
- explain why the first breaths of air are relatively difficult for a neonate;
- describe the major physiological problems of a premature infant; and
- discuss some common causes of birth defects.

Development is by no means complete at birth. For example, the liver and kidneys still are not fully functional, most joints are not yet ossified, and myelination of the nervous system is not completed until adolescence. Indeed, humans are born in a very immature state compared with other mammals—a fact necessitated by the narrow outlet of the female pelvis, which in turn was necessitated by the evolution of bipedal locomotion.

The Transitional Period

The period immediately following birth is a crisis in which the neonate suddenly must adapt to life outside the mother's body. The first 6 to 8 hours are a **transitional period** in which the heart and respiratory rates increase and the body temperature falls. Physical activity then declines and the baby sleeps for about 3 hours. In its second period of activity, the baby often gags on mucus and debris in the pharynx. The baby then sleeps again, becomes more stable, and begins a cycle of waking every 3 to 4 hours to feed. The first 6 weeks of life constitute the **neonatal period**.

Circulatory Adaptations

After the umbilical cord is clamped and cut, the umbilical arteries and vein collapse and become fibrotic. The proximal part of each umbilical artery becomes the *superior vesical artery*, which remains to supply the bladder. Other obliterated vessels become fibrous cords or ligaments: the distal parts of the umbilical arteries become the *median umbilical ligaments* of the abdominal wall; the umbilical vein becomes the *round ligament (ligamentum teres)* of the liver; and the ductus venosus (the former shunt around the liver) becomes the *ligamentum venosum* on the inferior surface of the liver (fig. 29.10b).

When the lungs expand with air, resistance and blood pressure in the pulmonary circuit drop rapidly and pressure in the right heart falls below that in the left. Blood

flows briefly from the left atrium to the right through the foramen ovale (opposite from its prenatal flow) and pushes two flaps of tissue into place to close this shunt. In most people, these flaps fuse and permanently seal the foramen during the first year, leaving a depression, the *fossa ovalis*, in the interatrial septum. In about 25% of people, however, the foramen ovale remains unsealed and the flaps are held in place only by the relatively high blood pressure in the left atrium. Pressure changes in the pulmonary trunk and aorta also cause the ductus arteriosus to collapse. It closes permanently around 3 months of age and leaves a permanent cord, the *ligamentum arteriosum*, between the two vessels.

Respiratory Adaptations

It is an old misconception that a neonate must be spanked to stimulate it to breathe. During birth, CO₂ accumulates in the baby's blood and strongly stimulates the respiratory chemoreceptors. Unless the infant is depressed by over-sedation of the mother, it normally begins breathing spontaneously. It requires a great effort, however, to take the first few breaths and inflate the collapsed alveoli. For the first 2 weeks, a baby takes about 45 breaths per minute, but subsequently stabilizes at about 12 breaths per minute.

Immunological Adaptations

Cellular immunity begins to appear early in fetal development, but the immune responses of the neonate are still weak. Fortunately, an infant is born with a near-adult level of IgG acquired from the mother through the placenta. This maternal IgG breaks down rapidly after birth, declining to about half the initial level in the first month and to essentially none by 10 months. Nevertheless, maternal IgG levels remain high enough for 6 months to

INSIGHT 29.3 Clinical Application

Neonatal Assessment

A newborn infant is immediately evaluated for general appearance, vital signs (temperature, pulse, and respiratory rate), weight, length, and head circumference and other dimensions, and it is screened for congenital disorders such as phenylketonuria (PKU). At 1 minute and 5 minutes after birth, the heart rate, respiratory effort, muscle tone, reflexes, and skin color are noted and given a score of 0 (poor), 1, or 2 (excellent). The total (0–10), called the *Apgar*¹¹ score, is a good predictor of infant survival. Infants with low Apgar scores may have neurological damage and need immediate attention if they are to survive. A low score at 1 minute suggests asphyxiation and may demand assisted ventilation. A low score at 5 minutes indicates a high probability of death.

¹¹Virginia Apgar (1909–74), American anesthesiologist

protect the infant from measles, diphtheria, polio, and most other infectious diseases (but not whooping cough). By 6 months, the infant's own IgG reaches about half the typical adult level. The lowest total (maternal + infant) level of IgG exists around 5 to 6 months of age, and respiratory infections are especially common at that age. A breast-fed neonate also acquires protection from gastroenteritis from the IgA present in the colostrum.

Other Adaptations

Thermoregulation and fluid balance are also critical aspects of neonatal physiology. An infant has a larger ratio of surface area to volume than an adult does, so it loses heat more easily. One of its defenses against hypothermia is brown fat, a special adipose tissue deposited from weeks 17 to 20 of fetal development. The mitochondria of brown fat release all the energy of pyruvic acid as heat rather than using it to make ATP; thus, this is a heat-generating tissue. As a baby grows, its metabolic rate increases and it accumulates even more subcutaneous fat, thus producing and retaining more heat. Nevertheless, body temperature is more variable in infants and children than in adults.

The kidneys are not fully developed at birth and cannot concentrate the urine as much as a mature kidney can. Consequently, infants have a relatively high rate of water loss and require more fluid intake, relative to body weight, than adults do.

Premature Infants

Neonates weighing under 2.5 kg (5.5 lb) are generally considered **premature**. They have multiple difficulties in respiration, thermoregulation, excretion, digestion, and liver function. Most neonates weighing 1.5 to 2.5 kg are viable, but with difficulty. Those weighing under 500 g rarely survive.

The respiratory system is adequately developed by 7 months of gestation to support independent life. Infants born before this have a deficiency of pulmonary surfactant, causing **infant respiratory distress syndrome (IRDS)**, also called *hyaline membrane disease*. The alveoli collapse each time the infant exhales, and a great effort is needed to reinflate them. The infant becomes very fatigued by the high energy demand of breathing. IRDS may be treated by ventilating the lungs with oxygen-enriched air at a positive pressure to keep the lungs inflated between breaths, and by administering surfactant as an inhalant. Nevertheless, IRDS remains the most common cause of neonatal death.

A premature infant has an incompletely developed hypothalamus and therefore cannot thermoregulate effectively. Body temperature must be controlled by placing the infant in a warmer.

It is difficult for premature infants to ingest milk because of their small stomach volume and undeveloped sucking and swallowing reflexes. Some must be fed by nasogastric or nasoduodenal tubes. Most of them, however, can tolerate human milk or formulas. Infants under 1.5 kg (3.3 lb) require nutritional supplements of calcium, phosphorus, and protein.

The liver is also poorly developed, and bearing in mind its very diverse functions (see table 26.6, p. 1035), you can probably understand why this would have several serious consequences. The liver synthesizes inadequate amounts of albumin, so the baby suffers hypoproteinemia. This upsets the balance between capillary filtration and reabsorption and leads to edema. The infant bleeds easily because of a deficiency of the clotting factors synthesized by the liver. This is true to some degree even in full-term infants, however, because the baby's intestines are not yet colonized by the bacteria that synthesize vitamin K, which is essential for the synthesis of clotting factors. Vitamin K injections are now routine (but somewhat controversial) for newborns in the United States. Jaundice is common in neonates, especially premature babies, because the liver cannot dispose of bile pigments efficiently.

Birth Defects

A birth defect, or **congenital anomaly**,¹² is the abnormal structure or position of an organ at birth, resulting from a defect in prenatal development. The study of birth defects is called **teratology**.¹³ Birth defects are the most common cause of infant mortality in North America. Not all of them are noticeable at birth; some are detected months to years later. Thus, by the age of 2 years, 6% of children are diagnosed with congenital anomalies, and by age 5 the incidence is 8%. The following sections discuss some known causes of congenital anomalies, but in 50% to 60% of cases, the cause is unknown.

Teratogens

Teratogens¹⁴ are agents that cause anatomical deformities in the fetus. They fall into three major classes: drugs and other chemicals, infectious diseases, and radiation such as X-rays. The effect of a teratogen depends on the genetic susceptibility of the embryo, the dosage of the teratogen, and the time of exposure. Teratogen exposure during the first 2 weeks usually does not cause birth defects, but may cause spontaneous abortion. Teratogens can exert destructive effects at any stage of development, but the period of

¹²con = with + gen = born

¹³terato = monster + logy = study of

¹⁴terato = monster + gen = producing

FIGURE 29.12 The Teratogenic Effect of Thalidomide.

The infant in this photo was born in 2004 in Kenya to a woman believed to have used thalidomide during her pregnancy. He has no arms or legs and only rudimentary hands and feet. His birth father wanted to kill him, a common fate for deformed infants in Kenya, but he was adopted and taken to England. On the right is Mr. Freddie Astbury, president of Thalidomide UK in Liverpool. Mr. Astbury also was born with rudimentary limbs because of this teratogen.

greatest vulnerability is weeks 3 through 8. Different organs have different critical periods. For example, limb abnormalities are most likely to result from teratogen exposure at 24 to 36 days, and brain abnormalities from exposure at 3 to 16 weeks.

Perhaps the most notorious teratogenic drug is thalidomide, a sedative first marketed in 1957. Thalidomide was taken by women in early pregnancy, often before they knew they were pregnant. It caused over 5,000 babies to be born with unformed arms or legs and often with defects of the ears, heart, and intestines. It was taken off the American market in 1961 but has recently been reintroduced for limited purposes. People still take thalidomide in a misguided attempt to treat leprosy and AIDS in some Third World countries, resulting in an upswing in severe birth defects (fig. 29.12). A general lesson to be learned from the thalidomide tragedy and other cases is that pregnant women should avoid all sedatives, barbiturates, and opiates. Even the acne medicine isotretinoin (Accutane) has caused severe birth defects. Many teratogens produce less obvious or delayed effects, including physical or mental retardation, inattention, hyperirritability, strokes, seizures, respiratory arrest, crib death, and cancer.

Alcohol causes more birth defects than any other drug. Even one drink a day can have noticeable effects on fetal and childhood development, some of which are not

noticed until a child begins school. Alcohol abuse during pregnancy can cause **fetal alcohol syndrome (FAS)**, characterized by a small head, malformed facial features, cardiac and central nervous system defects, stunted growth, and behavioral signs such as hyperactivity, nervousness, and a poor attention span. Cigarette smoking also contributes to fetal and infant mortality, ectopic pregnancy, anencephaly (failure of the cerebrum to develop), cleft palate and lip, and cardiac abnormalities. Diagnostic X-rays should be avoided during pregnancy because radiation can have teratogenic effects.

Infectious diseases are largely beyond the scope of this book, but it must be noted at least briefly that several microorganisms can cross the placenta and cause serious congenital anomalies, stillbirth, or neonatal death. Common viral infections of the fetus and newborn include herpes simplex, rubella, cytomegalovirus, and human immunodeficiency virus (HIV). Congenital bacterial infections include gonorrhea and syphilis. *Toxoplasma*, a protozoan contracted from meat, unpasteurized milk, and housecats, is another common cause of fetal deformity. Some of these pathogens have relatively mild effects on adults, but because of its immature immune system, the fetus is vulnerable to devastating effects such as blindness, hydrocephalus, cerebral palsy, seizures, and profound physical and mental retardation. These diseases are treated in greater detail in microbiology textbooks.

Mutagens and Genetic Anomalies

Genetic anomalies are the most common known cause of birth defects, accounting for an estimated one-third of all cases and 85% of those with an identifiable cause. One cause of genetic defects is **mutations**, or changes in DNA structure. Among other disorders, mutations cause achondroplastic dwarfism (see Insight 7.2, p. 226), microcephaly (abnormal smallness of the head), stillbirth, and childhood cancer. Mutations can occur through errors in DNA replication during the cell cycle or under the influence of environmental agents called **mutagens**, including some chemicals, viruses, and radiation.

Some of the most common genetic disorders result not from mutagens, however, but from the failure of homologous chromosomes to separate during meiosis. Recall that homologous chromosomes pair up during prophase I and normally separate from each other at anaphase I (see p. 1064). This separation, called **disjunction**, produces daughter cells with 23 chromosomes each.

In **nondisjunction**, a pair of chromosomes fails to separate. Both chromosomes then go to the same daughter cell, which receives 24 chromosomes while the other daughter cell receives 22. **Aneuploidy**¹⁵ (AN-you-PLOY-dee), the

¹⁵an = not, without + eu = true, normal + ploid, from diplo = double, paired

presence of an extra chromosome or lack of one, accounts for about 50% of spontaneous abortions. The lack of a chromosome, leaving one chromosome without a match, is called **monosomy**, whereas the presence of one extra chromosome, producing a triple set, is called **trisomy**. Aneuploidy can be detected prior to birth by *amniocentesis*, the examination of cells in a sample of amniotic fluid, or by *chorionic villus sampling*, the removal and examination of cells from the chorion.

Figure 29.13 compares normal disjunction of the X chromosomes with some effects of nondisjunction. In nondisjunction, an egg cell may receive both X chromosomes. If it is fertilized by an X-bearing sperm, the result is an XXX zygote and a set of anomalies called the **triplo-X syndrome**. Triplo-X females are sometimes infertile and

sometimes have mild intellectual impairments. If an XX egg is fertilized by a Y-bearing sperm, the result is an XXY combination and **Klinefelter¹⁶ syndrome**. People with Klinefelter syndrome are sterile males, usually of average intelligence, but with undeveloped testes, sparse body hair, unusually long arms and legs, and enlarged breasts (*gynecomastia*). This syndrome often goes undetected until puberty, when failure to develop the secondary sex characteristics may prompt genetic testing.

The other possible outcome of X chromosome nondisjunction is that an egg cell may receive no X chromosome (both X chromosomes are discarded in the first polar body). If fertilized by a Y-bearing sperm, it dies for lack of

¹⁶Harry F. Klinefelter, Jr. (1912–), American physician

FIGURE 29.13 Disjunction and Nondisjunction. (a) The outcome of normal disjunction and fertilization by X- or Y-bearing sperm. (b) Two of the possible outcomes of nondisjunction followed by fertilization with an X-bearing sperm.

❏ In the right half of the figure, what would the two outcomes be if the sperm carried a Y chromosome instead of an X?

the indispensable genes on the X chromosome. If it is fertilized by an X-bearing sperm, however, the result is a female with **Turner¹⁷ syndrome**, with an XO combination (O represents the absence of one sex chromosome). About 97% of fetuses with Turner syndrome die before birth. Survivors show no serious impairments as children, but tend to have a webbed neck and widely spaced nipples. At puberty, the secondary sex characteristics fail to develop (fig. 29.14). The ovaries are nearly absent, the girl remains sterile, and she usually has a short stature.

The other 22 pairs of chromosomes (the *autosomes*) are also subject to nondisjunction. Only three autosomal trisomies are survivable: those involving chromosomes 13, 18, and 21. The reason is that these three chromosomes are relatively gene-poor. In all other autosomal cases, trisomy gives the embryo a lethal “overdose” of genes. Even the nonlethal trisomies are

¹⁷Henry H. Turner (1892–1970), American endocrinologist

FIGURE 29.14 Turner Syndrome. A 22-year-old woman with Turner syndrome, with an XO karyotype (see figure 29.13, far right). Note her short stature (about 145 cm, or 4 ft 9 in.), lack of sexual development, webbed neck, and widely spaced nipples.

the leading genetic cause of mental and developmental abnormalities.

Nondisjunction of chromosomes 13 and 18 results in *Patau syndrome (trisomy-13)* and *Edward syndrome (trisomy-18)*, respectively. Nearly all fetuses with these trisomies die before birth. Infants born with these syndromes are severely deformed, and fewer than 5% survive for 1 year.

The most survivable trisomy, and therefore the most common among children and adults, is **Down¹⁸ syndrome (trisomy-21)**. Its signs include impaired physical development; short stature; a relatively flat face with a flat nasal bridge; low-set ears; *epicanthal folds* at the medial corners of the eyes; an enlarged, protruding tongue; stubby fingers; and a short broad hand with only one palmar crease (fig. 29.15). People with Down syndrome tend to have outgoing, affectionate personalities. Mental retardation is common and sometimes severe, but is not inevitable. Down syndrome occurs in about 1 out of 700 to 800 live births in the United States.

About 75% of the victims of trisomy-21 die before birth, and 20% of infants born with it die before the age of 10 from such causes as immune deficiency and abnormalities of the heart or kidneys. For those who survive beyond that age, modern medical care has extended life expectancy to about 60 years. After the age of 40, however, many of these people develop early-onset Alzheimer disease, linked to a gene on chromosome 21.

Aneuploidy is far more common in humans than in any other species, and 90% of cases are of maternal rather than paternal origin. These facts seem to result from the extraordinarily long time it takes for human oocytes to complete meiosis—as long as 50 years (see chapter 28). For various reasons including defects in the mitotic spindle and in chromosomal crossing over, aging eggs become less and less able to separate their chromosomes into two identical sets. This is evident in the statistics of Down syndrome: The chance of having a child with Down syndrome is about 1 in 3,000 for a woman under 30, 1 in 365 by age 35, and 1 in 9 by age 48.

• Before You Go On

Answer the following questions to test your understanding of the preceding section.

- How does inflation of the lungs at birth affect the route of blood flow through the heart?
- Why is respiratory distress syndrome common in premature infants?
- Define nondisjunction and explain how it causes aneuploidy. Name two syndromes resulting from aneuploidy.

29.4 Aging and Senescence

Objectives

When you have completed this section, you should be able to

- define *senescence* and distinguish it from aging;
- describe some major changes that occur with aging in each organ system;
- summarize some current theories of senescence; and
- be able to explain how exercise and other factors can slow the rate of senescence.

Like Ponce de León searching for the legendary fountain of youth in Florida, people yearn for a way to preserve their youthful appearance and function. Our real concern, however, is not aging but senescence. The term **aging** is used in various ways but is taken here to mean all changes that occur in the body with the passage of time—including the growth, development, and increasing functional efficiency that occur from childhood to adulthood, as well as the degenerative changes that occur later in life. **Senescence** is the degeneration that occurs in an organ system after the age of peak functional efficiency. It includes a gradual loss of reserve capacities, reduced ability to repair damage and compensate for stress, and increased susceptibility to disease.

Senescence is not just a personal concern but an important issue for health-care providers. One in nine Americans is 65 or older. As the average age of the population rises, health-care professionals will find themselves increasingly occupied by the prevention and treatment of the diseases of age. The leading causes of death change markedly with age. Accidents, homicide, suicide, and AIDS figure prominently in the deaths of people 18 to 34 years old, whereas the major causes of death after age 55 are clearly related to senescence of the organ systems: heart disease, cancer, stroke, diabetes, and lung disease. The causes of senescence, however, remain as much a scientific mystery today as cancer was 50 years ago and heredity was 100 years ago.

As we survey the senescence of the organ systems, you should notice many points relevant not only to caring for an aging population but also to personal health and fitness practices that can lessen the effects of senescence and improve the quality of life in your later years. In addition, the study of senescence calls renewed attention to the multiple interactions among organ systems. As you will see, the senescence of one organ system typically contributes to the senescence of others. Your study of this topic will bring together many concepts introduced in earlier chapters of the book. You may find the glossary helpful in refreshing your memory of concepts revisited in the following discussion.

Senescence of the Organ Systems

Organ systems do not all degenerate at the same rate. For example, from ages 30 to 80, the speed of nerve conduction declines only 10% to 15%, but the number of functional glomeruli in the kidneys declines about 60%. Some physiological functions show only moderate changes at rest but more pronounced differences when tested under exercise conditions. The organ systems also vary widely in the age at which senescence becomes noticeable. There are fore-runners of atherosclerosis, for example, even in infants, and visual and auditory sensitivities begin to decline soon after puberty. By contrast, the female reproductive system does not show significant senescence until menopause and then its decline is relatively abrupt. Aside from these unusual examples, most physiological measures of performance peak between the late teens and age 30, then decline at a rate influenced by the level of use of the organs.

Integumentary System

Two-thirds of people age 50 and over, and nearly all people over age 70, have medical concerns or complaints about their skin. Senescence of the integumentary system often becomes noticeable by the late 40s. The hair turns grayer and thinner as melanocytes die out, mitosis slows down, and dead hairs are not replaced. The atrophy of sebaceous glands leaves the skin and hair drier. As epidermal mitosis

declines and collagen is lost from the dermis, the skin becomes almost paper-thin and translucent. It becomes looser because of a loss of elastic fibers and flattening of the dermal papillae, which normally form a stress-resistant corrugated boundary between the dermis and epidermis. If you pinch a fold of skin on the back of a child's hand, it quickly springs back when you let go; do the same on an older person and the skinfold remains longer. Because of its loss of elasticity, aged skin sags to various degrees and may hang loosely from the arm and other places.

Aged skin has fewer blood vessels than younger skin, and those that remain are more fragile. The skin can become reddened as broken vessels leak into the connective tissue. Many older people exhibit **rosacea**—patchy networks of tiny, dilated blood vessels visible especially on the nose and cheeks. Because of the fragility of the dermal blood vessels, aged skin bruises more easily. Injuries to the skin are more common and severe in old age, partly because the cutaneous nerve endings decline by two-thirds from age 20 to age 80, leaving one less aware of touch, pressure, and injurious stimuli. Injured skin heals slowly in old age because of poorer circulation and a relative scarcity of immune cells and fibroblasts. Antigen-presenting dendritic cells decline by as much as 40% in the aged epidermis, leaving the skin more susceptible to recurring infections.

Thermoregulation can be a serious problem in old age because of the atrophy of cutaneous blood vessels, sweat glands, and subcutaneous fat. Older people are more vulnerable to hypothermia in cold weather and heatstroke in hot weather. Heat waves and cold spells take an especially heavy toll among the elderly poor, who suffer from a combination of reduced homeostasis and inadequate housing.

These are all “normal” changes in the skin, or **intrinsic aging**—changes that occur more or less inevitably with the passage of time. In addition, there is **photoaging**—degenerative changes in proportion to a person's lifetime exposure to ultraviolet radiation. UV radiation accounts for more than 90% of the integumentary changes that people find medically troubling or cosmetically disagreeable: skin cancer; yellowing and mottling of the skin; age spots, which resemble enlarged freckles on the back of the hand and other sun-exposed areas; and wrinkling, which affects the face, hands, and arms more than areas of the body that receive less exposure. A lifetime of outdoor activity can give the skin a leathery, deeply wrinkled, “outdoorsy” appearance (fig. 29.16), but beneath this rugged exterior is a less happy histological appearance. The sun-damaged skin shows many malignant and premalignant cells, extensive damage to the dermal blood vessels, and dense masses of coarse, frayed elastic fibers underlying the surface wrinkles and creases.

Senescence of the skin has far-reaching effects on other organ systems. Cutaneous vitamin D production declines as much as 75% in old age. This is all the more

FIGURE 29.16 Senescence of the Skin. The skin exhibits both intrinsic aging and photoaging. The deep creases seen in the old woman's face result mainly from photoaging.

significant because the elderly spend less time outdoors; and because of increasing lactose intolerance, they often avoid dairy products, the only dietary source of vitamin D. Consequently, the elderly are at high risk of calcium deficiency, which, in turn, contributes to bone loss, muscle weakness, and impaired glandular secretion and synaptic transmission.

Skeletal System

After age 30, osteoblasts become less active than osteoclasts. This imbalance results in **osteopenia**, the loss of bone; when the loss is severe enough to compromise a person's physical activity and health, it is called *osteoporosis* (see p. 236). After age 40, women lose about 8% of their bone mass per decade and men about 3%. Bone loss from the jaws is a contributing factor in tooth loss.

Not only does bone density decline with age, but the bones become more brittle as the cells synthesize less protein. Fractures occur more easily and heal more slowly. A fracture may impose a long period of immobility, which

makes a person more vulnerable to pneumonia and other infectious diseases.

People notice more stiffness and pain in the synovial joints as they age, and degenerative joint diseases affect the lifestyle of 85% of people over age 75. Synovial fluid is less abundant and the articular cartilage is thinner or absent. Exposed bone surfaces abrade each other and cause friction, pain, and reduced mobility. *Osteoarthritis* is the most common joint disease of older people and one of the most common causes of physical disability (p. 314). Even breathing becomes more difficult and tiring in old age because expansion of the thorax is restricted by calcification of the sternocostal joints. Degeneration of the intervertebral discs causes back pain and stiffness, but herniated discs are less common in old age than in youth because the discs become more fibrous and stronger, with less nucleus pulposus.

Muscular System

One of the most noticeable changes we experience with age is the replacement of lean body mass (muscle) with fat. The change is dramatically exemplified by CT scans of the thigh. In a young well-conditioned male, muscle accounts for 90% of the cross-sectional area of the midthigh, whereas in a frail 90-year-old woman, it is only 30%. Muscular strength and mass peak in the 20s; by the age of 80, most people have only half as much strength and endurance. A large percentage of people over age 75 cannot lift a 4.5 kg (10 lb) weight with their arms; such simple tasks as carrying a sack of groceries into the house may become impossible. The loss of strength is a major contributor to falls, fractures, and dependence on others for the routine activities of daily living. Fast-twitch fibers exhibit the earliest and most severe atrophy, thus increasing reaction time and reducing coordination.

There are multiple reasons for the loss of strength. Aged muscle fibers have fewer myofibrils, so they are smaller and weaker. The sarcomeres are increasingly disorganized, and muscle mitochondria are smaller and have reduced quantities of oxidative enzymes. Aged muscle has less ATP, creatine phosphate, glycogen, and myoglobin; consequently, it fatigues quickly. Muscles also exhibit more fat and fibrosis with age, which limits their movement and blood circulation. With reduced circulation, muscle injuries heal more slowly and with more scar tissue.

But the weakness and easy fatigue of aged muscle also stem from the senescence of other organ systems. There are fewer motor neurons in the spinal cord, and some muscle shrinkage may represent denervation atrophy. The remaining neurons produce less acetylcholine and show less efficient synaptic transmission, which makes the muscles slower to respond to stimulation. As muscle atrophies, motor units have fewer muscle fibers per motor neuron, and more motor units must be recruited to

perform a given task. Tasks that used to be easy, such as buttoning the clothes or eating a meal, take more time and effort. The sympathetic nervous system is also less efficient in old age; consequently, blood flow to the muscles does not respond efficiently to exercise and this contributes to their rapid fatigue.

Nervous System

The nervous system reaches its peak development around age 30. The average brain weighs 56% less at age 75 than at age 30. The cerebral gyri are narrower, the sulci are wider, the cortex is thinner, and there is more space between the brain and meninges. The remaining cortical neurons have fewer synapses, and for multiple reasons, synaptic transmission is less efficient: The neurons produce less neurotransmitter, they have fewer receptors, and the neuroglia around the synapses is more leaky and allows neurotransmitter to diffuse away. The degeneration of myelin sheaths with age also slows down signal conduction.

Neurons exhibit less rough ER and Golgi complex with age, which indicates that their metabolism is slowing down. Old neurons accumulate lipofuscin pigment and show more neurofibrillary tangles—dense mats of cytoskeletal elements in their cytoplasm. In the extracellular material, plaques of fibrillar protein (amyloid) appear, especially in people with Down syndrome and Alzheimer disease (AD). AD is the most common nervous disability of old age (p. 474).

Not all functions of the central nervous system are equally affected by senescence. Motor coordination, intellectual function, and short-term memory decline more than language skills and long-term memory. Elderly people are often better at remembering things in the distant past than remembering recent events.

The sympathetic nervous system loses adrenergic receptors with age and becomes less sensitive to norepinephrine. This contributes to a decline in homeostatic control of such variables as body temperature and blood pressure. Many elderly people experience *orthostatic hypotension*—a drop in blood pressure when they stand, which sometimes results in dizziness, loss of balance, or fainting.

Sense Organs

Some sensory functions decline shortly after adolescence. Presbyopia (loss of flexibility in the lenses) makes it more difficult for the eyes to focus on nearby objects. Visual acuity declines and often requires corrective lenses by middle age. Cataracts (cloudiness of the lenses) are more common in old age. Night vision is impaired as more and more light is needed to stimulate the retina. This has several causes: There are fewer receptor cells in the retina, the vitreous body becomes less transparent, and the pupil becomes narrower as the pupillary dilators

atrophy. Dark adaptation takes longer as the enzymatic reactions of the photoreceptor cells become slower. Changes in the structure of the iris, ciliary body, or lens can block the reabsorption of aqueous humor, thereby increasing the risk of glaucoma. Having to give up reading and driving can be among the most difficult changes of lifestyle in old age.

Auditory sensitivity peaks in adolescence and declines afterward. The tympanic membrane and the joints between the auditory ossicles become stiffer, so vibrations are transferred less effectively to the inner ear, creating a degree of conductive deafness. Nerve deafness occurs as the number of cochlear hair cells and auditory nerve fibers declines. The greatest hearing loss occurs at high frequencies and in the frequency range of most conversation. The death of receptor cells in the semicircular ducts, utricle, and saccule, and of nerve fibers in the vestibular nerve and neurons in the cerebellum, results in poor balance and dizziness—another factor in falls and bone fractures.

The senses of taste and smell are blunted as the taste buds, olfactory cells, and second-order neurons in the olfactory bulbs decline in number. Food may lose its appeal, and declining sensory function can therefore be a factor in malnutrition.

Endocrine System

The endocrine system degenerates less than any other organ system. The reproductive hormones drop sharply and growth hormone and thyroid hormone secretion decline steadily after adolescence, but other hormones continue to be secreted at fairly stable levels even into old age. Target cell sensitivity declines, however, so some hormones have less effect. For example, the pituitary gland is less sensitive to negative feedback inhibition by adrenal glucocorticoids; consequently, the response to stress is more prolonged than usual. Diabetes mellitus is more common in old age, largely because target cells have fewer insulin receptors. In part, this is an effect of the greater percentage of body fat in the elderly. The more fat at any age, the less sensitive other cells are to insulin. Body fat increases as the muscles atrophy, and muscle is one of the body's most significant glucose-buffering tissues. Because of the blunted insulin response, glucose levels remain elevated longer than normal after a meal.

Circulatory System

Cardiovascular disease is a leading cause of death in old age. Senescence has multiple effects on the blood, heart, arteries, and veins. Anemia may result from nutritional deficiencies, inadequate exercise, disease, and other causes. The factors that cause anemia in older people are so complicated it is almost impossible to control them enough to determine whether aging alone causes it. Evidence suggests that there is no change in the baseline

rate of erythropoiesis in old age. Hemoglobin concentration, cell counts, and other variables are about the same among healthy people in their 70s as in the 30s. However, older people do not adapt well to stress on the hemopoietic system, perhaps because of the senescence of other organ systems. As the gastric mucosa atrophies, for example, it produces less of the intrinsic factor needed for vitamin B₁₂ absorption. This increases the risk of pernicious anemia. As the kidneys age and the number of nephrons declines, less erythropoietin is secreted. There may also be a limit to how many times the hemopoietic stem cells can divide and continue giving rise to new blood cells. Whatever its cause, anemia limits the amount of oxygen that can be transported and thus contributes to the atrophy of tissues everywhere in the body.

Think About It

Draw a positive feedback loop showing how anemia and senescence of the kidneys could affect each other.

Everyone exhibits coronary atherosclerosis with age. Consequently, myocardial cells die; angina pectoris and myocardial infarction become more common; the heart wall becomes thinner and weaker; and stroke volume, cardiac output, and cardiac reserve decline. Like other connective tissues, the fibrous skeleton of the heart becomes less elastic. This limits cardiac distension and reduces the force of systole. Degenerative changes in the nodes and conduction pathways of the heart lead to a higher incidence of cardiac arrhythmia and heart block. Physical endurance is compromised by the drop in cardiac output.

Arteries stiffened by atherosclerosis cannot expand as effectively to accommodate the pressure surges of cardiac systole. Blood pressure therefore rises steadily with age (see table 20.1, p. 766). Atherosclerosis also narrows the arteries and reduces the perfusion of most organs. The effects of reduced circulation on the skin, skeletal muscles, and brain have already been noted. The combination of atherosclerosis and hypertension also weakens the arteries and increases the risk of aneurysm and stroke.

Atherosclerotic plaques trigger thrombosis, especially in the lower limbs, where flow is relatively slow and the blood clots more easily. About 25% of people over age 50 experience venous blockage by thrombosis—especially people who do not exercise regularly.

Degenerative changes in the veins are most evident in the limbs. The valves become weaker and less able to stop the backflow of blood. Blood pools in the legs and feet, raises capillary blood pressure, and causes edema. Chronic stretching of the vessels often produces varicose veins and hemorrhoids. Support hose can reduce edema by compressing the tissues and forcing tissue fluid to return to the bloodstream, but physical activity is even more important in promoting venous return.

Immune System

The amounts of lymphatic tissue and red bone marrow decline with age; consequently there are fewer hemopoietic stem cells, disease-fighting leukocytes, and antigen-presenting cells (APCs). Also, the lymphocytes produced in these tissues often fail to mature and become immunocompetent. Both humoral and cellular immunity depend on APCs and helper T cells, and therefore both types of immune response are blunted. As a result, an older person is less protected against cancer and infectious diseases. It becomes especially important in old age to be vaccinated against influenza and other acute seasonal infections.

Respiratory System

Pulmonary ventilation declines steadily after the 20s and is one of several factors in the gradual loss of stamina. The costal cartilages and joints of the thoracic cage become less flexible, the lungs have less elastic tissue, and the lungs have fewer alveoli. Vital capacity, minute respiratory volume, and forced expiratory volume fall. The elderly are also less capable of clearing the lungs of irritants and pathogens and are therefore increasingly vulnerable to respiratory infections. Pneumonia causes more deaths than any other infectious disease and is often contracted in hospitals and nursing homes.

The chronic obstructive pulmonary diseases (COPDs)—emphysema and chronic bronchitis—are more common in old age since they represent the cumulative effects of a lifetime of degenerative change. They are among the leading causes of death in old age. Pulmonary obstruction also contributes to cardiovascular disease, hypoxemia, and hypoxic degeneration in all the organ systems. Respiratory health is therefore a major concern in aging.

Urinary System

The kidneys exhibit a striking degree of atrophy with age. From ages 25 to 85, the number of nephrons declines 30% to 40% and up to a third of the remaining glomeruli become atherosclerotic, bloodless, and nonfunctional. The kidneys of a 90-year-old are 20% to 40% smaller than those of a 30-year-old and receive only half as much blood. The glomerular filtration rate is proportionately lower and the kidneys are less efficient at clearing wastes from the blood. Although baseline renal function is adequate even in old age, there is little reserve capacity; thus other diseases can lead to surprisingly rapid renal failure. Drug doses often need to be reduced in old age because the kidneys cannot clear drugs from the blood as rapidly; this is a contributing factor in overmedication among the aged.

Water balance becomes more precarious in old age because the kidneys are less responsive to antidiuretic hormone and because the sense of thirst is sharply reduced. Even when given free access to water, elderly people may not drink enough to maintain normal blood osmolarity.

Dehydration is therefore common. It is often said that aged kidneys are deficient in maintaining electrolyte balance, but the evidence for this remains questionable.

Voiding and bladder control become a problem for both men and women. About 80% of men over the age of 80 are affected by benign prostatic hyperplasia. The enlarged prostate compresses the urethra and interferes with emptying of the bladder. Urine retention may cause pressure to back up in the kidneys, aggravating the failure of the nephrons. Older women are subject to incontinence (leakage of urine), especially if their history of pregnancy and childbearing has weakened the pelvic muscles and urethral sphincters. Senescence of the sympathetic nervous system and nervous disorders such as stroke and Alzheimer disease can also cause incontinence.

Digestive System and Nutrition

The stratified squamous epithelium of the oral cavity and esophagus is thinner and more vulnerable to abrasion in old age. Less saliva is secreted, making food less flavorful, swallowing more difficult, and the teeth more prone to caries. Dentures are an unpleasant fact of life for many people over age 65, having lost their teeth to caries and periodontitis.

The gastric mucosa atrophies and secretes less acid and intrinsic factor. Acid deficiency reduces the absorption of calcium, iron, zinc, and folic acid. Heartburn becomes more common as the weakening lower esophageal sphincter fails to prevent reflux into the esophagus. The most common digestive complaint of older people is constipation, which results from the reduced muscle tone and weaker peristalsis of the colon. This seems to stem from a combination of factors: atrophy of the muscularis externa, reduced sensitivity to neurotransmitters, less fiber and water in the diet, and less exercise. The liver, gallbladder, and pancreas show only slightly reduced function. Any drop in liver function, however, makes it harder to detoxify drugs and can contribute to overmedication.

Older people tend to reduce their food intake because of lower energy demand and appetite, because declining sensory functions make food less appealing, and because reduced mobility makes it more troublesome to shop and prepare meals. However, they need fewer calories than younger people because they have lower basal metabolic rates and tend to be less physically active. Protein, vitamin, and mineral requirements remain essentially unchanged, although vitamin and mineral supplements may be needed to compensate for reduced food intake and intestinal absorption. Malnutrition is common among older people and is an important factor in anemia and reduced immunity.

Reproductive System

In men, the senescent changes in the reproductive system are relatively gradual; they include declining testosterone secretion, sperm count, and libido. By age 65, sperm

count is about one-third of what it was in a man's 20s. Men remain fertile (capable of fathering a child) well into old age, but impotence (inability to maintain an erection) can occur because of atherosclerosis, hypertension, medication, and psychological reasons.

In women, the changes are more pronounced and develop more rapidly. Over the course of menopause, the ovarian follicles are used up, gametogenesis ceases, and the ovaries stop producing sex steroids. This may result in vaginal dryness, genital atrophy, and reduced libido and may make sex less enjoyable. With the loss of ovarian steroids, a postmenopausal woman has an elevated risk of osteoporosis and atherosclerosis.

Exercise and Senescence

Other than the mere passage of time, senescence results from obesity and insufficient exercise more than from any other causes. Conversely, good nutrition and exercise are the best ways to slow its progress.

There is no clear evidence that exercise will prolong your life, but there is little doubt that it improves the quality of life in old age. It maintains endurance, strength, and joint mobility, and reduces the incidence and severity of hypertension, osteoporosis, obesity, and diabetes mellitus. This is especially true if you begin a program of regular physical exercise early in life and make a lasting habit of it. If you stop exercising regularly after middle age, the body rapidly becomes deconditioned, although appreciable reconditioning can be achieved even when an exercise program is begun late in life. A person in his or her 90s can increase muscle strength two- or threefold in 6 months with as little as 40 minutes of isometric exercise a week. The improvement results from a combination of muscle hypertrophy and neural efficiency.

Resistance exercises may be the most effective way of reducing accidental injuries such as bone fractures, whereas endurance exercises reduce body fat and increase cardiac output and maximum oxygen uptake. A general guideline for ideal endurance training is to have three to five periods of aerobic exercise per week, each 20 to 60 minutes long and vigorous enough to reach 60% to 90% of your maximum heart rate. The maximum is best determined by a stress test but averages about 220 beats per minute minus one's age in years.

An exercise program should ideally be preceded by a complete physical examination and stress test. Warm-up and cool-down periods are especially important in avoiding soft tissue injuries. Because of their lower capacity for thermoregulation, older people must be careful not to overdo exercise, especially in hot weather. At the outset of a new exercise program, it is best to "start low and go slow."

Theories of Senescence

Why do our organs wear out? Why must we die? There still is no general theory on this. The question actually

comes down to two issues: (1) What are the mechanisms that cause the organs to deteriorate with age? (2) Why has natural selection not eliminated these and produced bodies capable of longer life?

Mechanisms of Senescence

Numerous hypotheses have been proposed and discarded to explain why organ function degenerates with age. Some authorities maintain that senescence is an intrinsic process governed by inevitable or even preprogrammed changes in cellular function. Others attribute senescence to extrinsic (environmental) factors that progressively damage our cells over the course of a lifetime.

There is good evidence of a hereditary component to longevity. Unusually long and short lives tend to run in families. Monozygotic (identical) twins are more likely than dizygotic twins to die at a similar age. One striking genetic defect called *progeria*¹⁹ is characterized by greatly accelerated senescence (fig. 29.17). Symptoms begin to appear by age 2. The child's growth rate declines, the muscles and skin become flaccid, most victims lose their hair, and most die in early adolescence from advanced atherosclerosis. In Werner syndrome, caused by a defective gene on chromosome 8, people show marked senescence beginning in their 20s and usually die by age 50. There is some controversy over the relevance or similarity of these syndromes to normal senescence, but they do demonstrate that many of the changes associated with old age can be brought on by a genetic anomaly.

Knowing that senescence is partially hereditary, however, does not answer the question about why tissues degenerate. Quite likely, no one theory explains all forms of senescence, but let's briefly examine some of them.

Replicative Senescence Normal organ function usually depends on a rate of cell renewal that keeps pace with cell death. There is a limit, however, to how many times cells can divide. Human cells cultured in the laboratory divide 80 to 90 times if taken from a fetus, but only 20 to 30 times if taken from older people. After reaching their maximum number of divisions, cultured cells degenerate and die. This decline in mitotic potential with age is called **replicative senescence**.

Why this occurs is a subject of lively current research. Much of the evidence points to the **telomere**,²⁰ a “cap” on each end of a chromosome analogous to the plastic tip of a shoelace. In humans, it consists of a noncoding nucleotide sequence CCCTAA repeated 1,000 times or more. One of its functions may be to stabilize the chromosome and prevent it from unraveling or sticking to other chromosomes. Also, during DNA replication, DNA polymerase cannot reproduce the very ends of the DNA molecule. If there

FIGURE 29.17 Progeria. This is a genetic disorder in which senescence appears to be greatly accelerated. The individuals here, from left to right, are 15, 12, and 26 years old. Few people with progeria live as long as the woman on the right.

were functional genes at the end, they would not get duplicated. The telomere may therefore provide a bit of “disposable” DNA at the end, so that DNA polymerase doesn't fail to replicate genes that would otherwise be there. Every time DNA is replicated, 50 to 100 bases are lost from the telomere. In old age, the telomere may be exhausted and the polymerase may then indeed fail to replicate some of the terminal genes. Old chromosomes may therefore be more vulnerable to damage, replication errors, or both, causing old cells to be increasingly dysfunctional. The “immortality” of cancer cells results from an enzyme called *telomerase*, lacking from healthy cells, which enables cancer cells to repair telomere damage and escape the limit on number of cell divisions.

Replicative senescence is clearly not the entire answer to why organs degenerate, however. Skeletal muscles and the brain exhibit extreme senescence, yet muscle fibers and neurons are nonmitotic. Their senescence obviously is not a result of repeated mitosis and cumulative telomere damage. A full explanation of senescence must embrace additional processes and theories.

Cross-Linking Theory About one-fourth of the body's protein is collagen. With age, collagen molecules become cross-linked by more and more disulfide bridges, thus

¹⁹*pro* = before + *ger* = old age

²⁰*telo* = end + *mer* = piece

making the fibers less soluble and more stiff. This is thought to be a factor in several of the most noticeable changes of the aging body, including stiffening of the joints, lenses, and arteries. Similar cross-linking of DNA and enzyme molecules could progressively impair their functions as well.

Other Protein Abnormalities Not only collagen but also many other proteins exhibit increasingly abnormal structure in older tissues and cells. The changes are not in amino acid sequence—therefore not attributable to DNA mutations—but lie in the way the proteins are folded and other moieties such as carbohydrates are attached to them. This is another reason that cells accumulate more dysfunctional proteins as they age.

Free Radical Theory Free radicals have very destructive effects on macromolecules (see chapter 2). We have a number of antioxidants to protect us from them, but it is believed that some of these antioxidants become less abundant with age and are eventually overwhelmed by free radicals, or that some of the molecules damaged by free radicals are long-lived and accumulate in cells. Free radical damage may therefore be a contributing factor in some of the other mechanisms of senescence discussed here.

Autoimmune Theory Some of the altered macromolecules described previously may be recognized as foreign antigens and stimulate lymphocytes to mount an immune response against the body's own tissues. Autoimmune diseases do, in fact, become more common in old age.

Evolution and Senescence

If certain genes contribute to senescence, it raises an evolutionary question—Why does natural selection not eliminate them? In an attempt to answer this, biologists once postulated that senescence and death were for the good of the species—a way for older, worn-out individuals to make way for younger, healthier ones. We can see the importance of death for the human population by imagining that science had put an end to senescence and people died at a rate of only 1 per 1,000 per year regardless of age (the rate at which American 18-year-olds now die). If so, the median age of the population would be 163, and 13% of us would live to be 2,000 years old. The implications for world population and competition for resources would be staggering. Thus it is easy to understand why death was once interpreted as a self-sacrificing phenomenon for the good of the species.

But this hypothesis has several weaknesses. One of them is the fact that natural selection works exclusively through the effects of genes on the reproductive rates of individuals. A species evolves only because some mem-

bers reproduce more than others. A gene that does not affect reproductive rate can be neither eliminated nor favored by natural selection. Genes for disorders such as Alzheimer disease have little or no effect until a person is past reproductive age. Our prehistoric and even fairly recent ancestors usually died of accidents, predation, starvation, weather, and infectious diseases at an early age. Few people lived long enough to be affected by atherosclerosis, colon cancer, or Alzheimer disease. Natural selection would have been “blind” to such death-dealing genes, which would escape the selection process and remain with us today.

Death

Life expectancy, the average length of life in a given population, has steadily increased in industrialized countries. People born in the United States at the beginning of the twentieth century had a life expectancy of only 45 to 50 years; nearly half of them died of infectious disease. The average boy born today can expect to live 75 years and the average girl 81 years. This is due mostly to victories over infant and child mortality, not to advances at the other end of the life span. **Life span**, the maximum age attainable by humans, has not increased for many centuries and there seems to be little prospect that it ever will. There is no verifiable record of anyone living past the age of 122 years.

There is no definable instant of biological death. Some organs function for an hour or more after the heart stops beating. During this time, even if a person is declared legally dead, living organs may be removed for transplantation. For legal purposes, death was once defined as the loss of a spontaneous heartbeat and respiration. Now that cardiopulmonary functions can be artificially maintained for years, this criterion is less distinct. Clinical death is now widely defined in terms of **brain death**—a lack of cerebral activity indicated by a flat electroencephalogram for 30 minutes to 24 hours (depending on state laws), accompanied by a lack of reflexes or lack of spontaneous respiration and heartbeat.

Death usually results from the failure of a particular organ, which then has a cascading effect on other organs. Kidney failure, for example, leads to the accumulation of toxic wastes in the blood, which in turn leads to loss of consciousness, brain function, respiration, and heartbeat.

Ninety-nine percent of us will die before age 100, and there is little chance that this outlook will change within our lifetimes. We cannot presently foresee any “cure for old age” or significant extension of the human life span. The real issue is to maintain the best possible quality of life, and when the time comes to die, to do so in comfort and dignity.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

13. Define aging and senescence.
14. List some tissues or organs in which changes in collagenous and elastic connective tissues lead to senescence.
15. Many older people have difficulty with mobility and simple self-maintenance tasks such as dressing and cooking. Name some organ systems whose senescence is most relevant to these limitations.
16. Explain why both endurance and resistance exercises are important in old age.
17. Summarize five mechanisms that may be responsible for senescence.

INSIGHT 29.4 Clinical Application

Reproductive Technology—Making Babies in the Laboratory

Fertile heterosexual couples who have frequent intercourse and use no contraception have a 90% chance of conceiving within 1 year. About one in six American couples, however, is *infertile*—unable to conceive. Infertility can sometimes be corrected by hormone therapy or surgery, but when this fails, parenthood may still be possible through other reproductive technologies discussed here.

Artificial Insemination

If only the male is infertile, the oldest and simplest solution is *artificial insemination (AI)*, in which a physician introduces donor semen into or near the cervix. This was first done in the 1890s, when the donor was often the physician himself or a medical student who donated semen for payment. In 1953, a technique was developed for storing semen in glass ampules frozen in liquid nitrogen; the first commercial sperm banks opened in 1970. Most women undergoing AI use sperm from anonymous donors but are able to select from a catalog that specifies the donors' physical and intellectual traits. A man with a low sperm count can donate semen at intervals over a course of several weeks and have it pooled, concentrated, and used to artificially inseminate his partner. Men planning vasectomies sometimes donate sperm for storage as insurance against the death of a child, divorce and remarriage, or a change in family planning. Some cases of infertility are due to sperm destruction by the woman's immune system. This can sometimes be resolved by *sperm washing*—a technique in which the sperm are collected, washed to remove antigenic proteins from their surfaces, and then introduced by AI.

Oocyte Donation

The counterpart to sperm donation is *oocyte donation*, in which fresh oocytes are obtained from one woman, fertilized, and transplanted to the uterus of another. A woman may choose this procedure for a variety of reasons: being past menopause, having had her ovaries removed, or having a hereditary disorder she does not want to pass to her children, for example. The donated oocytes are sometimes provided by a relative or may

be left over from another woman's in vitro fertilization (see next paragraph). The first baby conceived by oocyte donation was born in 1984. This procedure has a success rate of 20% to 50%.

In Vitro Fertilization

In some women the uterus is normal but the uterine tubes are scarred by pelvic inflammatory disease or other causes. *In vitro fertilization (IVF)* is an option in some of these cases. The woman is given gonadotropins to induce the "superovulation" of multiple eggs. The physician views the ovary with a laparoscope and removes eggs by suction. These are placed in a solution that mimics the chemical environment of her reproductive tract, and sperm are added to the dish. The term *in vitro*²¹ fertilization refers to the fact that fertilization occurs in laboratory glassware; children conceived by IVF are often misleadingly called "test-tube babies." In some cases, fertilization is assisted by piercing the zona pellucida before the sperm are added (*zona drilling*) or by injecting sperm directly into the egg through a micropipet. By the day after fertilization, some of the preembryos reach the 8- to 16-celled stage. Several of these are transferred to the mother's uterus through the cervix and her blood HCG level is monitored to determine whether implantation has occurred. Excess IVF preembryos may be donated to other infertile couples or frozen and used in later attempts. In cases where a woman has lost her ovaries to disease, the oocytes may be provided by another donor, often a relative.

IVF costs up to \$10,000 per attempt; it results in pregnancy about 34% of the time and live birth in 28% of the attempts. A couple can easily spend \$100,000 before IVF is successful, and then some attempts are "too successful." Multiple preembryos are usually introduced to the uterus as insurance against the low probability that any one of them will implant and survive. Sometimes, however, this results in multiple births—in rare cases, up to seven babies (septuplets). One advantage of IVF is that when the preembryo reaches the eight-celled stage, one or two cells can be removed and tested for genetic defects before the preembryo is introduced to the uterus.

IVF has been used in animal breeding since the 1950s, but the first child conceived this way was Louise Joy Brown (fig. 29.18), born in England in 1978. The practice grew rapidly, and in 2003, more than 48,000 babies were born through IVF in the United States alone.

²¹*in vitro* = in glass

Surrogate Mothers

IVF is an option only for women who have a functional uterus. A woman who has had a hysterectomy or is otherwise unable to become pregnant or maintain a pregnancy may contract with a *surrogate mother* who provides a “uterus for hire.” Some surrogates are both genetic and gestational mothers, and others gestational only. In the former case, the surrogate is artificially inseminated by a man’s sperm and agrees to give the baby to the man and his partner at birth. In the latter case, oocytes are collected from one woman’s ovaries, fertilized in vitro, and the preembryos are placed in the surrogate’s uterus. This is typical of cases in which a woman has functional ovaries but no functional uterus. A surrogate typically receives a fee of about \$10,000 plus medical and legal costs. Several hundred babies have been produced this way in the United States. In at least one case, a woman carried the child of her infertile daughter, thus giving birth to her own granddaughter.

Gamete Intrafallopian Transfer

The low success rate of IVF led to a search for more reliable and cost-effective techniques. *Gamete intrafallopian transfer (GIFT)* was developed in the mid-1980s on the conjecture that pregnancy would be more successful if the oocyte was fertilized and began cleavage in a more natural environment. Eggs are obtained from a woman after a weeklong course of ovulation-inducing drug treatment. The most active sperm cells are isolated from the semen, and the eggs and sperm are introduced into her uterine tube proximal to any existing obstruction. GIFT is about half as expensive as IVF and succeeds about 40% of the time. In a modification called *zygote intrafallopian transfer (ZIFT)*, fertilization occurs in vitro and the preembryo is introduced into the uterine tube. Traveling down the uterine tube seems to improve the chance of implantation when the conceptus reaches the uterus.

Embryo Adoption

Embryo adoption is used when a woman has malfunctioning ovaries but a normal uterus. A man’s sperm are used to artificially inseminate another woman. A few days later, the preembryo is flushed from the donor’s uterus before it implants and is transferred to the uterus of the woman who wishes to have a child.

Ethical and Legal Issues

Like many other advances in medicine, reproductive technology has created its own ethical and legal dilemmas, some of which are especially confounding. Perhaps the most common problem is the surrogate mother who changes her mind. Surrogates enter into a contract to surrender the baby to a couple at birth, but after carrying a baby for 9 months and giving birth, they sometimes feel differently. This raises questions about the definition of motherhood, especially if she is the gestational but not the genetic mother.

The converse problem is illustrated by a case in which the child had hydrocephalus and neither the contracting couple nor the surrogate mother wanted it. In this case, genetic testing showed that the child actually had been fathered by the surrogate’s husband, not the man who had contracted for her service. The surrogate then accepted the baby as her own. Nevertheless, the case raised the question of whether the birth

FIGURE 29.18 New Beginnings Through Reproductive Technology. Louise Joy Brown, shown here at age 10, was the first child ever conceived by in vitro fertilization (IVF). She is holding Andrew Macheta, another IVF baby, at a 10-year anniversary celebration at the clinic near London where both were conceived.

of a genetically defective child constituted fulfillment of the contract and obligated the contracting couple to accept the child, or whether such a contract implied that the surrogate mother must produce a healthy child.

In another case, a wealthy couple was killed in an accident and left frozen preembryos in an IVF clinic. A lawsuit was filed on behalf of the preembryos on the grounds that they were heirs to the couple’s estate and should be carried to birth by a surrogate mother so they could inherit it. The court ruled against the suit and the preembryos were allowed to die. In still another widely publicized case, a man sued his wife for custody of their frozen preembryos as part of a divorce settlement.

IVF also creates a question of what to do with the excess preembryos. Some people view their disposal as a form of abortion, even if the preembryo is only a mass of 8 to 16 undifferentiated cells. On the other hand, there are those who see such excess preembryos as a research opportunity to obtain information that could not be obtained in any other way. In 1996, an IVF clinic in England was allowed to destroy 3,300 unclaimed preembryos, but only after heated public controversy.

It is common for scientific advances to require new advances in law and ethics. The parallel development of these disciplines is necessary if we are to benefit from the developments of science and ensure that knowledge is applied in an ethical and humane manner.

CHAPTER REVIEW

Review of Key Concepts

29.1 Fertilization and the Preembryonic Stages (p. 1118)

1. Sperm must travel to the distal one-third of the uterine tube if they are to encounter the egg before it dies. This traveling, or *sperm migration*, may be aided by the cervical mucus, female orgasm, and chemical attractants emitted by the egg.
2. Freshly ejaculated sperm cannot fertilize an egg. They undergo *capacitation*, becoming capable of fertilization, as they migrate.
3. When a sperm encounters an egg, it releases enzymes from its acrosome (the *acrosomal reaction*), enabling it to penetrate the cumulus oophorus, zona pellucida, and egg membrane. Hundreds of sperm may be needed to clear a path for the one that fertilizes the egg.
4. The egg has a *fast block* and a *slow block* to prevent fertilization by more than one sperm (*polyspermy*). The fast block is a change in egg membrane voltage that inhibits the binding of additional sperm. The slow block involves exocytosis of the egg's *cortical granules* to produce an impenetrable *fertilization membrane* around the egg.
5. The fertilized egg completes meiosis II and casts off a second polar body. The sperm and egg nuclei swell and form *pronuclei*. When the pronuclei rupture and their chromosomes mingle, the egg is a diploid *zygote*.
6. Pregnancy is clinically divided into three *trimesters* of about 12 weeks each, and biologically divided into *preembryonic*, *embryonic*, and *fetal stages*.
7. The preembryonic stage comprises the first 16 days of development and includes cleavage, implantation, and embryogenesis, culminating in a three-layered embryo.
8. *Cleavage* is the mitotic division of the zygote into cells called *blastomeres*. The stage that arrives at the uterus is a *morula* of about 16 blastomeres. It develops into a hollow ball called the *blastocyst*, with an outer cell mass

called the *trophoblast* and inner cell mass called the *embryoblast*.

9. *Implantation* is the attachment of the blastocyst to the uterine wall. The trophoblast differentiates into a cellular mass called the *cytotrophoblast* next to the embryo, and a multinucleate mass called the *syncytiotrophoblast*, which grows rootlets into the endometrium. The endometrium grows over the blastocyst and soon completely covers it.
10. The trophoblast secretes human chorionic gonadotropin, the hormone that stimulates growth and secretion by the corpus luteum.
11. During implantation, the embryoblast undergoes *gastrulation* and its cells stratify into three *primary germ layers*: *ectoderm*, *mesoderm*, and *endoderm*. This process is *embryogenesis*. When the three primary germ layers have formed, 16 days after conception, the individual is an *embryo*.

29.2 The Embryonic and Fetal Stages (p. 1124)

1. The embryonic stage extends from 16 days through the end of week 8. It is marked by formation of the embryonic membranes, placental nutrition, and appearance of the organ systems.
2. During this stage the embryo curls longitudinally into a C shape; its lateral margins fold ventrally and convert the flat embryonic disc into a cylindrical body; a primitive gut and body cavity form; and all of the organ systems first appear. Differentiation of the organs is called *organogenesis*.
3. Four membranes are associated with the embryo and fetus: the amnion, yolk sac, allantois, and chorion.
4. The *amnion* is a translucent sac that encloses the embryo in a pool of *amniotic fluid*. This fluid protects the embryo from trauma and temperature fluctuations and allows freedom of movement and symmetric development.
5. The *yolk sac* contributes to development of the digestive tract and produces the first blood and germ cells of the embryo.
6. The *allantois* is an outgrowth of the yolk sac that forms a structural foundation for umbilical cord development and becomes part of the urinary bladder.
7. The *chorion* encloses all of the other membranes and forms the fetal part of the placenta.
8. Until it implants in the endometrium, the conceptus is nourished by a secretion called *uterine milk*.
9. After implantation, the conceptus is fed by *trophoblastic nutrition*, in which the trophoblast digests *decidual cells* of the endometrium. This is the dominant mode of nutrition for 8 weeks.
10. The *placenta* begins to form 11 days after conception as chorionic villi of the trophoblast eat into uterine blood vessels, eventually creating a blood-filled cavity called the *placental sinus*. The chorionic villi grow into branched treelike structures surrounded by the maternal blood in the sinus. Nutrients diffuse from the maternal blood into embryonic blood vessels in the villi, and embryonic wastes diffuse the other way to be disposed of by the mother. *Placental nutrition* becomes dominant after 8 weeks and continues until birth.
11. The placenta communicates with the embryo and fetus by way of two arteries and a vein contained in the *umbilical cord*.
12. Traces of all organ systems are present by the end of 8 weeks. The individual is considered a *fetus* from then until birth.
13. In the fetal stage, organs undergo growth and differentiation and become capable of functioning outside the mother's body. Major developments in the fetal stage are summarized in table 29.4.
14. The circulatory system differs most markedly from prenatal to neonatal life. In the fetus, a pair of umbilical arteries arise from the internal iliac arteries and supply the placenta.

A single umbilical vein returns from the placenta and drains most of its blood into the inferior vena cava (IVC).

15. Three bypasses or shunts divert fetal blood from organs that are not very functional before birth: The *ductus venosus* bypasses the liver and carries most umbilical vein blood directly to the IVC; the foramen ovale in the interatrial septum of the heart allows blood to pass directly from the right atrium to the left atrium, bypassing the lungs, and the *ductus arteriosus* allows blood in the pulmonary trunk to pass directly into the aorta and bypass the lungs.

29.3 The Neonate (p. 1134)

1. The first 6 to 8 hours after birth are a *transitional period* marked by increasing heart and respiratory rates and falling temperature. The first 6 weeks of postpartum life are the *neonatal period*.
2. After severance of the umbilical cord, the proximal parts of the umbilical arteries become *vesical arteries*, which supply the urinary bladder. Other blood vessels unique to the fetus close and become fibrous cords or ligaments. The foramen ovale and ductus arteriosus close so that blood from the right heart is forced to circulate through the lungs.
3. Breathing is very difficult for the neonate as it first inflates the pulmonary alveoli.
4. Neonatal immunity depends heavily on IgG acquired through the placenta and IgA from colostrum. By 6 months, the infant produces ample IgG of its own.
5. Neonatal thermoregulation is critical because infants lose heat easily. This heat loss is compensated for to some extent by a form of heat-producing adipose tissue called *brown fat*.
6. The neonatal kidneys are not very efficient at concentrating urine, so neonates have a relatively high rate of water loss and require more fluid intake than adults do relative to their body weight.
7. Premature infants suffer especially from infant respiratory distress syndrome, poor thermoregulation, and multiple dysfunctions resulting from inadequate liver function.

8. *Congenital anomalies* (birth defects) can result from infectious diseases, teratogens, mutagens, and genetic disorders.
9. *Teratogens*, agents that cause anatomical deformities, include chemicals such as alcohol and nicotine, radiation such as X-rays, and infectious diseases.
10. Some of the more common and serious infectious diseases and pathogens of the newborn are herpes simplex, cytomegalovirus, HIV, gonorrhea, and syphilis.
11. *Nondisjunction*, the failure of homologous chromosomes to separate during meiosis, can result in such congenital defects as triplo-X, Klinefelter, Turner, and Down syndromes.

29.4 Aging and Senescence (p. 1139)

1. *Senescence* is the degeneration that occurs in an organ system as we age. It begins at very different ages and progresses at different rates in different organ systems. Senescence of one organ system often contributes to the senescence of others.
2. Senescence of the integumentary system is marked by graying and thinning of the hair, atrophy of sebaceous glands, thinning and loss of elasticity in the skin, fragility of cutaneous blood vessels, decline in cutaneous sensory function, slower healing, and poorer thermoregulation. *Intrinsic aging* occurs inevitably with time, while *photoaging* is an added effect proportional to the amount of lifetime UV exposure. Senescence of the skin contributes to bone loss, muscle weakness, and poorer glandular secretion and synaptic transmission.
3. Senescence of the skeletal system is marked by loss of bone density (*osteopenia* or, when more severe, *osteoporosis*), increasing susceptibility to fractures, slower healing of fractures, osteoarthritis, and other degenerative joint diseases.
4. The aging muscular system exhibits muscular atrophy, loss of strength, and easy fatigue. Some loss of muscular function results from degenerative changes in the nervous system.
5. Senescence of the nervous system is marked by substantial loss of brain tissue and synapses, less efficient synaptic transmission, and declining motor coordination, intellectual function, and short-term memory, but relatively little loss of language skills and long-term memory. Senescence of the sympathetic division results in less effective homeostasis in other organ systems.
6. Visual acuity and auditory sensitivity begin to decline shortly after adolescence. Vision can be impaired by cataracts, glaucoma, and reduced dark adaptation. Declining inner-ear function can result in poor balance. Taste and smell become less sensitive.
7. The endocrine system shows relatively little senescence except for the decline in reproductive hormones. Reduced densities of hormone receptors can contribute to type 2 diabetes mellitus and poorer negative feedback control of the pituitary.
8. Senescence of the circulatory system is a leading cause of death. Anemia, atherosclerosis, thrombosis, varicose veins, hemorrhoids, and edema become more common in old age. Atherosclerosis contributes to weakening of the heart, myocardial infarction, aneurysm, stroke, and atrophy of all organs.
9. Senescence of the immune system makes older people more subject to cancer and infectious diseases.
10. Pulmonary functions decline as the thoracic cage becomes less flexible and the lungs have fewer alveoli. Pneumonia and chronic obstructive pulmonary diseases are major causes of death.
11. The kidneys atrophy a great deal with age, and thus elderly people are less able to maintain water balance and to clear drugs or toxins from the body. Elderly men are increasingly subject to prostatic enlargement and urine retention, and women to urinary incontinence.
12. Senescence of the digestive system includes reduced salivation, difficulty swallowing, poorer dental health, atrophy of the stomach, gastroesophageal reflux, constipation, loss of appetite, and impaired liver function.
13. Reproductive senescence is marked in men by reduced testosterone secretion, sperm count, and libido, and in women by menopause and multiple effects of reduced estrogen secretion.
14. Exercise slows the rate of senescence and improves the quality of life in old age by maintaining strength,

endurance, flexibility, and independence. It reduces the incidence and severity of hypertension, osteoporosis, obesity, and diabetes mellitus.

15. There are numerous theories of what causes senescence. *Replicative senescence*, a limit on how many times cells can divide, may stem from shortening of the chromosomal *telomeres* at each cell division. Cross-linking of proteins and DNA and the misfolding and other structural defects in proteins may cause increasing cellular dysfunction. The cumulative effects of free radical damage and increased incidence of autoimmune disease may be other factors in senescence.
16. Longevity is known to be partially hereditary. Natural selection has presumably been unable to eliminate genes that cause some of the diseases of old age because such genes have no effects until after the individual has reproduced.
17. *Life expectancy* has increased in modern times mostly because of our ability to reduce infant and childhood mortality. *Life span*, the maximum attainable age, has not markedly changed, however.
18. Death is usually clinically defined by an absence of brain waves, reflexes, or spontaneous respiration or heartbeat.

Testing Your Recall

1. When a conceptus arrives in the uterus, it is at what stage of development?
 - a. zygote
 - b. morula
 - c. blastomere
 - d. blastocyst
 - e. embryo
2. The entry of a sperm nucleus into an egg must be preceded by
 - a. the cortical reaction.
 - b. the acrosomal reaction.
 - c. the fast block.
 - d. implantation.
 - e. cleavage.
3. The stage of the conceptus that implants in the uterine wall is
 - a. a blastomere.
 - b. a morula.
 - c. a blastocyst.
 - d. an embryo.
 - e. a zygote.
4. Chorionic villi develop from
 - a. the zona pellucida.
 - b. the endometrium.
 - c. the syncytiotrophoblast.
 - d. the embryoblast.
 - e. the corona radiata.
5. Which of these results from aneuploidy?
 - a. Turner syndrome
 - b. fetal alcohol syndrome
 - c. nondisjunction
 - d. progeria
 - e. rubella
6. Fetal urine accumulates in the _____ and contributes to the fluid there.
 - a. placental sinus
 - b. yolk sac
 - c. allantois
 - d. chorion
 - e. amnion
7. One theory of senescence is that it results from a lifetime of damage by
 - a. teratogens.
 - b. aneuploidy.
 - c. free radicals.
 - d. cytomegalovirus.
 - e. nondisjunction.
8. Photoaging is a major factor in the senescence of
 - a. the integumentary system.
 - b. the eyes.
 - c. the nervous system.
 - d. the skeletal system.
 - e. the cardiovascular system.
9. Which of these is *not* a common effect of senescence?
 - a. reduced synthesis of vitamin D
 - b. atrophy of the kidneys
 - c. atrophy of the cerebral gyri
 - d. increased herniation of the intervertebral discs
 - e. reduced pulmonary vital capacity
10. For the first 8 weeks of gestation, a conceptus is nourished mainly by
 - a. the placenta.
 - b. amniotic fluid.
 - c. colostrum.
 - d. decidual cells.
 - e. yolk cytoplasm.
11. Viruses and chemicals that cause congenital anatomical deformities are called _____.
12. Aneuploidy is caused by _____, the failure of two homologous chromosomes to separate in meiosis.
13. The maximum age attainable by a member of the human species is called the _____.
14. The average age attained by humans in a given population is called the _____.
15. Fetal blood flows through growths called _____, which project into the placental sinus.
16. The enzymes with which a sperm penetrates an egg are contained in an organelle called the _____.
17. Stiffening of the arteries, joints, and lenses in old age may be a result of cross-linking between _____ molecules.
18. An enlarged tongue, epicanthal folds of the eyes, and mental retardation are characteristic of a genetic anomaly called _____.
19. The fossa ovalis is a remnant of a fetal shunt called the _____.
20. A developing individual is first classified as a/an _____ when the three primary germ layers have formed.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Freshly ejaculated sperm are more capable of fertilizing an egg than are sperm several hours old.
- Fertilization normally occurs in the lumen of the uterus.
- An egg is usually fertilized by the first sperm that contacts it.
- By the time a conceptus reaches the uterus, it has already undergone several cell divisions and consists of 16 cells or more.
- The conceptus is first considered a fetus when all of the organ systems are present.
- The placenta becomes increasingly permeable as it develops.
- The endocrine system shows less senescence in old age than most other organ systems.
- Fetal blood bypasses the nonfunctional liver by passing through the foramen ovale.
- Blood in the umbilical vein has a higher PO_2 than blood in the umbilical arteries.
- It is well established that people who exercise regularly live longer than those who do not.

Answers in appendix B

Testing Your Comprehension

- Suppose a woman had a mutation resulting in a tough zona pellucida that did not disintegrate after the egg was fertilized. How would this affect her fertility? Why?
- Suppose a drug were developed that could slow down the rate of collagen cross-linking with age. What diseases of old age could be made less severe with such a drug?
- Some health-food stores market the enzyme superoxide dismutase (SOD) as an oral antioxidant to retard senescence. Explain why it would be a waste of your money to buy it.
- In some children, the ductus arteriosus fails to close after birth—a condition that eventually requires surgery. Predict how this condition would affect (a) pulmonary blood pressure, (b) systemic diastolic pressure, and (c) the right ventricle of the heart.
- Only one sperm is needed to fertilize an egg, yet a man who ejaculates fewer than 10 million sperm is usually infertile. Explain this apparent contradiction. Supposing 10 million sperm were ejaculated, predict how many would come within close range of the egg. How likely is it that any one of these sperm would fertilize it?

Download mp3 audio summaries and movies to study when it fits your schedule. Practice quizzes, labeling activities, games, and flashcards offer fun ways to master the chapter concepts. Or, download image PowerPoint files for each chapter to create a study guide or for taking notes during lecture.

Appendix A

CHANGES IN TERMINOLOGY IN THE FIFTH EDITION

These changes have been made to conform to changing practices in the field of anatomy and physiology, such as the *Terminologia Anatomica* and *Terminologia Histologica*—although not limited to those and not always conforming in every detail to them. This list does not include other synonyms already discontinued in earlier editions. See the preface for terminology changes made for reasons other than changing professional practices.

Old Term (Fourth Edition)

adipose capsule of kidney
agonist
antral follicle
bronchus, primary
bronchus, secondary
bronchus, tertiary
buccal cavity
choanae, nasal
condyloid process
convergent muscle
cones, blue
cones, green
cones, red
cornu
diabetes mellitus, type I and type II
dorsal root ganglion
epiploic appendages
fascia, superficial and deep
gastric inhibitory peptide
gastroepiploic arteries
Golgi tendon organ
humeroscapular joint
internal nares
Krause end bulb
lamellated (pacinian) corpuscle
male climacteric
membrane skeleton
motor end plate
myringotomy
navicular bone
neuron cell body
oral orifice
organ of Corti
os coxae
palatal rugae
pneumotaxic center
renal capsule
Ruffini corpuscle
soma (of neuron)
sphenopalatine ganglion
sternal notch
superficial inguinal ring
tropic (trophic) hormones

New Term (Fifth Edition)

perirenal fat
prime mover
tertiary follicle
main bronchus
lobar bronchus
segmental bronchus
oral cavity
posterior nasal apertures
condylar process
triangular muscle
cones, short-wavelength (S cones)
cones, medium-wavelength (M cones)
cones, long-wavelength (L cones)
horn
type 1 and type 2
posterior root ganglion
omental appendages
fascia (distinction abandoned)
glucose-dependent insulinotropic peptide
gastro-omental arteries
tendon organ
glenohumeral joint
posterior nasal apertures
end bulb
lamellar corpuscle
andropause
terminal web
neuromuscular junction
tympanostomy
scaphoid bone
neurosoma, soma
oral fissure
spiral organ
hipbone
palatine rugae
pontine respiratory group
fibrous capsule
bulbous corpuscle
neurosoma, soma
pterygopalatine ganglion
suprasternal notch
external inguinal ring
(in declining use, discontinued)

Appendix B

ANSWER KEYS

This appendix provides answers to the end-of-chapter Testing Your Recall and True or False questions and the questions in the figure legends. In the True or False sections, all statements are true except those listed and explained here. Answers to Think About It and Testing Your Comprehension questions are posted by chapter at www.mhhe.com/saladin5.

Chapter 1

Testing Your Recall

- | | | |
|------|-------------------|-----------------------|
| 1. a | 8. c | 15. homeostasis |
| 2. e | 9. d | 16. set point |
| 3. d | 10. b | 17. negative feedback |
| 4. a | 11. dissection | 18. organ |
| 5. c | 12. Robert Hooke | 19. stereoscopic |
| 6. c | 13. deduction | 20. prehensile, |
| 7. a | 14. psychosomatic | opposable |

True or False (explanation of the false statements only)

- Auscultation means listening to body sounds, not inspecting its appearance.
- Leeuwenhoek was a textile merchant who built microscopes to examine fabric.
- A scientific theory is founded on a large body of evidence and summarizes what is already known.
- Both the treatment and control groups consist of volunteer patients.
- Negative feedback is a self-corrective process with a beneficial effect on the body.

Answers to Figure Legend Questions

- Human bodies are highly variable in their anatomy and physicians must be highly aware of such variations.
- The word *influenza* originated from the belief that organ systems are under the influence of the constellations of the zodiac.
- The thermostat is the sensor; the furnace is the effector.
- Vasodilation allows more blood to flow close to the body surface and to lose heat through the skin; thus, it cools the body.

Atlas A

Testing Your Recall

- | | | |
|------|-----------------|------------------------|
| 1. d | 8. d | 15. hand, foot |
| 2. c | 9. b | 16. meninges |
| 3. e | 10. d | 17. retroperitoneal |
| 4. d | 11. supinated | 18. medial |
| 5. d | 12. parietal | 19. inferior |
| 6. a | 13. mediastinum | 20. cubital, popliteal |
| 7. a | 14. nuchal | |

True or False (explanation of the false statements only)

- The diaphragm is inferior to the lungs.
- The esophagus is superior to the stomach.
- The liver is in the hypochondriac region, superior to the lumbar region.
- The peritoneum lines the outside of the stomach and intestines.
- The sigmoid colon is in the lower left quadrant.

Answers to Figure Legend Questions

- A.3 Median (midsagittal)
 A.10 No, it is inferior to the peritoneal cavity.
 A.14 The lungs, heart, liver, stomach, gallbladder, and spleen, among others
 A.19 Posterior
 A.21 Fat

Chapter 2

Testing Your Recall

- | | | |
|------|---------------------------|------------------------------------|
| 1. a | 9. b | 16. -ose, -ase |
| 2. c | 10. d | 17. phospholipids |
| 3. a | 11. cation | 18. cyclic adenosine monophosphate |
| 4. c | 12. free radicals | 19. anaerobic fermentation |
| 5. a | 13. catalyst, | 20. substrate |
| 6. e | enzymes | |
| 7. b | 14. anabolism | |
| 8. c | 15. dehydration synthesis | |

True or False (explanation of the false statements only)

- The monomers of a polysaccharide are monosaccharides (simple sugars).
- Such molecules are called isomers, not isotopes.
- A saturated fat is one to which no more hydrogen can be added.
- Above a certain temperature, enzymes denature and cease working.
- These solutes have different molecular weights, so 2% solutions would not contain the same number of molecules per unit volume.

Answers to Figure Legend Questions

- 2.1 Potassium gives up an electron.
 2.6 By sharing four pairs of electrons, the carbon and two oxygens each have eight valence electrons, fulfilling the octet rule.
 2.8 Because water molecules are attracted to each other, it requires more thermal energy for any one of them to break free and evaporate.
 2.13 Decomposition
 2.26 No, the amount of energy released is the same with or without an enzyme.

Chapter 3

Testing Your Recall

- | | | |
|------|-----------------------|----------------------|
| 1. e | 9. d | 16. exocytosis |
| 2. b | 10. b | 17. nucleus, |
| 3. d | 11. micrometers | mitochondria |
| 4. b | 12. second messenger | 18. smooth ER, |
| 5. e | 13. voltage-regulated | peroxisomes |
| 6. e | 14. hydrostatic | 19. ligand-regulated |
| 7. a | pressure | gate |
| 8. c | 15. hypertonic | 20. cisterna |

True or False (explanation of the false statements only)

- Osmosis does not require ATP.
- Second messengers activate enzymes in the cell; they are not transport proteins.
- A channel could not move material from the outside of a cell to the inside unless it extended all the way across the membrane; it must be a transmembrane protein.
- The plasma membrane consists primarily of phospholipid molecules.
- The brush border is composed of microvilli.

Answers to Figure Legend Questions

- Adenylate cyclase is a transmembrane protein. The G protein is peripheral.
- The Na⁺-K⁺ pump requires ATP, whereas osmosis does not. ATP is quickly depleted after a cell dies.
- Transcytosis is a combination of endocytosis and exocytosis.
- Large molecules such as enzymes and RNA must pass through the nuclear pores, but pores in the plasma membrane must be small enough to prevent such large molecules from escaping the cell.
- A centriole is composed of a cylinder of nine groups of microtubules, but in a centriole, there are three microtubules in each group and in an axoneme there are only two. Also, an axoneme usually has a central pair of microtubules, whereas a centriole does not.

Chapter 4

Testing Your Recall

- | | | |
|------|------------------|--------------------|
| 1. a | 8. d | 15. RNA polymerase |
| 2. e | 9. d | 16. genome |
| 3. c | 10. a | 17. 46, 92, 92 |
| 4. c | 11. cytokinesis | 18. ribosome |
| 5. e | 12. alleles | 19. growth factors |
| 6. b | 13. genetic code | 20. autosomes |
| 7. a | 14. polyribosome | |

True or False (explanation of the false statements only)

- There are no ribosomes on the Golgi complex; they are on the rough ER.
- There are no genes for steroids, carbohydrates, or phospholipids, but only for proteins.
- This law describes the pairing of bases between the two strands of DNA, not between mRNA and tRNA.
- Males have only one X chromosome, but have two sex chromosomes (the X and Y).
- Several RNA polymerase molecules at once can transcribe a gene.

Answers to Figure Legend Questions

- The helix would bulge where two purines were paired and would be constricted where two pyrimidines were paired.
- The ribosome would have no way of holding the partially completed peptide in place while adding the next amino acid.
- It would show two X chromosomes instead of an X and a Y.

Chapter 5

Testing Your Recall

- | | | |
|------|---------------------|---------------------------|
| 1. a | 9. b | 17. basement |
| 2. b | 10. b | membrane |
| 3. c | 11. necrosis | 18. matrix (extracellular |
| 4. e | 12. mesothelium | material) |
| 5. c | 13. lacunae | 19. multipotent |
| 6. a | 14. fibers | 20. simple |
| 7. b | 15. collagen | |
| 8. e | 16. skeletal muscle | |

True or False (explanation of the false statements only)

- The esophageal epithelium is nonkeratinized.
- Adipose tissue is an exception; cells constitute most of its volume.
- Adipocytes are also found in areolar tissue, either singly or in small clusters.
- Tight junctions serve mainly to restrict the passage of material between cells.
- Perichondrium is lacking from fibrocartilage and from hyaline articular cartilage.

Answers to Figure Legend Questions

- They are longitudinal sections. In a cross section, both the egg white and yolk would look circular. In an oblique section, the white would look elliptical but the yolk would still look circular.
- The epithelia of the tongue, oral cavity, esophagus, and anal canal would look similar to this.
- Gap junctions
- A holocrine gland, to replace the cells that disintegrate in becoming the secretion

Chapter 6

Testing Your Recall

- | | | |
|------|-----------------|----------------------|
| 1. d | 8. a | 14. cyanosis |
| 2. c | 9. a | 15. dermal papillae |
| 3. d | 10. d | 16. earwax |
| 4. b | 11. insensible | 17. sebaceous glands |
| 5. a | perspiration | 18. anagen |
| 6. e | 12. piloerector | 19. dermal papilla |
| 7. c | 13. debridement | 20. third-degree |

True or False (explanation of the false statements only)

- Keratin is the protein of the epidermis; the dermis is composed mainly of collagen.
- Vitamin D synthesis begins in the keratinocytes.
- The hypodermis is not considered to be a layer of the skin.
- Different races have about the same density of melanocytes but different amounts of melanin.
- A genetic lack of melanin causes albinism, not pallor. Pallor is a temporary, nonhereditary paleness of the skin.

Answers to Figure Legend Questions

- Keratinocytes
- Cuticle
- Holocrine, because cells die to become the secretion and thus require rapid replacement
- Asymmetry (A), irregular border (B), and color (C). The photo does not provide enough information to judge the diameter of the lesion (D).

Chapter 7*Testing Your Recall*

- | | | |
|------|------------------------|------------------|
| 1. e | 8. e | 15. hypocalcemia |
| 2. a | 9. b | 16. osteoblasts |
| 3. d | 10. d | 17. calcitriol |
| 4. c | 11. hydroxyapatite | 18. osteoporosis |
| 5. d | 12. canaliculi | 19. metaphysis |
| 6. a | 13. appositional | 20. osteomalacia |
| 7. d | 14. solubility product | |

True or False (explanation of the false statements only)

- The most common bone disease is osteoporosis, not fractures.
- Bones elongate at the epiphyseal plate, not the articular cartilage.
- Osteoclasts develop from stem cells in the bone marrow, not from osteoblasts.
- Hydroxyapatite is the major mineral of bone; the major protein is collagen.
- The major effect of vitamin D is bone resorption, though it also promotes deposition.

Answers to Figure Legend Questions

- 7.2 The wider epiphyses provide surface area for muscle attachment and bone articulation, while the narrowness of the diaphysis minimizes weight.
- 7.5 Spongy bone
- 7.7 Places where bone comes close to the skin, such as the sternum and hips
- 7.8 Temporal bone, parietal bone, and several others
- 7.10 Humerus, radius, ulna, femur, tibia, fibula
- 7.11 An infant's joints are still cartilaginous.
- 7.13 The zones of cell proliferation and cell hypertrophy

Chapter 8*Testing Your Recall*

- | | | |
|------|---------------|---------------------|
| 1. b | 8. b | 15. anulus fibrosus |
| 2. e | 9. e | 16. dens |
| 3. a | 10. b | 17. auricular |
| 4. d | 11. fontanels | 18. styloid |
| 5. a | 12. temporal | 19. pollex, hallux |
| 6. e | 13. sutures | 20. medial |
| 7. c | 14. sphenoid | longitudinal |

True or False (explanation of the false statements only)

- Each hand and foot has 14 phalanges.
- The female pelvis is wider and shallower than the male's.
- The lumbar vertebrae have transverse processes but no transverse costal facets.
- The most frequently broken bone is the clavicle.
- Arm* refers to the region containing only the humerus; *leg* refers to the region containing the tibia and fibula.

Answers to Figure Legend Questions

- 8.10 Any five of these: the occipital, parietal, sphenoid, zygomatic, and palatine bones, and the mandible and maxilla
- 8.12 Any five of these: the frontal, lacrimal, and sphenoid bones, and the vomer, maxilla, and inferior concha
- 8.24 Rupture of this ligament allows the atlas to slip anteriorly and the dens of the axis to tear into the spinal cord.
- 8.34 The adult hand lacks epiphyseal plates, the growth zones of a child's long bones.
- 8.40 The three cuneiforms and the cuboid bone of the tarsus are arranged in a row similar to the distal carpal bones (trapezium, trapezoid, capitate, and hamate), with the trapezium corresponding to the median cuneiform (proximal to digit I in each case). In the

proximal row, the navicular bone of the tarsus is somewhat similar to the scaphoid of the carpus, being proximal to digit I and articulating with three bones of the distal row, but the calcaneus and talus are very different, being adapted to their load-bearing role.

Chapter 9*Testing Your Recall*

- | | | |
|------|--------------------|---------------------|
| 1. c | 8. d | 15. gomphosis |
| 2. b | 9. b | 16. serrate |
| 3. a | 10. d | 17. extension |
| 4. e | 11. synovial fluid | 18. range of motion |
| 5. c | 12. bursa | 19. articular disc |
| 6. c | 13. pivot | 20. talus |
| 7. a | 14. kinesiology | |

True or False (explanation of the false statements only)

- Osteoarthritis occurs in almost everyone after a certain age; rheumatoid arthritis is less common.
- A kinesiologist studies joint movements; a rheumatologist treats arthritis.
- Synovial joints are diarthroses and amphiarthroses, but never synarthroses.
- The round ligament is somewhat slack and probably does not secure the femoral head.
- Synovial fluid is secreted by the synovial membrane of the joint capsule and fills the bursae.

Answers to Figure Legend Questions

- 9.2 The gomphosis, because a tooth is not a bone
- 9.4 The pubic symphysis consists of the cartilaginous interpubic disc and the adjacent parts of the two pubic bones.
- 9.5 Interphalangeal joints are not subjected to a great deal of compression.
- 9.7 $MA = 1.0$. Shifting the fulcrum to the left would increase the MA of this lever, while the lever would remain first-class.

Chapter 10*Testing Your Recall*

- | | | |
|------|-----------------|-------------------------|
| 1. b | 8. a | 14. hamstring |
| 2. b | 9. d | 15. flexor retinacula |
| 3. a | 10. c | 16. urogenital triangle |
| 4. c | 11. origin | 17. linea alba |
| 5. e | 12. fascicle | 18. synergist |
| 6. e | 13. prime mover | 19. bipennate |
| 7. b | (agonist) | 20. sphincter |

True or False (explanation of the false statements only)

- The mastoid process is its insertion.
- The trapezius is superficial to the scalenes.
- Normal exhalation does not employ these muscles.
- They result from rapid extension of the knee, not flexion.
- They are on opposite sides of the tibia and act as antagonists.

Answers to Figure Legend Questions

- 10.3 The brachialis and lateral head of the triceps brachii have direct attachments; the biceps brachii and long head of the triceps brachii have indirect attachments.
- 10.6 The zygomaticus major, levator palpebrae superioris, and orbicularis oris
- 10.11 A1 contains the sternohyoid, sternothyroid, and anterior belly of the omohyoid; A4 contains the mylohyoid and anterior belly of the digastric; and P1 contains the scalenes and part of the splenius capitis.

- 10.15 Pectoralis minor, serratus anterior, and all three layers of the upper intercostal muscles
- 10.27 *Teres* refers to the round or cordlike shape of the first muscle, and *quadratus* refers to the four-sided shape of the second.
- 10.28 Part (c) represents a cross section cut too high on the forearm to include these muscles.
- 10.34 Climbing stairs, walking, running, or riding a bicycle
- 10.39 The soleus

Atlas B

Answers to Figure Legend Questions

- B.1 Orbicularis oris; trapezius
- B.2 Sternocleidomastoids
- B.7 One tendon proximally (at the humerus) and four distally (in the hand)
- B.8 The mark would belong close to where the leader for the styloid process of the radius ends in figure B.8b.
- B.9 The mark would belong close to where the leader for the rectus femoris ends; the vastus intermedius is deep to this.
- B.10 The fibula
- B.13 There is no such bone; digit I (the hallux) has only a proximal and distal phalanx.
- B.15 Answers to the muscle test are as follows:

1. f	11. x	21. k
2. b	12. m	22. d
3. k	13. n	23. s
4. p	14. e	24. b
5. h	15. g	25. a
6. y	16. v	26. u
7. z	17. f	27. j
8. w	18. c	28. i
9. c	19. x	29. g
10. a	20. w	30. q

Chapter 11

Testing Your Recall

- | | | |
|------|------------------------|-------------------|
| 1. a | 8. c | 15. acetylcholine |
| 2. c | 9. e | 16. myoglobin |
| 3. b | 10. b | 17. Z discs |
| 4. d | 11. threshold | 18. varicosities |
| 5. a | 12. complete tetanus | 19. muscle tone |
| 6. c | 13. terminal cisternae | 20. lactic acid |
| 7. e | 14. myosin | |

True or False (explanation of the false statements only)

- 1. A motor neuron may supply 1,000 or more muscle fibers; a motor unit consists of one motor neuron and all the muscle fibers it innervates.
- 2. Calcium binds to troponin, not to myosin.
- 6. Thick and thin filaments are present but not arranged in a way that produces striations.
- 7. Under natural conditions, a muscle seldom or never attains complete tetanus.
- 9. A muscle produces most of its ATP during this time by anaerobic fermentation, which generates lactic acid; it does not consume lactic acid.

Answers to Figure Legend Questions

- 11.1 The striations distinguish it from smooth muscle; the multiple nuclei adjacent to the plasma membrane and the parallel fibers distinguish it from both cardiac and smooth muscle.
- 11.2 The electrical excitation spreading down the T tubule must excite the opening of calcium gates in the terminal cisternae.
- 11.13 ATP is needed to pump Ca^{2+} back into the sarcoplasmic

reticulum by active transport and to induce each myosin head to release actin so the sarcomere can relax.

- 11.16 The gluteus maximus and quadriceps femoris
- 11.17 The muscle tension curve would drop gradually while the muscle length curve would rise.

Chapter 12

Testing Your Recall

- | | | |
|------|--------------------------------|-----------------------------------|
| 1. e | 9. d | 15. oligodendrocytes |
| 2. c | 10. b | 16. nodes of Ranvier |
| 3. d | 11. afferent | 17. axon hillock, initial segment |
| 4. a | 12. conductivity | 18. norepinephrine |
| 5. c | 13. absolute refractory period | 19. facilitated zone |
| 6. e | 14. dendrites | 20. neuromodulators |
| 7. d | | |
| 8. a | | |

True or False (explanation of the false statements only)

- 4. Only a small fraction of the neuron's Na^+ and K^+ exchange places across the plasma membrane.
- 5. The threshold stays the same but an EPSP brings the membrane potential closer to the threshold.
- 7. The effect of a neurotransmitter varies from place to place depending on the type of receptor present.
- 8. The signals travel rapidly through the internodes and slow down at each node of Ranvier.
- 9. Learning involves modification of the synapses of existing neurons, not an increase in the neuron population.

Answers to Figure Legend Questions

- 12.8 Its conduction speed is relatively slow, but it has a small diameter and contributes relatively little bulk to the nervous tissue.
- 12.11 The membrane potential will become lower (more negative).
- 12.19 Axosomatic
- 12.24 One EPSP is a voltage change of only 0.5 mV or so. A change of about 15 mV is required to reach threshold and make a neuron fire.
- 12.28 The CNS interprets a stimulus as more intense if it receives signals from high-threshold sensory neurons than if it receives signals only from low-threshold neurons.
- 12.30 A reverberating circuit, because a neuron early in the circuit is continually restimulated

Chapter 13

Testing Your Recall

- | | | |
|------|-----------------------|-----------------------|
| 1. e | 8. a | 15. intrafusal fibers |
| 2. c | 9. e | 16. phrenic |
| 3. d | 10. b | 17. decussation |
| 4. d | 11. ganglia | 18. proprioception |
| 5. e | 12. ramus | 19. posterior root |
| 6. c | 13. spinocerebellar | 20. tibial, common |
| 7. c | 14. crossed extension | fibular |

True or False (explanation of the false statements only)

- 1. The gracile fasciculus is an ascending (sensory) tract.
- 4. All spinal nerves are mixed nerves; none are purely sensory or motor.
- 5. The dura is separated from the bone by a fat-filled epidural space.
- 8. Dermatomes overlap each other by as much as 50%.
- 9. Some somatic reflexes are mediated primarily through the brainstem and cerebellum.

Answers to Figure Legend Questions

- 13.4 If it were T10, there would be no cuneate fasciculus; that exists only from T6 up.
- 13.9 They are in the anterior horn of the spinal cord.

A-6 APPENDIX B Answer Keys

- 13.12 They are afferent, because they arise from the posterior root of the spinal nerve.
- 13.21 Motor neurons are capable only of exciting skeletal muscle (end-plate potentials are always excitatory). To inhibit muscle contraction, it is necessary to inhibit the motor neuron at the CNS level (point 7).
- 13.22 They would show more synaptic delay, because there are more synapses in the pathway.

Chapter 14*Testing Your Recall*

- | | | |
|------|---------------------|-----------------------|
| 1. c | 8. d | 14. hydrocephalus |
| 2. a | 9. e | 15. choroid plexus |
| 3. e | 10. e | 16. precentral |
| 4. a | 11. corpus callosum | 17. frontal |
| 5. b | 12. ventricles, | 18. association areas |
| 6. c | cerebrospinal | 19. categorical |
| 7. a | 13. arbor vitae | 20. Broca area |

True or False (explanation of the false statements only)

- This fissure separates the cerebral hemispheres, not the cerebellar hemispheres.
- The cerebral hemispheres do not develop from neural crest tissue.
- The choroid plexuses produce only 30% of the CSF.
- Hearing is a temporal lobe function; vision resides in the occipital lobe.
- The cerebellum contains more than half of all brain neurons.

Answers to Figure Legend Questions

- 14.7 The most common sites of obstruction are the interventricular foramen at label 2, the cerebral aqueduct at label 4, and the lateral and median apertures indicated by label 6.
- 14.9 Signals in the cuneate fasciculus ascend to the cuneate nucleus in part (c), and signals in the gracile fasciculus ascend to the nearby gracile nucleus. Both of them decussate together to the contralateral medial lemniscus in parts (b) and (a) and travel this route to the thalamus.
- 14.11 The reticular formation is labeled on all three parts of the figure.
- 14.14 Commissural tracts also cross through the anterior and posterior commissures shown in figure 14.2
- 14.15 Dendrites
- 14.23 Regions with numerous small muscles

Chapter 15*Testing Your Recall*

- | | | |
|------|----------------------|--------------------|
| 1. b | 8. d | 15. enteric |
| 2. c | 9. a | 16. norepinephrine |
| 3. e | 10. c | 17. sympathetic |
| 4. e | 11. adrenergic | 18. preganglionic, |
| 5. a | 12. dual innervation | postganglionic |
| 6. e | 13. autonomic tone | 19. cAMP |
| 7. d | 14. vagus | 20. vasomotor tone |

True or False (explanation of the false statements only)

- Both systems are always simultaneously active.
- In biofeedback and other circumstances, limited voluntary control of the ANS is possible.
- The sympathetic division inhibits digestion.
- Waste elimination can occur by autonomic spinal reflexes without necessarily involving the brain.
- All parasympathetic fibers are cholinergic.

Answers to Figure Legend Questions

- 15.4 No; inhaling and exhaling are controlled by the somatic motor system and skeletal muscles.
- 15.5 The soma of the somatic efferent neuron is in the anterior horn and the soma of the sympathetic preganglionic neuron is in the lateral horn.
- 15.7 The vagus nerve
- 15.9 The pupils dilate because fear increases sympathetic output, which induces dilation.

Chapter 16*Testing Your Recall*

- | | | |
|------|---------------------|------------------------|
| 1. a | 8. c | 15. outer hair cells |
| 2. c | 9. c | 16. stapes |
| 3. b | 10. b | 17. inferior colliculi |
| 4. a | 11. fovea centralis | 18. basal cells |
| 5. e | 12. ganglion | 19. olfactory bulb |
| 6. e | 13. photopsin | 20. referred pain |
| 7. d | 14. otoliths | |

True or False (explanation of the false statements only)

- These fibers end in the medulla oblongata.
- Because of hemidecussation, each hemisphere receives signals from both eyes.
- The posterior chamber, the space between iris and lens, is filled with aqueous humor.
- Descending analgesic fibers block signals that have reached the dorsal horn of the spinal cord.
- The trochlear and abducens nerves control the superior oblique and lateral rectus, respectively.

Answers to Figure Legend Questions

- 16.1 Yes; two touches are felt separately if they straddle the boundary between two separate receptive fields.
- 16.9 The lower margin of the blue zone ("all sound") would be higher in that frequency range.
- 16.15 It would oppose the inward movement of the tympanic membrane and, thus, reduce the amount of vibration transferred to the inner ear.
- 16.23 This would prevent tears from draining into the lacrimal canals, resulting in more watery eyes.
- 16.24 Cranial nerve III, because it controls more eye movements than IV or VI
- 16.28 It is the right eye. The optic disc is always medial to the fovea, so this has to be a view of the observer's left and the subject's right.
- 16.40 Approximately 68:20:0, and yellow
- 16.43 It would cause blindness in the left half of the visual field. It would not affect the visual reflexes.

Chapter 17*Testing Your Recall*

- | | | |
|------|---------------------|-----------------------|
| 1. b | 9. a | 16. interstitial |
| 2. d | 10. e | 17. negative feedback |
| 3. a | 11. adenohypophysis | inhibition |
| 4. c | 12. tyrosine | 18. hypophyseal |
| 5. c | 13. acromegaly | portal system |
| 6. c | 14. cortisol | 19. permissive |
| 7. d | 15. glucocorticoids | 20. up-regulation |
| 8. c | | |

True or False (explanation of the false statements only)

- Hormones are also secreted by the heart, liver, kidneys, and other organs not generally regarded as glands.
- The pineal gland and thymus undergo involution with age.

8. Without iodine, there is no thyroid hormone (TH); without TH, there can be no negative feedback inhibition.
9. The tissue at the center is the adrenal medulla.
10. There are also two testes, two ovaries, and four parathyroid glands.

Answers to Figure Legend Questions

- 17.1 Heart, liver, stomach, small intestine, placenta (any three)
- 17.4 The neurohypophysis
- 17.22 Steroids enter the target cell; they do not bind to membrane receptors or activate second messengers.
- 17.26 Such a drug would block leukotriene synthesis and thus inhibit allergic and inflammatory responses.
- 17.27 She would have been a pituitary giant.

Chapter 18

Testing Your Recall

- | | | |
|------|-------------------------------------|-----------------------------|
| 1. b | 9. d | 15. hemophilia |
| 2. c | 10. c | 16. hemostasis |
| 3. c | 11. hemopoiesis | 17. sickle-cell disease |
| 4. a | 12. hematocrit (packed cell volume) | 18. polycythemia |
| 5. b | 13. thromboplastin | 19. vitamin B ₁₂ |
| 6. d | 14. agglutinogens | 20. erythropoietin |
| 7. d | | |
| 8. c | | |

True or False (explanation of the false statements only)

3. Oxygen deficiency is the result of anemia, not its cause.
4. Clotting is one mechanism of hemostasis, but hemostasis includes others. Agglutination is unrelated to either of these.
6. The most abundant WBCs are neutrophils.
9. The heme is excreted; the globin is broken down into amino acids that can be reused.
10. In leukemia, there is an excess of WBCs. A WBC deficiency is leukopenia.

Answers to Figure Legend Questions

- 18.1 A nucleus
- 18.4 The sunken center represents the former location of the nucleus.
- 18.5 Hemoglobin consists of a noncovalent association of four protein chains. The prosthetic group is the heme moiety of each of the four chains.
- 18.18 *Myelo-* refers to the bone marrow, where these cells develop.
- 18.19 Although numerous, these WBCs are immature and incapable of performing their defensive roles.
- 18.21 A platelet plug lacks the fibrin mesh that a blood clot has.
- 18.22 Fibrin
- 18.23 It would affect only the intrinsic mechanism.
- 18.24 In both blood clotting and the enzyme amplification mechanism of hormone action, the product of one reaction step is an enzyme that catalyzes the production of many more molecules of product at the next step. Thus, there is a geometric increase in the number of product molecules at each step and ultimately, a large final result from a small beginning.
- 18.26 The older theory of leeching was that many disorders are caused by “bad blood,” which could be removed painlessly by medicinal leeches. The modern practice is to take advantage of the anticoagulants in the leech saliva to promote blood flow to a tissue or to dissolve and remove clots that have already formed.

Chapter 19

Testing Your Recall

- | | | |
|------|------|------|
| 1. d | 3. d | 5. a |
| 2. b | 4. a | 6. d |

- | | | |
|-----------------------|--|---------------------------|
| 7. d | 13. atrioventricular (coronary) sulcus | 18. myocardial infarction |
| 8. c | 14. Na ⁺ | 19. endocardium |
| 9. a | 15. gap junctions | 20. cardiac output |
| 10. e | 16. T wave | |
| 11. systole, diastole | 17. vagus | |
| 12. systemic | | |

True or False (explanation of the false statements only)

1. The coronary circulation is part of the systemic circuit; the other division is the pulmonary circuit.
3. The first two-thirds of ventricular filling occurs before the atria contract. The atria add only about 31% of the blood that fills the ventricles.
6. The first heart sound occurs at the time of the QRS complex.
7. The heart has its own internal pacemaker and would continue beating; the nerves only alter the heart rate.
10. The ECG is a composite record of the electrical activity of the entire myocardium, not a record from a single myocyte. It looks much different from an action potential.

Answers to Figure Legend Questions

- 19.1 Both; they receive pulmonary arteries from the pulmonary circuit and bronchial arteries from the systemic circuit.
- 19.2 To the left
- 19.7 The trabeculae carneae
- 19.12 The right atrium
- 19.14 It ensures that wave summation and tetanus will not occur, thus ensuring relaxation and refilling of the heart chambers.
- 19.19 They prevent prolapse of the AV valves during ventricular systole.
- 19.20 This is the point at which the aortic valve opens and blood is ejected into the aorta, raising its blood pressure.

Chapter 20

Testing Your Recall

- | | | |
|------|----------------------------|-------------------------|
| 1. c | 8. a | 14. thoracic pump |
| 2. b | 9. e | 15. oncotic pressure |
| 3. a | 10. d | 16. transcytosis |
| 4. e | 11. systolic, diastolic | 17. sympathetic |
| 5. b | 12. continuous capillaries | 18. baroreceptors |
| 6. c | 13. anaphylactic | 19. the arterial circle |
| 7. e | | 20. basilic, cephalic |

True or False (explanation of the false statements only)

4. Some veins have valves, but arteries do not.
5. By the formula $F \propto r^4$, the flow increases 16-fold.
8. The capillaries normally reabsorb about 85% of the fluid they filter; the rest is absorbed by the lymphatic system.
9. An aneurysm is a weak, bulging vessel that may rupture.
10. The response to falling blood pressure is a corrective vasoconstriction.

Answers to Figure Legend Questions

- 20.2 Veins are subjected to less pressure than arteries and have less need of elasticity.
- 20.6 Endocrine glands, kidneys, the small intestine, and choroid plexuses of the brain
- 20.8 Veins have less muscular and elastic tissue, so they expand more easily than arteries.
- 20.9 Arterial anastomoses: the arterial circle of the brain, the celiac circulation, encircling the heads of the humerus and femur, and the arterial arches of the hand and foot. Venous anastomoses: the jugular veins, the azygos system, the mesenteric veins, and venous networks of the hand and foot. Portal systems: the hepatic portal system and (outside of this chapter) the hypophyseal portal system. Answers may vary.

A-8 APPENDIX B Answer Keys

- 20.18 Nothing would happen if he lifted his finger from point O because the valve at that point would prevent blood from flowing downward and filling the vein. If he lifted his finger from point H, blood would flow upward, fill the vein, and the vein between O and H would stand out.
- 20.24 Aorta → left common carotid a. → external carotid a. → superficial temporal a.
- 20.32 The ovaries and testes begin their embryonic development near the kidneys. The gonadal veins elongate as the gonads descend to the pelvic cavity and scrotum.
- 20.34 Joint movements may temporarily compress an artery. Anastomoses allow for continued blood flow through alternative routes to more distal regions.
- 20.35 The cephalic, basilic, and median cubital vv.

Chapter 21

Testing Your Recall

- | | | |
|------|-------------------|-----------------------------------|
| 1. b | 9. a | 15. opsonization |
| 2. c | 10. c | 16. pyrogen |
| 3. a | 11. pathogen | 17. interleukins |
| 4. a | 12. lysozyme | 18. antigen-binding site, epitope |
| 5. d | 13. lymphadenitis | 19. clonal deletion |
| 6. b | 14. diapidesis | 20. autoimmune |
| 7. e | (emigration) | |
| 8. d | | |

True or False (explanation of the false statements only)

- Lysozyme is a bacteria-killing enzyme.
- Interferons promote inflammation.
- Helper T cells are also necessary to humoral immunity.
- Anergy is a loss of lymphocyte activity, whereas autoimmune diseases result from misdirected activity.
- Interferons inhibit viral replication; perforins lyse bacteria.

Answers to Figure Legend Questions

- 21.3 There are much larger gaps between the endothelial cells of lymphatic capillaries than between those of blood capillaries.
- 21.4 There would be no consistent one-way flow of lymph. Lymph and tissue fluid would accumulate, especially in the lower regions of the body.
- 21.5 (1) Prevention of excess tissue fluid accumulation and (2) monitoring the tissue fluids for pathogens
- 21.6 Lymph flows from the breast to the axillary lymph nodes. Therefore, metastatic cancer cells tend to lodge first in those nodes.
- 21.14 Erythrocytes in the red pulp; lymphocytes and macrophages in the white pulp
- 21.16 Both of these produce a ring of proteins in the target cell plasma membrane, opening a hole in the membrane through which the cell contents escape.
- 21.23 All three defenses depend on the action of helper T cells, which are destroyed by HIV.
- 21.26 The ER is the site of antibody synthesis.
- 21.31 AZT targets reverse transcriptase. If this enzyme is unable to function, HIV cannot produce viral DNA and insert it into the host cell DNA, and the virus therefore cannot be replicated.

Chapter 22

Testing Your Recall

- | | | |
|------|------|------|
| 1. c | 4. e | 7. b |
| 2. c | 5. e | 8. a |
| 3. a | 6. c | 9. d |

- | | | |
|--------------------|-----------------|-------------------|
| 10. a | 15. obstructive | respiratory group |
| 11. epiglottis | 16. anatomical | 19. ventilation– |
| 12. bronchial tree | dead space | perfusion |
| 13. pulmonary | 17. compliance, | coupling |
| surfactant | elasticity | 20. alkalosis, |
| 14. atmospheric | 18. ventral | hypocapnia |

True or False (explanation of the false statements only)

- They also fire during expiration (although at a lower rate) to exert a braking action on the diaphragm.
- When volume increases, pressure decreases.
- Atelectasis can have other causes such as airway obstruction.
- In an average 500 mL tidal volume, 350 mL reaches the alveoli.
- Most CO₂ is transported as bicarbonate ions.

Answers to Figure Legend Questions

- 22.3 The line would cross the figure just slightly above the trachea label.
- 22.4 Epiglottic, corniculate, and arytenoid
- 22.7 The right main bronchus is slightly wider and more vertical than the left, making it easier for aspirated objects to fall into the right.
- 22.8 To secrete mucus
- 22.11 They lack cartilage.
- 22.19 Po₂ drops from 104 to 95 mm Hg on its way out of the lungs because of some mixing with systemic blood. It drops farther to 40 mm Hg when the blood gives up O₂ to respiring tissues, and remains at this level until the blood is reoxygenated back in the lungs. Pco₂ is 40 mm Hg leaving the lungs and rises to 46 mm Hg when CO₂ is picked up from respiring tissues. It remains at that level until the blood returns to the lungs and unloads CO₂.
- 22.23 About 70%
- 22.25 In the alveoli, CO₂ leaves the blood, O₂ enters, and all the chemical reactions are the reverse of those in figure 22.24. The blood bicarbonate concentration will be reduced following alveolar gas exchange.
- 22.26 A higher temperature suggests a relatively high metabolic rate and, thus, an elevated demand for oxygen. Comparison of these curves shows that for a given PO₂, hemoglobin gives up more oxygen at warmer temperatures.

Chapter 23

Testing Your Recall

- | | | |
|------|------------------|-----------------------|
| 1. a | 9. c | 16. transport |
| 2. d | 10. a | maximum |
| 3. b | 11. micturition | 17. antidiuretic |
| 4. c | 12. renal | hormone |
| 5. b | autoregulation | 18. internal urethral |
| 6. b | 13. trigone | 19. protein |
| 7. d | 14. macula densa | 20. arcuate |
| 8. e | 15. podocytes | |

True or False (explanation of the false statements only)

- Calcium and sodium reabsorption by the PCT are influenced by parathyroid hormone and angiotensin II.
- Urine contains more urea and chloride than sodium.
- A substantial amount of tubular fluid is reabsorbed by the paracellular route, passing through leaky tight junctions.
- Glycosuria does not occur in diabetes insipidus.
- Urine can be as dilute as 50 mOsm/L.

Answers to Figure Legend Questions

- 23.2 Ammonia is produced by the deamination of amino acids; urea is produced from ammonia and carbon dioxide; uric acid is produced from nucleic acids; and creatinine is produced from creatine phosphate.
- 23.3 It would be in the dark space at the top of the figure, where the jejunum, colon, and spleen are shown.
- 23.10 The afferent arteriole is larger. The relatively large inlet to the glomerulus and its small outlet result in high blood pressure in the glomerulus. This is the force that drives glomerular filtration.
- 23.16 It lowers the urine pH because of the $\text{Na}^+ - \text{H}^+$ antiport. The more Na^+ that is reabsorbed, the more H^+ is secreted into the tubular fluid.
- 23.21 Osmolarity in the collecting duct would be lower because of more water in the urine; the number now shown as 1,200 mOsm/L could be as low as 50 mOsm/L.
- 23.23 The relatively short female urethra is less of an obstacle for bacteria traveling from the perineum to the urinary bladder.

Chapter 24

Testing Your Recall

- | | | |
|------|-----------------------------|--------------------------|
| 1. c | 9. d | 15. fluid sequestration |
| 2. a | 10. b | 16. hyperkalemia |
| 3. a | 11. Na^+ | 17. hyponatremia |
| 4. a | 12. K^+ | 18. respiratory acidosis |
| 5. d | 13. metabolic water | 19. limiting pH |
| 6. c | 14. cutaneous transpiration | 20. osmolarity |
| 7. e | | |
| 8. b | | |

True or False (explanation of the false statements only)

- Aldosterone has only a small influence on blood pressure.
- PTH promotes calcium absorption but phosphate excretion.
- Protein buffers more acid than bicarbonate or phosphates do.
- More water than salt is lost, so the body fluids become hypertonic.
- Oral wetting and cooling have only a short-term effect on thirst.

Answers to Figure Legend Questions

- 24.1 The tissue fluid compartment
- 24.8 Ingestion of water
- 24.10 It would decrease.
- 24.13 Reverse both arrows to point to the left.

Chapter 25

Testing Your Recall

- | | | |
|------|---------------------|----------------------|
| 1. b | 8. a | 15. vagus |
| 2. d | 9. a | 16. gastrin |
| 3. c | 10. a | 17. sinusoids |
| 4. e | 11. occlusal | 18. maltase, maltose |
| 5. a | 12. amylase, lipase | 19. chylomicrons |
| 6. c | 13. parotid | 20. iron |
| 7. a | 14. enteric | |

True or False (explanation of the false statements only)

- Fat digestion begins in the stomach.
- Most of the tooth is dentin.
- Hepatocytes secrete bile into the bile canaliculi.
- Intrinsic factor is involved in the absorption of vitamin B_{12} .
- Water, glucose, and other nutrients pass between cells, through the tight junctions.

Answers to Figure Legend Questions

- 25.6 The first and second premolars and the third molar
- 25.7 The enamel is a secretion, not a tissue; all the rest are living tissues.
- 25.11 Blockage of the mouth by the root of the tongue and blockage of the nose by the soft palate
- 25.12 The muscularis externa of the esophagus has two layers of muscle, with skeletal muscle in the upper to middle regions and smooth muscle in the middle to lower regions. In the stomach, it has three layers of muscle, all of which is smooth muscle.
- 25.14 It exchanges H^+ for K^+ ($\text{H}^+ - \text{K}^+$ ATPase is an active transport pump).
- 25.20 The hepatic artery and the hepatic portal vein
- 25.31 The internal anal sphincter is composed of smooth muscle and therefore controlled by the autonomic nervous system. The external anal sphincter is composed of skeletal muscle and therefore controlled by the somatic nervous system.

Chapter 26

Testing Your Recall

- | | | |
|------|---------------------|-----------------------|
| 1. a | 8. a | 15. liver |
| 2. c | 9. d | 16. insulin |
| 3. b | 10. d | 17. core temperature |
| 4. e | 11. incomplete | 18. arcuate |
| 5. b | 12. glycogenolysis | 19. cytochromes |
| 6. e | 13. gluconeogenesis | 20. ATP synthase, ATP |
| 7. c | 14. urea | |

True or False (explanation of the false statements only)

- Leptin suppresses the appetite.
- Most of the cholesterol is endogenous, not dietary.
- Excessive protein intake can cause renal damage.
- Gluconeogenesis is a postabsorptive phenomenon.
- Brown fat does not generate ATP.

Answers to Figure Legend Questions

- 26.2 A high HDL:LDL ratio indicates that excess cholesterol is being transported to the liver for removal from the body. A high LDL:HDL ratio indicates a high rate of cholesterol deposition in the walls of the arteries.
- 26.3 It would stop at step 3 and PGAL would accumulate. Anaerobic fermentation replenishes NAD^+ .
- 26.5 NADH and FADH_2
- 26.9 Acidosis (or ketoacidosis or metabolic acidosis)
- 26.10 From amino acids to keto acids to pyruvic acid to glucose

Chapter 27

Testing Your Recall

- | | | |
|------|-----------------------------|----------------------------|
| 1. a | 9. d | 15. tunica albuginea |
| 2. a | 10. d | 16. seminal vesicles |
| 3. a | 11. mesonephric | 17. sustentacular |
| 4. c | 12. fructose | 18. secondary spermatocyte |
| 5. a | 13. pampiniform plexus | 19. deep |
| 6. d | 14. secondary spermatocytes | 20. acrosome |
| 7. e | | |
| 8. c | | |

True or False (explanation of the false statements only)

- Only the testes are primary sex organs.
- Female development results from a low testosterone level, not from estrogen.
- The pampiniform plexus prevents the testes from overheating.
- Sperm are stored in the epididymis.
- There is no such phenomenon as male menopause, and sperm production normally continues throughout old age.

A-10 APPENDIX B Answer Keys

Answers to Figure Legend Questions

- 27.1 Both disorders result from defects in hormone receptors rather than from a lack of the respective hormone.
- 27.5 The word *vagina* means “sheath.” The tunica vaginalis partially ensheathes the testis.
- 27.11 An enlarged prostate gland compresses the urethra and interferes with emptying of the bladder.
- 27.12 An overly engorged corpus spongiosum would compress the urethra and obstruct the expulsion of semen.
- 27.14 The crossing over in prophase I
- 27.15 The next cell stage in meiosis, the secondary spermatocyte, is genetically different from the other cells of the body and would be subject to immune attack if not isolated from the antibodies in the blood.

Chapter 28*Testing Your Recall*

- | | | |
|------|-------------------|-------------------------------|
| 1. a | 8. b | 15. corona radiata |
| 2. d | 9. c | 16. antrum |
| 3. c | 10. c | 17. climacteric |
| 4. a | 11. follicle | 18. conceptus |
| 5. e | 12. endometrium | 19. infundibulum,
fimbriae |
| 6. b | 13. menarche | 20. lochia |
| 7. b | 14. corpus luteum | |

True or False (explanation of the false statements only)

- Only the ovum and corona radiata enter the uterine tube, not the whole follicle.
- HCG is secreted by the placenta.
- Many eggs and follicles undergo atresia during childhood, so their number is greatly reduced by the age of puberty.
- Prolactin is secreted during pregnancy but does not induce lactation then.
- Only the superficial layer (functionalis) is shed.

Answers to Figure Legend Questions

- 28.4 To move the egg or conceptus toward the uterus

- 28.8 The paraurethral glands
- 28.9 They cause milk to flow from the acinus into the ducts of the mammary gland.
- 28.10 This results in a clearer image since the X-rays do not have to penetrate such a thick mass of tissue.
- 28.18 The rising ratio of estrogen to progesterone makes the uterus more irritable.

Chapter 29*Testing Your Recall*

- | | | |
|------|---------------------|-----------------------------------|
| 1. b | 8. a | 15. chorionic villi |
| 2. b | 9. d | 16. acrosome |
| 3. c | 10. d | 17. collagen |
| 4. c | 11. teratogens | 18. Down syndrome
(trisomy-21) |
| 5. a | 12. nondisjunction | 19. foramen ovale |
| 6. e | 13. life span | 20. embryo |
| 7. c | 14. life expectancy | |

True or False (explanation of the false statements only)

- Sperm require about 10 hours to become capacitated and able to fertilize an egg.
- Fertilization occurs in the uterine tube.
- Several early-arriving sperm clear a path for the one that fertilizes the egg.
- Blood bypasses the lungs via the foramen ovale.
- Exercise improves the quality of life in old age, but has not been shown to increase life expectancy significantly.

Answers to Figure Legend Questions

- 29.2 An unfertilized egg dies long before it reaches the uterus.
- 29.8 Eight weeks
- 29.13 XXY (Klinefelter syndrome) and YO (a zygote that would not survive)
- 29.15 Female, as seen from the two X chromosomes at the lower right.

Appendix C

PERIODIC TABLE OF THE ELEMENTS

Nineteenth-century chemists discovered that when they arranged the known elements by atomic weight, certain properties reappeared periodically. In 1869, Russian chemist Dmitri Mendeleev published the first modern periodic table of the elements, leaving gaps for those that had not yet been discovered. He accurately predicted properties of the missing elements, which helped other chemists discover and isolate them.

Each row in the table is a *period* and each column is a *group (family)*. Each period has one electron shell more than the period above it, and as we progress from left to right within a period, each element has one more proton and electron than the one before. The dark step-like line from boron (5) to astatine (85) separates the metals to the left of it (except hydrogen) from the non-metals to the right. Each period begins with a soft, light, highly reactive *alkali metal*, with one valence electron,

in family IA. Progressing from left to right, the metallic properties of the elements become less and less pronounced. Elements in family VIIA are highly reactive gases called *halogens*, with seven valence electrons. Elements in family VIIIA, called *noble (inert) gases*, have a full valence shell of eight electrons, which makes them chemically unreactive.

Ninety-one of the elements occur naturally on earth. Physicists have created elements up to atomic number 118 in the laboratory, but the International Union of Pure and Applied Chemistry has established formal names only through element 109 to date.

The 24 elements with normal roles in human physiology are color-coded according to their relative abundance in the body (see chapter 2). Others, however, may be present as contaminants with very destructive effects (such as arsenic, lead, and radiation poisoning).

Period	IA		Transition metals										VIIA					VIIIA	
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18

Percent of human body (by weight)

- 98.5% (6 elements)
- 0.8% (6 elements)
- 0.7% (12 trace elements)
- Not found naturally on earth

Appendix D

SYMBOLS, WEIGHTS, AND MEASURES

UNITS OF LENGTH

m	meter
km	kilometer (10^3 m)
cm	centimeter (10^{-2} m)
mm	millimeter (10^{-3} m)
μm	micrometer (10^{-6} m)
nm	nanometer (10^{-9} m)

UNITS OF MASS AND WEIGHT

amu	atomic mass unit
MW	molecular weight
mole	MW in grams
g	gram
kg	kilograms (10^3 g)
mg	milligrams (10^{-3} g)

UNITS OF PRESSURE

atm	atmospheres (1 atm = 760 mm Hg)
mm Hg	millimeters of mercury
P_x	partial pressure of gas \times (as in P_{O_2})

CONVERSION FACTORS

1 in. = 2.54 cm	1 cm = 0.394 in.
1 fl oz = 29.6 mL	1 mL = 0.034 fl oz
1 qt = 0.946 L	1 L = 1.057 qt
1 g = 0.0035 oz	1 oz = 28.38 g
1 lb = 0.45 kg	1 kg = 2.2 lb
$^{\circ}\text{C} = (5/9)(^{\circ}\text{F} - 32)$	$^{\circ}\text{F} = (9/5)(^{\circ}\text{C}) + 32$

UNITS OF VOLUME

L	liter
dL	deciliter (= 100 mL) (10^{-1} L)
mL	milliliter (10^{-3} L)
μL	microliter (= 1 mm ³) (10^{-6} L)

UNITS OF CONCENTRATION

mEq/L	milliequivalents per liter
Osm/L	osmoles per liter
mOsm/L	milliosmoles per liter
M	molar
mM	millimolar
pH	negative log of H^+ molarity

UNITS OF HEAT

cal	"small" calories
kcal	kilocalories (Calories; 1 kcal = 1,000 cal)
Cal	"large" (dietary) calories (1 Cal = 1,000 cal)

GREEK LETTERS

α	alpha
β	beta
γ	gamma
Δ	delta (uppercase)
δ	delta (lowercase)
η	eta
θ	theta
μ	mu

Appendix E

BIOMEDICAL ABBREVIATIONS

$\delta+$, $\delta-$	slight positive or negative charge	HIV	human immunodeficiency virus
$2n$	diploid	Hz	hertz (cycles per second)
a., aa.	artery, arteries	I^-	iodide ion
A	adenine	ICF	intracellular fluid
Ab	antibody	Ig	immunoglobulin
ACh	acetylcholine	IL	interleukin
AChE	acetylcholinesterase	I.M.	intramuscular
ACTH	adrenocorticotropic hormone	IPSP	inhibitory postsynaptic potential
AD	Alzheimer disease	IR	infrared
ADH	antidiuretic hormone	I.V.	intravenous
ADP	adenosine diphosphate	K^+	potassium ion
Ag	antigen	LDL	low-density lipoprotein
AIDS	acquired immunodeficiency syndrome	LH	luteinizing hormone
amu	atomic mass unit	LM	light microscope
ANF	atrial natriuretic factor	l.s.	longitudinal section
ANS	autonomic nervous system	m., mm.	muscle, muscles
APC	antigen-presenting cell	MHC	major histocompatibility complex
ATP	adenosine triphosphate	MI	myocardial infarction
AV	atrioventricular	mRNA	messenger ribonucleic acid
BBB	blood-brain barrier	MS	multiple sclerosis
BMR	basal metabolic rate	MSH	melanocyte-stimulating hormone
BP	blood pressure	mV	millivolts
bpm	beats per minute	MW	molecular weight
C	cytosine, carbon	n	haploid
Ca^{2+}	calcium ion	n., nn.	nerve, nerves
CAH	carbonic anhydrase	Na^+	sodium ion
cAMP	cyclic adenosine monophosphate	NAD^+	nicotinamide adenine dinucleotide
CCK	cholecystokinin	NE	norepinephrine
CHF	congestive heart failure	NFP	net filtration pressure
Cl^-	chloride ion	OH^-	hydroxyl ion
CNS	central nervous system	OT	oxytocin
COP	colloid osmotic pressure	P_i	inorganic phosphate group
COPD	chronic obstructive pulmonary disease	PG	prostaglandin
CP	creatine phosphate	PIH	prolactin-inhibiting hormone
CRH	corticotropin-releasing hormone	PNS	peripheral nervous system
c.s.	cross section	PRL	prolactin (luteotropin)
CSF	cerebrospinal fluid	PTH	parathyroid hormone (parathormone)
DNA	deoxyribonucleic acid	RBC	red blood cell
ECF	extracellular fluid	Rh	rhesis factor
ECG	electrocardiogram	RMP	resting membrane potential
EPSP	excitatory postsynaptic potential	RNA	ribonucleic acid
ER	endoplasmic reticulum	rRNA	ribosomal ribonucleic acid
FAD	flavin adenine dinucleotide	SA	sinoatrial
Fe^{2+}	ferrous ion	SEM	scanning electron microscope
Fe^{3+}	ferric ion	T	thymine
FSH	follicle-stimulating hormone	$T_{1/2}$	half-life
G	guanine	T_3	triiodothyronine
GABA	gamma-aminobutyric acid	T_4	thyroxine (tetraiodothyronine)
GAG	glycosaminoglycan	T_m	transport maximum
GFR	glomerular filtration rate	TEM	transmission electron microscope
GH	growth hormone	TRH	thyrotropin-releasing hormone
GHRH	growth hormone-releasing hormone	tRNA	transfer ribonucleic acid
GnRH	gonadotropin-releasing hormone	TSH	thyroid-stimulating hormone
H^+	hydrogen ion	UV	ultraviolet
Hb	hemoglobin	v., vv.	vein, veins
HCG	human chorionic gonadotropin	VLDL	very low-density lipoprotein
HCO_3^-	bicarbonate ion	VO_{2max}	maximum oxygen uptake
HDL	high-density lipoprotein	WBC	white blood cell

GLOSSARY

Terms defined here are not necessarily the most important ones in the book, but are terms that are reintroduced most often and not redefined each time they arise. The index indicates where you can find definitions or explanations of additional terms. Terms are defined only in the sense that they are used in this book. Some have broader meanings, even within biology and medicine, that are beyond its scope. Terms that are commonly abbreviated, such as *ATP* and *PET*, are defined under the full spelling.

A

- abdominal cavity** The body cavity between the diaphragm and pelvic brim. fig. A.7
- abduction** (ab-DUC-shun) Movement of a body part away from the median plane, as in raising an arm away from the side of the body. fig. 9.13
- absorption** **1.** Process in which a chemical passes through a membrane or tissue surface and becomes incorporated into a body fluid or tissue. **2.** Any process in which one substance passes into another and becomes a part of it. *Compare* adsorption.
- acetylcholine (ACh)** (ASS-eh-till-CO-leen) A neurotransmitter released by somatic motor fibers, parasympathetic fibers, and some other neurons, composed of choline and an acetyl group. fig. 12.21
- acetylcholinesterase (AChE)** (ASS-eh-till-CO-lin-ESS-ter-ase) An enzyme that hydrolyzes acetylcholine, thus halting signal transmission at a cholinergic synapse.
- acid** A proton (H^+) donor; a chemical that releases protons into solution.
- acidosis** An acid–base imbalance in which the blood pH is lower than 7.35.
- acinus** (ASS-ih-nus) A sac of secretory cells at the inner end of a gland duct. fig. 5.29
- actin** A filamentous intracellular protein that provides cytoskeletal support and interacts with other proteins, especially myosin, to cause cellular movement; important in muscle contraction and membrane actions such as phagocytosis, amoeboid movement, and cytokinesis.
- action** The movement produced by the contraction of a particular muscle.
- action potential** A rapid voltage change in which a plasma membrane briefly reverses electrical polarity; has a self-propagating effect that produces a traveling wave of excitation in nerve and muscle cells.
- active site** The region of a protein that binds to a ligand, such as the substrate-binding site of an enzyme or the hormone-binding site of a receptor.
- active transport** Transport of particles through a selectively permeable membrane, up their concentration gradient, with the aid of a carrier that consumes ATP.
- acute** Pertaining to a disease with abrupt onset, intense symptoms, and short duration. *Compare* chronic.
- adaptation** **1.** An evolutionary process leading to the establishment of species characteristics that favor survival and reproduction. **2.** Any characteristic of anatomy, physiology, or behavior that promotes survival and reproduction. **3.** A sensory process in which a receptor adjusts its sensitivity or response to the prevailing level of stimulation, such as dark adaptation of the eye.
- adduction** (ah-DUC-shun) Movement of a body part toward the median plane, such as bringing the feet together from a spread-legged position. fig. 9.13
- adenosine triphosphate (ATP)** (ah-DEN-oh-seen tri-FOSS-fate) A molecule composed of adenine, ribose, and three phosphate groups that functions as a universal energy-transfer molecule; yields adenosine diphosphate (ADP) and an inorganic phosphate group (P_i) upon hydrolysis. fig. 2.29a
- adenylate cyclase** (ah-DEN-ih-late SY-clase) An enzyme of the plasma membrane that removes two phosphate molecules from ATP and makes cyclic adenosine monophosphate (cAMP); important in the activation of the cAMP second-messenger system.
- adipocyte** (AD-ih-po-site) A fat cell.
- adipose tissue** A connective tissue composed predominantly of adipocytes; fat.
- adsorption** The binding of one substance to the surface of another without becoming a part of the latter. *Compare* absorption.
- aerobic exercise** (air-OH-bic) Exercise in which oxygen is used to produce ATP; endurance exercise.
- aerobic respiration** Oxidation of organic compounds in a reaction series that requires oxygen and produces ATP.
- afferent** (AFF-uh-rent) Carrying toward, as in *afferent neurons*, which carry signals toward the central nervous system, and *afferent arterioles*, which carry blood toward a tissue.
- agglutination** (ah-GLUE-tih-NAY-shun) Clumping of cells or molecules by antibodies. fig. 18.13
- albumin** (al-BYU-min) A class of small proteins constituting about 60% of the protein fraction of the blood plasma; plays roles in blood viscosity, colloid osmotic pressure, and solute transport.
- aldosterone** (AL-doe-steh-RONE, al-DOSS-teh-ron) A steroid hormone secreted by the adrenal cortex that acts on the kidneys to promote sodium retention and potassium excretion.
- alkalosis** An acid–base imbalance in which the blood pH is higher than 7.45.
- allele** (ah-LEEL) Any of the alternative forms that one gene can take, such as dominant and recessive alleles.
- alveolus** (AL-vee-OH-lus) **1.** A microscopic air sac of the lung. **2.** A gland acinus. **3.** A tooth socket. **4.** Any small anatomical space.
- amino acids** Small organic molecules with an amino group and a carboxyl group; the monomers of which proteins are composed.
- ampulla** (am-PULL-uh) A wide or saclike portion of a tubular organ such as a semicircular duct or uterine tube.
- anabolism** (ah-NAB-oh-lizm) Any metabolic reactions that consume energy and construct more complex molecules with higher free energy from less complex molecules with lower free energy; for example, the synthesis of proteins from amino acids. *Compare* catabolism.
- anaerobic fermentation** (AN-err-OH-bic) A reduction reaction independent of oxygen that converts pyruvic acid to lactic acid and enables glycolysis to continue under anaerobic conditions.
- anastomosis** (ah-NASS-tih-MO-sis) An anatomical convergence, the opposite of a branch; a point where two blood vessels merge and combine their bloodstreams or where two nerves or ducts converge. fig. 20.9
- anatomical position** A reference posture that allows for standardized anatomical terminology. A subject in anatomical position is standing with the feet flat on the floor, arms down to the sides, and the palms and eyes directed forward. fig. A.1
- androgen** (AN-dro-jen) Testosterone or a related steroid hormone. Stimulates somatic changes at puberty in both sexes, adult libido in both sexes, development of male

- anatomy in the fetus and adolescent, and spermatogenesis.
- aneurysm** (AN-you-rizm) A weak, bulging point in the wall of a heart chamber or blood vessel that presents a threat of hemorrhage.
- angiogenesis** (AN-jee-oh-GEN-eh-sis) The growth of new blood vessels.
- angiotensin II** (AN-jee-oh-TEN-sin) A hormone produced from angiotensinogen (a plasma protein) by the kidneys and lungs; raises blood pressure by stimulating vasoconstriction and stimulating the adrenal cortex to secrete aldosterone.
- anion** (AN-eye-on) An ion with more electrons than protons and consequently a net negative charge.
- antagonist 1.** A muscle that opposes the agonist at a joint. **2.** Any agent, such as a hormone or drug, that opposes another.
- antebrachium** (AN-teh-BRAY-kee-um) The region from elbow to wrist; the forearm.
- anterior** Pertaining to the front (facial-abdominal aspect) of the body; ventral.
- anterior root** The branch of a spinal nerve that emerges from the anterior side of the spinal cord and carries efferent (motor) nerve fibers; often called *ventral root*. fig. 13.2b
- antibody** A protein of the gamma globulin class that reacts with an antigen; found in the blood plasma, in other body fluids, and on the surfaces of certain leukocytes and their derivatives.
- antidiuretic hormone (ADH)** (AN-tee-DYE-you-RET-ic) A hormone released by the posterior lobe of the pituitary gland in response to low blood pressure; promotes water retention by the kidneys. Also known as *vasopressin*.
- antigen** (AN-tih-jen) Any large molecule capable of binding to an antibody and triggering an immune response.
- antigen-presenting cell (APC)** A cell that phagocytizes an antigen and displays fragments of it on its surface for recognition by other cells of the immune system; chiefly macrophages and B lymphocytes.
- antiport** A cotransport protein that moves two or more solutes in opposite directions through a cellular membrane; for example, the Na^+-K^+ pump.
- apical surface** The uppermost surface of an epithelial cell, usually exposed to the lumen of an organ. fig. 3.5
- apocrine** Pertaining to certain sweat glands with large lumens and relatively thick, aromatic secretions and to similar glands such as the mammary gland; formerly thought to form secretions by pinching off bits of apical cytoplasm.
- apoptosis** (AP-op-TOE-sis) Programmed cell death; the normal death of cells that have completed their function. *Compare* necrosis.
- appendicular** (AP-en-DIC-you-lur) Pertaining to the extremities and their supporting skeletal girdles. fig. 8.1
- areolar tissue** (AIR-ee-OH-lur) A fibrous connective tissue with loosely organized, widely spaced fibers and cells and an abundance of fluid-filled space; found under nearly every epithelium, among other places. fig. 5.14
- arteriole** (ar-TEER-ee-ole) A small artery that empties into a metarteriole or capillary.
- articular cartilage** A thin layer of hyaline cartilage covering the articular surface of a bone at a synovial joint, serving to reduce friction and ease joint movement. fig. 9.5
- articulation** A skeletal joint; any point at which two bones meet; may or may not be movable.
- aspect** A particular view of the body or one of its structures, or a part that faces in a particular direction, such as the anterior aspect.
- atherosclerosis** (ATH-ur-oh-skleh-ROE-sis) A degenerative disease of the blood vessels characterized by the presence of atheromas and often leading to calcification of the vessel wall.
- atrioventricular (AV) node** (AY-tree-oh-ventric-you-lur) A group of autorhythmic cells in the interatrial septum of the heart that relays excitation from the atria to the ventricles.
- atrioventricular (AV) valves** The bicuspid (left) and tricuspid (right) valves between the atria and ventricles of the heart.
- atrophy** (AT-ro-fee) Shrinkage of a tissue due to age, disuse, or disease.
- autoantibody** An antibody that fails to distinguish the body's own molecules from foreign molecules and thus attacks host tissues, causing autoimmune diseases.
- autoimmune disease** Any disease in which antibodies fail to distinguish between foreign and self-antigens and attack the body's own tissues; for example, systemic lupus erythematosus and rheumatic fever.
- autolysis** (aw-TOLL-ih-sis) Digestion of cells by their own internal enzymes.
- autonomic nervous system (ANS)** (AW-toe-NOM-ic) A motor division of the nervous system that innervates glands, smooth muscle, and cardiac muscle; consists of sympathetic and parasympathetic divisions and functions largely without voluntary control. *Compare* somatic nervous system.
- autoregulation** The ability of a tissue to adjust its own blood supply through vasomotion or angiogenesis.
- autosome** (AW-toe-some) Any chromosome except the sex chromosomes. Genes on the autosomes are inherited without regard to the sex of the individual.
- axial** (AC-see-ul) Pertaining to the head, neck, and trunk; the part of the body excluding the appendicular portion. fig. 8.1
- axillary** (ACK-sih-LERR-ee) Pertaining to the armpit.
- axon** A process of a neuron that transmits action potentials; also called a *nerve fiber*. There is only one axon to a neuron, and it is usually much longer and much less branched than the dendrites. fig. 12.4
- B**
- baroreceptors** (BAR-oh-re-SEP-turz) Pressure sensors located in the heart, aortic arch, and carotid sinuses that trigger autonomic reflexes in response to fluctuations in blood pressure.
- base 1.** A chemical that binds protons from solution; a proton acceptor. **2.** Any of the purines or pyrimidines of a nucleic acid (adenine, thymine, guanine, cytosine, or uracil) serving in part to code for protein structure. **3.** The broadest part of a tapered organ such as the uterus or the inferior aspect of an organ such as the brain.
- basement membrane** A thin layer of glycoproteins, collagen, and glycosaminoglycans beneath the deepest cells of an epithelium, serving to bind the epithelium to the underlying tissue. fig. 5.32
- basophil** (BAY-so-fill) A granulocyte with coarse cytoplasmic granules that produces heparin, histamine, and other chemicals involved in inflammation. table 18.6
- belly** The thick part of a skeletal muscle between its origin and insertion. fig. 10.3
- bicarbonate buffer system** An equilibrium mixture of carbonic acid, bicarbonate ions, and hydrogen ions ($\text{H}_2\text{CO}_3 \leftrightarrow \text{HCO}_3^- + \text{H}^+$) that stabilizes the pH of the body fluids.
- bicarbonate ion** An anion, HCO_3^- , that functions as a base in the buffering of body fluids.
- biogenic amines** A class of chemical messengers with neurotransmitter and hormonal functions, synthesized from amino acids and retaining an amino group; also called *monoamines*. Examples include epinephrine and thyroxine.
- bipedalism** The habit of walking on two legs; a defining characteristic of the family Hominidae that underlies many skeletal and other characteristics of humans.
- blood-brain barrier (BBB)** A barrier between the bloodstream and nervous tissue of the brain that is impermeable to many blood solutes and thus prevents them from affecting the brain tissue; formed by the tight junctions between capillary endothelial cells, the basement membrane of the endothelium, and the perivascular feet of astrocytes.
- B lymphocyte** A lymphocyte that functions as an antigen-presenting cell and, in humoral immunity, differentiates into an antibody-producing plasma cell; also called a *B cell*.
- body 1.** The entire organism. **2.** Part of a cell, such as a neuron, containing the nucleus and most other organelles. **3.** The largest or principal part of an organ such as the stomach or uterus; also called the *corpus*.
- brachial** (BRAY-kee-ul) Pertaining to the arm proper, the region from shoulder to elbow.
- bradykinin** (BRAD-ee-KY-nin) An oligopeptide produced in inflammation that stimulates vasodilation, increases capillary permeability, and stimulates pain receptors.
- brainstem** The stalklike lower portion of the brain, composed of all of the brain except the cerebrum and cerebellum. (Many authorities also exclude the diencephalon and regard only the medulla oblongata, pons, and midbrain as the brainstem.) fig. 14.8
- bronchiole** (BRONK-ee-ole) A pulmonary air passage that is usually 1 mm or less in diameter and lacks cartilage but has relatively abundant smooth muscle, elastic tissue, and a simple cuboidal, usually ciliated epithelium.
- bronchus** (BRONK-us) A relatively large pulmonary air passage with supportive cartilage in the wall; any passage beginning

G-3 GLOSSARY

- with the primary bronchus at the fork in the trachea and ending with tertiary bronchi, from which air continues into the bronchioles.
- brush border** A fringe of microvilli on the apical surface of an epithelial cell, serving to enhance surface area and promote absorption. fig. 5.6
- bursa** A sac filled with synovial fluid at a diarthrosis, serving to facilitate muscle or joint action. fig. 9.24
- C**
- calcification** The hardening of a tissue due to the deposition of calcium salts.
- calorie** The amount of thermal energy that will raise the temperature of 1 g of water by 1°C. Also called a *small calorie*.
- Calorie** See kilocalorie.
- canaliculus** (CAN-uh-LIC-you-lus) A microscopic canal, as in osseous tissue. fig. 7.5
- capillary** (CAP-ih-LERR-ee) The narrowest type of vessel in the cardiovascular and lymphatic systems; engages in fluid exchanges with surrounding tissues.
- capillary exchange** The process of fluid transfer between the bloodstream and tissue fluid.
- capsule** The fibrous covering of a structure such as the spleen or a diarthrosis.
- carbohydrate** A hydrophilic organic compound composed of carbon and a 2:1 ratio of hydrogen to oxygen; includes sugars, starches, glycogen, and cellulose.
- carbonic anhydrase** An enzyme found in erythrocytes and kidney tubule cells that catalyzes the decomposition of carbonic acid into carbon dioxide and water or the reverse reaction ($H_2CO_3 \leftrightarrow CO_2 + H_2O$).
- carcinogen** (car-SIN-oh-jen) An agent capable of causing cancer, including certain chemicals, viruses, and ionizing radiation.
- cardiac output (CO)** The amount of blood pumped by each ventricle of the heart in one minute.
- cardiovascular system** An organ system consisting of the heart and blood vessels, serving for the transport of blood. *Compare* circulatory system.
- carpal** Pertaining to the wrist (carpus).
- carrier** **1.** A protein in a cellular membrane that performs carrier-mediated transport. **2.** A person who is heterozygous for a recessive allele and does not exhibit the associated phenotype, but may transmit this allele to his or her children; for example, a carrier for sickle-cell disease.
- carrier-mediated transport** A process of transporting materials through a cellular membrane that involves reversible binding to a membrane transport protein.
- catabolism** (ca-TAB-oh-lizm) Any metabolic reactions that release energy and break relatively complex molecules with high free energy into less complex molecules with lower free energy; for example, digestion and glycolysis. *Compare* anabolism.
- catecholamine** (CAT-eh-COAL-uh-meen) A subclass of biogenic amines that includes epinephrine, norepinephrine, and dopamine. fig. 12.21
- cation** (CAT-eye-on) An ion with more protons than electrons and consequently a net positive charge.
- caudal** (CAW-dul) **1.** Pertaining to a tail or narrow tail-like part of an organ. **2.** Pertaining to the inferior part of the trunk of the body, where the tail of other animals arises. *Compare* cranial. **3.** Relatively distant from the forehead, especially in reference to structures of the brain and spinal cord; for example, the medulla oblongata is caudal to the pons. *Compare* rostral.
- celiac** (SEE-lee-ac) Pertaining to the abdomen.
- central** Located relatively close to the median axis of the body, as in the central nervous system; opposite of peripheral.
- central nervous system (CNS)** The brain and spinal cord.
- centriole** (SEN-tree-ole) An organelle composed of a short cylinder of nine triplets of microtubules, usually paired with another centriole perpendicular to it; origin of the mitotic spindle; identical to the basal body of a cilium or flagellum. fig. 3.30
- cephalic** (seh-FAL-ic) Pertaining to the head.
- cerebellum** (SERR-eh-BEL-um) A large portion of the brain posterior to the brainstem and inferior to the cerebrum, responsible for equilibrium, motor coordination, and memory of learned motor skills. fig. 14.11
- cerebrospinal fluid (CSF)** (SERR-eh-bro-SPY-nul, seh-REE-bro-SPY-nul) A liquid that fills the ventricles of the brain, the central canal of the spinal cord, and the space between the CNS and dura mater.
- cerebrum** (SERR-eh-brum, seh-REE-brum) The largest and most superior part of the brain, divided into two convoluted cerebral hemispheres separated by a deep longitudinal fissure.
- cervical** (SUR-vih-cul) Pertaining to the neck or any cervix.
- cervix** (SUR-vix) **1.** The neck. **2.** A narrow or necklike part of an organ such as the uterus and gallbladder. fig. 28.3
- channel protein** A protein in the plasma membrane that has a pore through it for the passage of materials between the cytoplasm and extracellular fluid. fig. 3.8
- chemical bond** A force that attracts one atom to another, such as their opposite charges or the sharing of electrons.
- chemical synapse** A meeting of a nerve fiber and another cell with which the neuron communicates by releasing neurotransmitters. fig. 12.20
- chemoreceptor** An organ or cell specialized to detect chemicals, as in the carotid bodies and taste buds.
- chief cells** The majority type of cell in an organ or tissue such as the parathyroid glands or gastric glands.
- cholecystokinin (CCK)** (CO-lee-SIS-toe-KY-nin) A polypeptide employed as a hormone and neurotransmitter, secreted by some brain neurons and cells of the digestive tract. fig. 12.21
- cholesterol** (co-LESS-tur-ol) A steroid that functions as part of the plasma membrane and as a precursor for all other steroids in the body.
- cholinergic** (CO-lin-UR-jic) Pertaining to acetylcholine (ACh), as in cholinergic nerve fibers that secrete ACh, cholinergic receptors that bind it, or cholinergic effects on a target organ.
- chondrocyte** (CON-dro-site) A cartilage cell; a former chondroblast that has become enclosed in a lacuna in the cartilage matrix. fig. 5.21
- chorion** (CO-ree-on) A fetal membrane external to the amnion; forms part of the placenta and has diverse functions including fetal nutrition, waste removal, and hormone secretion. fig. 29.7
- chromatin** (CRO-muh-tin) Filamentous material in the interphase nucleus, composed of DNA and associated proteins.
- chromosome** A complex of DNA and protein carrying the genetic material of a cell's nucleus. Normally there are 46 chromosomes in the nucleus of each cell except germ cells. fig. 4.5
- chronic** **1.** Long-lasting. **2.** Pertaining to a disease that progresses slowly and has a long duration. *Compare* acute.
- chronic bronchitis** A chronic obstructive pulmonary disease characterized by damaged and immobilized respiratory cilia, excessive mucus secretion, infection of the lower respiratory tract, and bronchial inflammation; caused especially by cigarette smoking. *See also* chronic obstructive pulmonary disease.
- chronic obstructive pulmonary disease (COPD)** Certain lung diseases (chronic bronchitis and emphysema) that result in long-term obstruction of airflow and substantially reduced pulmonary ventilation; one of the leading causes of death in old age.
- cilium** (SIL-ee-um) A hairlike process, with an axoneme, projecting from the apical surface of an epithelial cell; often motile and serving to propel matter across the surface of an epithelium, but sometimes nonmotile and serving sensory roles. fig. 3.11
- circulatory shock** A state of cardiac output inadequate to meet the metabolic needs of the body.
- circulatory system** An organ system consisting of the heart, blood vessels, and blood. *Compare* cardiovascular system.
- circumduction** A joint movement in which one end of an appendage remains relatively stationary and the other end is moved in a circle. fig. 9.16
- cirrhosis** (sih-RO-sis) A degenerative liver disease characterized by replacement of functional parenchyma with fibrous and adipose tissue; causes include alcohol, other poisons, and viral and bacterial inflammation.
- cisterna** (sis-TUR-nuh) A fluid-filled space or sac, such as the cisterna chyli of the lymphatic system and a cisterna of the endoplasmic reticulum or Golgi complex. fig. 3.26
- climacteric** A period in the lives of men and women, usually in the early 50s, marked by changes in the level of reproductive hormones, a variety of somatic and psychological effects, and in women, cessation of ovulation and menstruation (menopause).
- clone** A population of cells that are mitotically descended from the same parent cell and are identical to each other genetically or in other respects.

- coagulation** (co-AG-you-LAY-shun) The clotting of blood, lymph, tissue fluid, or semen.
- coenzyme** (co-EN-zime) A small organic molecule, usually derived from a vitamin, that is needed to make an enzyme catalytically active; acts by accepting electrons from an enzymatic reaction and transferring them to a different reaction chain.
- cofactor** A nonprotein such as a metal ion or coenzyme needed for an enzyme to function.
- cohesion** The clinging of identical molecules such as water to each other.
- collagen** (COLL-uh-jen) The most abundant protein in the body, forming the fibers of many connective tissues in places such as the dermis, tendons, and bones.
- colloid** An aqueous mixture of particles that are too large to pass through most selectively permeable membranes but small enough to remain evenly dispersed through the solvent by the thermal motion of solvent particles; for example, the proteins in blood plasma.
- colloid osmotic pressure (COP)** A portion of the osmotic pressure of a body fluid that is due to its protein. *Compare* oncotic pressure.
- columnar** A cellular shape that is roughly significantly taller than it is wide. fig. 5.6
- commissure** (COM-ih-shur) **1.** A bundle of nerve fibers that crosses from one side of the brain or spinal cord to the other. fig. 14.2 **2.** A corner or angle at which the eyelids, lips, or genital labia meet; in the eye, also called the *canthus*. fig. 16.22
- complement** **1.** To complete or enhance the structure or function of something else, as in the coordinated action of two different hormones. **2.** A system of plasma proteins involved in nonspecific defense against pathogens.
- computerized tomography (CT)** A method of medical imaging that uses X-rays and a computer to create an image of a thin section of the body; also called a *CT scan*.
- concentration gradient** A difference in chemical concentration from one point to another, as on two sides of a plasma membrane.
- conception** The fertilization of an egg, producing a zygote.
- conceptus** All products of conception, ranging from a fertilized egg to the full-term fetus with its embryonic membranes, placenta, and umbilical cord. *Compare* embryo, fetus, preembryo.
- condyle** (CON-dile) A rounded knob on a bone serving to produce smooth motion at a joint. fig. 8.2
- conformation** The three-dimensional structure of a protein that results from interaction among its amino acid side groups, its interactions with water, and the formation of disulfide bonds.
- congenital** Present at birth; for example, an anatomical defect, a syphilis infection, or a hereditary disease.
- conjugated** A state in which one organic compound is bound to another compound of a different class, such as a protein conjugated with a carbohydrate to form a glycoprotein.
- connective tissue** A tissue usually composed of more extracellular than cellular volume and usually with a substantial amount of extracellular fiber; forms supportive frameworks and capsules for organs, binds structures together, holds them in place, stores energy (as in adipose tissue), or transports materials (as in blood).
- contractility** **1.** The ability to shorten. **2.** The amount of force that a contracting muscle fiber generates for a given stimulus; may be increased by epinephrine, for example, while stimulus strength remains constant.
- contralateral** On opposite sides of the body, as in reflex arcs in which the stimulus comes from one side of the body and a response is given by muscles on the other side. *Compare* ipsilateral.
- cooperative effect** Effect in which two hormones, or both divisions of the autonomic nervous system, work together to produce a single overall result.
- corona** A halo- or crownlike structure, as in the corona radiata or the coronal suture of the skull.
- corona radiata** **1.** An array of nerve tracts in the brain that arise mainly from the thalamus and fan out to different regions of the cerebral cortex. **2.** The first layer of cuboidal cells immediately external to the zona pellucida around an egg cell.
- coronal plane** *See* frontal plane.
- coronary circulation** A system of blood vessels that serve the wall of the heart. fig. 19.10
- corpus** Body or mass; the main part of an organ, as opposed to such regions as a head, tail, or cervix.
- cortex** (plural, *cortices*) The outer layer of some organs such as the adrenal gland, cerebellum, lymph node, and ovary; usually covers or encloses tissue called the medulla.
- corticosteroid** (COR-tih-co-STERR-oyd) Any steroid hormone secreted by the adrenal cortex, such as aldosterone, cortisol, and sex steroids.
- costal** (COSS-tul) Pertaining to the ribs.
- cotransport** A form of carrier-mediated transport in which a membrane protein transports two solutes simultaneously or within the same cycle of action by either facilitated diffusion or active transport; for example the sodium-glucose transport protein and the Na⁺-K⁺ pump.
- countercurrent** A situation in which two fluids flow side by side in opposite directions, as in the countercurrent multiplier of the kidney and the countercurrent heat exchanger of the scrotum.
- cranial** (CRAY-nee-ul) **1.** Pertaining to the cranium. **2.** In a position relatively close to the head or a direction toward the head. *Compare* caudal.
- cranial nerve** Any of 12 pairs of nerves connected to the base of the brain and passing through foramina of the cranium.
- crista** A crestlike structure, such as the crista galli of the ethmoid bone or the crista of a mitochondrion.
- cross section** A cut perpendicular to the long axis of the body or an organ.
- crural** (CROO-rul) Pertaining to the leg proper or to the crus of an organ. *See* crus.
- crus** (cruss) (plural, *crura*) **1.** The leg proper; the region from the knee to the ankle. **2.** A leglike extension of an organ such as the penis and clitoris. figs. 27.11b, 28.8
- cuboidal** (cue-BOY-dul) A cellular shape that is roughly like a cube or in which the height and width are about equal; typically looks squarish in tissue sections. fig. 5.5
- current** A moving stream of charged particles such as ions or electrons.
- cuspid** **1.** One of the flaps of a valve of the heart, veins, and lymphatic vessels. **2.** A conical projection on the occlusal surface of a premolar or molar tooth.
- cutaneous** (cue-TAY-nee-us) Pertaining to the skin.
- cyanosis** (SY-uh-NO-sis) A bluish color of the skin and mucous membranes due to ischemia or hypoxemia.
- cyclic adenosine monophosphate (cAMP)** A cyclic molecule produced from ATP by the action of adenylate cyclase; serves as a second messenger in many hormone and neurotransmitter actions. fig. 2.29b
- cytolysis** (sy-TOL-ih-sis) The rupture and destruction of a cell by such agents as complement proteins and hypotonic solutions.
- cytoplasm** The contents of a cell between its plasma membrane and its nuclear envelope, consisting of cytosol, organelles, inclusions, and the cytoskeleton.
- cytoskeleton** A system of protein microfilaments, intermediate filaments, and microtubules in a cell, serving in physical support, cellular movement, and the routing of molecules and organelles to their destinations within the cell. fig. 3.31
- cytosol** A clear, featureless, gelatinous colloid in which the organelles and other internal structures of a cell are embedded.
- cytotoxic T cell** A T lymphocyte that directly attacks and destroys infected body cells, cancerous cells, and the cells of transplanted tissues.
- D**
- daughter cells** Cells that arise from a parent cell by mitosis or meiosis.
- deamination** (dee-AM-ih-NAY-shun) Removal of an amino group from an organic molecule; a step in the catabolism of amino acids.
- decomposition reaction** A chemical reaction in which a larger molecule is broken down into smaller ones. *Compare* synthesis reaction.
- decussation** (DEE-cuh-SAY-shun) The crossing of nerve fibers from the right side of the central nervous system to the left or vice versa, especially in the spinal cord, medulla oblongata, and optic chiasma.
- deep** Relatively far from the body surface; opposite of *superficial*. For example, the bones are deep to the skeletal muscles.
- degranulation** Exocytosis and disappearance of cytoplasmic granules, especially in platelets and granulocytes.
- denaturation** A change in the three-dimensional conformation of a protein that destroys its enzymatic or other functional properties, usually caused by extremes of temperature or pH.
- dendrite** Process of a neuron that receives information from other cells or from environmental stimuli and conducts signals to the soma. Dendrites are usually shorter, more

G-5 GLOSSARY

branched, and more numerous than the axon and are incapable of producing action potentials. fig. 12.4

dendritic cell An antigen-presenting cell of the epidermis. fig. 6.3a

denervation atrophy The shrinkage of skeletal muscle that occurs when the motor neuron dies or is severed from the muscle.

dense connective tissue A connective tissue with a high density of fiber, relatively little ground substance, and scanty cells; seen in tendons and the dermis, for example.

depolarization A shift in the electrical potential across a plasma membrane toward 0 mV, associated with excitation of a nerve or muscle cell. *Compare* hyperpolarization.

dermal papilla Bump or ridge of dermis that extends upward to interdigitate with the epidermis and create a wavy boundary that resists stress and slippage of the epidermis.

dermis The deeper of the two layers of the skin, underlying the epidermis and composed of fibrous connective tissue.

desmosome (DEZ-mo-some) A patchlike intercellular junction that mechanically links two cells together. fig. 5.28

diabetes (DY-uh-BEE-teez) Any disease characterized by chronic polyuria of metabolic origin; diabetes mellitus unless otherwise specified.

diabetes insipidus (in-SIP-ih-dus) A form of diabetes that results from hyposecretion of antidiuretic hormone; unlike other forms, it is not characterized by hyperglycemia or glycosuria.

diabetes mellitus (DM) (mel-EYE-tus) A form of diabetes that results from hyposecretion of insulin or from a deficient target cell response to it; signs include hyperglycemia and glycosuria.

diaphysis (dy-AFF-ih-sis) The shaft of a long bone. fig. 7.2

diarthrosis (DY-ar-THRO-sis) A freely movable synovial joint such as the knuckle, elbow, shoulder, or knee.

diastole (dy-ASS-tuh-lee) A period in which a heart chamber relaxes and fills with blood; especially ventricular relaxation.

diencephalon (DY-en-SEFF-uh-lon) A portion of the brain between the midbrain and corpus callosum; composed of the thalamus, epithalamus, and hypothalamus. fig. 14.12

differentiation Development of a relatively unspecialized cell or tissue into one with a more specific structure and function.

diffusion Spontaneous net movement of particles from a place of high concentration to a place of low concentration (down a concentration gradient).

disaccharide (dy-SAC-uh-ride) A carbohydrate composed of two simple sugars (monosaccharides) joined by a glycosidic bond; for example, lactose, sucrose, and maltose. fig. 2.17

disseminated intravascular coagulation (DIC) Widespread clotting of the blood within unbroken vessels, leading to hemorrhaging, congestion of the vessels with clotted blood, and ischemia and necrosis of organs.

distal Relatively distant from a point of origin or attachment; for example, the wrist is distal to the elbow. *Compare* proximal.

disulfide bond A covalent bond between the sulfur atoms of two cysteine residues, serving to link one polypeptide chain to another or to hold a single chain in its three-dimensional conformation.

diuretic (DY-you-RET-ic) A chemical that increases urine output.

dominant **1.** Pertaining to a genetic allele that is phenotypically expressed in the presence of any other allele. **2.** Pertaining to a trait that results from a dominant allele.

dopamine (DOE-puh-meen) An inhibitory catecholamine neurotransmitter of the central nervous system, especially of the basal nuclei, where it acts to suppress unwanted motor activity. fig. 12.21

dorsal Toward the back (spinal) side of the body; in humans, usually synonymous with *posterior*.

dorsal root *See* posterior root.

dorsiflexion (DOR-sih-FLEC-shun) A movement of the ankle that reduces the joint angle and raises the toes. fig. 9.22

duodenum (DEW-oh-DEE-num, dew-ODD-eh-num) The first portion of the small intestine extending for about 25 cm from the pyloric valve of the stomach to a sharp bend called the duodenojejunal flexure; receives chyme from the stomach and secretions from the liver and pancreas. fig. 25.24

dynein (DINE-een) A motor protein involved in the beating of cilia and flagella and in the movement of molecules and organelles within cells, as in retrograde transport in a nerve fiber.

E

ectopic (ec-TOP-ic) In an abnormal location; for example, ectopic pregnancy and ectopic pacemakers of the heart.

edema (eh-DEE-muh) Abnormal accumulation of tissue fluid resulting in swelling of the tissue.

effector A molecule, cell, or organ that carries out a response to a stimulus.

efferent (EFF-ur-unt) Carrying away or out, such as a blood vessel that carries blood away from a tissue or a nerve fiber that conducts signals away from the central nervous system.

elastic fiber A connective tissue fiber, composed of the protein elastin, that stretches under tension and returns to its original length when released; responsible for the resilience of organs such as the skin and lungs.

elasticity The tendency of a stretched structure to return to its original dimensions when tension is released.

electrical synapse A gap junction that enables one cell to stimulate another directly, without the intermediary action of a neurotransmitter; such synapses connect the cells of cardiac muscle and single-unit smooth muscle.

electrolyte A salt that ionizes in water and produces a solution that conducts electricity; loosely speaking, any ion that results from the dissociation of such salts, such as sodium, potassium, calcium, chloride, and bicarbonate ions.

elevation A joint movement that raises a body part, as in hunching the shoulders or closing the mouth.

embolism (EM-bo-lizm) The obstruction of a blood vessel by an embolus.

embolus (EM-bo-lus) Any abnormal traveling object in the bloodstream, such as agglutinated bacteria or blood cells, a blood clot, or an air bubble.

embryo A developing individual from the sixteenth day of gestation when the three primary germ layers have formed, through the end of the eighth week when all of the organ systems are present. *Compare* conceptus, fetus, preembryo.

emphysema (EM-fih-SEE-muh) A degenerative lung disease characterized by a breakdown of alveoli and diminishing surface area available for gas exchange; occurs with aging of the lungs but is greatly accelerated by smoking or air pollution.

endocrine gland (EN-doe-crin) A ductless gland that secretes hormones into the bloodstream; for example, the thyroid and adrenal glands. *Compare* *exocrine gland*.

endocytosis (EN-doe-sy-TOE-sis) Any process in which a cell forms vesicles from its plasma membrane and takes in large particles, molecules, or droplets of extracellular fluid; for example, phagocytosis and pinocytosis.

endoderm The innermost of the three primary germ layers of an embryo; gives rise to the mucosae of the digestive and respiratory tracts and to their associated glands.

endogenous (en-DODJ-eh-nus) Originating internally, such as the endogenous cholesterol synthesized in the body in contrast to the exogenous cholesterol coming from the diet. *Compare* exogenous.

endometrium (EN-doe-MEE-tree-um) The mucosa of the uterus; the site of implantation and source of menstrual discharge.

endoplasmic reticulum (ER) (EN-doe-PLAZ-mic reh-TIC-you-lum) An extensive system of interconnected cytoplasmic tubules or channels; classified as rough ER or smooth ER depending on the presence or absence of ribosomes on its membrane. fig. 3.26

endothelium (EN-doe-THEEL-ee-um) A simple squamous epithelium that lines the lumens of the blood vessels, heart, and lymphatic vessels.

enteric (en-TERR-ic) Pertaining to the small intestine, as in enteric hormones.

eosinophil (EE-oh-SIN-oh-fill) A granulocyte with a large, often bilobed nucleus and coarse cytoplasmic granules that stain with eosin; phagocytizes antigen-antibody complexes, allergens, and inflammatory chemicals and secretes enzymes that combat parasitic infections. table 18.6

epidermis A stratified squamous epithelium that constitutes the superficial layer of the skin, overlying the dermis. fig. 6.3

epinephrine (EP-ih-NEFF-rin) A catecholamine that functions as a neurotransmitter in the sympathetic nervous system and as a hormone secreted by the adrenal medulla; also called *adrenaline*. fig. 12.21

epiphyseal plate (EP-ih-FIZZ-ee-ul) A plate of hyaline cartilage between the epiphysis and diaphysis of a long bone in a child or adolescent, serving as a growth zone for bone elongation. figs. 7.10, 7.12

epiphysis (eh-PIF-ih-sis) **1.** The head of a long bone. fig. 7.2 **2.** The pineal gland (epiphysis cerebri).

epithelium A type of tissue consisting of one or more layers of closely adhering cells with little intercellular material and no blood vessels; forms the coverings and linings of many organs and the parenchyma of the glands.

erectile tissue A tissue that functions by swelling with blood, as in the penis and clitoris and inferior concha of the nasal cavity.

erythrocyte (eh-RITH-ro-site) A red blood cell.

erythropoiesis (eh-RITH-ro-poy-EE-sis) The production of erythrocytes.

erythropoietin (eh-RITH-ro-POY-eh-tin) A hormone that is secreted by the kidneys and liver in response to hypoxemia and stimulates erythropoiesis.

estrogens (ESS-tro-jenz) A family of steroid hormones known especially for producing female secondary sex characteristics and regulating various aspects of the menstrual cycle and pregnancy; major forms are estradiol, estriol, and estrone.

evolution A change in the relative frequencies of alleles in a population over a period of time; the mechanism that produces adaptations in human form and function. *See also* adaptation.

excitability The ability of a cell to respond to a stimulus, especially the ability of nerve and muscle cells to produce membrane voltage changes in response to stimuli; irritability.

excitation–contraction coupling Events that link the synaptic stimulation of a muscle cell to the onset of contraction.

excitatory postsynaptic potential (EPSP) A partial depolarization of a postsynaptic neuron or muscle cell in response to a neurotransmitter, making it more likely to reach threshold and produce an action potential.

excretion The process of eliminating metabolic waste products from a cell or from the body. *Compare* secretion.

exocrine gland (EC-so-crin) A gland that secretes its products into another organ or onto the body surface, usually by way of a duct; for example, salivary and gastric glands. *Compare* endocrine gland.

exocytosis (EC-so-sy-TOE-sis) A process in which a vesicle in the cytoplasm of a cell fuses with the plasma membrane and releases its contents from the cell; used in the elimination of cellular wastes and in the release of gland products and neurotransmitters.

exogenous (ec-SODJ-eh-nus) Originating externally, such as exogenous (dietary) cholesterol; extrinsic. *Compare* endogenous.

expiration **1.** Exhaling. **2.** Dying.

extension Movement of a joint that increases the angle between articulating bones (straightens the joint). (fig. 9.12) *Compare* flexion.

extracellular fluid (ECF) Any body fluid that is not contained in the cells; for example, blood, lymph, and tissue fluid.

extrinsic (ec-STRIN-sic) **1.** Originating externally, such as extrinsic blood-clotting factors; exogenous. **2.** Not fully contained within an organ but acting on it, such as the extrinsic muscles of the hand and eye. *Compare* intrinsic.

F

facilitated diffusion The process of transporting a chemical through a cellular membrane, down its concentration gradient, with the aid of a carrier that does not consume ATP; enables substances to diffuse through the membrane that would do so poorly, or not at all, without a carrier.

facilitation Making a process more likely to occur, such as the firing of a neuron, or making it occur more easily or rapidly, as in facilitated diffusion.

fascia (FASH-ee-uh) A layer of connective tissue between the muscles or separating the muscles from the skin. fig. 10.1

fascicle (FASS-ih-cul) A bundle of muscle or nerve fibers ensheathed in connective tissue; multiple fascicles bound together constitute a muscle or nerve as a whole. figs. 10.1, 13.8

fat **1.** A triglyceride molecule. **2.** Adipose tissue.

fatty acid An organic molecule composed of a chain of an even number of carbon atoms with a carboxyl group at one end and a methyl group at the other; one of the structural subunits of triglycerides and phospholipids.

fenestrated (FEN-eh-stray-ted) Perforated with holes or slits, as in fenestrated blood capillaries and the elastic sheets of large arteries. fig. 20.6

fetus In human development, an individual from the beginning of the ninth week when all of the organ systems are present, through the time of birth. *Compare* conceptus, embryo, preembryo.

fibrin (FY-brin) A sticky fibrous protein formed from fibrinogen in blood, tissue fluid, lymph, and semen; forms the matrix of a blood clot.

fibroblast A connective tissue cell that produces collagen fibers and ground substance; the only type of cell in tendons and ligaments.

fibrosis Replacement of damaged tissue with fibrous scar tissue rather than by the original tissue type; scarring. *Compare* regeneration.

fibrous connective tissue Any connective tissue with a preponderance of fiber, such as areolar, reticular, dense regular, and dense irregular connective tissues.

filtrate A fluid formed by filtration, as at the renal glomerulus and other capillaries.

filtration A process in which hydrostatic pressure forces a fluid through a selectively permeable membrane (especially a capillary wall).

fire To produce an action potential, as in nerve and muscle cells.

fix **1.** To hold a structure in place, for example, by fixator muscles that prevent unwanted joint movements. **2.** To preserve a tissue by means of a fixative such as formalin.

flexion A joint movement that, in most cases, decreases the angle between two bones. (fig. 9.12) *Compare* extension.

fluid balance *See* water balance.

fluid compartment Any of the major categories of fluid in the body, separated by selectively permeable membranes and differing from each other in chemical composition. Primary examples are the intracellular fluid, tissue fluid, blood, and lymph.

follicle (FOLL-ih-cul) **1.** A small space, such as a hair follicle, thyroid follicle, or ovarian follicle. **2.** An aggregation of lymphocytes in a lymphatic organ or mucous membrane.

follicle-stimulating hormone (FSH) A hormone secreted by the anterior pituitary gland that stimulates development of the ovarian follicles and egg cells.

foramen (fo-RAY-men) A hole through a bone or other organ, in many cases providing passage for blood vessels and nerves.

formed element An erythrocyte, leukocyte, or platelet; any cellular component of blood or lymph as opposed to the extracellular fluid component.

fossa (FOSS-uh) A depression in an organ or tissue, such as the fossa ovalis of the heart or a cranial fossa of the skull.

fovea (FOE-vee-uh) A small pit, such as the fovea capitis of the femur or fovea centralis of the retina.

free energy The potential energy in a chemical that is available to do work.

free radical A particle derived from an atom or molecule, having an unpaired electron that makes it highly reactive and destructive to cells; produced by intrinsic processes such as aerobic respiration and by extrinsic agents such as chemicals and ionizing radiation.

frenulum (FREN-you-lum) A fold of tissue that attaches a movable structure to a relatively immovable one, such as the lip to the gum or the tongue to the floor of the mouth. fig. 25.4

frontal plane An anatomical plane that passes through the body or an organ from right to left and superior to inferior; also called a *coronal plane*. fig. A.3

fundus The base, the broadest part, or the part farthest from the opening of certain viscera such as the stomach and uterus.

fusiform (FEW-zih-form) Spindle-shaped; elongated, thick in the middle, and tapered at both ends, such as the shape of a smooth muscle cell or a muscle spindle.

G

gamete (GAM-eet) An egg or sperm cell.

gametogenesis (GAM-eh-toe-JEN-eh-sis) The production of eggs or sperm.

ganglion (GANG-gee-un) A cluster of nerve cell bodies in the peripheral nervous system, often resembling a knot in a string.

gangrene Tissue necrosis resulting from ischemia.

gap junction A junction between two cells consisting of a pore surrounded by a ring of proteins in the plasma membrane of each cell, allowing solutes to diffuse from the cytoplasm of one cell to the next; functions include cell-to-cell nutrient transfer in the developing embryo and electrical commu-

G-7 GLOSSARY

- nication between cells of cardiac and smooth muscle. *See also* electrical synapse. fig. 5.28
- gastric** Pertaining to the stomach.
- gate** A protein channel in a cellular membrane that can open or close in response to chemical, electrical, or mechanical stimuli, thus controlling when substances are allowed to pass through the membrane.
- gene** An information-containing segment of DNA that codes for the production of a molecule of RNA, which in most cases goes on to play a role in the synthesis of one or more proteins.
- gene locus** The site on a chromosome where a given gene is located.
- genome** (JEE-nome) All the genes of one individual, estimated at 35,000 genes in humans.
- genotype** (JEE-no-type) The pair of alleles possessed by an individual at one gene locus on a pair of homologous chromosomes; strongly influences the individual's phenotype for a given trait.
- germ cell** A gamete or any precursor cell destined to become a gamete.
- germ layer** Any of first three tissue layers of an embryo: ectoderm, mesoderm, or endoderm.
- gestation** (jess-TAY-shun) Pregnancy.
- globulin** (GLOB-you-lin) A globular protein such as an enzyme, antibody, or albumin; especially a family of proteins in the blood plasma that includes albumin, antibodies, fibrinogen, and prothrombin.
- glomerular capsule** (glo-MERR-you-lur) A double-walled capsule around each glomerulus of the kidney; receives glomerular filtrate and empties into the proximal convoluted tubule. Also called *Bowman's capsule*. fig. 23.7
- glomerulus 1.** A spheroid mass of blood capillaries in the kidney that filters plasma and produces glomerular filtrate, which is further processed to form the urine. fig. 23.7 **2.** A spheroidal mass of nerve endings in the olfactory bulb where olfactory neurons from the nose synapse with mitral and dendritic cells of the bulb. fig. 16.7
- glucagon** (GLUE-ca-gon) A hormone secreted by α cells of the pancreatic islets in response to hypoglycemia; promotes glycogenolysis and other effects that raise blood glucose concentration.
- glucocorticoid** (GLUE-co-COR-tih-coyd) Any hormone of the adrenal cortex that affects carbohydrate, fat, and protein metabolism; chiefly cortisol and corticosterone.
- gluconeogenesis** (GLUE-co-NEE-oh-JEN-eh-sis) The synthesis of glucose from noncarbohydrates such as fats and amino acids.
- glucose** A monosaccharide ($C_6H_{12}O_6$) also known as blood sugar; glycogen, starch, cellulose, and maltose are made entirely of glucose, and glucose constitutes half of a sucrose or lactose molecule. The isomer involved in human physiology is also called *dextrose*.
- glucose-sparing effect** An effect of fats or other energy substrates in which they are used as fuel by most cells, so that those cells do not consume glucose; this makes more glucose available to cells such as neurons that cannot use alternative energy substrates.
- glycocalyx** (GLY-co-CAY-licks) A layer of carbohydrate molecules covalently bonded to the phospholipid and protein molecules of a plasma membrane; forms a surface coat on all human cells.
- glycogen** (GLY-co-jen) A glucose polymer synthesized by liver, muscle, uterine, and vaginal cells that serves as an energy-storage polysaccharide.
- glycogenesis** (GLY-co-JEN-eh-sis) The synthesis of glycogen.
- glycogenolysis** (GLY-co-jeh-NOLL-ih-sis) The hydrolysis of glycogen, releasing glucose.
- glycolipid** (GLY-co-LIP-id) A phospholipid molecule with a carbohydrate covalently bonded to it, found in the plasma membranes of cells.
- glycolysis** (gly-COLL-ih-sis) A series of anaerobic oxidation reactions that break a glucose molecule into two molecules of pyruvic acid and produce a small amount of ATP.
- glycoprotein** (GLY-co-PRO-teen) A protein molecule with a smaller carbohydrate covalently bonded to it; found in mucus and the glycocalyx of cells, for example.
- glycosaminoglycan (GAG)** (GLY-cose-am-ih-no-GLY-can) A polysaccharide composed of modified sugars with amino groups; the major component of a proteoglycan. GAGs are largely responsible for the viscous consistency of tissue gel and the stiffness of cartilage.
- glycosuria** (GLY-co-SOOR-ee-uh) The presence of glucose in the urine, typically indicative of a kidney disease, diabetes mellitus, or other endocrine disorder.
- goblet cell** A mucus-secreting gland cell, shaped somewhat like a wineglass, found in the epithelia of many mucous membranes. fig. 5.32
- Golgi complex** (GOAL-jee) An organelle composed of several parallel cisternae, somewhat like a stack of saucers, that modifies and packages newly synthesized proteins and synthesizes carbohydrates. fig. 3.27
- Golgi vesicle** A membrane-bounded vesicle pinched from the Golgi complex, containing its chemical product; may be retained in the cell as a lysosome or become a secretory vesicle that releases the product by exocytosis.
- gonad** The ovary or testis.
- gonadotropin** (go-NAD-oh-TRO-pin) A pituitary hormone that stimulates the gonads; specifically FSH and LH.
- G protein** A protein of the plasma membrane that is activated by a membrane receptor and, in turn, opens an ion channel or activates an intracellular physiological response; important in linking ligand-receptor binding to second-messenger systems.
- gradient** A difference or change in any variable, such as pressure or chemical concentration, from one point in space to another; provides a basis for molecular movements such as gas exchange, osmosis, and facilitated diffusion, and for bulk movements such as blood flow and air flow.
- gray matter** A zone or layer of tissue in the central nervous system where the neuron cell bodies, dendrites, and synapses are found; forms the core of the spinal cord, nuclei of the brainstem, basal nuclei of the cerebrum, cerebral cortex, and cerebellar cortex. fig. 14.6c
- gross anatomy** Bodily structure that can be observed without magnification.
- growth factor** A chemical messenger that stimulates mitosis and differentiation of target cells that have receptors for it; important in such processes as fetal development, tissue maintenance and repair, and hemopoiesis; sometimes a contributing factor in cancer.
- growth hormone (GH)** A hormone of the anterior pituitary gland with multiple effects on many tissues, generally promoting tissue growth.
- gyrus** (JY-rus) A wrinkle or fold in the cortex of the cerebrum or cerebellum.
- H**
- hair cell** Sensory cell of the cochlea, semicircular ducts, utricle, and saccule, with a fringe of surface microvilli that respond to the relative motion of a gelatinous membrane at their tips; responsible for the senses of hearing and equilibrium.
- hair follicle** An oblique epidermal pit that contains a hair and extends into the dermis or hypodermis.
- half-life ($T_{1/2}$) 1.** The time required for one-half of a quantity of a radioactive element to decay to a stable isotope (*physical half-life*) or to be cleared from the body through a combination of radioactive decay and physiological excretion (*biological half-life*). **2.** The time required for one-half of a quantity of hormone to be cleared from the bloodstream.
- haploid (n)** In humans, having 23 unpaired chromosomes instead of the usual 46 chromosomes in homologous pairs; in any organism or cell, having half the normal diploid number of chromosomes for that species.
- helper T cell** A type of lymphocyte that performs a central coordinating role in humoral and cellular immunity; target of the human immunodeficiency virus (HIV).
- hematocrit** (he-MAT-oh-crit) The percentage of blood volume that is composed of erythrocytes.
- hematoma** (HE-muh-TOE-muh) A mass of clotted blood in the tissues; forms a bruise when visible through the skin.
- heme** (heem) The nonprotein, iron-containing prosthetic group of hemoglobin or myoglobin; oxygen binds to its ferrous ion. fig. 18.5
- hemoglobin** (HE-mo-GLO-bin) The red gas transport pigment of an erythrocyte.
- hemopoiesis** (HE-mo-poy-EE-sis) Production of any of the formed elements of blood.
- heparin** (HEP-uh-rin) A polysaccharide secreted by basophils and mast cells that inhibits blood clotting.
- hepatic** (heh-PAT-ic) Pertaining to the liver.
- hepatic portal system** A network of blood vessels that connect capillaries of the intestines to capillaries (sinusoids) of the liver, thus delivering newly absorbed nutrients directly to the liver.

- heterozygous** (HET-er-oh-ZY-gus) Having non-identical alleles at the same gene locus of two homologous chromosomes.
- high-density lipoprotein (HDL)** A lipoprotein of the blood plasma that is about 50% lipid and 50% protein; functions to transport phospholipids and cholesterol from other organs to the liver for disposal. A high proportion of HDL to low-density lipoprotein (LDL) is desirable for cardiovascular health.
- hilum** (HY-lum) A point on the surface of an organ where blood vessels, lymphatic vessels, or nerves enter and leave, usually marked by a depression and slit; the midpoint of the concave surface of any organ that is roughly bean-shaped, such as the lymph nodes, kidneys, and lungs. Also called the *hilus*. fig. 22.9b
- histamine** (HISS-ta-me-en) An amino acid derivative secreted by basophils, mast cells, and some neurons; functions as a paracrine secretion and neurotransmitter to stimulate effects such as gastric secretion, bronchoconstriction, and vasodilation. fig. 12.21
- histology** **1.** The microscopic structure of tissues and organs. **2.** The study of such structure.
- homeostasis** (HO-me-oh-STAY-sis) The tendency of a living body to maintain relatively stable internal conditions in spite of greater changes in its external environment.
- homologous** (ho-MOLL-uh-gus) **1.** Having the same embryonic or evolutionary origin but not necessarily the same function, such as the scrotum and labia majora. **2.** Pertaining to two chromosomes with identical structures and gene loci but not necessarily identical alleles; each member of the pair is inherited from a different parent.
- homozygous** (HO-mo-ZY-gus) Having identical alleles at the same gene locus of two homologous chromosomes.
- hormone** A chemical messenger that is secreted into the blood by an endocrine gland or isolated gland cell and triggers a physiological response in distant cells with receptors for it.
- host cell** Any cell belonging to the human body, as opposed to foreign cells introduced to it by such causes as infections and tissue transplants.
- human chorionic gonadotropin (HCG)** (COR-ee-ON-ic) A hormone of pregnancy secreted by the chorion that stimulates continued growth of the corpus luteum and secretion of its hormones. HCG in urine is the basis for pregnancy testing.
- human immunodeficiency virus (HIV)** A virus that infects human helper T cells and other cells, suppresses immunity, and causes AIDS.
- hyaline cartilage** (HY-uh-lin) A form of cartilage with a relatively clear matrix and fine collagen fibers but no conspicuous elastic fibers or coarse collagen bundles as in other types of cartilage.
- hyaluronic acid** (HY-uh-loo-RON-ic) A glycosaminoglycan that is particularly abundant in connective tissues, where it becomes hydrated and forms the tissue gel.
- hydrogen bond** A weak attraction between a slightly positive hydrogen atom on one molecule and a slightly negative oxygen or nitrogen atom on another molecule, or between such atoms on different parts of the same molecule; responsible for the cohesion of water and the coiling of protein and DNA molecules, for example.
- hydrolysis** (hy-DROL-ih-sis) A chemical reaction that breaks a covalent bond in a molecule by adding an -OH group to one side of the bond and -H to the other side, thus consuming a water molecule.
- hydrophilic** (HY-dro-FILL-ic) Pertaining to molecules that attract water or dissolve in it because of their polar nature.
- hydrophobic** (HY-dro-FOE-bic) Pertaining to molecules that do not attract water or dissolve in it because of their nonpolar nature; such molecules tend to dissolve in lipids and other nonpolar solvents.
- hydrostatic pressure** The physical force generated by a liquid such as blood or tissue fluid, as opposed to osmotic and atmospheric pressures.
- hypercapnia** (HY-pur-CAP-nee-uh) An excess of carbon dioxide in the blood.
- hyperextension** A joint movement that increases the angle between two bones beyond 180°. fig. 9.12
- hyperglycemia** (HY-pur-gly-SEE-me-uh) An excess of glucose in the blood.
- hyperkalemia** (HY-pur-ka-LEE-me-uh) An excess of potassium ions in the blood.
- hypernatremia** (HY-pur-na-TREE-me-uh) An excess of sodium ions in the blood.
- hyperplasia** (HY-pur-PLAY-zhuh) The growth of a tissue through cellular multiplication, not cellular enlargement. *Compare* hypertrophy.
- hyperpolarization** A shift in the electrical potential across a plasma membrane to a value more negative than the resting membrane potential, tending to inhibit a nerve or muscle cell. *Compare* depolarization.
- hypersecretion** Excessive secretion of a hormone or other gland product; can lead to endocrine disorders such as Addison disease or gigantism, for example.
- hypertension** Excessively high blood pressure; criteria vary but it is often considered to be a condition in which systolic pressure exceeds 140 mm Hg or diastolic pressure exceeds 90 mm Hg.
- hypertonic** Having a higher osmotic pressure than human cells or some other reference solution and tending to cause osmotic shrinkage of cells.
- hypertrophy** (hy-PUR-tro-fee) The growth of a tissue through cellular enlargement, not cellular multiplication; for example, the growth of muscle under the influence of exercise. *Compare* hyperplasia.
- hypocalcemia** (HY-po-cal-SEE-me-uh) A deficiency of calcium ions in the blood.
- hypocapnia** (HY-po-CAP-nee-uh) A deficiency of carbon dioxide in the blood.
- hypodermis** (HY-po-DUR-miss) A layer of connective tissue deep to the skin; also called *superficial fascia*, *subcutaneous tissue*, or when it is predominantly adipose, *subcutaneous fat*.
- hypoglycemia** (HY-po-gly-SEE-me-uh) A deficiency of glucose in the blood.
- hypokalemia** (HY-po-ka-LEE-me-uh) A deficiency of potassium ions in the blood.
- hyponatremia** (HY-po-na-TREE-me-uh) A deficiency of sodium ions in the blood.
- hyposecretion** Inadequate secretion of a hormone or other gland product; can lead to endocrine disorders such as diabetes mellitus or pituitary dwarfism, for example.
- hypothalamic thermostat** (HY-po-thuh-LAM-ic) A nucleus in the hypothalamus that monitors body temperature and sends afferent signals to hypothalamic heat-promoting or heat-losing centers to maintain thermal homeostasis.
- hypothalamus** (HY-po-THAL-uh-mus) The inferior portion of the diencephalon of the brain, forming the walls and floor of the third ventricle and giving rise to the posterior pituitary gland; controls many fundamental physiological functions such as appetite, thirst, and body temperature and exerts many of its effects through the endocrine and autonomic nervous systems. fig. 14.12b
- hypothesis** An informed conjecture that is capable of being tested and potentially falsified by experimentation or data collection.
- hypotonic** Having a lower osmotic pressure than human cells or some other reference solution and tending to cause osmotic swelling and lysis of cells.
- hypoxemia** (HY-pock-SEE-me-uh) A deficiency of oxygen in the bloodstream.
- hypoxia** (hy-POCK-see-uh) A deficiency of oxygen in any tissue.
- immunity** The ability to ward off a specific infection or disease, usually as a result of prior exposure and the body's production of antibodies or lymphocytes against a pathogen. *Compare* resistance.
- immunoglobulin** (IM-you-no-GLOB-you-lin) *See* antibody.
- implantation** The attachment of a conceptus to the endometrium of the uterus.
- inclusion** Any visible object in the cytoplasm of a cell other than an organelle or cytoskeletal element; usually a foreign body or a stored cell product, such as a virus, dust particle, lipid droplet, glycogen granule, or pigment.
- infarction** (in-FARK-shun) **1.** The sudden death of tissue from a lack of blood perfusion; also called an *infarct*. **2.** An area of necrotic tissue produced by this process.
- inferior** Lower than another structure or point of reference from the perspective of anatomical position; for example, the stomach is inferior to the diaphragm.
- inflammation** (IN-fluh-MAY-shun) A complex of tissue responses to trauma or infection serving to ward off a pathogen and promote tissue repair; recognized by the cardinal signs of redness, heat, swelling, pain, and compromised function.
- inguinal** (IN-gwih-nul) Pertaining to the groin.
- inhibitory postsynaptic potential (IPSP)** Hyperpolarization of a postsynaptic neuron in response to a neurotransmitter,

G-9 GLOSSARY

- making it less likely to reach threshold and fire.
- innervation** (IN-ur-VAY-shun) The nerve supply to an organ.
- insertion** The point at which a muscle attaches to another tissue (usually a bone) and produces movement, opposite from its stationary origin; the origin and insertion of a given muscle sometimes depend on what muscle action is being considered. *Compare* origin. fig. 10.3
- inspiration** Inhaling.
- integration** A process in which a neuron receives input from multiple sources and their combined effects determine its output; the cellular basis of information processing by the nervous system.
- intercalated disc** (in-TUR-kuh-LAY-ted) A complex of fascia adherens, gap junctions, and desmosomes that join two cardiac muscle cells end to end, microscopically visible as a dark line that helps to histologically distinguish this muscle type; functions as a mechanical and electrical link between cells. fig. 19.11
- intercellular** Between cells.
- intercostal** (IN-tur-COSS-tul) Between the ribs, as in the intercostal muscles, arteries, veins, and nerves.
- interdigitate** (IN-tur-DIDJ-ih-tate) To fit together like the fingers of two folded hands; for example, at the dermal-epidermal boundary, intercalated discs of the heart, and pedicels of the podocytes in the kidney. fig. 23.10b, d
- interleukin** (IN-tur-LOO-kin) A hormonelike chemical messenger from one leukocyte to another, serving as a means of communication and coordination during immune responses.
- interneuron** (IN-tur-NEW-ron) A neuron that is contained entirely in the central nervous system and, in the path of signal conduction, lies anywhere between an afferent pathway and an efferent pathway.
- interosseous membrane** (IN-tur-OSS-ee-us) A fibrous membrane that connects the radius to the ulna and the tibia to the fibula along most of the shaft of each bone. fig. 8.33
- interphase** That part of the cell cycle between one mitotic phase and the next, from the end of cytokinesis to the beginning of the next prophase.
- interstitial** (IN-tur-STISH-ul) **1.** Pertaining to the extracellular spaces in a tissue. **2.** Located between other structures, as in the interstitial cells of the testis.
- intervertebral disc** A cartilaginous pad between the bodies of two adjacent vertebrae.
- intracellular** Within a cell.
- intracellular fluid (ICF)** The fluid contained in the cells; one of the major fluid compartments.
- intravenous (I.V.)** **1.** Present or occurring within a vein, such as an intravenous blood clot. **2.** Introduced directly into a vein, such as an intravenous injection or I.V. drip.
- intrinsic** (in-TRIN-sic) **1.** Arising from within, such as intrinsic blood-clotting factors; endogenous. **2.** Fully contained within an organ, such as the intrinsic muscles of the hand and eye. *Compare* extrinsic.
- involuntary** Not under conscious control, including tissues such as smooth and cardiac muscle and events such as reflexes.
- involution** (IN-vo-LOO-shun) Shrinkage of a tissue or organ by autolysis, such as involution of the thymus after childhood and of the uterus after pregnancy.
- ion** A chemical particle with unequal numbers of electrons or protons and consequently a net negative or positive charge; it may have a single atomic nucleus as in a sodium ion or a few atoms as in a bicarbonate ion, or it may be a large molecule such as a protein.
- ionic bond** The force that binds a cation to an anion.
- ionizing radiation** High-energy electromagnetic rays that eject electrons from atoms or molecules and convert them to ions, frequently causing cellular damage; for example, X-rays and gamma rays.
- ipsilateral** (IP-sih-LAT-ur-ul) On the same side of the body, as in reflex arcs in which a muscular response occurs on the same side of the body as the stimulus. *Compare* contralateral.
- ischemia** (iss-KEE-me-uh) Insufficient blood flow to a tissue, typically resulting in metabolite accumulation and sometimes tissue death.
- isotonic** Having the same osmotic pressure as human cells or some other reference solution.
- J**
- jaundice** (JAWN-diss) A yellowish color of the skin, corneas, mucous membranes, and body fluids due to an excessive concentration of bilirubin; usually indicative of a liver disease, obstructed bile secretion, or hemolytic disease.
- K**
- ketone** (KEE-tone) Any organic compound with a carbonyl (C=O) group covalently bonded to two other carbons.
- ketone bodies** Certain ketones (acetone, acetoacetic acid, and β -hydroxybutyric acid) produced by the incomplete oxidation of fats, especially when fats are being rapidly catabolized. *See also* ketosis.
- ketonuria** (KEE-toe-NEW-ree-uh) The abnormal presence of ketones in the urine as an effect of ketosis.
- ketosis** (kee-TOE-sis) An abnormally high concentration of ketone bodies in the blood, occurring in pregnancy, starvation, diabetes mellitus, and other conditions; tends to cause acidosis and to depress the nervous system.
- kilocalorie** The amount of heat energy needed to raise the temperature of 1 kg of water by 1°C; 1,000 calories. Also called a *Calorie* or *large calorie*.
- kinase** Any enzyme that adds an inorganic phosphate (P_i) group to another organic molecule. Also called a *phosphokinase*.
- L**
- labium** (LAY-bee-um) A lip, such as those of the mouth and the labia majora and minora of the vulva.
- lactic acid** A small organic acid produced as an end product of the anaerobic fermentation of pyruvic acid; a contributing factor in muscle fatigue.
- lacuna** (la-CUE-nuh) A small cavity or depression in a tissue such as bone, cartilage, and the erectile tissues.
- lamella** (la-MELL-uh) A little plate, such as the lamellae of bone. fig. 7.5
- lamina** (LAM-ih-nuh) A thin layer, such as the lamina of a vertebra or the lamina propria of a mucous membrane. fig. 8.22
- lamina propria** (PRO-pree-uh) A thin layer of areolar tissue immediately deep to the epithelium of a mucous membrane. fig. 5.32
- larynx** (LAIR-inks) A cartilaginous chamber in the neck containing the vocal cords; the voicebox.
- latent period** The interval between a stimulus and response, especially in the action of nerve and muscle cells.
- lateral** Away from the midline of an organ or median plane of the body; toward the side. *Compare* medial.
- law** A verbal or mathematical description of a predictable natural phenomenon or of the relationship between variables; for example, Boyle's law and the law of complementary base pairing.
- lesion** A circumscribed zone of tissue injury, such as a skin abrasion or myocardial infarction.
- leukocyte** (LOO-co-site) A white blood cell.
- leukotriene** (LOO-co-TRY-een) Eicosanoid that promotes allergic and inflammatory responses such as vasodilation and neutrophil chemotaxis; secreted by basophils, mast cells, and damaged tissues.
- libido** (lih-BEE-do) Sex drive.
- ligament** A cord or band of tough collagenous tissue binding one organ to another, especially one bone to another, and serving to hold organs in place; for example, the cruciate ligaments of the knee, broad ligament of the uterus, and falciform ligament of the liver.
- ligand** (LIG-and, LY-gand) A chemical that binds reversibly to a receptor site on a protein, such as a neurotransmitter that binds to a membrane receptor or a substrate that binds to an enzyme.
- ligand-gated channel** A channel protein in a plasma membrane that opens or closes when a ligand binds to it, enabling the ligand to determine when substances can enter or leave the cell.
- light microscope (LM)** A microscope that produces images with visible light.
- linea** (LIN-ee-uh) An anatomical line, such as the linea alba.
- lingual** (LING-gwul) Pertaining to the tongue, as in lingual papillae.
- lipase** (LY-pase) An enzyme that hydrolyzes a triglyceride into fatty acids and glycerol.
- lipid** A hydrophobic organic compound composed mainly of carbon and a high ratio of hydrogen to oxygen; includes fatty acids, fats, phospholipids, steroids, and prostaglandins.
- lipoprotein** (LIP-oh-PRO-teen) A protein-coated lipid droplet in the blood plasma or lymph, serving as a means of lipid transport; for example, chylomicrons and the high- and low-density lipoproteins.

load **1.** To pick up a gas for transport in the bloodstream. **2.** The resistance acted upon by a muscle.

lobule (LOB-yool) A small subdivision of an organ or of a lobe of an organ, especially of a gland.

locus See gene locus.

long bone A bone such as the femur or humerus that is markedly longer than wide and that generally serves as a lever.

longitudinal Oriented along the longest dimension of the body or of an organ.

loose connective tissue See areolar tissue.

low-density lipoprotein (LDL) A blood-borne droplet of about 20% protein and 80% lipid (mainly cholesterol) that transports cholesterol from the liver to other tissues.

lumbar Pertaining to the lower back and sides, between the thoracic cage and pelvis.

lumen (LOO-men) The internal space of a hollow organ such as a blood vessel or the esophagus, or a space surrounded by gated channel cells as in a gland acinus.

lymph The fluid contained in lymphatic vessels and lymph nodes, produced by the absorption of tissue fluid.

lymphatic system (lim-FAT-ic) An organ system consisting of lymphatic vessels, lymph nodes, the tonsils, spleen, and thymus; functions include tissue fluid recovery and immunity.

lymph node A small organ found along the course of a lymphatic vessel that filters the lymph and contains lymphocytes and macrophages, which respond to antigens in the lymph. fig. 21.12

lymphocyte (LIM-foe-site) A relatively small agranulocyte with numerous types and roles in nonspecific defense, humoral immunity, and cellular immunity. table 18.6

lysosome (LY-so-some) A membrane-bounded organelle containing a mixture of enzymes with a variety of intracellular and extracellular roles in digesting foreign matter, pathogens, and expired organelles.

lysozyme (LY-so-zime) An enzyme found in tears, milk, saliva, mucus, and other body fluids that destroys bacteria by digesting their cell walls. Also called *muramidase*.

M

macromolecule Any molecule of large size and high molecular weight, such as a protein, nucleic acid, polysaccharide, or triglyceride.

macrophage (MAC-ro-faje) Any cell of the body, other than a leukocyte, that is specialized for phagocytosis; usually derived from blood monocytes and often functioning as an antigen-presenting cell.

macula (MAC-you-luh) A patch or spot, such as the *macula lutea* of the retina.

malignant (muh-LIG-nent) Pertaining to a cell or tumor that is cancerous; capable of metastasis.

mast cell A connective tissue cell, similar to a basophil, that secretes histamine, heparin, and other chemicals involved in inflammation; often concentrated along the course of blood capillaries.

matrix **1.** The extracellular material of a tissue. **2.** The fluid within a mitochondrion containing enzymes of the citric acid cycle. **3.** The substance or framework within which other structures are embedded, such as the fibrous matrix of a blood clot. **4.** A mass of epidermal cells from which a hair root or nail root develops.

mechanoreceptor A sensory nerve ending or organ specialized to detect mechanical stimuli such as touch, pressure, stretch, or vibration.

medial Toward the midline of an organ or median plane of the body. Compare lateral.

median plane The sagittal plane that divides the body or an organ into equal right and left halves; also called *midsagittal plane*. fig. A.3

mediastinum (ME-dee-ass-TY-num) The thick median partition of the thoracic cavity that separates one pleural cavity from the other and contains the heart, great blood vessels, and thymus. fig. A.7

medulla (meh-DULE-uh, meh-DULL-uh) Tissue deep to the cortex of certain two-layered organs such as the adrenal glands, lymph nodes, hairs, and kidneys.

medulla oblongata (OB-long-GAH-ta) The most caudal part of the brainstem, immediately superior to the foramen magnum of the skull, connecting the spinal cord to the rest of the brain. figs. 14.2, 14.8

meiosis (my-OH-sis) A form of cell division in which a diploid cell divides twice and produces four haploid daughter cells; occurs only in gametogenesis.

melanocyte A cell of the stratum basale of the epidermis that synthesizes melanin and transfers it to the keratinocytes.

meninges (meh-NIN-jeez) (singular, *meninx*) Three fibrous membranes between the central nervous system and surrounding bone: the dura mater, arachnoid mater, and pia mater. fig. 14.5

merocrine (MERR-oh-crin) Pertaining to gland cells that release their product by exocytosis; also called *eccrine*.

mesenchyme (MEZ-en-kime) A gelatinous embryonic connective tissue derived from the mesoderm; differentiates into all permanent connective tissues and most muscle.

mesentery (MESS-en-tare-ee) A serous membrane that binds the intestines together and suspends them from the abdominal wall; the visceral continuation of the peritoneum. fig. 25.3

mesoderm (MEZ-oh-durm) The middle layer of the three primary germ layers of an embryo; gives rise to muscle and connective tissue.

metabolism (meh-TAB-oh-lizm) The sum of all chemical reactions in the body.

metabolite (meh-TAB-oh-lite) Any chemical produced by metabolism.

metaplasia Transformation of one mature tissue type into another; for example, a change from pseudostratified to stratified squamous epithelium in an overventilated nasal cavity.

metastasis (meh-TASS-tuh-sis) The spread of cancer cells from the original tumor to a new location, where they seed the development of a new tumor.

microtubule An intracellular cylinder composed of the protein tubulin, forming centrioles, the axonemes of cilia and flagella, and part of the cytoskeleton.

microvillus An outgrowth of the plasma membrane that increases the surface area of a cell and functions in absorption and some sensory processes; distinguished from cilia and flagella by its smaller size and lack of an axoneme.

milliequivalent One-thousandth of an equivalent, which is the amount of an electrolyte that would neutralize 1 mole of H⁺ or OH⁻. Electrolyte concentrations are commonly expressed in milliequivalents per liter (mEq/L).

mitochondrion (MY-toe-CON-dree-un) An organelle specialized to synthesize ATP, enclosed in a double unit membrane with infoldings of the inner membrane called cristae.

mitosis (my-TOE-sis) A form of cell division in which a cell divides once and produces two genetically identical daughter cells; sometimes used to refer only to the division of the genetic material or nucleus and not to include cytokinesis, the subsequent division of the cytoplasm.

moiety (MOY-eh-tee) A chemically distinct subunit of a macromolecule, such as the heme and globin moieties of hemoglobin or the lipid and carbohydrate moieties of a glycolipid.

molarity A measure of chemical concentration expressed as moles of solute per liter of solution.

mole The mass of a chemical equal to its molecular weight in grams, containing 6.023×10^{23} molecules.

monocyte An agranulocyte specialized to migrate into the tissues and transform into a macrophage. table 18.6

monomer (MON-oh-mur) **1.** One of the identical or similar subunits of a larger molecule in the dimer to polymer range; for example, the glucose monomers of starch, the amino acids of a protein, or the nucleotides of DNA. **2.** One subunit of an antibody molecule, composed of four polypeptides.

monosaccharide (MON-oh-SAC-uh-ride) A simple sugar, or sugar monomer; chiefly glucose, fructose, and galactose.

motor end plate See neuromuscular junction.

motor neuron A neuron that transmits signals from the central nervous system to any effector (muscle or gland cell); its axon is an efferent nerve fiber.

motor protein Any protein that produces movements of a cell or its components owing to its ability to undergo quick repetitive changes in conformation and to bind reversibly to other molecules; for example, myosin, dynein, and kinesin.

motor unit One motor neuron and all the skeletal muscle fibers innervated by it.

mucosa (mew-CO-suh) A tissue layer that forms the inner lining of an anatomical tract that is open to the exterior (the respiratory, digestive, urinary, and reproductive tracts). Composed of epithelium, connective tissue (*lamina propria*), and often smooth muscle (*mucularis mucosae*). fig. 5.32

mucous membrane A mucosa.

G-11 GLOSSARY

multipotent Pertaining to a stem cell that has the potential to develop into two or more types of fully differentiated, functional cells, but not into an unlimited variety of cell types.

muscle fiber One skeletal muscle cell.

muscle tone A state of continual, partial contraction of resting skeletal or smooth muscle.

muscularis externa The external muscular wall of certain viscera such as the esophagus and small intestine. fig. 25.2

muscularis mucosae (MUSS-cue-LERR-iss mew-CO-see) A layer of smooth muscle immediately deep to the lamina propria of a mucosa. fig. 5.32

muscular system An organ system composed of the skeletal muscles, specialized mainly for maintaining postural support and producing movements of the bones.

mutagen (MEW-tuh-jen) Any agent that causes a mutation, including viruses, chemicals, and ionizing radiation.

mutation Any change in the structure of a chromosome or a DNA molecule, often resulting in a change of organismal structure or function.

myelin (MY-eh-lin) A lipid sheath around a nerve fiber, formed from closely spaced spiral layers of the plasma membrane of a Schwann cell or oligodendrocyte. fig. 12.7

myocardium (MY-oh-CAR-dee-um) The middle, muscular layer of the heart.

myocyte A muscle cell, especially a cell of cardiac or smooth muscle.

myoepithelial cell An epithelial cell that has become specialized to contract like a muscle cell; important in dilation of the pupil and ejection of secretions from gland acini.

myofilament A protein microfilament responsible for the contraction of a muscle cell, composed mainly of myosin or actin. fig. 11.3

myoglobin (MY-oh-GLO-bin) A red oxygen-storage pigment of muscle; supplements hemoglobin in providing oxygen for aerobic muscle metabolism.

myosin A motor protein that constitutes the thick myofilaments of muscle and has globular, mobile heads of ATPase that bind to actin molecules.

N
necrosis (neh-CRO-sis) Pathological tissue death due to such causes as infection, trauma, or hypoxia. *Compare* apoptosis.

negative feedback A self-corrective mechanism that underlies most homeostasis, in which a bodily change is detected and responses are activated that reverse the change and restore stability and preserve normal body function.

negative feedback inhibition A mechanism for limiting the secretion of a pituitary tropic hormone. The tropic hormone stimulates another endocrine gland to secrete its own hormone, and that hormone inhibits further release of the tropic hormone.

neonate (NEE-oh-nate) An infant up to 6 weeks old.

neoplasia (NEE-oh-PLAY-zee-uh) Abnormal growth of new tissue, such as a tumor, with no useful function.

nephron One of approximately 1 million blood-filtering, urine-producing units in each kidney; consists of a glomerulus, glomerular capsule, proximal convoluted tubule, nephron loop, and distal convoluted tubule. fig. 23.8

nerve A cordlike organ of the peripheral nervous system composed of multiple nerve fibers ensheathed in connective tissue.

nerve fiber The axon of a single neuron.

nerve impulse A wave of self-propagating action potentials traveling along a nerve fiber.

nervous tissue A tissue composed of neurons and neuroglia.

net filtration pressure A net force favoring filtration of fluid from a capillary or venule when all the hydrostatic and osmotic pressures of the blood and tissue fluids are taken into account.

neural pool A group of interconnected neurons of the central nervous system that perform a single collective function; for example, the vasomotor center of the brainstem and speech centers of the cerebral cortex.

neural tube A dorsal hollow tube in the embryo that develops into the central nervous system. fig. 14.3

neuroglia (noo-ROG-lee-uh) All cells of nervous tissue except neurons; cells that perform various supportive and protective roles for the neurons.

neuromuscular junction A synapse between a nerve fiber and a muscle fiber; also called a *motor end plate*. fig. 11.7

neuron (NOOR-on) A nerve cell; an electrically excitable cell specialized for producing and transmitting action potentials and secreting chemicals that stimulate adjacent cells.

neuropeptide A peptide secreted by a neuron, often serving to modify the action of a neurotransmitter; for example, endorphins, enkephalin, and cholecystokinin. fig. 12.21

neurotransmitter A chemical released at the distal end of an axon that stimulates an adjacent cell; for example, acetylcholine, norepinephrine, or serotonin.

neutrophil (NOO-tro-fill) A granulocyte, usually with a multilobed nucleus, that serves especially to destroy bacteria by means of phagocytosis, intracellular digestion, and secretion of bactericidal chemicals. table 18.6

nitrogenous base (ny-TRODJ-eh-nus) An organic molecule with a single or double carbon-nitrogen ring that forms one of the building blocks of ATP, other nucleotides, and nucleic acids; the basis of the genetic code. fig. 4.1

nitrogenous waste Any nitrogen-containing substance produced as a metabolic waste and excreted in the urine; chiefly ammonia, urea, uric acid, and creatinine.

nociceptor (NO-sih-SEP-tur) A nerve ending specialized to detect tissue damage and produce a sensation of pain; pain receptor.

norepinephrine (nor-EP-ih-NEF-rin) A catecholamine that functions as a neurotransmitter and adrenal hormone, especially in the sympathetic nervous system. fig. 12.21

nuclear envelope (NEW-clee-ur) A pair of unit membranes enclosing the nucleus of

a cell, with prominent pores allowing traffic of molecules between the nucleoplasm and cytoplasm. fig. 3.25

nucleic acid (new-CLAY-ic) An acidic polymer of nucleotides found or produced in the nucleus, functioning in heredity and protein synthesis; of two types, DNA and RNA.

nucleotide (NEW-clee-oh-tide) An organic molecule composed of a nitrogenous base, a monosaccharide, and a phosphate group; the monomer of a nucleic acid.

nucleus (NEW-clee-us) **1.** A cell organelle containing DNA and surrounded by a double unit membrane. **2.** A mass of neurons (gray matter) surrounded by white matter of the brain, including the basal nuclei and brainstem nuclei. **3.** The positively charged core of an atom, consisting of protons and neutrons. **4.** A central structure, such as the nucleus pulposus of an intervertebral disc.

O
olfaction (ole-FAC-shun) The sense of smell.

oncotic pressure (ong-COT-ic) The difference between the colloid osmotic pressure of the blood and that of the tissue fluid, usually favoring fluid absorption by the blood capillaries. *Compare* colloid osmotic pressure.

oocyte (OH-oh-site) In the development of an egg cell, any haploid stage between meiosis I and fertilization.

oogenesis (OH-oh-JEN-eh-sis) The production of a fertilizable egg cell through a series of mitotic and meiotic cell divisions; female gametogenesis.

opposition A movement of the thumb in which it touches any fingertip of the same hand.

orbit The eye socket of the skull.

organ Any anatomical structure that is composed of at least two different tissue types, has recognizable structural boundaries, and has a discrete function different from the structures around it. Many organs are microscopic and many organs contain smaller organs, such as the skin containing numerous microscopic sense organs.

organelle Any structure within a cell that carries out one of its metabolic roles, such as mitochondria, centrioles, endoplasmic reticulum, and the nucleus; an intracellular structure other than the cytoskeleton and inclusions.

origin The relatively stationary attachment of a skeletal muscle. fig. 10.3 *Compare* insertion.

osmolality (OZ-mo-LAL-ih-tee) The molar concentration of dissolved particles in 1 kg of water.

osmolarity (OZ-mo-LERR-ih-tee) The molar concentration of dissolved particles in 1 L of solution.

osmoreceptor (OZ-mo-re-SEP-tur) A neuron of the hypothalamus that responds to changes in the osmolarity of the extracellular fluid.

osmosis (oz-MO-sis) The net flow of water through a selectively permeable membrane, resulting from either a chemical concentration difference or a mechanical force across the membrane.

osmotic pressure The amount of pressure that would have to be applied to one side of a selectively permeable membrane to stop osmosis; proportional to the concentration of nonpermeating solutes on that side and therefore serving as an indicator of solute concentration.

osseous (OSS-ee-us) Pertaining to bone.

ossification (OSS-ih-fih-CAY-shun) Bone formation.

osteoblast Bone-forming cell that arises from an osteogenic cell, deposits bone matrix, and eventually becomes an osteocyte.

osteoclast Macrophage of the bone surface that dissolves the matrix and returns minerals to the extracellular fluid.

osteocyte A mature bone cell formed when an osteoblast becomes surrounded by its own matrix and entrapped in a lacuna.

osteon A structural unit of compact bone consisting of a central canal surrounded by concentric cylindrical lamellae of matrix. fig. 7.5

osteoporosis (OSS-tee-oh-pore-OH-sis) A degenerative bone disease characterized by a loss of bone mass, increasing susceptibility to spontaneous fractures, and sometimes deformity of the vertebral column; causes include aging, estrogen hyposecretion, and insufficient resistance exercise.

ovulation (OV-you-LAY-shun) The release of a mature oocyte by the bursting of an ovarian follicle.

ovum Any stage of the female gamete from the conclusion of meiosis I until fertilization; a primary or secondary oocyte; an egg.

oxidation A chemical reaction in which one or more electrons are removed from a molecule, lowering its free energy content; opposite of reduction and always linked to a reduction reaction.

P

pancreatic islet (PAN-cree-AT-ic EYE-let)

A small cluster of endocrine cells in the pancreas that secretes insulin, glucagon, somatostatin, and other intercellular messengers; also called *islet of Langerhans*. fig. 17.12

papilla (pa-PILL-uh) A conical or nipplelike structure, such as a lingual papilla of the tongue or the papilla of a hair bulb.

papillary (PAP-ih-lerr-ee) **1.** Pertaining to or shaped like a nipple, such as the papillary muscles of the heart. **2.** Having papillae, such as the papillary layer of the dermis.

paracrine (PERR-uh-crin) **1.** A chemical messenger similar to a hormone whose effects are restricted to the immediate vicinity of the cells that secrete it; sometimes called a local hormone. **2.** Pertaining to such a secretion, as opposed to *endocrine*.

parasympathetic nervous system (PERR-uh-SIM-pa-THET-ic) A division of the autonomic nervous system that issues efferent fibers through the cranial and sacral nerves and exerts cholinergic effects on its target organs.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that raises blood calcium concentration by stimulating bone resorption by osteoclasts, promoting intestinal absorption of calci-

um, and inhibiting urinary excretion of calcium.

parenchyma (pa-REN-kih-muh) The tissue that performs the main physiological functions of an organ, especially a gland, as opposed to the tissues (stroma) that mainly provide structural support.

parietal (pa-RY-eh-tul) **1.** Pertaining to a wall, as in the parietal cells of the gastric glands and parietal bone of the skull. **2.** The outer or more superficial layer of a two-layered membrane such as the pleura, pericardium, or glomerular capsule. *Compare* visceral. fig. A.8

pathogen Any disease-causing organism or chemical.

pedicle (PED-ih-cul) A small footlike process, as in the vertebrae and the renal podocytes; also called a *pedicel*.

pelvic cavity The space enclosed by the true (lesser) pelvis, containing the urinary bladder, rectum, and internal reproductive organs.

pelvis A basinlike structure such as the pelvic girdle of the skeleton or the urine-collecting space near the hilum of the kidney. figs. 8.35, 23.4

peptide Any chain of two or more amino acids. *See also* polypeptide, protein.

peptide bond A group of four covalently bonded atoms (a—C=O group bonded to an —NH group) that links two amino acids in a protein or other peptide. fig. 2.23b

perfusion The amount of blood supplied to a given mass of tissue in a given period of time.

perichondrium (PERR-ih-CON-dree-um) A layer of fibrous connective tissue covering the surface of hyaline or elastic cartilage.

perineum (PERR-ih-NEE-um) The region between the thighs bordered by the coccyx, pubic symphysis, and ischial tuberosities; contains the orifices of the urinary, reproductive, and digestive systems. figs. 27.6, 28.8

periosteum (PERR-ee-OSS-tee-um) A layer of fibrous connective tissue covering the surface of a bone. fig. 7.2

peripheral (peh-RIF-eh-rul) Away from the center of the body or of an organ, as in peripheral vision and peripheral blood vessels.

peripheral nervous system (PNS) A subdivision of the nervous system composed of all nerves and ganglia; all of the nervous system except the central nervous system.

peristalsis (PERR-ih-STAL-sis) A wave of constriction traveling along a tubular organ such as the esophagus or ureter, serving to propel its contents.

peritoneum (PERR-ih-toe-NEE-um) A serous membrane that lines the peritoneal cavity of the abdomen and covers the mesenteries and viscera.

perivascular (PERR-ih-VASS-cue-lur) Pertaining to the region surrounding a blood vessel.

phagocytosis (FAG-oh-sy-TOE-sis) A form of endocytosis in which a cell surrounds a foreign particle with pseudopods and engulfs it, enclosing it in a cytoplasmic vesicle called a phagosome.

pharynx (FAIR-inks) A muscular passage in the throat at which the respiratory and digestive tracts cross.

phospholipid An amphiphilic molecule composed of two fatty acids and a phosphate-containing group bonded to the three carbons of a glycerol molecule; composes most of the molecules of the plasma membrane and other cellular membranes.

phosphorylation Addition of an inorganic phosphate (P_i) group to an organic molecule.

piloerector A bundle of smooth muscle cells associated with a hair follicle, responsible for erection of the hair; also called a *pilomotor muscle* or *arrector pili*. fig. 6.7

pinocytosis (PIN-oh-sy-TOE-sis) A form of endocytosis in which the plasma membrane sinks inward and imbibes droplets of extracellular fluid.

plantar (PLAN-tur) Pertaining to the sole of the foot.

plaque A small scale or plate of matter, such as dental plaque, the fatty plaques of atherosclerosis, and the amyloid plaques of Alzheimer disease.

plasma The noncellular portion of the blood.

plasma membrane The unit membrane that encloses a cell and controls the traffic of molecules in and out of the cell. fig. 3.6

platelet A formed element of the blood derived from the peripheral cytoplasm of a megakaryocyte, known especially for its role in stopping bleeding but also serves in dissolving blood clots, stimulating inflammation, promoting tissue growth, and destroying bacteria.

pleura (PLOOR-uh) A double-walled serous membrane that encloses each lung.

plexus A network of blood vessels, lymphatic vessels, or nerves, such as a choroid plexus of the brain or brachial plexus of nerves.

pluripotent stem cell (PPSC) **1.** A cell of the inner cell mass of a blastocyst that is capable of developing into any type of embryonic cell, but not into cells of the accessory organs of pregnancy. **2.** A cell of the red bone marrow that can give rise, through a series of intermediate cells, to leukocytes, erythrocytes, platelets, and various kinds of macrophages.

polymer A molecule that consists of a long chain of identical or similar subunits, such as protein, DNA, or starch.

polypeptide Any chain of more than 10 or 15 amino acids.

polysaccharide (POL-ee-SAC-uh-ride) A polymer of simple sugars; for example, glycogen, starch, and cellulose.

polyuria (POL-ee-YOU-ree-uh) Excessive output of urine.

popliteal (po-LIT-ee-ul) Pertaining to the posterior aspect of the knee.

positron emission tomography (PET) A method of producing a computerized image of the physiological state of a tissue using injected radioisotopes that emit positrons.

posterior Near or pertaining to the back or spinal side of the body; dorsal.

posterior root The branch of a spinal nerve that enters the posterior side of the spinal cord and carries afferent (sensory) nerve fibers; often called *dorsal root*. fig. 13.2b

G-13 GLOSSARY

- postganglionic** (POST-gang-gee-ON-ic) Pertaining to a neuron that transmits signals from a ganglion to a more distal target organ.
- postsynaptic** (POST-sih-NAP-tic) Pertaining to a neuron or other cell that receives signals from the presynaptic neuron at a synapse. fig. 12.18
- potential** A difference in electrical charge from one point to another, especially on opposite sides of a plasma membrane; usually measured in millivolts.
- preembryo** A developing individual from the time of fertilization to the time, at 16 days, when the three primary germ layers have formed. *Compare* conceptus, embryo, fetus.
- preganglionic** (PRE-gang-gee-ON-ic) Pertaining to a neuron that transmits signals from the central nervous system to a ganglion.
- presynaptic** (PRE-sih-NAP-tic) Pertaining to a neuron that transmits signals to a synapse. fig. 12.18
- primary germ layers** The ectoderm, mesoderm, and endoderm; the three tissue layers of an early embryo from which all later tissues and organs arise.
- prime mover** The muscle primarily responsible for a given joint action; agonist.
- programmed cell death** See apoptosis.
- pronation** (pro-NAY-shun) A rotational movement of the forearm that turns the palm downward or posteriorly. fig. 9.18
- proprioception** (PRO-pree-oh-SEP-shun) The nonvisual perception, usually subconscious, of the position and movements of the body, resulting from input from proprioceptors and the vestibular apparatus of the inner ear.
- proprioceptor** (PRO-pree-oh-SEP-tur) A sensory receptor of the muscles, tendons, and joint capsules that detects muscle contractions and joint movements.
- prostaglandin** (PROSS-ta-GLAN-din) An eicosanoid with a five-sided carbon ring in the middle of a hydrocarbon chain, playing a variety of roles in inflammation, neurotransmission, vasomotion, reproduction, and metabolism. fig. 2.21
- prostate gland** (PROSS-tate) A male reproductive gland that encircles the urethra immediately inferior to the bladder and contributes to the semen. fig. 27.11
- protein** A large polypeptide; while criteria for a protein are somewhat subjective and variable, polypeptides over 100 amino acids long are generally classified as proteins.
- proteoglycan** (PRO-tee-oh-GLY-can) A large molecule composed of a bristlelike arrangement of glycosaminoglycans surrounding a protein core in a shape resembling a bottle brush. Binds cells to extracellular materials and gives the tissue fluid a gelatinous consistency.
- proximal** Relatively near a point of origin or attachment; for example, the shoulder is proximal to the elbow. *Compare* distal.
- pseudopod** (SOO-doe-pod) A temporary cytoplasmic extension of a cell used for locomotion (ameboid movement) and phagocytosis.
- pseudostratified columnar** A type of epithelium with tall columnar cells reaching the free surface and shorter basal cells that do not reach the surface, but with all cells resting on the basement membrane; creates a false appearance of stratification. fig. 5.7
- pulmonary circuit** A route of blood flow that supplies blood to the pulmonary alveoli for gas exchange and then returns it to the heart; all blood vessels between the right ventricle and the left atrium of the heart.
- pyrogen** (PY-ro-jen) A fever-producing agent.
- R**
- ramus** (RAY-mus) An anatomical branch, as in a nerve or in the pubis.
- receptor** 1. A cell or organ specialized to detect a stimulus, such as a taste cell or the eye. 2. A protein molecule that binds and responds to a chemical such as a hormone, neurotransmitter, or odor molecule.
- receptor-mediated endocytosis** A process in which certain molecules in the extracellular fluid bind to receptors in the plasma membrane, these receptors gather together, the membrane sinks inward at that point, and the molecules become incorporated into vesicles in the cytoplasm.
- receptor potential** A variable change in membrane voltage produced by a stimulus acting on a receptor cell; generates an action potential if it reaches threshold.
- reduction** 1. A chemical reaction in which one or more electrons are added to a molecule, raising its free energy content; opposite of oxidation and always linked to an oxidation reaction. 2. Treatment of a fracture by restoring the broken parts of a bone to their proper alignment.
- reflex** A stereotyped, automatic, involuntary response to a stimulus; includes somatic reflexes, in which the effectors are skeletal muscles, and visceral (autonomic) reflexes, in which the effectors are usually visceral muscle, cardiac muscle, or glands.
- reflex arc** A simple neural pathway that mediates a reflex; involves a receptor, an afferent nerve fiber, sometimes one or more interneurons, an efferent nerve fiber, and an effector.
- refractory period** 1. A period of time after a nerve or muscle cell has responded to a stimulus in which it cannot be reexcited by a threshold stimulus. 2. A period of time after male orgasm when it is not possible to reattain erection or ejaculation.
- regeneration** Replacement of damaged tissue with new tissue of the original type. *Compare* fibrosis.
- renin** (REE-nin) An enzyme secreted by the kidneys in response to hypotension; converts the plasma protein angiotensinogen to angiotensin I, leading indirectly to a rise in blood pressure.
- repolarization** Reattainment of the resting membrane potential after a nerve or muscle cell has depolarized.
- resistance** 1. A nonspecific ability to ward off infection or disease regardless of whether the body has been previously exposed to it. *Compare* immunity. 2. A force that opposes the flow of a fluid such as air or blood. 3. A force, or load, that opposes the action of a muscle or lever.
- resting membrane potential (RMP)** A stable voltage across the plasma membrane of an unstimulated cell.
- reticular cell** (reh-TIC-you-lur) A delicate, branching macrophage found in the reticular connective tissue of the lymphatic organs.
- reticular fiber** A fine, branching collagen fiber coated with glycoprotein, found in the stroma of lymphatic organs and some other tissues and organs.
- reticular tissue** A connective tissue composed of reticular cells and reticular fibers, found in bone marrow, lymphatic organs, and in lesser amounts elsewhere.
- ribosome** A granule found free in the cytoplasm or attached to the rough endoplasmic reticulum, composed of ribosomal RNA and enzymes; specialized to read the nucleotide sequence of messenger RNA and assemble a corresponding sequence of amino acids to make a protein.
- risk factor** Any environmental factor or characteristic of an individual that increases one's chance of developing a particular disease; includes such intrinsic factors as age, sex, and race and such extrinsic factors as diet, smoking, and occupation.
- rostral** Relatively close to the forehead, especially in reference to structures of the brain and spinal cord; for example, the frontal lobe is rostral to the parietal lobe. *Compare* caudal.
- ruqa** (ROO-ga) 1. An internal fold or wrinkle in the mucosa of a hollow organ such as the stomach and urinary bladder; typically present when the organ is empty and relaxed but not when the organ is full and stretched. 2. Tissue ridges in such locations as the hard palate and vagina. fig. 25.12
- S**
- saccule** (SAC-yule) A saclike receptor in the inner ear with a vertical patch of hair cells, the macula sacculi; senses the orientation of the head and responds to vertical acceleration, as when riding in an elevator or standing up. fig. 16.19
- sagittal plane** (SADJ-ih-tul) Any plane that extends from anterior to posterior and cephalic to caudal and that divides the body into right and left portions. *Compare* median plane.
- sarcomere** (SAR-co-meer) In skeletal and cardiac muscle, the portion of a myofibril from one Z disc to the next, constituting one contractile unit. fig. 11.5
- sarcoplasmic reticulum (SR)** The smooth endoplasmic reticulum of a muscle cell, serving as a calcium reservoir. fig. 11.2
- scanning electron microscope (SEM)** A microscope that uses an electron beam in place of light to form high-resolution, three-dimensional images of the surfaces of objects; capable of much higher magnifications than a light microscope.
- sclerosis** (scleh-RO-sis) Hardening or stiffening of a tissue, as in multiple sclerosis of the central nervous system or atherosclerosis of the blood vessels.
- sebum** (SEE-bum) An oily secretion of the sebaceous glands that keeps the skin and hair pliable.
- second messenger** A chemical that is produced within a cell (such as cAMP) or that enters a cell (such as calcium ions) in

- response to the binding of a messenger to a membrane receptor, and that triggers a metabolic reaction in the cell.
- secondary active transport** A mechanism in which solutes are moved through a plasma membrane by a carrier that does not itself use ATP but depends on a concentration gradient established by an active transport pump elsewhere in the cell.
- secretion** **1.** A chemical released by a cell to serve a physiological function, such as a hormone or digestive enzyme. **2.** The process of releasing such a chemical, often by exocytosis. *Compare* excretion.
- selectively permeable membrane** A membrane that allows some substances to pass through while excluding others; for example, the plasma membrane and dialysis membranes.
- semicircular ducts** Three ring-shaped, fluid-filled tubes of the inner ear that detect angular accelerations of the head; each is enclosed in a bony passage called the semicircular canal. fig. 16.20
- semilunar valve** A valve that consists of crescent-shaped cusps, including the aortic and pulmonary valves of the heart and valves of the veins and lymphatic vessels. fig. 19.8
- semipermeable membrane** *See* selectively permeable membrane.
- senescence** (seh-NESS-ense) Degenerative changes that occur with age.
- sensation** Conscious perception of a stimulus; pain, taste, and color, for example, are not stimuli but sensations resulting from stimuli.
- sensory nerve fiber** An axon that conducts information from a receptor to the central nervous system; an afferent nerve fiber.
- serosa** (seer-OH-sa) *See* serous membrane.
- serous fluid** (SEER-us) A watery, low-protein fluid similar to blood serum, formed as a filtrate of the blood or tissue fluid or as a secretion of serous gland cells; moistens the serous membranes.
- serous membrane** A membrane such as the peritoneum, pleura, or pericardium that lines a body cavity or covers the external surfaces of the viscera; composed of a simple squamous mesothelium and a thin layer of areolar connective tissue.
- sex chromosomes** The X and Y chromosomes, which determine the sex of an individual.
- shock** **1.** Circulatory shock, a state of cardiac output that is insufficient to meet the body's physiological needs, with consequences ranging from fainting to death. **2.** Insulin shock, a state of severe hypoglycemia caused by administration of insulin. **3.** Spinal shock, a state of depressed or lost reflex activity inferior to a point of spinal cord injury. **4.** Electrical shock, the effect of a current of electricity passing through the body, often causing muscular spasm and cardiac arrhythmia or arrest.
- sign** An objective manifestation of illness that any observer can see, such as cyanosis or edema. *Compare* symptom.
- simple epithelium** An epithelium in which all cells rest directly on the basement membrane; includes simple squamous, cuboidal, and columnar types, and pseudostratified columnar. fig. 5.3
- sinus** **1.** An air-filled space in the cranium. **2.** A modified, relatively dilated vein that lacks smooth muscle and is incapable of vasomotion, such as the dural sinuses of the cerebral circulation and coronary sinus of the heart. **3.** A small fluid-filled space in an organ such as the spleen and lymph nodes. **4.** Pertaining to the sinoatrial node of the heart, as in *sinus rhythm*.
- sodium-glucose transport protein (SGLT)** A symport that simultaneously transports Na⁺ and glucose into a cell.
- somatic** **1.** Pertaining to the body as a whole. **2.** Pertaining to the skin, bones, and skeletal muscles as opposed to the viscera. **3.** Pertaining to cells other than germ cells.
- somatic nervous system** A division of the nervous system that includes efferent fibers mainly from the skin, muscles, and skeleton and afferent fibers to the skeletal muscles. *Compare* autonomic nervous system.
- somesthetic** **1.** Pertaining to widely distributed *general senses* in the skin, muscles, tendons, joint capsules, and viscera, as opposed to the *special senses* found in the head only; also called *somatosensory*. **2.** Pertaining to the cerebral cortex of the post-central gyrus, which receives input from such receptors.
- spermatogenesis** (SPUR-ma-toe-JEN-eh-sis) The production of sperm cells through a series of mitotic and meiotic cell divisions; male gametogenesis.
- spermatozoon** (SPUR-ma-toe-ZOE-on) A sperm cell.
- sphincter** (SFINK-tur) A ring of muscle that opens or closes an opening or passageway; found, for example, in the eyelids, around the urinary orifice, and at the beginning of a blood capillary.
- spinal nerve** Any of the 31 pairs of nerves that arise from the spinal cord and pass through the intervertebral foramina.
- spindle** **1.** An elongated structure that is thick in the middle and tapered at the ends (fusiform). **2.** A football-shaped complex of microtubules that guide the movement of chromosomes in mitosis and meiosis. fig. 4.16 **3.** A stretch receptor in the skeletal muscles. fig. 13.20
- spine** **1.** The vertebral column. **2.** A pointed process or sharp ridge on a bone, such as the styloid process of the cranium and spine of the scapula.
- splanchnic** (SPLANK-nic) Pertaining to the digestive tract.
- squamous** (SKWAY-mus) Having a flat, scaly shape; pertains especially to a class of epithelial cells. figs. 5.4, 5.12
- stem cell** Any undifferentiated cell that can divide and differentiate into more functionally specific cell types such as blood cells and germ cells.
- stenosis** (steh-NO-sis) The narrowing of a passageway such as a heart valve or uterine tube; a permanent, pathological constriction as opposed to physiological constriction of a passageway.
- steroid** (STERR-oyd, STEER-oyd) A lipid molecule that consists of four interconnected carbon rings; cholesterol and several of its derivatives.
- stimulus** A chemical or physical agent in a cell's surroundings that is capable of creating a physiological response in the cell; especially agents detected by sensory cells, such as chemicals, light, and pressure.
- strain** The extent to which a body, such as a bone, is deformed when subjected to stress. *Compare* stress.
- stratified epithelium** A type of epithelium in which some cells rest on top of others instead of on the basement membrane; includes stratified squamous, cuboidal, and columnar types, and transitional epithelium. fig. 5.3
- stress** **1.** A mechanical force applied to any part of the body; important in stimulating bone growth, for example. *Compare* strain. **2.** A condition in which any environmental influence disturbs the homeostatic equilibrium of the body and stimulates a physiological response, especially involving the increased secretion of certain adrenal hormones.
- stroke volume** The volume of blood ejected by one ventricle of the heart in one contraction.
- stroma** The connective tissue framework of a gland, lymphatic organ, or certain other viscera, as opposed to the tissue (parenchyma) that performs the physiological functions of the organ.
- subcutaneous** (SUB-cue-TAY-nee-us) Beneath the skin.
- substrate** **1.** A chemical that is acted upon and changed by an enzyme. **2.** A chemical used as a source of energy, such as glucose and fatty acids.
- substrate specificity** The ability of an enzyme to bind only one substrate or a limited range of related substrates.
- sulcus** (SUL-cuss) A groove in the surface of an organ, as in the cerebrum or heart.
- summation** **1.** A phenomenon in which multiple stimuli combine their effects on a cell to produce a response; seen especially in nerve and muscle cells. **2.** A phenomenon in which multiple muscle twitches occur so closely together that a muscle fiber cannot fully relax between twitches but develops more tension than a single twitch produces. fig. 11.15
- superficial** Relatively close to the surface; opposite of deep. For example, the ribs are superficial to the lungs.
- superior** Higher than another structure or point of reference from the perspective of anatomical position; for example, the lungs are superior to the diaphragm.
- supination** (SOO-pih-NAY-shun) A rotational movement of the forearm that turns the palm so that it faces upward or forward. fig. 9.18
- surfactant** (sur-FAC-tent) A chemical that reduces the surface tension of water and enables it to penetrate other substances more effectively. Examples include pulmonary surfactant and bile acids.
- sympathetic nervous system** A division of the autonomic nervous system that issues efferent fibers through the thoracic and lumbar nerves and usually exerts adrenergic effects on its target organs; includes a chain of paravertebral ganglia adjacent to the vertebral column, and the adrenal medulla.

G-15 GLOSSARY

symphysis (SIM-fih-sis) A joint in which two bones are held together by fibrocartilage; for example, between bodies of the vertebrae and between the right and left pubic bones.

symport A cotransport protein that moves two solutes simultaneously through a plasma membrane in the same direction, such as the sodium-dependent glucose transporter.

symptom A subjective manifestation of illness that only the ill person can sense, such as dizziness or nausea. *Compare* sign.

synapse (SIN-aps) **1.** A junction at the end of an axon where it stimulates another cell. **2.** A gap junction between two cardiac or smooth muscle cells at which one cell electrically stimulates the other; called an *electrical synapse*.

synaptic cleft (sih-NAP-tic) A narrow space between the synaptic knob of an axon and the adjacent cell, across which a neurotransmitter diffuses. fig. 12.20

synaptic knob The swollen tip at the distal end of an axon; the site of synaptic vesicles and neurotransmitter release. fig. 12.20

synaptic vesicle A spheroid organelle in a synaptic knob containing neurotransmitter.

synergist (SIN-ur-jist) A muscle that works with the agonist to contribute to the same overall action at a joint.

synergistic An effect in which two agents working together (such as two hormones) exert an effect that is greater than the sum of their separate effects. For example, neither follicle-stimulating hormone nor testosterone alone stimulates significant sperm production, but the two of them together stimulate production of vast numbers of sperm.

synovial fluid (sih-NO-vee-ul) A lubricating fluid similar to egg white in consistency, found in the synovial joint cavities and bursae.

synovial joint A point where two bones are separated by a narrow, encapsulated space filled with lubricating synovial fluid; most such joints are relatively mobile.

systemic (sis-TEM-ic) Widespread or pertaining to the body as a whole, as in the systemic circulation.

systemic circuit All blood vessels that convey blood from the left ventricle to all organs of the body and back to the right atrium of the heart; all of the cardiovascular system except the heart and pulmonary circuit.

systole (SIS-toe-lee) The contraction of any heart chamber; ventricular contraction unless otherwise specified.

systolic pressure (sis-TOLL-ic) The peak arterial blood pressure measured during ventricular systole.

T

target cell A cell acted upon by a nerve fiber, hormone, or other chemical messenger.

tarsal Pertaining to the ankle (tarsus).

T cell A type of lymphocyte involved in non-specific defense, humoral immunity, and cellular immunity; occurs in several forms including helper, cytotoxic, and suppressor T cells and natural killer cells.

tendon A collagenous band or cord associated with a muscle, usually attaching it to a bone and transferring muscular tension to it.

tetanus 1. A state of sustained muscle contraction produced by temporal summation as a normal part of contraction; also called *tetany*. **2.** Spastic muscle paralysis produced by the toxin of the bacterium *Clostridium tetani*.

thalamus (THAL-uh-muss) The largest part of the diencephalon, located immediately inferior to the corpus callosum and bulging into each lateral ventricle; a point of synaptic relay of nearly all signals passing from lower levels of the CNS to the cerebrum. figs. 14.8, 14.12a

theory An explanatory statement, or set of statements, that concisely summarizes the state of knowledge on a phenomenon and provides direction for further study; for example, the fluid mosaic theory of the plasma membrane and the sliding filament theory of muscle contraction.

thermogenesis The production of heat, for example, by shivering or by the action of thyroid hormones.

thermoreceptor A neuron specialized to respond to heat or cold, found in the skin and mucous membranes, for example.

thermoregulation Homeostatic regulation of the body temperature within a narrow range by adjustments of heat-promoting and heat-losing mechanisms.

thorax A region of the trunk between the neck and the diaphragm; the chest.

threshold 1. The minimum voltage to which the plasma membrane of a nerve or muscle cell must be depolarized before it produces an action potential. **2.** The minimum combination of stimulus intensity and duration needed to generate an afferent signal from a sensory receptor.

thrombosis (throm-BO-sis) The formation or presence of a thrombus.

thrombus A clot that forms in a blood vessel or heart chamber; may break free and travel in the bloodstream as a thromboembolus.

thyroid hormone Either of two similar hormones, thyroxine and triiodothyronine, synthesized from iodine and tyrosine.

thyroid-stimulating hormone (TSH) A hormone of the anterior pituitary gland that stimulates the thyroid gland; also called *thyrotropin*.

thyroxine (T₄) (thy-ROCK-seen) The thyroid hormone secreted in greatest quantity, with four iodine atoms; also called *tetraiodothyronine*. fig. 17.19

tight junction A region in which adjacent cells are bound together by fusion of the outer phospholipid layer of their plasma membranes; forms a zone that encircles each cell near its apical pole and reduces or prevents flow of material between cells. fig. 5.28

tissue An aggregation of cells and extracellular materials, usually forming part of an organ and performing some discrete function for it; the four primary classes are epithelial, connective, muscular, and nervous tissue.

totipotent Pertaining to a stem cell of the early preembryo, prior to development of a blastocyst, that has the potential to develop into any type of embryonic or adult cell.

trabecula (tra-BEC-you-la) A thin plate or layer of tissue, such as the calcified trabeculae of spongy bone or the fibrous trabeculae that subdivide a gland. fig. 7.5

trachea (TRAY-kee-uh) A cartilage-supported tube from the inferior end of the larynx to the origin of the primary bronchi; conveys air to and from the lungs; the “windpipe.”

translation The process of enzymatically reading an mRNA molecule and synthesizing the protein encoded in its nucleotide sequence.

transmembrane protein A protein that extends through a plasma membrane and contacts both the extracellular and intracellular fluid. fig. 3.7

transmission electron microscope (TEM) A microscope that uses an electron beam in place of light to form high-resolution, two-dimensional images of ultrathin slices of cells or tissues; capable of extremely high magnification.

triglyceride (try-GLISS-ur-ide) A lipid composed of three fatty acids joined to a glycerol; also called a *triacylglycerol* or *neutral fat*. fig. 2.19

trunk 1. That part of the body excluding the head, neck, and appendages. **2.** A major blood vessel, lymphatic vessel, or nerve that gives rise to smaller branches; for example, the pulmonary trunk and spinal nerve trunks.

T tubule Transverse tubule; a tubular extension of the plasma membrane of a muscle cell that conducts action potentials into the sarcoplasm and excites the sarcoplasmic reticulum. fig. 11.2

tunic (TOO-nic) A layer that encircles or encloses an organ, such as the tunics of a blood vessel or eyeball.

tympanic membrane The eardrum.

U

ultraviolet radiation Invisible, ionizing, electromagnetic radiation with shorter wavelength and higher energy than violet light; causes skin cancer and photoaging of the skin but is required in moderate amounts for the synthesis of vitamin D.

unipotent Pertaining to a stem cell that has the potential to develop into only one type of fully differentiated, functional cell, such as an epidermal cell that can become only a keratinocyte.

unit membrane Any cellular membrane composed of a bilayer of phospholipids and embedded proteins. A single unit membrane forms the plasma membrane and encloses many organelles of a cell, whereas double unit membranes enclose the nucleus and mitochondria.

unmyelinated (un-MY-eh-lih-nay-ted) Lacking a myelin sheath. fig. 12.8

urea (you-REE-uh) A nitrogenous waste produced from two ammonia molecules and carbon dioxide; the most abundant nitrogenous waste in the blood and urine. fig. 23.2

uterine tube A duct that extends from the ovary to the uterus and conveys an egg or conceptus to the uterus; also called *fallopian tube* or *oviduct*.

V

van der Waals force A weak attraction between two atoms occurring when a brief fluctuation in the electron cloud density of one atom induces polarization of an adjacent atom; important in association of lipids with each other, protein folding, and protein–ligand binding.

varicose vein A vein that has become permanently distended and convoluted due to a loss of competence of the venous valves; especially common in the lower extremity, esophagus, and anal canal (where they are called hemorrhoids).

vas (vass) (plural, *vasa*) A vessel or duct.

vascular Pertaining to blood vessels.

vasoconstriction (VAY-zo-con-STRIC-shun) The narrowing of a blood vessel due to muscular constriction of its tunica media.

vasodilation (VAY-zo-dy-LAY-shun) The widening of a blood vessel due to relaxation of the muscle of its tunica media and the outward pressure of the blood exerted against the wall.

vasomotion (VAY-zo-MO-shun) Collective term for vasoconstriction and vasodilation.

vasomotor center A nucleus in the medulla oblongata that transmits efferent signals to the blood vessels and regulates vasomotion.

ventral Pertaining to the front of the body, the regions of the chest and abdomen; anterior.

ventral root See anterior root.

ventricle (VEN-trih-cul) A fluid-filled chamber of the brain or heart.

venule (VEN-yool) The smallest type of vein, receiving drainage from capillaries.

vertebra (VUR-teh-bra) One of the bones of the vertebral column.

vertebral column (VUR-teh-brul) A posterior series of usually 33 vertebrae; encloses the spinal cord, supports the skull and thoracic cage, and provides attachment for the limbs and postural muscles. Also called *spine* or *spinal column*.

vesicle (VESS-ih-cul) A fluid-filled tissue sac or an organelle such as a synaptic or secretory vesicle.

vesicular transport The movement of particles or fluid droplets through the plasma membrane by the process of endocytosis or exocytosis.

viscera (VISS-er-uh) (singular, *viscus*) The organs contained in the body cavities, such as the brain, heart, lungs, stomach, intestines, and kidneys.

visceral (VISS-er-ul) **1.** Pertaining to the viscera. **2.** The inner or deeper layer of a two-layered membrane such as the pleura, pericardium, or glomerular capsule. *Compare* parietal. fig. A.8

visceral muscle Single-unit smooth muscle found in the walls of blood vessels and the digestive, respiratory, urinary, and reproductive tracts.

viscosity The resistance of a fluid to flow; the thickness or stickiness of a fluid.

voluntary muscle Muscle that is usually under conscious control; skeletal muscle.

vulva The female external genitalia; the mons, labia majora, and all superficial structures between the labia majora.

W

water balance An equilibrium between fluid intake and output or between the amounts of fluid contained in the body's different fluid compartments.

white matter White myelinated nervous tissue deep to the cortex of the cerebrum and cerebellum and superficial to the gray matter of the spinal cord. fig. 14.6

X

X chromosome The larger of the two sex chromosomes; males have one X chromosome and females have two in each somatic cell.

X-ray 1. A high-energy, penetrating electromagnetic ray with wavelengths in the range of 0.1 to 10 nm; used in diagnosis and therapy. **2.** A photograph made with X-rays; radiograph.

Y

Y chromosome Smaller of the two sex chromosomes, found only in males and having little if any genetic function except development of the testis.

yolk sac An embryonic membrane that encloses the yolk in vertebrates that lay eggs and serves in humans as the origin of the first blood and germ cells.

Z

zygomatic arch An arch of bone anterior to the ear, formed by the zygomatic processes of the temporal, frontal, and zygomatic bones; origin of the masseter muscle.

zygote A single-celled, fertilized egg.

INDEX

Page numbers in *italics* indicate figures; page numbers followed by *t* indicate material in tables. The names of specific arteries, bones, muscles, and other such structures may be found under headings such as *Arteries*, *specific*, and so forth, following the general headings for these topics.

A

- A band, 408, 408, 409t
 Abbe, Ernst, 6
 “ABCD rule,” 206–207
 Abdominal cavity, 35t, 36, 47, 341t, 341–343
 Abdominal lymph nodes, 817
 Abdominal pregnancy, 1123
 Abdominal region, 31, 33, 390, 817
 arteries of, 791–793, 791t–795t
 muscles of. *See* Muscles, specific
 Abdominopelvic cavity, 34, 34, 35t, 36, 36, 37, 41, 43, 44, 49
 Abduction, 299, 300, 303, 303, 304, 359t
 ABO blood group, 144, 146, 696, 697t, 698, 698, 699
 Abruptio placentae, 1108t
 Abscess, 837
 Absorption
 of alcohol, 1041
 of carbohydrates, 996–997, 997
 in digestion, 966, 983, 1004
 of fat-soluble vitamins, 999, 1019
 of lipids in lymphatic system, 816
 transdermal, 189
 Absorptive cells, 993, 994
 Absorptive state, 1036–1037, 1037t
 Abstinence, 1108
 Accessory organs
 of digestive tract, 966
 of skin, 188, 197–202, 210–211
 Accessory pancreatic duct, 989, 990
 Accommodation of lens, 621, 621, 622
 ACE inhibitors, 769, 808
 Acetabular labrum, 308, 309
 Acetabulum, 21, 273, 274, 274
 Acetic acid, 1028, 1028, 1034
 Acetylcholine, 412, 413t, 414, 415, 991
 in cholinergic synapse, 464–465, 466
 deficiencies of, 475
 dissociation from receptors, 418, 419
 as neurotransmitter, 463, 464, 465t, 468
 in autonomic nervous system, 576–577, 577t, 577
 stimulation of gastric secretion, 983–984
 stimulation of smooth muscle, 432
 Acetylcholinesterase, 412, 413t, 579
 Acetyl-coenzyme A, 1028, 1028
 Acetyl groups, 1028, 1028, 1034
 Acholic feces, 989
 Achondroplastic dwarfism, 226, 226, 1136
 Acid(s), 63–64, 64
 in mineral resorption, 228
 strong or weak, 954
 See also specific acids
 Acid-base balance, 954–959, 960t, 962–963
 acids, bases, and buffers, 954–955
 compensation for imbalances, 959
 disorders of, 957, 957–959, 958t, 958
 fluid replacement therapy, 961
 osseous tissue and, 214, 228
 renal control of pH, 955–956, 956, 957
 respiratory control of pH, 864, 955
 tubular secretion and, 923
 See also Acidosis; Alkalosis; pH
 Acid mantle, 188, 202, 829
 Acidosis, 228, 746, 957, 959, 960t
 CNS depression due to, 957
 ketoacidosis, 675, 895, 1034
 metabolic, 958t, 958–959
 potassium homeostasis and, 952
 respiratory, 864, 894, 895, 897, 958, 958t
 vasoconstriction induced by, 769
 See also Acid-base balance; Alkalosis; pH
 Acid phosphatase, 228, 1060
 Acid reflux, 975, 1144
 Acinus (acini)
 of exocrine gland, 175, 175, 176
 pancreatic, 990, 990
 of salivary gland, 974, 975
 Acne, 205t, 1062
 Acoustic organ, 603–605, 604
 Acquired immunodeficiency syndrome (AIDS), 107, 453, 844, 853–855, 854
 Acromegaly, 672, 672, 676t
 Acromial region, 32
 Acromion, 268, 269, 306, 307, 390, 391, 394
 Acronyms, 21
 Acrosin, 1119
 Acrosomal enzymes, 1119
 Acrosomal reaction, 1119, 1119
 Acrosome, 1066, 1066
 ACTH. *See* Adrenocorticotropic hormone
 Actin, 97, 97, 115, 689
 fibrous (F) actin, 406–407, 407, 409t
 globular (G) actin, 407, 407, 409t
 Action potentials, 413, 456t, 457, 457–459, 458
 cardiac contractility and, 734, 734
 of cardiocytes, 735, 735–736
 created by excitation, 414, 415
 in excitation-contraction coupling, 414, 416
 local potentials distinguished from, 456, 456t
 nerve impulses as, 413
 nerve signals distinguished from, 460, 460
 refractory period in, 459, 459
 Activation energy, 78, 79
 Active immunity, 838
 Active sites, 78, 407
 Active transport, 100, 104
 primary, 109t
 secondary, 105, 106, 109t, 921, 921
 Active transport pumps, 418, 419
 Adduction, 299, 300, 303, 303, 304, 359t
 Adenine, 80, 124, 125, 126
 Adenocarcinoma, 898
 Adenohypophysis, 642, 643, 644, 644
 Adenoids, 827, 827
 Adenosine, 582, 582
 Adenosine diphosphate, 80–82, 81, 82, 425, 426
 Adenosine triphosphatases, 80–82, 81, 82, 81, 82
 production of, 1026, 1028, 1031, 1031, 1032t
 role of sodium-potassium pump, 455
 sources of, 425–426, 426
 Adenylate cyclase, 95, 96, 466, 466–467
 Adhesion, 60, 77, 94, 95
 Adhesive glycoproteins, 162
 Adipocytes, 161, 166, 166
 Adipose tissue, 72, 578t, 669, 675, 691
 of breast, 46, 166, 1085, 1086
 brown fat, 166, 1040, 1135
 in Cushing syndrome, 673, 673
 endocrine functions of, 657, 658t
 of female, 166, 1088, 1142
 histology, 161, 166, 166t, 166
 in hypodermis, 47, 189, 194, 194t
 “Adiposity signals,” 1015
 Adjectival forms of medical terms, 21–22
 Adolescence, 216, 1061
 egg development in, 1090, 1091
 endochondral ossification in, 224, 224
 See also Puberty
 Adrenal disorders, 673, 673, 674
 Adrenal glands, 43, 639
 anatomy and function of, 651, 652, 653–654, 679
 of autonomic nervous system, 572, 573
 cortex, 572, 573, 652, 653–654, 657t
 medulla, 572, 573, 578t, 651, 653, 657t
 See also Adrenal medulla
 Adrenergic fibers, 577, 577
 Adrenergic receptors, 577, 577, 665
 Adrenergic synapse, 466, 466–467
 Adrenocorticotropic hormone (ACTH), 75, 647
 during pregnancy, 1100, 1101t
 secretion of, 641t, 643, 645, 645t, 646
 Adrenogenital syndrome, 673, 674
 Adult hemoglobin (HbA), 690
 Adult respiratory distress syndrome, 898t

 - extensor digitorum brevis, 379t, 380, 399, 400
 - extensor digitorum longus, 326, 373t, 373, 374t, 374
 - extensor hallucis longus, 327, 373t, 373, 374t, 374
 - extensor indicis, 362t, 362
 - extensor pollicis brevis, 362t, 362
 - extensor pollicis longus, 362t, 362
 - external abdominal oblique, 40, 41, 326, 327, 341t, 341–343, 390, 876, 877
 - fibularis brevis, 373, 374, 376t, 378
 - fibularis longus, 326, 327, 373, 374, 376t, 378, 397, 399
 - fibularis tertius, 373t, 373, 374t, 374
 - flexor carpi radialis, 323, 326, 359t, 360, 361, 394
 - flexor carpi ulnaris, 271, 327, 359t, 360, 361, 391, 394, 402
 - flexor digiti minimi brevis, 364t, 365, 379t, 380
 - flexor digitorum brevis, 379t, 380
 - flexor digitorum longus, 327, 376t, 377
 - flexor digitorum profundus, 326, 359t, 360, 361
 - flexor digitorum superficialis, 359t, 360, 361
 - flexor hallucis brevis, 379t, 380
 - flexor hallucis longus, 376t, 377
 - flexor pollicis brevis, 364t, 365
 - flexor pollicis longus, 326, 359t, 360, 361
 - frontalis, 201, 326, 328, 329, 330t, 331
 - gastrocnemius, 326, 327, 375t, 375, 376t, 397, 402
 - fast glycolytic fibers of, 428, 429
 - large motor units, 410
 - medial and lateral heads, 398, 399
 - study of contraction (in frog), 421
 - gemellus inferior, 368, 369t
 - gemellus superior, 368, 369t
 - genioglossus, 333t, 333, 971, 971
 - geniohyoid, 335t, 336
 - gluteus maximus, 327, 368t, 368, 391, 429
 - adaptation for bipedalism, 281, 281–282
 - attachment to femur, 276, 277
 - gluteus medius, 44, 281, 281–282, 327, 368t, 368, 369t, 391
 - gluteus minimus, 281, 281–282, 327, 368t, 368, 369t
 - gracilis, 40, 42, 43, 44, 326, 327, 367, 369t, 396, 402
 - hamstring, 371t–372t, 372, 399, 402
 - in range of motion, 295
 - reciprocal inhibition of, 506, 507
 - hyoglossus, 333t, 333, 971, 971
 - hyoid muscles
 - infrahyoid group, 335t, 336, 868–869
 - suprahyoid group, 334t–335t, 336 - iliacus, 44, 275, 367t, 367
 - iliocostalis group, 344t, 345, 346
 - iliopsoas, 367t, 367
 - inferior oblique, 615–616, 616
 - inferior rectus, 615, 616
 - infraspinatus, 306, 307, 327, 356t, 356, 402
 - intercostal, 349, 876, 876, 877
 - external, 41, 44, 339t, 340
 - internal, 41, 44, 339t, 340 - internal abdominal oblique, 41, 326, 341t, 341–343
 - interosseous
 - dorsal, 364t, 365, 379t, 380
 - palmar, 322, 322, 364t, 365
 - plantar, 379t, 380 - ischiocavernosus, 347t, 348, 1070, 1071
 - lateral rectus, 554, 615, 616
 - lateral rotator, 327, 368, 369t
 - latissimus dorsi, 327, 342, 344t, 344, 353t, 354, 355, 391, 393, 402
 - levator anguli oris, 329, 330t, 331
 - levator ani, 347t, 348, 1071
 - levator labii superioris, 328, 329, 330t, 331
 - levator palpebrae superioris, 329, 329, 330t, 331
 - levator scapulae, 327, 351, 352t
 - longissimus group, 344t, 345, 346
 - lumbricals, 292, 379t, 380
 - masseter, 322, 326, 334t, 334, 554
 - medial rectus, 615, 616
 - mentalis, 329, 331, 332t
 - multifidus, 345t, 345, 346t
 - mylohyoid, 335t, 336
 - nasalis, 328, 329, 330t, 331
 - obducor internus, 368, 369t
 - oblique muscles of eye, 615–616, 616
 - occipitalis, 327, 329, 330t, 331
 - occipitofrontalis, 329, 330t, 331
 - omohyoid, 41, 335t, 336
 - opponens digiti minimi, 364t, 365
 - opponens pollicis, 364t, 365
 - orbicularis oculi, 322, 323, 326, 328, 329, 330t, 331
 - orbicularis oris, 326, 328, 329, 330t, 331

I-23 INDEX

Muscles, specific (*continued*)
 palatoglossus, 333t, 333, 971, 971
 palmaris longus, 14, 323, 359t, 360,
 361, 394
 papillary, 726, 726
 pectinate, 725, 726
 pectineus, 42, 43, 367, 369t, 402
 of pectoral girdle, 342, 351, 352t,
 354, 355
 pectoralis major, 40, 46, 307, 322,
 322, 326, 342, 353t, 354,
 355, 390, 393, 402
 pectoralis minor, 326, 351, 352t,
 876, 877
 pharyngeal constrictors, 335t, 336,
 975, 977
 piloerector, 10, 189, 192–193, 198,
 198–199
 piriformis, 368, 369t
 plantar flexor, 375t, 375, 376t
 plantaris, 14, 375t, 375, 376t
 platysma, 326, 329, 331, 332t
 popliteus, 372t, 376t, 377
 pronator quadratus, 326, 357t, 358
 pronator teres, 357t, 358
 psoas major, 44, 367t, 367
 pterygoid, 334t, 334, 554
 pubococcygeus, 347t, 348
 puborectalis, 347t, 348
 pupillary constrictor, 575, 620
 pupillary dilator, 620
 quadratus femoris, 368, 369t
 quadratus lumborum, 44, 345t,
 345, 346t
 quadratus plantae, 379t, 380
 quadriceps femoris, 310, 323–324,
 370t, 370, 371, 506, 507
 quadrilateral, 322
 rectus, 615, 616
 rectus abdominis, 40, 47, 322, 322,
 326, 341t, 341–343, 390,
 402, 876, 877
 rectus femoris, 40, 42, 43, 322, 322,
 326, 370t, 370, 371, 396, 402
 rhomboideus major, 327, 351, 352t
 rhomboideus minor, 327, 351, 352t
 rhomboids, 323, 324
 sartorius (tailor’s muscle), 40, 43,
 322, 326
 scalenes, 337t, 876, 877
 scapular, 353t, 354, 355
 semimembranosus, 310, 327, 371t,
 372t, 372
 semispinalis capitis, 327, 337t,
 338t, 338
 semispinalis cervicis, 337t, 338t, 338
 semispinalis thoracis, 345t, 345, 346
 semitendinosus, 327, 371t, 372t, 372
 serratus anterior, 326, 327, 351,
 352t, 390, 402
 serratus posterior inferior, 327,
 344t, 344
 serratus posterior superior, 344t, 344
 soleus, 326, 327, 375t, 375, 376t, 397,
 398, 399, 401, 402, 428, 429
 spinalis group, 344t, 345, 346
 splenius capitis, 327, 337t, 338t,
 338, 402
 splenius cervicis, 337t, 338t, 338
 stapedius, 602, 605
 sternocleidomastoid, 326, 327,
 336–338, 337t, 390, 402,
 558, 876, 877
 sternohyoid, 335t, 336

sternothyroid, 335t, 336
 styloglossus, 333t, 333, 971, 971
 stylohyoid, 257, 257, 335t, 336
 subscapularis, 41, 306, 307, 356t,
 356, 402
 superior oblique, 552, 615–616, 616
 superior rectus, 615, 616
 supinator, 326
 suprahyoid group, 334t–335t, 336
 supraspinatus, 306, 307, 327,
 356t, 356
 temporalis, 251, 293, 293, 322,
 334t, 334, 554
 tensor fasciae latae, 40, 42, 43, 326,
 368t, 368
 tensor tympani, 602, 602, 605
 teres major, 327, 353t, 354, 355,
 391, 402
 teres minor, 306, 307, 327, 356t, 356
 thyrohyoid, 335t, 336
 tibialis anterior, 326, 373t, 373,
 374t, 374, 397, 399, 401, 402
 tibialis posterior, 327, 376t, 377
 trabecular, 1059, 1060
 trachealis, 869, 870
 transverse abdominal, 41, 326, 341t,
 341–343
 transverse perineal, 347t, 348
 trapezius, 40, 326, 327, 337t, 338,
 344t, 344, 351, 352t, 390,
 391, 394, 402, 558
 triceps brachii, 323, 323, 324, 327,
 357t, 358, 391, 393, 394, 402
 triceps surae, 375t, 375, 376t
 vastus intermedius, 43, 326
 vastus lateralis, 40, 43, 326, 370t, 370,
 371, 396, 397, 402
 vastus medialis, 43, 326, 370t, 370,
 371, 396, 398, 402
 zygomaticus major, 322, 326, 328,
 329, 330t, 331
 zygomaticus minor, 329, 330t, 331
 Muscle spindles, 504–505, 505,
 590, 591t
 Muscle tone, 295, 420, 420
 Muscle twitch, 421, 421
 contraction strength of, 421–423,
 422, 423
 fast- and slow-twitch fibers, 428,
 428t, 428
 See also Muscle contraction
 Muscular dystrophy, 407, 435
 Muscularis, of ureters, 931
 Muscularis externa, 967, 967, 975
 Muscularis mucosae, 177, 178, 871,
 967, 967
 Muscular massage, blood flow and, 763
 Muscular system, 37, 38, 49, 319–385
 disorders of, 435t
 head and neck muscles, 328, 328,
 329t–338t, 383
 of hip and lower limb, 366,
 367t–380t, 384–385
 intrinsic muscles. *See*
 Intrinsic muscles
 learning strategy (mnemonic), 325
 senescence of, 1141–1142
 of shoulder and upper limb,
 349–350, 350, 351t–362t,
 364t–365t, 384
 structural and functional organiza-
 tion, 320–327, 383
 trunk muscles, 339, 339t–348t,
 383–384

of wrist and hand, 359t–362t,
 360–362
 Muscular tissue, 13, 152t, 403–438
 cardiac muscle, 430, 431t, 438
 histology, 171, 172t, 172, 184
 skeletal muscle.
 See Skeletal muscle(s)
 smooth muscle, 431–434, 433, 438
 types and characteristics of,
 404–405, 437
 Muscular venules, 762
 Musculoskeletal system, 37
 Musical ability, 549
 Mussolini, Benito, 454
 Mutagenesis, 54
 Mutagens, 1136–1138, 1137–1139
 Mutations, 130, 847, 1136
 achondroplastic dwarfism, 226, 226
 in DNA replication, 16, 131t,
 138–139
 Myasthenia gravis, 412, 435–436, 436

I-37 INDEX

- Visceral nerve fibers, 492, 492*t*
Visceral pain, 592
Visceral pericardium, 35, 35*t*, 35, 49,
722–723, 722–724
Visceral peritoneum, 36, 36, 37, 49
Visceral pleura, 35, 35, 49, 873, 875, 881
Visceral sensory division of PNS,
443, 443
Viscosity of blood, 686, 687
Vision, 543, 544, 614–631, 634
accessory structures of orbit,
614–616, 614–616
anatomy of eye, 616–619, 617
cataracts and glaucoma, 618
cerebral lateralization and, 549
color blindness, 145, 146, 628, 629
color vision, 11, 627–628, 629
dark and light adaptation, 627, 1142
day or night vision, 624, 627
disorders of
blindness, 675, 896
corrective lenses, 622*t*, 622
diplopia, 436, 621
in image formation, 622*t*
dual visual system, 627, 628
formation of image, 620–622, 622*t*
light and, 614
panoramic, 628, 630
sensory transduction in retina, 623,
623–627, 624
stereoscopic, 11, 11, 628–629, 629
visual projection pathway,
629–631, 630
Visual acuity, 627, 1142
Visual association areas, 543, 544, 631
Visual cortex, 543, 544, 631
Visual pigments, 624, 625
Visual purple, 623, 624, 625, 626
Vital capacity, 884*t*, 884, 885
Vital signs, 539
Vitamin(s), 1017*t*
affecting calcium and bone
metabolism, 232, 232*t*
B complex, 981, 989, 1004,
1024, 1024*t*
digestion and absorption, 999
metabolism of, 1035*t*
RDA and dietary requirements,
1024*t*, 1024–1025
Vitamin A (retinol)
deficiency of, 1024–1025
effects on calcium and bone
metabolism, 232*t*
RDA and dietary requirements,
1024, 1024*t*
Vitamin B₁, 1024*t*
Vitamin B₂ (riboflavin), 1024, 1024*t*
Vitamin B₆ (pyridoxine), 1024*t*
Vitamin B₁₂ (cobalamin)
absorption of, 999
intrinsic factor and, 981
RDA and dietary
requirements, 1024*t*
Vitamin C (ascorbic acid), 57
effects on calcium and bone
metabolism, 232*t*
RDA and dietary requirements,
1024, 1024*t*
Vitamin D (calcitriol)
calcium homeostasis and, 229, 230,
923, 950
cutaneous production of, 1140–1141
effects on calcium and bone
metabolism, 232*t*
effects on renal function, 928*t*
elevation of phosphate level, 232
RDA and dietary requirements,
1024, 1024*t*
supplements in pregnancy, 1101
synthesized in kidneys, 656, 658*t*
synthesized in skin, 188, 656
Vitamin E, 57, 1024, 1024*t*
Vitamin K (phylloquinone)
RDA and dietary requirements,
1024, 1024*t*
role in coagulation, 713, 715
supplements in pregnancy, 1101
synthesis of, 1004
in treating premature
infants, 1135
Vitreous body of eye, 617, 618
Vitreous chamber, 618, 618
VLDL/LDL pathway, 1020, 1021
Vocabulary. *See* Anatomical
terminology
Vocal cords, 45, 868, 868, 869
Vocal sound, 549
Voice, resonance of, 248
Volar surface of fingers, 394
Volkmann canals, 219, 220
Volta, Alessandro, 421
Voltage-regulated ion gates, 94, 414,
415, 457, 458
Volume. *See* Blood volume
Voluntary control of
breathing, 880
Voluntary muscle, 172, 404
Vomiting, 983
Vulva, 1084, 1084, 1085
W
Warfarin, 715
Warm receptors, 590
Wastes, 906, 915, 923
Water, 59, 60, 1017*t*
absorption in small intestine, 1001
chemical reactivity of, 60–61
conservation of. *See* Water
conservation
in digestion, 1001
epidermal barrier, 192
metabolic, 944, 944, 1029–1030
in osmosis, 102
in plasma, 685, 687*t*
preformed, 944, 944
reabsorption of, 922
total body water, 943
tubular reabsorption and
secretion, 922, 923
Water balance, 943–948, 959, 960*t*, 962
cold weather and, 947
disorders of, 946–948, 948*t*
fluid compartments, 943, 944
fluid replacement therapy, 961
negative (dehydration), 257,
946, 948*t*
neonatal adaptation, 1135
regulation of, 945, 945–946, 946
senescence and, 1143–1144
water gain and loss, 943–945, 944
Water-channel proteins, 102, 922,
926, 965
Water conservation, 925–928, 939
collecting duct, 925, 925
control of water loss, 926
countercurrent exchange system, 927
countercurrent multiplier, 926,
926–927, 927
Water diuresis, 926
Water-insoluble fiber, 1019
Water intoxication, 948, 948*t*
Water loss, 926, 944, 944
Water-soluble fiber, 1019
Water-soluble vitamins, 999,
1024, 1024*t*
Watson, James, 126, 126
Wave summation, 422–423
Weak acid, 954
Weak base, 954
“Wear-and-tear” granules, 444, 446
Weight. *See* Body weight
Weight-control drugs, 1015
Weight per volume, 62
Wells, Horace, 632
Werner syndrome, 1145
Wernicke area, 546, 548
“Wet dreams,” 1062
White blood cells. *See* Leukocytes
White fat, 166
White fibers, 161–162, 162
Whiteheads, 205*t*
White matter
of brain, 518, 520, 522
of spinal cord, 484, 485, 486
White muscle fibers, 428, 428*t*, 428
White pulp of spleen, 828, 828
“Widow’s hump,” 236, 236, 260, 260
Wilkins, Maurice, 126
Wilms tumor, 147, 147
Wisdom teeth, 972, 973
Withdrawal (coitus interruptus), 1108
Wolffian duct, 1050, 1051
Wolff’s law of bone, 221, 227
Women. *See* Female(s)
Work, energy and, 65
Wormian bones, 244, 248, 251
Wound repair, 180, 181
Wrist, 34, 269
arteries of, 799, 800*t*
bones of, 271, 272
flexion of, 359*t*
muscles acting on, 359*t*–362*t*,
360–362
surface anatomy, 395
Wrist drop, 500
X
X chromosomes, 143, 143
chromatin and, 127, 127–128, 128
disjunction of, 1136, 1137
nondisjunction of, 1136–1137, 1137
Xenograft, 208
X-linked traits, 145–146, 146
X-ray diffraction, 126, 126
X-rays, 23, 23–24, 54
Y
Y chromosome, 143, 143
Yellow elastic tissue, 163
Yellow fibers, 162
Yolk sac, 688, 1123, 1123, 1124,
1125, 1126
Z
Z disc, 408, 408, 409, 409*t*
Zeiss, Carl, 6
Zero position, 298, 304, 304
Zinc, 1023*t*
Zona drilling, 1146
Zona fasciculata, 652, 653
Zona glomerulosa, 652, 653
Zona pellucida, 1090, 1091
Zona reticularis, 652, 653
Zygote, 1048, 1120, 1120, 1121*t*
Zygote intrafallopian transfer, 1148
Zymogens, 981, 982, 990, 990,
991, 991*t*
