THE EVOLUTION OF A Storyteller

Ken in 1964

Ken Saladin's first step into authoring was a 318-page paper on the ecology of hydras written for his 10th-grade biology class. With his "first book," featuring 53 original India ink drawings and photomicrographs, a true storyteller was born.

"When I first became a textbook writer, I found myself bringing the same enjoyment of writing and illustrating to this book that I first discovered back when I was 15."

—Ken Saladin

Ken's "first book," *Hydra Ecology*, 1965

One of Ken's drawings from *Hydra Ecology*

Ken began working on his first book for McGraw-Hill in 1993, and in 1997 the first edition of *The Unity of Form and Function* was published. In 2009 the story continues with the fifth edition of Ken's best-selling A&P textbook.

The first edition (1997)

The story continues (2009)

SALADIN ANATOMY & PHYSIOLOGY

A Good Story

Anatomy & Physiology: The Unity of Form and Function tells a story made of many layers including the core science, clinical applications, the history of medicine, and the evolution of the human body. Saladin combines this humanistic perspective on anatomy and physiology with vibrant photos and art to convey the beauty and excitement of the subject to beginning students.

To help students manage the tremendous amount of information in this introductory course, the narrative is broken into short segments, each framed by learning objectives and self-testing review questions. This presentation strategy works as a whole to create a more efficient and effective way for students to learn A&P.

“This book is a great marriage of form and function. It provides students with interesting, accurate information, introduces them to clinical situations, and cleverly distinguishes between the important and the unnecessary.”

New in the Fifth Edition

It's not unusual to hear textbook cynics say that new editions are just the same material bound in new covers, but that certainly isn't true of this one. Just listing my fifth-edition changes came to 113 pages and 50,000 words.

—Ken Saladin

New! Revision of Chapter 20 This chapter on blood vessels now takes a regional approach. Instead of describing all the systemic arteries from head to toe and then starting over at the head to describe all systemic veins, the author now addresses each body region and describes its arterial inflow and venous outflow back-to-back. For example, Saladin treats the arteries and veins of the head and neck, then arteries and veins of the thorax, then arteries and veins of the upper limb, and so on. This is a more structurally and functionally integrated approach that is more conducive to memory. Students will also see more clearly that the arteries and veins of a given region often have parallel names (*subclavian artery* and *subclavian vein*, for example).

New! Science Updates in the Fifth Edition!

- mechanism of osmosis
- gene regulation
- cancer genes
- epidermal keratinization

- Review activities integrated in the chapter
- Self-teaching prompts and simple experiments liberally seeded through the narrative
- Learning aids such as pronunciation guides and insights into the origins and root meanings of medical terms

Temporal Bones

If you palpate your skull just above and anterior to the ear—that is, the temporal region—you can feel the **temporal bone**, which forms the lower wall and part of the floor of the cranial cavity (fig. 8.10). The temporal bone derives its name from the fact that people often develop their first gray hairs on the temples with the passage of time.¹⁰ The relatively complex shape of the

Self-teaching prompts make reading more active.

Word origins are footnoted.

Pro-NUN-see-AY-shun guides help beginning students master A&P.

Familiarity with word origins helps students retain meaning and spelling.

"I like the way the author identifies situations in which completely explaining an idea or concept would be too overwhelming at this point in the student's academic career, as when he says, 'To understand the units of measurement [for radiation exposure] requires a grounding in physics beyond the scope of this book.' From the student's perspective, I think this builds a connection between the student and the author. As a result, I think the student is more likely to listen to the author's written words on the important matters than if the author tried to explain the concept perhaps in an effort to show how well educated he is."

—Tina Jones
Shelton State Community College

Homeostasis and Negative Feedback

The human body has a remarkable capacity for self-restoration. Hippocrates commented that it usually returns to a state of equilibrium by itself, and people recover from most illnesses even without the help of a physician. This tendency results from **homeostasis**¹⁰ (HO-me-oh-STAY-sis), the body's ability to detect change, activate mechanisms that oppose it, and thereby maintain relatively stable internal conditions.

French physiologist **Claude Bernard** (1813–78) observed that the internal conditions of the body remain quite constant even when external conditions vary greatly. For example, whether it is freezing cold or swelteringly hot outdoors, the internal temperature of the body stays within a range of about 36° to 37°C (97°–99°F). American physiologist **Walter Cannon** (1871–1945) coined the term *homeostasis* for this tendency to maintain internal stability. Homeostasis has been one of the

¹⁰homeo = the same + stas = to place, stand, stay

Writing Style

Interesting Reading

- Students say the enlightening analogies, clinical applications, historical notes, biographical vignettes, and evolutionary insights make the book not merely informative, but a pleasure to read.
- Even instructors say they often learn something new and interesting from Saladin's innovative perspectives.

Clinical applications

make the abstract science more relevant.

312 PART TWO Support and Movement

INSIGHT 9.4 Clinical Application

Knee Injuries and Arthroscopic Surgery

Although the knee can bear a lot of weight, it is highly vulnerable to rotational and horizontal stress, especially when the knee is flexed (as in skiing or running) and receives a blow from behind or from the side. The most common injuries are to a meniscus or the anterior cruciate ligament (ACL) (fig. 9.30). Knee injuries heal slowly because ligaments and tendons have a very scanty blood supply and cartilage usually has no blood vessels at all.

The diagnosis and surgical treatment of knee injuries has been greatly improved by *arthroscopy*, a procedure in which the interior of a joint is viewed with a pencil-thin instrument, the arthroscope, inserted through a small incision. The arthroscope has a light source, a lens, and fiber optics that allow a viewer to see into the cavity, take photographs or videotapes of the joint, and withdraw samples of synovial fluid. Saline is often introduced through one incision to expand the joint and provide a clearer view of its structures. If surgery is required, additional small incisions can be made for the surgical instruments and the procedures can be observed through the arthroscope or on a monitor. Arthroscopic surgery produces much less tissue damage than conventional surgery and enables patients to recover more quickly.

Orthopedic surgeons now often replace a damaged ACL with a graft from the patellar ligament or a hamstring tendon. The surgeon "harvests" a strip from the middle of the patient's ligament (or tendon), drills a hole into the femur and tibia within the joint cavity, threads the ligament through the holes, and fastens it with screws. The grafted ligament is more taut and "competent" than the damaged ACL. It becomes ingrown with blood vessels and serves as a substrate for the deposition of more collagen, which further strengthens it in time. Following arthroscopic ACL reconstruction, a patient typically must use crutches for 7 to 10 days and undergo supervised physical therapy for 6 to 10 weeks, followed by self-directed exercise therapy. Healing is completed in about 9 months.

FIGURE 9.30 Knee Injuries.

An important aspect of human bipedalism is the ability to "lock" the knees and stand erect without firing the extensor muscles of the leg. When the knee is extended to the fullest degree allowed by the ACL, the femur rotates medially on the tibia. This action locks the knee, and in this state, all the major knee ligaments are twisted and taut. To unlock the knee, the *popliteus* muscle rotates the femur laterally and untwists the ligaments.

The knee joint has at least 13 bursae. Four of these are anterior: the *superficial infrapatellar*, *suprapatellar*, *prepatellar*, and *deep infrapatellar*. Located in the popliteal region are the *popliteal bursa* and *semimembranosus bursa* (not illustrated). At least seven more bursae are found on the lateral and medial sides of the knee joint. From figure 9.29c, your knowledge of the relevant word

elements (*infra-, supra-, pre-*), and the terms *superficial* and *deep*, you should be able to work out the reasoning behind most of these names and develop a system for remembering the locations of these bursae.

The Ankle Joint

The *talocrural*²⁹ (ankle) joint includes two articulations—a medial joint between the tibia and talus and a lateral joint between the fibula and talus, both enclosed in one joint capsule (fig. 9.31). The malleoli of the tibia and fibula overhang the talus on each side like a cap and prevent most side-to-side motion. The ankle therefore has a more restricted range of motion than the wrist.

²⁹tal = ankle + crural = pertaining to the leg

FIGURE 12.16 Conduction of a Nerve Signal in an Unmyelinated Fiber. Note that the membrane polarity is reversed in the region of the action potential (red). A region of membrane in its refractory period (yellow) trails the action potential and prevents the nerve signal from going backward toward the soma. The other membrane areas (green) are fully polarized and ready to respond.

Note that an action potential itself does not travel along an axon; rather, it stimulates the production of a new action potential in the membrane just ahead of it. Thus, we can distinguish an *action potential* from a *nerve signal*. The nerve signal is a traveling wave of excitation produced by self-propagating action potentials. It is like a line of falling dominoes. No one domino travels to the end of the line, but each domino pushes over the next one and there is a transmission of energy from the first domino to the last. Similarly, no one action potential travels to the end of an axon; a nerve signal is a chain reaction of action potentials.

If one action potential stimulates the production of a new one next to it, you might think that the signal could also start traveling backward and return to the soma. This does not occur, however, because the membrane behind the nerve signal is still in its refractory period and cannot respond. It is sensitive to an external current, but it through a wire leads per second

and is decremental—it gets weaker with distance. A nerve signal is much slower (not more than 2 m/sec; in unmyelinated fibers), but it is nondecremental. Even in the longest axons, the last action potential generated at a synaptic knob has the same voltage as the first one generated at the trigger zone. To clarify this concept, we can compare the nerve signal to a burning fuse. When a fuse is lit, the heat ignites powder immediately in front of this point, and this repeats itself as the flame moves down the length of the fuse. The flame is not as it did at the start; it is the so-called energy of the membrane. distance: it

unmyelinated

ones (up to 2

m/sec).

Analogies explain tough scientific content in a way students can understand.

Note that an action potential itself does not travel along an axon; rather, it stimulates the production of a new action potential in the membrane just ahead of it. Thus, we can distinguish an *action potential* from a *nerve signal*. The nerve signal is a traveling wave of excitation produced by self-propagating action potentials. It is like a line of falling dominoes. No one domino travels to the end of the line, but each domino pushes over the next one and there is a transmission of energy from the first domino to the last. Similarly, no one action potential travels to the end of an axon; a nerve signal is a chain reaction of action potentials.

If one action potential stimulates the production of a new one next to it, you might think that the signal could also start traveling backward and return to the soma. This does not occur, however, because the membrane behind the nerve signal is still in its refractory period and cannot respond. It is sensitive to an external current, but it through a wire leads per second

"Saladin clearly describes anatomical structures and physiological processes in a way that engages students. His great use of historical references and clinical applications gives the students something tangible to relate to their newly acquired information."

—Patricia Bernard
Erie Community College

INSIGHT 25.5 Medical History

The Man with a Hole in His Stomach

Perhaps the most famous episode in the history of digestive physiology began in 1822 on Mackinac Island between Lake Michigan and Lake Huron. Alexis St. Martin, a 28-year-old Canadian voyageur (fig. 25.33), was standing outside a trading post when he was accidentally hit by a shotgun blast from 3 feet away. An Army doctor stationed at Fort Mackinac, William Beaumont, was summoned to examine St. Martin. As Beaumont later wrote, "a portion of the lung as large as a turkey's egg" protruded through St. Martin's lacerated and burnt flesh. Below that was a portion of the stomach with a puncture in it "large enough to receive my forefinger." Beaumont did his best to pick out bone fragments and dress the wound, though he did not expect St. Martin to survive.

Surprisingly, he lived. Over a period of months the wound extruded pieces of bone, cartilage, quailshot, and gun wadding. As the wound healed, a fistula (hole) remained in the stomach, so large that Beaumont had to cover it with a compress to prevent food from coming out. A fold of tissue later grew over the fistula, but it was easily opened. A year later, St. Martin was still feebly. Town authorities decided they could no longer support him on public funds and wanted to ship him 1,500 miles to his home. Beaumont, however, was imbued with a passionate sense of destiny. Very little was known about digestion, and he saw the accident as a unique opportunity to learn. He took St. Martin in at his personal expense and performed 238 experiments on him over several years. Beaumont had never attended medical school and had little idea how scientists work, yet he proved to be an astute experimenter. Under crude frontier conditions and with almost no equipment, he discovered many of the basic facts of gastric physiology discussed in this chapter.

"I can look directly into the cavity of the stomach, observe its motion, and almost see the process of digestion," Beaumont wrote. "I can pour in water with a funnel and put in food with a spoon, and draw them out again with a siphon." He put pieces of meat on a string into the stomach and removed them hourly for examination. He sent vials of gastric juice to the leading chemists of America and Europe, who could do little but report that it contained hydrochloric acid. He proved that digestion required HCl and could even occur outside the stomach, but he found that HCl alone did not digest meat; gastric juice must contain some other digestive ingredient. Theodor Schwann, one of the founders of the cell theory, identified that ingredient as pepsin. Beaumont also demonstrated that gastric juice is secreted only in response to food; it did not accumulate between meals as previously thought. He disproved the idea that hunger is caused by the walls of the empty stomach rubbing against each other.

For his part, St. Martin felt helpless and humiliated by Beaumont's experiments. The fur trappers taunted him as "the

man with a hole in his stomach," and he longed to return to his work in the wilderness. He had a wife and daughter in Canada whom he rarely got to see, and he ran away repeatedly to join them. He was once gone for 4 years before poverty made him yield to Beaumont's financial enticement to come back. Beaumont despised St. Martin's drunkenness and profanity and was quite insensitive to his embarrassment and discomfort over the experiments. Yet St. Martin's temper enabled Beaumont to make the first direct observations of the relationship between emotion and digestion. When St. Martin was particularly angry, his digestive system functioned normally. Beaumont later wrote, "a portion of the lung as large as a turkey's egg" protruded through St. Martin's lacerated and burnt flesh. Below that was a portion of the stomach with a puncture in it "large enough to receive my forefinger." Beaumont did his best to pick out bone fragments and dress the wound, though he did not expect St. Martin to survive.

FIGURE 25.33 Doctor and Patient in a Pioneering Study of Digestion.

Medical History Saladin "puts the human in human A&P" with his occasional vignettes on the people behind the science. Students say these stories make learning A&P more fun and stimulating.

Evolutionary Medicine Rapidly growing, increasingly fascinating

Evolutionary medicine provides novel and intriguing ways of looking at:

- menopause
- the sweet tooth
- bipedalism
- the origin of mitochondria
- skin color
- body hair
- lactose intolerance
- the kidney and life on dry land
- the palate
- theories of aging and death

INSIGHT 8.2 Evolutionary Medicine

Evolutionary Significance of the Palate

In most vertebrates, the nasal passages open into the oral cavity. Mammals, by contrast, have a palate that separates the nasal cavity from the oral cavity. In order to maintain our high metabolic rate, we must digest our food rapidly; in order to do this, we chew it thoroughly to break it up into small, easily digested particles before swallowing it. The palate allows us to continue breathing during this prolonged chewing.

256 PART TWO Support and Movement

INSIGHT 8.2 Evolutionary Medicine

Evolutionary Significance of the Palate

In most vertebrates, the nasal passages open into the oral cavity. Mammals, by contrast, have a palate that separates the nasal cavity from the oral cavity. In order to maintain our high metabolic rate, we must digest our food rapidly; in order to do this, we chew it thoroughly to break it up into small, easily digested particles before swallowing it. The palate allows us to continue breathing during this prolonged chewing.

Palatine Bones

The palatine bones form the rest of the hard palate, part of the wall of the nasal cavity, and part of the floor of the orbit (see figs. 8.5a and 8.13). At the posterolateral corners of the hard palate are two large **greater palatine foramina**.

the ethmoid bone. The **inferior nasal concha**—the largest of the three—is a separate bone (see fig. 8.13).

Vomer

The vomer forms the inferior half of the nasal septum (see figs. 8.3 and 8.4b). Its name literally means "plowshare," which refers to its resemblance to the blade of a plow. The superior half of the nasal septum is formed by the perpendicular plate of the ethmoid bone, as mentioned earlier. The vomer and perpendicular plate support a wall of septal cartilage that forms most of the anterior part of the nasal septum.

Mandible

The mandible (fig. 8.15) is the strongest bone of the skull and the only one that can move noticeably. It supports the lower teeth and provides attachment for muscles of mastication and facial expression. It develops as separate

left bones in the fetus, joined by a median cartilaginous joint called the **mental symphysis** (SIM-fib-iss) (not of the chin. This joint ossifies in early childhood, fusing the two halves into a single bone. The point in itself is called the **mental protuberance**.

The mandible has two major parts on each side—the **body** that supports the teeth, and a vertical or posterior portion, the **ramus** (RAY-mus), that is with the cranium. The body and ramus meet at a ball-and-socket joint.

The body of the mandible, like the maxilla, exhibits alveolar processes between the teeth. Slightly behind the mental symphysis, it has a prominent **mental protuberance** that permits the passage of nerves and blood vessels to the chin. The inner surface of the body is marked by depressions and ridges that accommodate and salivary glands. In the region of the mental protuberance, the inner surface has a pair of small points,

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Cations and anions (p. 56)
- Ligand- and voltage-regulated gates (p. 94)
- Cyclic AMP as a second messenger (p. 95)
- Simple diffusion (p. 100)
- Active transport and the sodium-potassium pump (p. 104)

Nervous System

Tiered Assessments Based on Key Learning Objectives

- Chapters are divided into more easily manageable chunks, which help students budget study time effectively.
- Section-ending questions allow students to check their understanding before moving on.

Each numbered section begins with **Learning Objectives** to help focus the reader's attention on the larger concepts.

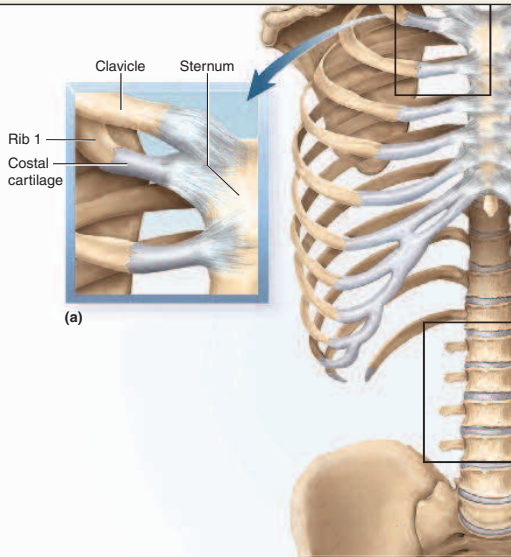

FIGURE 9.4 Cartilaginous Joints. (a) A synchondrosis, represented by the costal cartilage joining rib 1 to the sternum. (b) The pubic symphysis. (c) Intervertebral discs, which join adjacent vertebrae to each other by symphyses.

What is the difference between the pubic symphysis and the interpubic disc?

Questions in figure legends and **Think About It** items prompt students to think more deeply about the implications and applications of what they have learned.

178 PART ONE Organization of the Body

FIGURE 5.32 Histology of a Mucous Membrane.

tissue, which often rests in turn on an elastic sheet. Collectively, these tissues make up a membrane called the *tunica interna* of the blood vessels and *endocardium* of the heart. The simple squamous epithelium that lines the pleural, pericardial, and peritoneal cavities is called *mesothelium*.

Some joints of the skeletal system are lined by fibrous *synovial* (sīh-NO-voe-ul) membranes, made only of connective tissue. These membranes span the gap from one bone to the next and secrete slippery *synovial fluid* into the joint.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

19. Compare the structure of tight junctions and gap junctions. Relate their structural differences to their functional differences.
20. Distinguish between a simple gland and a compound gland, and give an example of each. Distinguish between a tubular gland and an acinar gland, and give an example of each.
21. Contrast the merocrine and holocrine methods of secretion, and name a gland product produced by each method.
22. Describe the differences between a mucous and a serous membrane.
23. Name the layers of a mucous membrane, and state which of the four primary tissue classes composes each layer.

5.6 Tissue Growth, Development, Repair, and Death

Objectives

When you have completed this section, you should be able to

- name and describe the modes of tissue growth;
- define *adult* and *embryonic stem cells* and their varied degrees of developmental plasticity;
- name and describe the ways that a tissue can change from one type to another;
- name and describe the modes and causes of tissue shrinkage and death; and
- name and describe the ways the body repairs damaged tissues.

Tissue Growth

Tissues grow either because their cells increase in number or because the existing cells grow larger. Most embryonic and childhood growth occurs by **hyperplasia**⁴⁹ (HY-pur-PLAY-zhū), tissue growth through cell multiplication. Exercised muscles grow, however, through **hypertrophy**⁴⁹ (hy-PUR-truh-fee), the enlargement of preexisting cells.

⁴⁹Hyper = excessive + plus = growth
⁴⁹Hyper = excessive + trophy = nourishment

Before You Go On encourages students to self-assess before starting the next section.

Think About It

Suppose you were studying a skull with some teeth missing. How could you tell whether the teeth had been lost after the person's death or years before it?

Each maxilla extends from the teeth to the inferomedial wall of the orbit. Just below the orbit, it exhibits an **infraorbital foramen**, which provides passage for a blood vessel to the face and a nerve that receives sensations from the nasal region and cheek. This nerve emerges through the foramen rotundum into the cranial cavity. The maxilla forms part of the floor of the orbit, where it exhibits a gash called the **inferior orbital fissure** that angles downward and medially (fig. 8.14). The inferior and superior orbital fissures form a sideways V whose apex lies near the optic foramen. The inferior orbital fissure is a passage for blood vessels and sensory nerves from the face.

The **palate** forms the roof of the mouth and floor of the nasal cavity. It consists of a bony **hard palate** anteriorly and a fleshy **soft palate** posteriorly. Most of the hard

End-of-chapter questions

build on all levels of Bloom's taxonomy in three sections that:

1. test simple recall
2. combine recall with analytical thought
3. apply what you know to new clinical problems and other situations

INNOVATIVE

Chapter Sequencing

Innovative Chapter Order

Some chapters and topics are presented in a sequence that is more instructive than the conventional order.

Early Presentation of Heredity

Fundamental principles of heredity are presented in the last few pages of chapter 4 rather than at the back of the book to better integrate molecular and mendelian genetics. This organization also prepares students to learn about such genetic traits and conditions as cystic fibrosis, color blindness, blood types, hemophilia, cancer genes, or sickle-cell disease by first teaching them about dominant and recessive alleles, genotype and phenotype, and sex linkage.

Muscle Anatomy and Physiology Follow Skeleton and Joints

The functional morphology of the skeleton, joints, and muscles is treated in three consecutive chapters, 8 through 10, so when students learn muscle origins and insertions, these come only two chapters after the names of the relevant bone features. When they learn muscle actions, it is in the first chapter after learning the terms for the joint movements. This order brings another advantage: the physiology of muscle and nerve cells is treated in two consecutive chapters (11 and 12), which are thus closely integrated in their treatment of synapses, neurotransmitters, and membrane electrophysiology.

Urinary System Presented Close to Circulatory and Respiratory Systems

Most textbooks place this system near the end of the book because of its anatomical and developmental relationships with the reproductive system. However, its physiological ties to the circulatory and respiratory systems are much more important. Except for a necessary digression on lymphatics and immunity, the circulatory system is followed almost immediately with the respiratory and urinary systems.

ANOTHER LAYER TO ENHANCE THE CONNECTION

The Saladin Digital Story

The Complete Package

Connect. Learn. Succeed.

Presentation Materials:

PowerPoint files with embedded animations
Anatomy & Physiology Revealed PowerPoint files
Digital images (stepped-out images, split images, tables, photos)

Engaging Presentation Materials for Lecture and Lab

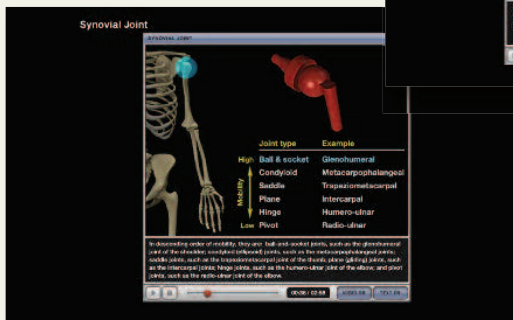

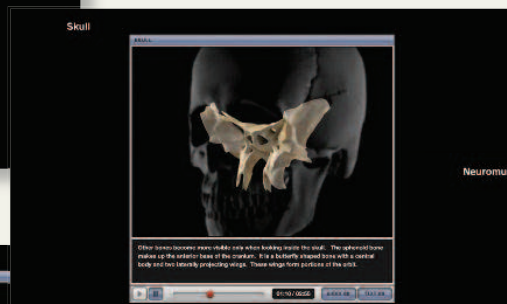

Incorporate customized lectures, visually enhanced tests and quizzes, compelling course websites, or attractive printed support materials using **McGraw-Hill's Presentation Assets.**

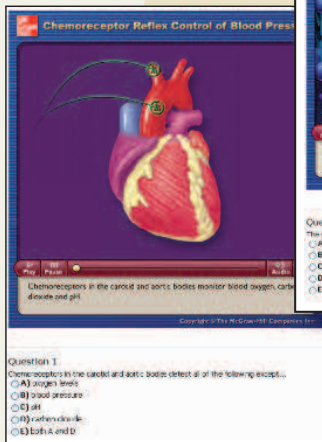

New! A complete set of premade PowerPoints linking Anatomy & Physiology Revealed to text material are now available for your use!

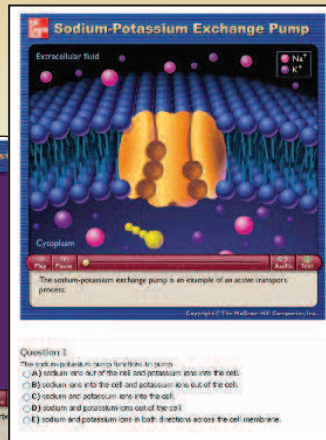

New! A complete set of animation embedded PowerPoint slides is now available!

Measure Your Students' Progress with Assessment Tools and Assignments

Animation Quizzing

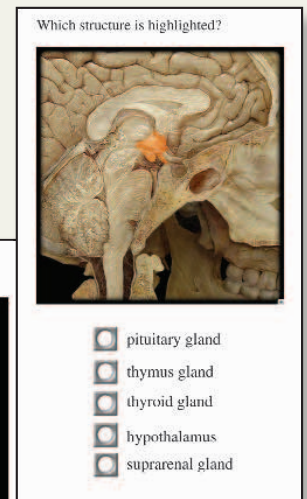

Animation Quizzing

McGraw-Hill Connect Anatomy & Physiology is a web-based assignment and assessment platform that gives students the means to better connect with their coursework, with their instructors, and with the important concepts that they will need to know for success now and in the future. With *Connect Anatomy & Physiology*, instructors can deliver assignments, quizzes, and tests easily online. Students can practice important skills at their own pace and on their own schedule. With *Connect Anatomy & Physiology Plus*, students also get 24/7 online access to an eBook—an online edition of the text—to aid them in successfully completing their work, wherever and whenever.

Computerized Test Bank Edited by Ken Saladin!

Powered by McGraw-Hill's flexible electronic testing program EZ Test Online

- Create paper and online tests or quizzes in one program!
- Create tests that can be easily shared with colleagues, adjuncts, WebCT, Blackboard, PageOut, and Apple's iQuiz.
- Sort questions by difficulty level, topic, and section.
- Create and access your test or quiz anywhere, at any time.
- Select questions from multiple McGraw-Hill test banks.
- Manage your tests online.
- Online automated scoring and reporting are also available.

Improve Performance by Providing **Self-Study Tools** for Students

In a recent student survey:

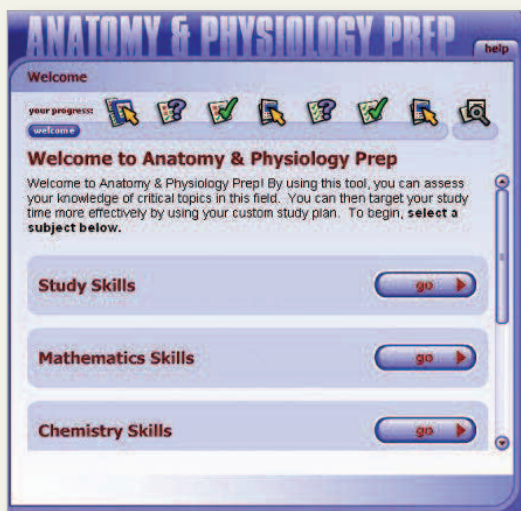

96% of students felt **APR** was fun to use!

80% of students reported they studied more often because of **APR**!

94% of students felt using **APR** helped improve their grade!

Anatomy & Physiology | Revealed 2.0

This amazing multimedia tool is designed to help students learn and review human anatomy using cadaver specimens. Detailed cadaver photographs blended together with a state-of-the-art layering technique provide a uniquely interactive dissection experience.

A&P Prep

A&P Prep, also available on the text website, helps students to prepare for their upcoming coursework in anatomy and physiology. This website enables students to perform self assessments, conduct self study sessions with tutorials, and perform a post assessment of their knowledge in the following areas:

- Introductory Biology Skills
- Mathematics Skills
- Chemistry Skills
- Study Skills
- Physics Skills
- Medical Terminology

Provide Low-Cost Textbook Alternatives for Your Class

Save **50%** on textbook cost!

Electronic Books

If you or your students are ready for an alternative version of the traditional textbook, McGraw-Hill eBooks offer a cheaper and eco-friendly alternative to traditional textbooks. By purchasing eBooks from McGraw-Hill, students can save as much as 50% on selected titles delivered on the most advanced eBook platform available.

Contact your McGraw-Hill sales representative to discuss eBook packaging options.

Other resources available:

Student Study Guide

This comprehensive study guide written by experienced instructor Jacque Homan in collaboration with Ken Saladin contains vocabulary-building and content-testing exercises, labeling exercises, and practice exams.

Physiology Tutorials

MediaPhys offers detailed explanations, high-quality illustrations, and animations to provide students with a thorough introduction to the world of physiology—giving them a virtual tour of physiological processes.

Physiology Interactive Lab Simulations

Ph.I.L.S. offers 37 lab simulations that may be used to supplement or substitute for wet labs.

Clinical Applications Manual

This manual expands on *Anatomy & Physiology's* clinical themes, introduces new clinical topics, and provides test questions and case studies to develop students' abilities to apply knowledge to realistic situations. A print version is available for students.

Lab Manual Options to Fit Your Course

The *Anatomy & Physiology Laboratory Manual* by Eric Wise of Santa Barbara City College is expressly written to coincide with chapters of Saladin's *Anatomy & Physiology*.

New! *The Laboratory Manual for Human Anatomy & Physiology* by Terry Martin of Kishwaukee College is written to coincide with Saladin or any A&P textbook.

- Three versions available including main, cat, and fetal pig
- Includes Ph.I.L.S. 3.0 CD-ROM
- Outcomes and assessments format
- Clear, concise writing style

Student Supplements

McGraw-Hill offers various tools and technology products to support the textbook. Students can order supplemental study materials by contacting their campus bookstore or online at www.shopmcgraw-hill.com.

Instructor Supplements

Instructors can obtain teaching aides by calling the McGraw-Hill Customer Service Department at 1-800-338-3987, visiting our online catalog at www.mhhe.com, or by contacting their local McGraw-Hill sales representative.

Letter to the Students

When I was a young boy, I became interested in what I then called “nature study” for two reasons. One was the sheer beauty of nature. I reveled in children’s books with abundant, colorful drawings and photographs of animals, plants, minerals, and gems. It was this esthetic appreciation of nature that made me want to learn more about it and made me happily surprised to discover I could make a career of it. At a slightly later age, another thing that drew me still deeper into biology was to discover writers who had a way with words—who could captivate my imagination and curiosity with their elegant prose. Once I was old enough to hold part-time jobs, I began buying zoology and anatomy books that mesmerized me with their gracefulness of writing and fascinating art and photography. I wanted to write and draw like that myself, and I began teaching myself by learning from “the masters.” I spent many late nights in my room peering into my microscope and jars of pond water, typing page after page of manuscript, and trying pen and ink as a medium. In short, I was the ultimate nerd. My “first book” was a 318-page paper on some little pond animals called hydras, with 53 India ink illustrations that I wrote for my tenth-grade biology class when I was 16.

Fast-forward about 30 years, to when I became a textbook writer, and I found myself bringing that same enjoyment of writing and illustrating to the first edition of this book you are now holding. Why? Not only for its intrinsic creative satisfaction, but because I’m guessing that you’re like I was—you can appreciate a book that does more than simply give you the information you need. You appreciate, I trust, a writer who makes it *enjoyable* for you through his scientific, storytelling prose and his concept of the way things should be illustrated to spark interest and facilitate understanding.

I know from my own students, however, that you need more than captivating illustrations and enjoyable reading. Let’s face it—A&P is a complex subject and it may seem a formidable task to acquire even a basic knowledge of the human body. It was difficult even for me to learn (and the learning never ends). So in addition to simply writing this book, I’ve given a lot of thought to its pedagogy—the art of teaching. I’ve designed my chapters to make them easier for you to study and to give you abundant opportunity to check whether you’ve understood what you read—to test yourself (as I advise my own students) before the instructor tests you.

Each chapter is broken down into short, digestible bits with a set of learning goals (Objectives) at the beginning of each section, and self-testing questions (Before You Go On) just a few pages later. Even if you have just 30 minutes to read during a lunch break or a bus ride, you can easily read or review one of these brief sections. There are also numerous self-testing questions at the end of each chapter, in some of the figure legends, and the occasional Think About It questions dispersed throughout each chapter. The questions cover a broad range of cognitive skills, from simple recall of a term to your ability to evaluate, analyze, and apply what you’ve learned to new clinical situations or other problems.

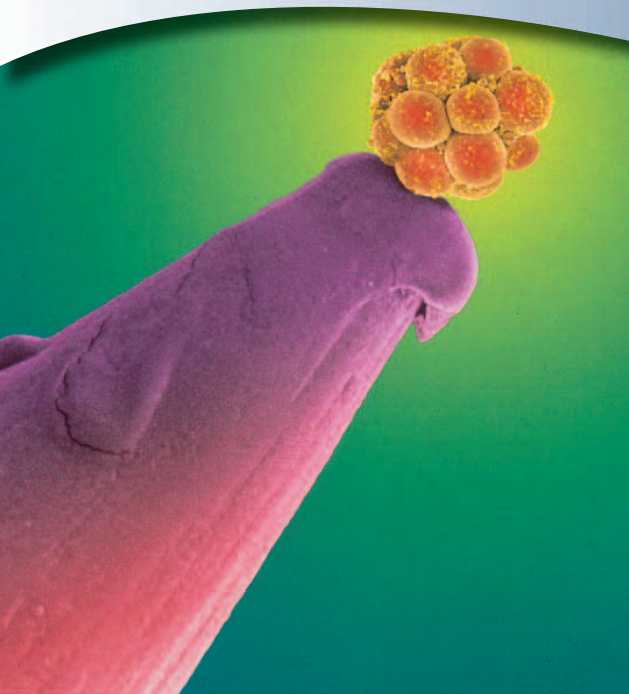

I hope you enjoy your study of this book, but I know there are always ways to make it even better. Indeed, what quality you may find in this edition owes a great deal to feedback I’ve received from students all over the world. If you find any typos or other errors, if you have any suggestions for improvement, if I can clarify a concept for you, or even if you just want to comment on something you really like about the book, I hope you’ll feel free to write to me. I correspond quite a lot with students and would enjoy hearing from you.

1.3 Medical History: Men in the Oven 18

1.4 Medical History: Obscure Word Origins 21

1.5 Clinical Application: Medical Imaging 23

No branch of science hits as close to home as the science of our own bodies. We're grateful for the dependability of our hearts; we're awed by the capabilities of muscles and joints displayed by Olympic athletes; and we ponder with philosophers the ancient mysteries of mind and emotion. We want to know how our body works, and when it malfunctions, we want to know what is happening and what we can do about it. Even the most ancient writings of civilization include medical documents that attest to humanity's timeless drive to know itself. You are embarking on a subject that is as old as civilization, yet one that grows by thousands of scientific publications every week.

This book is an introduction to human structure and function, the biology of the human body. It is meant primarily to give you a foundation for advanced study in health care, exercise physiology, pathology, and other fields related to health and fitness. Beyond that purpose, however, it can also provide you with a deeply satisfying sense of self-understanding.

As rewarding and engrossing as this subject is, the human body is highly complex, and understanding it requires us to comprehend a great deal of detail. The details will be more manageable if we relate them to a few broad, unifying concepts. The aim of this chapter, therefore, is to introduce such concepts and put the rest of the book into perspective. We consider the historical development of anatomy and physiology, the thought processes that led to the knowledge in this book, the meaning of human life, a central concept of physiology called *homeostasis*, and how to better understand medical terminology.

Anatomy is the study of structure, and **physiology** is the study of function. These approaches are complementary and never entirely separable. Together, they form the bedrock of the health sciences. When we study a structure, we want to know, What does it do? Physiology thus lends meaning to anatomy; and, conversely, anatomy is what makes physiology possible. This *unity of form and function* is an important point to bear in mind as you study the body. Many examples of it will be apparent throughout the book—some of them pointed out for you, and others you will notice for yourself.

Anatomy—The Study of Form

There are several ways to examine the structure of the human body. The simplest is **inspection**—simply looking at the body's appearance, as in performing a physical examination or making a clinical diagnosis from surface appearance. Physical examinations also involve touching and listening to the body. **Palpation**¹ means feeling a structure with the hands, such as palpating a swollen lymph node or taking a pulse. **Auscultation**² (AWS-cul-TAY-shun) is listening to the natural sounds made by the body, such as heart and lung sounds. In **percussion**, the examiner taps on the body, feels for abnormal resistance, and listens to the emitted sound for signs of abnormalities such as pockets of fluid or air.

But a deeper understanding of the body depends on **dissection**—the careful cutting and separation of tissues to reveal their relationships. The very words *anatomy*³ and *dissection*⁴ both mean “cutting apart”; until the nineteenth century, dissection was called “anatomizing.” In many schools of health science, one of the first steps in the training of students is dissection of the **cadaver**,⁵ a dead human body (fig. 1.1). Many insights into human structure are obtained from **comparative anatomy**—the study of more than one species in order to examine structural similarities and differences and analyze evolutionary trends. Anatomy students often begin by dissecting other animals with which we share a common ancestry and many structural similarities. Many of the reasons for human structure become apparent only when we look at the structure of other animals.

Dissection, of course, is not the method of choice when studying a living person! It was once common to diagnose disorders through **exploratory surgery**—opening the body and taking a look inside to see what was wrong and what could be done about it. Any breach of the body cavities is risky, however, and most exploratory surgery has now been replaced by **medical imaging** techniques—methods of viewing the inside of the body without surgery,

1.1 The Scope of Anatomy and Physiology

Objectives

When you have completed this section, you should be able to

- define *anatomy* and *physiology* and relate them to each other;
- describe several ways of studying human anatomy; and
- define a few subdisciplines of human physiology.

¹*palp* = touch, feel + *ation* = process

²*auscult* = listen + *ation* = process

³*ana* = apart + *tom* = cut

⁴*dis* = apart + *sect* = cut

⁵from *cadere* = to fall down or die

FIGURE 1.1 Early Medical Students in the Gross Anatomy Laboratory with Three Cadavers.

◀ Why should medical students study more than one cadaver?

discussed at the end of this chapter (see Insight 1.5). The branch of medicine concerned with imaging is called **radiology**. Structure that can be seen with the naked eye—whether by surface observation, radiology, or dissection—is called **gross anatomy**.

Ultimately, the functions of the body result from its individual cells. To see those, we usually take tissue specimens, thinly slice and stain them, and observe them under the microscope. This approach is called **histology**⁶ (**microscopic anatomy**). **Histopathology** is the microscopic examination of tissues for signs of disease. **Cytology**⁷ is the study of the structure and function of individual cells. **Ultrastructure** refers to fine detail, down to the molecular level, revealed by the electron microscope.

Physiology—The Study of Function

Physiology⁸ uses the methods of experimental science discussed later. It has many subdisciplines such as *neurophysiology* (physiology of the nervous system), *endocrinology* (physiology of hormones), and *pathophysiology* (mechanisms of disease). Partly because of limitations on experimentation with humans, much of what we know about bodily function has been gained through **comparative physiology**, the study of how different species have solved problems of life such as water balance, respiration, and reproduction. Comparative physiology is also the basis for the development of new drugs and medical procedures. For example, a cardiac surgeon may have to learn animal surgery before practicing on humans, and

⁶*histo* = tissue + *logy* = study of

⁷*cyto* = cell + *logy* = study of

⁸*physio* = nature + *logy* = study of

a vaccine cannot be used on human subjects until it has been demonstrated through animal research that it confers significant benefits without unacceptable risks.

1.2 The Origins of Biomedical Science

Objectives

When you have completed this section, you should be able to

- give examples of how modern biomedical science emerged from an era of superstition and authoritarianism; and
- describe the contributions of some key people who helped to bring about this transformation.

Any science is more enjoyable if we consider not just the current state of knowledge but how it compares to past understandings of the subject and how our knowledge was gained. Of all sciences, medicine has one of the most fascinating histories. Medical science has progressed far more in the last 50 years than in the 2,500 years before that, but the field did not spring up overnight. It is built upon centuries of thought and controversy, triumph and defeat. We cannot fully appreciate its present state without understanding its past—people who had the curiosity to try new things, the vision to look at human form and function in new ways, and the courage to question authority.

The Greek and Roman Legacy

As early as 3,000 years ago, physicians in Mesopotamia and Egypt treated patients with herbal drugs, salts, physical therapy, and faith healing. The “father of medicine,” however, is usually considered to be the Greek physician **Hippocrates** (c. 460–c. 375 BCE). He and his followers established a code of ethics for physicians, the Hippocratic Oath, that is still recited in modern form by many graduating medical students. Hippocrates urged physicians to stop attributing disease to the activities of gods and demons and to seek their natural causes, which could afford the only rational basis for therapy.

Aristotle (384–322 BCE) was one of the first philosophers to write about anatomy and physiology. He believed that diseases and other natural events could have either supernatural causes, which he called *theologi*, or natural ones, which he called *physici* or *physiologi*. We derive such terms as *physician* and *physiology* from the latter. Until the nineteenth century, physicians were called “doctors of physioc.” In his anatomy book, *Of the Parts of Animals*, Aristotle tried to identify unifying themes in nature. Among other points, he argued that

complex structures are built from a smaller variety of simple components—a perspective that we will find useful later in this chapter.

Think About It

When you have completed this chapter, discuss the relevance of Aristotle's philosophy to our current thinking about human structure.

Claudius Galen (c. 130–c. 200), physician to the Roman gladiators, wrote the most influential medical textbook of the ancient era—a book that was worshiped to excess by medical professors for centuries to follow. Cadaver dissection was banned in Galen's time because of some horrid excesses that preceded him, including public dissection of living slaves and prisoners. Aside from what he could learn by treating the gladiators' wounds, Galen was therefore limited to dissecting pigs, monkeys, and other animals. Because he was not permitted to dissect cadavers, he had to guess at much of human anatomy and made some incorrect deductions from animal dissections. He described the human liver, for example, as having five fingerlike lobes, somewhat like a baseball glove, because that is what he had seen in baboons. But Galen saw science as a method of discovery, not as a body of fact to be taken on faith. He warned that even his own books could be wrong and advised his followers to trust their own observations more than they trusted any book. Unfortunately, his advice was not heeded. For nearly 1,500 years, medical professors dogmatically taught what they read in Aristotle and Galen, seldom daring to question the authority of these “ancient masters.”

The Birth of Modern Medicine

In the Middle Ages, the state of medical science varied greatly from one religious culture to another. Science was severely repressed in the Christian culture of Europe until about the sixteenth century, although some of the most famous medical schools of Europe were founded during this era. Their professors, however, taught medicine primarily as a dogmatic commentary on Galen and Aristotle, not as a field of original research. Medieval medical illustrations were crude representations of the body intended more to decorate a page than to depict the body realistically. Some were astrological charts that showed which sign of the zodiac was thought to influence each organ of the body (fig. 1.2). From such pseudoscience came the word *influenza*, Italian for “influence.”

Free inquiry was less inhibited in Jewish and Muslim culture during this time. Jewish physicians were the most esteemed practitioners of their art—and none more famous than *Moses ben Maimon* (1135–1204), known in Christendom as **Maimonides**. Born in Spain, he fled to Egypt at age 24 to escape antisemitic persecution. There he served the rest of his life as physician to the court of the sultan, Saladin. A highly admired rabbi, Maimonides

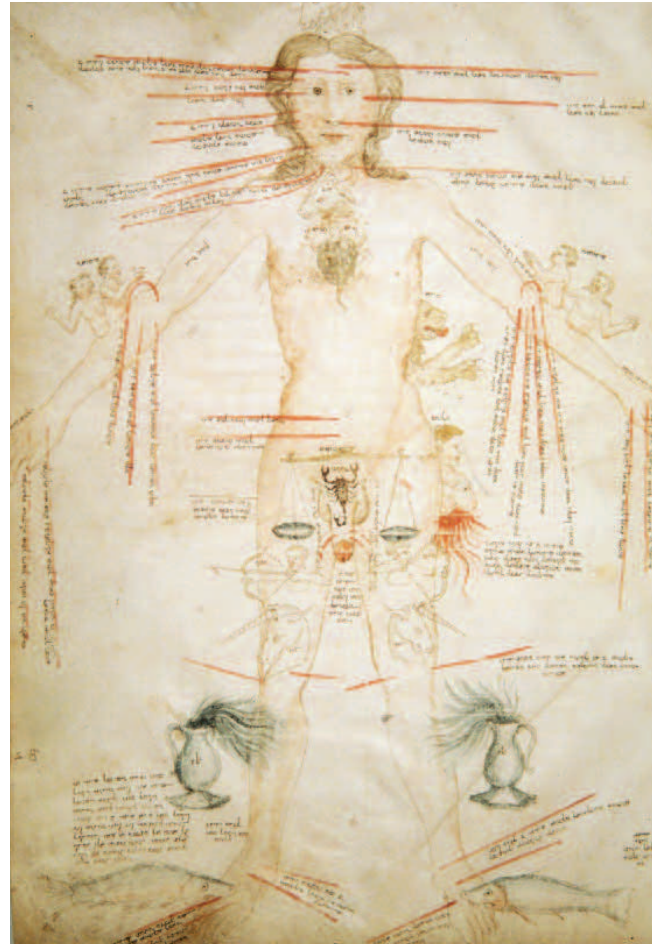

FIGURE 1.2 Zodiacal Man. This illustration from a fifteenth-century medical manuscript reflects the medieval belief in the influence of astrology on parts of the body.

◀ How does the word *influenza* stem from the belief reflected by this illustration?

wrote voluminously on Jewish law and theology, but also wrote 10 influential medical books and numerous treatises on specific diseases.

Among Muslims, probably the most highly regarded medical scholar was *Ibn Sina* (980–1037), known in the West as **Avicenna** or “the Galen of Islam.” He studied Galen and Aristotle, combined their findings with original discoveries, and questioned authority when the evidence demanded it. Medicine in the Mideast soon became superior to European medicine. Avicenna's textbook, *The Canon of Medicine*, became the leading authority in European medical schools for over 500 years.

Chinese medicine had little influence on Western thought and practice until relatively recently; the medical arts evolved in China quite independently of European medicine. Later chapters of this book describe some of the medical and anatomical insights of ancient China and India.

Modern Western medicine began around the sixteenth century in the innovative minds of such people as the anatomist Andreas Vesalius and the physiologist William Harvey. **Andreas Vesalius** (1514–64) taught anatomy in Italy. In his time, the Catholic Church relaxed its prohibition against cadaver dissection, primarily to allow autopsies in cases of suspicious death. Furthermore, the Italian Renaissance created an environment more friendly to innovative scholarship. Dissection gradually found its way into the training of medical students throughout Europe. It was an unpleasant business, however, and most professors considered it beneath their dignity. In those days before refrigeration or embalming, the odor from the decaying cadaver was unbearable. Dissections were conducted outdoors in a nonstop 4-day race against decay. Bleary medical students had to fight the urge to vomit, lest they incur the wrath of an overbearing professor. Professors typically sat in an elevated chair, the *cathedra*, reading dryly in Latin from Galen or Aristotle while a lower-ranking *barber-surgeon* removed putrefying organs from the cadaver and held them up for the students to see. Barbering and surgery were considered to be “kindred arts of the knife”; today’s barber poles date from this era, their red and white stripes symbolizing blood and bandages.

Vesalius broke with tradition by coming down from the *cathedra* and doing the dissections himself. He was quick to point out that much of the anatomy in Galen’s books was wrong, and he was the first to publish accurate illustrations for teaching anatomy (fig. 1.3). When others began to plagiarize his illustrations, Vesalius published the first atlas of anatomy, *De Humani Corporis Fabrica* (*On the Structure of the Human Body*), in 1543. This book began a rich tradition of medical illustration that has been handed down to us through such milestones as *Gray’s Anatomy* (1856) and the vividly illustrated atlases and textbooks of today.

Anatomy preceded physiology and was a necessary foundation for it. What Vesalius was to anatomy, the Englishman **William Harvey** (1578–1657) was to physiology. Harvey is remembered especially for his studies of blood circulation and a little book he published in 1628, known by its abbreviated title *De Motu Cordis* (*On the Motion of the Heart*). He and **Michael Servetus** (1511–53) were the first Western scientists to realize that blood must circulate continuously around the body, from the heart to the other organs and back to the heart again. This flew in the face of Galen’s belief that the liver converted food to blood, the heart pumped blood through the veins to all other organs, and those organs consumed it. Harvey’s colleagues, wedded to the ideas of Galen, ridiculed him for his theory, though we now know he was correct (see p. 756). Despite persecution and setbacks, Harvey lived to a ripe old age, served as physician to the kings of England, and later did important work in embryology. Most importantly, Harvey’s contributions represent the birth of experimental physiology—the method that generated most of the information in this book.

FIGURE 1.3 The Art of Vesalius. Andreas Vesalius revolutionized medical illustration with the comparatively realistic art prepared for his 1543 book, *De Humani Corporis Fabrica*.

Modern medicine also owes an enormous debt to two inventors from this era, Robert Hooke and Antony van Leeuwenhoek, who extended the vision of biologists to the cellular level.

Robert Hooke (1635–1703), an Englishman, designed scientific instruments of various kinds and made many improvements in the compound microscope. This is a tube with a lens at each end—an *objective lens* near the specimen, which produces an initial magnified image, and an *ocular lens* (eyepiece) near the observer’s eye, which magnifies the first image still further. Although crude compound microscopes had existed since 1595, Hooke improved the optics and invented several of the helpful features found in microscopes today—a stage to hold the specimen, an illuminator, and coarse and fine focus controls. His microscopes magnified only about 30 times, but with them, he was the first to see and name cells. In 1663, he observed thin shavings of cork and observed that they “consisted of a great

FIGURE 1.4 Hooke's Compound Microscope. (a) The compound microscope had a lens at each end of a tubular body. (b) Hooke's drawing of cork cells, showing the thick cell walls characteristic of plants.

many little boxes," which he called *cellulae* (little cells) after the cubicles of a monastery (fig. 1.4). He later observed thin slices of fresh wood and saw living cells "filled with juices." Hooke became particularly interested in microscopic examination of such material as insects, plant tissues, and animal parts. He published the first comprehensive book of microscopy, *Micrographia*, in 1665.

Antony van Leeuwenhoek (an-TOE-nee vahn LAY-wen-hook) (1632–1723), a Dutch textile merchant, invented a *simple* (single-lens) *microscope*, originally for the purpose of examining the weave of fabrics. His microscope was a bead-like lens mounted in a metal plate equipped with a movable specimen clip. Even though his microscopes were simpler than Hooke's, they achieved much greater useful magnification (up to 200 \times) owing to Leeuwenhoek's superior lens-grinding skill. Out of curiosity, he examined a drop of lake water and was astonished to find a variety of microorganisms—"little animalcules," he called them, "very prettily a-swimming." He went on to observe practically everything he could get his hands on, including blood cells, blood capillaries, sperm, muscular tissue, and bacteria from tooth scrapings. Leeuwenhoek began submitting his observations to the Royal Society of London in 1673. He was praised at first, and his observations were eagerly read by scientists, but enthusi-

asm for the microscope did not last. By the end of the seventeenth century, it was treated as a mere toy for the upper classes, as amusing and meaningless as a kaleidoscope. Leeuwenhoek and Hooke had even become the brunt of satire. But probably no one in history had looked at nature in such a revolutionary way. By taking biology to the cellular level, the two men had laid an entirely new foundation for the modern medicine to follow centuries later.

The Hooke and Leeuwenhoek microscopes produced poor images with blurry edges (*spherical aberration*) and rainbowlike distortions (*chromatic aberration*). These problems had to be solved before the microscope could be widely used as a biological tool. In nineteenth-century Germany, **Carl Zeiss** (1816–88) and his business partner, physicist **Ernst Abbe** (1840–1905), greatly improved the compound microscope, adding the condenser and developing superior optics. With improved microscopes, biologists began eagerly examining a wider variety of specimens. By 1839, botanist **Matthias Schleiden** (1804–81) and zoologist **Theodor Schwann** (1810–82) concluded that all organisms were composed of cells. Although it took another century for this idea to be generally accepted, it became the first tenet of the **cell theory**, added to by later biologists and summarized in chapter 3. The cell theory was perhaps the most important breakthrough in biomedical history; all functions of the body are now interpreted as the effects of cellular activity.

Although the philosophical foundation for modern medicine was largely established by the time of Leeuwenhoek, Hooke, and Harvey, clinical practice was still in a dismal state. Few doctors attended medical school or received any formal education in basic science or human anatomy. Physicians tended to be ignorant, ineffective, and pompous. Their practice was heavily based on expelling imaginary toxins from the body by bleeding their patients or inducing vomiting, sweating, or diarrhea. They performed operations with filthy hands and instruments, spreading lethal infections from one patient to another and refusing, in their vanity, to believe that they themselves were the carriers of disease. Countless women in childbirth died of infections acquired from their obstetricians. Fractured limbs often became gangrenous and had to be amputated, and there was no anesthesia to lessen the pain. Disease was still widely attributed to demons and witches, and many people felt they would be interfering with God's will if they tried to treat it.

Living in a Revolution

This short history brings us only to the threshold of modern biomedical science; it stops short of such momentous discoveries as the germ theory of disease, the mechanisms of heredity, and the structure of DNA. In the twentieth century, basic biology and biochemistry yielded a much deeper understanding of how the body works. Advances in medical imaging have enhanced our diagnostic ability and life-support strategies. We have witnessed monumental developments in chemotherapy, immunization, anesthesia, surgery, organ transplants, and human genetics. By the close of the twenti-

eth century, we had discovered the chemical “base sequence” of every human gene and begun attempting gene therapy to treat children born with diseases recently considered incurable. As future historians look back on the turn of this century, they may exult about the Genetic Revolution in which you are now living.

Several discoveries of the nineteenth and twentieth centuries, and the men and women behind them, are covered in short historical sketches in later chapters. Yet, the stories told in this chapter are different in a significant way. The people discussed here were pioneers in establishing the scientific way of thinking. They helped to replace superstition with an appreciation of natural law. They bridged the chasm between mystery and medication. Without this intellectual revolution, those who followed could not have conceived of the right questions to ask, much less a method for answering them.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. In what way did the followers of Galen disregard his advice? How does Galen's advice apply to you and this book?
2. Describe two ways in which Vesalius improved medical education and set standards that remain relevant today.
3. How is our concept of human form and function today affected by inventors from Hooke to Zeiss?

1.3 Scientific Method

Objectives

When you have completed this section, you should be able to

- describe the inductive and hypothetico-deductive methods of obtaining scientific knowledge;
- describe some aspects of experimental design that help to ensure objective and reliable results; and
- explain what is meant by *hypothesis*, *fact*, *law*, and *theory* in science.

Prior to the seventeenth century, science was done in a haphazard way by a small number of isolated individuals. The philosophers **Francis Bacon** (1561–1626) in England and **René Descartes** (1596–1650) in France envisioned science as a far greater, systematic enterprise with enormous possibilities for human health and welfare. They detested those who endlessly debated ancient philosophy without creating anything new. Bacon argued against biased thinking and for more objectivity in science. He outlined a systematic way of seeking similarities, differences, and trends in nature and drawing useful general-

izations from observable facts. You will see echoes of Bacon's philosophy in the discussion of scientific method that follows.

Though the followers of Bacon and Descartes argued bitterly with one another, both men wanted science to become a public, cooperative enterprise, supported by governments and conducted by an international community of scholars rather than a few isolated amateurs. Inspired by their vision, the French and English governments established academies of science that still flourish today. Bacon and Descartes are credited with putting science on the path to modernity, not by discovering anything new in nature or inventing any techniques—for neither man was a scientist—but by inventing new habits of scientific thought.

When we say “scientific,” we mean that such thinking is based on assumptions and methods that yield reliable, objective, testable information about nature. The assumptions of science are ideas that have proven fruitful in the past—for example, the idea that natural phenomena have natural causes and nature is therefore predictable and understandable. The methods of science are highly variable. **Scientific method** refers less to observational procedures than to certain habits of disciplined creativity, careful observation, logical thinking, and honest analysis of one's observations and conclusions. It is especially important in health science to understand these habits. This field is littered with more fads and frauds than any other. We are called upon constantly to judge which claims are trustworthy and which are bogus. To make such judgments depends on an appreciation of how scientists think, how they set standards for truth, and why their claims are more reliable than others.

The Inductive Method

The **inductive method**, first prescribed by Bacon, is a process of making numerous observations until one feels confident in drawing generalizations and predictions from them. What we know of anatomy is a product of the inductive method. We describe the normal structure of the body based on observations of many bodies.

This raises the issue of what is considered proof in science. We can never prove a claim beyond all possible refutation. We can, however, consider a statement as proven *beyond reasonable doubt* if it was arrived at by reliable methods of observation, tested and confirmed repeatedly, and not falsified by any credible observation. In science, all truth is tentative; there is no room for dogma. We must always be prepared to abandon yesterday's truth if tomorrow's facts disprove it.

The Hypothetico-Deductive Method

Most physiological knowledge was obtained by the **hypothetico-deductive method**. An investigator begins by asking a question and formulating a **hypothesis**—an educated speculation or possible answer to the question.

A good hypothesis must be (1) consistent with what is already known and (2) capable of being tested and possibly falsified by evidence. **Falsifiability** means that if we claim something is scientifically true, we must be able to specify what evidence it would take to prove it wrong. If nothing could possibly prove it wrong, then it is not scientific.

Think About It

The ancients thought that gods or invisible demons caused epilepsy. Today, epileptic seizures are attributed to bursts of abnormal electrical activity in nerve cells of the brain. Explain why one of these claims is falsifiable (and thus scientific), whereas the other claim is not.

The purpose of a hypothesis is to suggest a method for answering a question. From the hypothesis, a researcher makes a deduction, typically in the form of an “if-then” prediction: *If my hypothesis on epilepsy is correct and I record the brain waves of patients during seizures, then I should observe abnormal bursts of activity.* A properly conducted experiment yields observations that either support a hypothesis or require the scientist to modify or abandon it, formulate a better hypothesis, and test that one. Hypothesis testing operates in cycles of conjecture and disproof until one is found that is supported by the evidence.

Experimental Design

Doing an experiment properly involves several important considerations. What shall I measure and how can I measure it? What effects should I watch for and which ones should I ignore? How can I be sure that my results are due to the factors (*variables*) that I manipulate and not due to something else? When working on human subjects, how can I prevent the subject’s expectations or state of mind from influencing the results? Most importantly, how can I eliminate my own biases and be sure that even the most skeptical critics will have as much confidence in my conclusions as I do? Several elements of experimental design address these issues:

- **Sample size.** The number of subjects (animals or people) used in a study is the sample size. An adequate sample size controls for chance events and individual variations in response and thus enables us to place more confidence in the outcome. For example, would you rather trust your health to a drug that was tested on 5 people or one tested on 5,000? Why?
- **Controls.** Biomedical experiments require comparison between treated and untreated individuals so that we can judge whether the treatment has any effect. A **control group** consists of subjects that are as much like the **treatment group** as possible except with respect to the variable being tested. For example, there is evidence that garlic lowers blood cholesterol levels. In one study, a group of people with high cholesterol was given 800 mg of garlic powder daily for 4 months and exhibited an average 12% reduction in cholesterol. Was this a significant reduction, and was it due to the garlic? It is impossible to say without comparison to a control group of similar people who received no treatment. In this study, the control group averaged only a 3% reduction in cholesterol, so garlic *seems* to have made a difference.
- **Psychosomatic effects.** Psychosomatic effects (effects of the subject’s state of mind on his or her physiology) can have an undesirable effect on experimental results if we do not control for them. In drug research, it is therefore customary to give the control group a **placebo** (pla-SEE-bo)—a substance with no significant physiological effect on the body. If we were testing a drug, for example, we could give the treatment group the drug and the control group identical-looking starch tablets. Neither group must know which tablets it is receiving. If the two groups showed significantly different effects, we could feel confident that it did not result from a knowledge of what they were taking.
- **Experimenter bias.** In the competitive, high-stakes world of medical research, experimenters may want certain results so much that their biases, even subconscious ones, can affect their interpretation of the data. One way to control for this is the **double-blind method**. In this procedure, neither the subject to whom a treatment is given nor the person giving it and recording the results knows whether that subject is receiving the experimental treatment or placebo. A researcher might prepare identical-looking tablets, some with the drug and some with placebo; label them with code numbers; and distribute them to participating physicians. The physicians themselves do not know whether they are administering drug or placebo, so they cannot give the subjects even accidental hints of which substance they are taking. When the data are collected, the researcher can correlate them with the composition of the tablets and determine whether the drug had more effect than the placebo.
- **Statistical testing.** If you tossed a coin 100 times, you would expect it to come up about 50 heads and 50 tails. If it actually came up 48:52, you would probably attribute this to random error rather than bias in the coin. But what if it came up 40:60? At what point would you begin to suspect bias? This type of problem is faced routinely in research—how great a difference must there be between control and experimental groups before we feel confident that it was due to the treatment and not merely

random variation? What if a treatment group exhibited a 12% reduction in cholesterol level and the placebo group a 10% reduction? Would this be enough to conclude that the treatment was effective? Scientists are well grounded in **statistical tests** that can be applied to the data. Perhaps you have heard of the chi-square test, the *t* test, or analysis of variance, for example. A typical outcome of a statistical test might be expressed, “We can be 99.5% sure that the difference between group A and group B was due to the experimental treatment and not to random variation.” Science is grounded not in statements of absolute truth, but in statements of probability.

Peer Review

When a scientist applies for funds to support a research project or submits results for publication, the application or manuscript is submitted to **peer review**—a critical evaluation by other experts in that field. Even after a report is published, if the results are important or unconventional, other scientists may attempt to reproduce them to see if the author was correct. At every stage from planning to postpublication, scientists are therefore subject to intense scrutiny by their colleagues. Peer review is one mechanism for ensuring honesty, objectivity, and quality in science.

Facts, Laws, and Theories

The most important product of scientific research is understanding how nature works—whether it be the nature of a pond to an ecologist or the nature of a liver cell to a physiologist. We express our understanding as *facts*, *laws*, and *theories* of nature. It is important to appreciate the differences among these.

A scientific **fact** is information that can be independently verified by any trained person—for example, the fact that an iron deficiency leads to anemia. A **law of nature** is a generalization about the predictable ways in which matter and energy behave. It is the result of inductive reasoning based on repeated, confirmed observations. Some laws are expressed as concise verbal statements, such as the *law of complementary base-pairing*: In the double helix of DNA, a chemical base called adenine always pairs with one called thymine, and a base called guanine always pairs with cytosine (see p. 126). Other laws are expressed as mathematical formulae, such as *Boyle’s law*, used in respiratory physiology: Under specified conditions, the volume of a gas (*V*) is inversely proportional to its pressure (*P*)— $V \propto 1/P$.

A **theory** is an explanatory statement or set of statements derived from facts, laws, and confirmed hypotheses. Some theories have names, such as the *cell theory*, the *fluid-mosaic theory* of cell membranes, and the *sliding filament theory* of muscle contraction. Most, however, remain

unnamed. The purpose of a theory is not only to concisely summarize what we already know but, moreover, to suggest directions for further study and to help predict what the findings should be if the theory is correct.

Law and *theory* mean something different in science than they do to most people. In common usage, a law is a rule created and enforced by people; we must obey it or risk a penalty. A law of nature, however, is a description; laws do not *govern* the universe, they *describe* it. Laypeople tend to use the word *theory* for what a scientist would call a hypothesis—for example, “I have a theory why my car won’t start.” The difference in meaning causes significant confusion when it leads people to think that a scientific theory (such as the theory of evolution) is merely a guess or conjecture, instead of recognizing it as a summary of conclusions drawn from a large body of observed facts. The concepts of gravity and electrons are theories, too, but this does not mean they are merely speculations.

Think About It

Was the cell theory proposed by Schleiden and Schwann more a product of the hypothetico-deductive method or of the inductive method? Explain your answer.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe the general process involved in the inductive method.
- Describe some sources of potential bias in biomedical research. What are some ways of minimizing such bias?
- Is there more information in an individual scientific fact or in a theory? Explain.

1.4 Human Origins and Adaptations

Objectives

When you have completed this section, you should be able to

- explain why evolution is relevant to understanding human form and function;
- define *evolution* and *natural selection*;
- describe some human characteristics that can be attributed to the tree-dwelling habits of earlier primates; and
- describe some human characteristics that evolved later in connection with upright walking.

If any two theories have the broadest implications for understanding the human body, they are probably the cell theory and the theory of natural selection. *Natural selection*, an explanation of how species originate and change through time, was the brainchild of **Charles Darwin** (1809–82)—probably the most influential biologist who ever lived. His book, *On the Origin of Species by Means of Natural Selection* (1859), has been called “the book that shook the world.” In presenting the first well-supported theory of evolution, *On the Origin of Species* not only caused the restructuring of all of biology but also profoundly changed the prevailing view of our origin, nature, and place in the universe.

On the Origin of Species scarcely touched upon human biology, but its unmistakable implications for humans created an intense storm of controversy that continues even today. In *The Descent of Man* (1871), Darwin directly addressed the issue of human evolution and emphasized features of anatomy and behavior that reveal our relationship to other animals. No understanding of human form and function is complete without an understanding of our evolutionary history.

Evolution, Selection, and Adaptation

Evolution simply means change in the genetic composition of a population of organisms. Examples include the evolution of bacterial resistance to antibiotics, the appearance of new strains of the AIDS virus, and the emergence of new species of organisms.

Natural selection is the principal theory of how evolution works. It states essentially this: Some individuals within a species have hereditary advantages over their competitors—for example, better camouflage, disease resistance, or ability to attract mates—that enable them to produce more offspring. They pass these advantages on to their offspring, and such characteristics therefore become more and more common in successive generations. This brings about the genetic change in a population that constitutes evolution.

Natural forces that promote the reproductive success of some individuals more than others are called **selection pressures**. They include such things as climate, predators, disease, competition, and the availability of food. **Adaptations** are features of an organism’s anatomy, physiology, and behavior that have evolved in response to these selection pressures and enable the organism to cope with the challenges of its environment. We will consider shortly some selection pressures and adaptations that were important to human evolution and make the human body what it is today.

Darwin could scarcely have predicted the overwhelming mass of genetic, molecular, fossil, and other evidence of human evolution that would accumulate in the twentieth century and further substantiate his theory. A technique called DNA hybridization, for example, suggests

a difference of only 1.6% in DNA structure between humans and chimpanzees. Chimpanzees and gorillas differ by 2.3%. DNA structure suggests that a chimpanzee’s closest living relative is not the gorilla or any other ape—it is us.

Several aspects of our anatomy make little sense without an awareness that the human body has a history (see Insight 1.1). Our evolutionary relationship to other species is also important in choosing animals for biomedical research. If there were no issues of cost, availability, or ethics, we might test drugs on our close living relatives, the chimpanzees, before approving them for human use. Their genetics, anatomy, and physiology are most similar to ours, and their reactions to drugs therefore afford the best prediction of how the human body would react. On the other hand, if we had no kinship with any other species, the selection of a test species would be arbitrary; we might as well use frogs or snails. In reality, we compromise. Rats and mice are used extensively for research because they are fellow mammals with a physiology similar to ours, but they present fewer of the aforementioned issues than chimpanzees or other mammals do. An animal species or strain selected for research on a particular problem is called a **model**—for example, a mouse model for leukemia.

Life in the Trees

We belong to an order of mammals called the Primates, which also includes the monkeys and apes. Some of our anatomical and physiological features can be traced to the earliest primates, descended from certain squirrel-sized, insect-eating, African mammals (insectivores) that took up life in the trees 55 to 60 million years ago.

INSIGHT 1.1 Evolutionary Medicine

Vestiges of Human Evolution

One of the classic lines of evidence for evolution, debated even before Darwin was born, is *vestigial organs*. These structures are the remnants of organs that apparently were better developed and more functional in the ancestors of a species. They now serve little or no purpose or, in some cases, have been converted to new functions.

Our bodies, for example, are covered with millions of hairs, each equipped with a useless little muscle called a *piloerector*. In other mammals, these muscles fluff the hair and conserve heat. In humans, they merely produce goose bumps. Above each ear, we have three *auricularis muscles*. In other mammals, they move the ears to receive sounds better or to repel flies and other pests, but most people cannot contract them at all. As Darwin said, it makes no sense that humans would have such structures were it not for the fact that we came from ancestors in which they were functional.

FIGURE 1.5 **Opposable Thumbs.** The opposable thumb makes the primate hand prehensile, able to encircle and grasp objects.

This **arboreal**⁹ (treetop) habitat probably afforded greater safety from predators, less competition, and a rich food supply of leaves, fruit, insects, and lizards. But the forest canopy is a challenging world, with dim and dappled sunlight, swaying branches, and prey darting about in the dense foliage. Any new feature that enabled arboreal animals to move about more easily in the treetops would have been strongly favored by natural selection. Thus, the shoulder became more mobile and enabled primates to reach out in any direction (even overhead, which few other mammals can do). The thumbs became fully **opposable**—they could cross the palm to touch the fingertips—and enabled primates to hold small objects and manipulate them more precisely than other mammals can. Opposable thumbs made the hands **prehensile**¹⁰—able to grasp branches by encircling them with the thumb and fingers (fig. 1.5). The thumb is so important that it receives highest priority in the repair of hand injuries. If the thumb can be saved, the hand can be reasonably functional; if it is lost, hand functions are severely diminished.

The eyes of primates moved to a more forward-facing position (fig. 1.6), which allowed for **stereoscopic**¹¹ vision (depth perception). This adaptation provided better hand–eye coordination in catching and manipulating prey, with the added advantage of making it easier to

FIGURE 1.6 **Primitive Tool Use in a Primate.** Chimpanzees exhibit the prehensile hands and forward-facing eyes typical of primates. Such traits endow primates with stereoscopic vision (depth perception) and good hand–eye coordination, two supremely important factors in human evolution.

judge distances accurately in leaping from tree to tree. Color vision, rare among mammals, is also a primate hallmark. Primates eat mainly fruit and leaves. The ability to distinguish subtle shades of orange and red enables them to distinguish ripe, sugary fruits from unripe ones. Distinguishing subtle shades of green helps them to differentiate between tender young leaves and tough, more toxic older foliage.

Various fruits ripen at different times and in widely separated places in the tropical forest. This requires a good memory of what will be available, when, and how to get there. Larger brains may have evolved in response to the challenge of efficient food finding and, in turn, laid the foundation for more sophisticated social organization.

None of this is meant to imply that humans evolved from monkeys or apes—a common misconception about evolution that no biologist believes. Monkeys, apes, and humans do, however, share common ancestors. Our relationship is not like parent and child, but more like cousins who have the same grandparents. Observations of monkeys and apes provide insight into how primates adapt to the arboreal habitat and therefore how certain human adaptations probably originated.

Walking Upright

About 4 to 5 million years ago, parts of Africa became hotter and drier, and much of the forest was replaced by savanna (grassland). Some primates adapted to living on the savanna, but this was a dangerous place with

⁹*arbor* = tree + *eal* = pertaining to

¹⁰*prehens* = to seize

¹¹*stereo* = solid + *scop* = vision

more predators and less protection. Just as squirrels and monkeys stand briefly on their hind legs to look around for danger, so would these early ground dwellers. Being able to stand up not only helps an animal stay alert but also frees the forelimbs for purposes other than walking. Chimpanzees sometimes walk upright to carry food, infants, or weapons (sticks and rocks), and it is reasonable to suppose that our early ancestors did so too.

These advantages are so great that they favored skeletal modifications that made **bipedalism**¹²—standing and walking on two legs—easier. Fossil evidence indicates that bipedalism was firmly established more than 4 million years ago; footprints of bipedal primates have been preserved in volcanic ash in Tanzania dated to 3.6 million years ago. The anatomy of the human pelvis, femur, knee, great toe, foot arches, spinal column, skull, arms, and many muscles became adapted for bipedal locomotion, as did many aspects of human family life and society. As the skeleton and muscles became adapted for bipedalism, brain volume increased dramatically (table 1.1). It must have become increasingly difficult for a fully developed, large-brained infant to pass through the mother's pelvic outlet at birth. This may explain why humans are born in a relatively immature, helpless state compared with other mammals, before their nervous systems have matured and the bones of the skull have fused. The helplessness of human young and their extended dependence on parental care may help to explain why humans have such exceptionally strong family ties.

Most of the oldest bipedal primates are classified in the genus *Australopithecus* (aus-TRAL-oh-PITH-eh-cus). About 2.5 million years ago, hominids appeared with taller stature, greater brain volumes, simple stone tools, and probably articulate speech. These are the earliest members of the genus *Homo*. By at least 1.8 million years ago, *Homo erectus* migrated from Africa to parts of Asia. *Homo sapiens* originated in Africa about 200,000 years ago and is the sole surviving hominid species.

Our own species, *Homo sapiens*, has been notoriously difficult to define. Some authorities apply this name to various forms of “archaic *Homo*” dated as far back as 600,000 years, whereas others limit it to anatomically modern humans no more than 200,000 years old. Several other species of *Homo* between *Homo erectus* and modern *Homo sapiens* have been named in recent decades; their naming, classification, and relationships are still a matter of considerable debate.

This brief account barely begins to explain how human anatomy, physiology, and behavior have been shaped by ancient selection pressures. Later chapters further demonstrate that the evolutionary perspective provides a meaningful understanding of why humans are the way we are. Evolution is the basis for comparative

TABLE 1.1

Brain Volumes of the Hominidae

Genus or Species	Time of Origin (Millions of Years Ago)	Brain Volume (Milliliters)
<i>Australopithecus</i>	3.9–4.2	400
Early <i>Homo</i>	2.5	650
<i>Homo erectus</i>	2.0	1,100
<i>Homo sapiens</i>	0.2	1,350

anatomy and physiology, which have been so fruitful for the understanding of human biology. If we were not related to any other species, those sciences would be pointless. The emerging science of **evolutionary (darwinian) medicine** traces some of our diseases and imperfections to our evolutionary past.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. Define adaptation and selection pressure. Why are these concepts important in understanding human anatomy and physiology?
8. Select any two human characteristics and explain how they may have originated in primate adaptations to an arboreal habitat.
9. Select two other human characteristics and explain how they may have resulted from adaptation to a grassland habitat.

1.5 Human Structure

Objectives

When you have completed this section, you should be able to

- list the levels of human structure from the most complex to the simplest;
- discuss the value of both reductionistic and holistic viewpoints to understanding human form and function; and
- discuss the clinical significance of anatomical variation among humans.

Earlier in this chapter, we observed that human anatomy is studied by a variety of techniques—dissection, palpation, and so forth. In addition, anatomy is studied at several levels of detail, from the whole body down to the molecular level.

¹²bi = two + ped = foot

The Hierarchy of Complexity

Consider for the moment an analogy to human structure: The English language, like the human body, is very complex, yet an infinite variety of ideas can be conveyed with a limited number of words. All words in English are, in turn, composed of various combinations of just 26 letters. Between an essay and an alphabet are successively simpler levels of organization: paragraphs, sentences, words, and syllables. We can say that language exhibits a hierarchy of complexity, with letters, syllables, words, and so forth being successive levels of the hierarchy. Humans have an analogous hierarchy of complexity, as follows (fig. 1.7):

The organism is composed of organ systems,
 organ systems are composed of organs,
 organs are composed of tissues,
 tissues are composed of cells,
 cells are composed partly of organelles,
 organelles are composed of molecules, and
 molecules are composed of atoms.

The **organism** is a single, complete individual.

An **organ system** is a group of organs with a unique collective function, such as circulation, respiration, or digestion. The human body has 11 organ systems, illustrated in atlas A immediately following this chapter: the integumentary, skeletal, muscular, nervous, endocrine, circulatory, lymphatic, respiratory, urinary, digestive, and reproductive systems. Usually, the organs of one system are physically interconnected, such as the kidneys, ureters, urinary bladder, and urethra, which compose the urinary system. Beginning with chapter 6, this book is organized around the organ systems.

An **organ** is a structure composed of two or more tissue types that work together to carry out a particular function. Organs have definite anatomical boundaries and are visibly distinguishable from adjacent structures. Most organs and higher levels of structure are within the domain of gross anatomy. However, there are organs within organs—the large organs visible to the naked eye often contain smaller organs visible only with the microscope. The skin, for example, is the body's largest organ. Included within it are thousands of smaller organs: each hair, nail, gland, nerve, and blood vessel of the skin is an organ in itself. A single organ can belong to two organ systems. For example, the pancreas belongs to both the endocrine and digestive systems.

A **tissue** is a mass of similar cells and cell products that forms a discrete region of an organ and performs a specific function. The body is composed of only four primary classes of tissue: epithelial, connective, nervous, and muscular tissue. Histology, the study of tissues, is the subject of chapter 5.

Cells are the smallest units of an organism that carry out all the basic functions of life; nothing simpler than a cell is considered alive. A cell is enclosed in a *plasma membrane*

FIGURE 1.7 The Body's Structural Hierarchy.

composed of lipids and proteins. Most cells have one nucleus, an organelle that contains its DNA. *Cytology*, the study of cells and organelles, is the subject of chapters 3 and 4.

Organelles¹³ are microscopic structures in a cell that carry out its individual functions. Examples include mitochondria, centrioles, and lysosomes.

Organelles and other cellular components are composed of **molecules**. The largest molecules, such as proteins, fats, and DNA, are called *macromolecules*. A molecule is a particle composed of at least two **atoms**, the smallest particles with unique chemical identities.

The theory that a large, complex system such as the human body can be understood by studying its simpler components is called **reductionism**. First espoused by Aristotle, this has proven to be a highly productive approach; indeed, it is essential to scientific thinking.

¹³elle = little

Yet the reductionistic view is not the only way of understanding human life. Just as it would be very difficult to predict the workings of an automobile transmission merely by looking at a pile of its disassembled gears and levers, one could never predict the human personality from a complete knowledge of the circuitry of the brain or the genetic sequence of DNA. **Holism**¹⁴ is the complementary theory that there are “emergent properties” of the whole organism that cannot be predicted from the properties of its separate parts—human beings are more than the sum of their parts. To be most effective, a health-care provider treats not merely a disease or an organ system, but a whole person. A patient’s perceptions, emotional responses to life, and confidence in the nurse, therapist, or physician profoundly affect the outcome of treatment. In fact, these psychological factors often play a greater role in a patient’s recovery than the physical treatments administered.

Anatomical Variation

Anatomists, surgeons, and students must be constantly aware of how much one body can differ from another. A quick look around any classroom is enough to show that no two humans are exactly alike; on close inspection, even identical twins exhibit differences. Yet anatomy atlases and textbooks can easily give the impression that everyone’s internal anatomy is the same. This simply is not true. Books such as this one can teach you only the most common structure—the anatomy seen in about 70% or more of people. Someone who thinks that all human bodies are the same internally would make a very confused medical student or an incompetent surgeon.

Some people lack certain organs. For example, most of us have a *palmaris longus* muscle in the forearm and a *plantaris* muscle in the leg, but these are absent from others. Most of us have five lumbar vertebrae (bones of the lower spine), but some people have six and some have four. Most of us have one spleen and two kidneys, but some have two spleens or only one kidney. Most kidneys are supplied by a single *renal artery* and are drained by one *ureter*, but some have two renal arteries or ureters. Figure 1.8 shows some common variations in human anatomy, and Insight 1.2 describes a particularly dramatic and clinically important variation.

Think About It

People who are allergic to aspirin or penicillin often wear Medic Alert bracelets or necklaces that note this fact in case they need emergency medical treatment and are unable to communicate. Why would it be important for a person with *situs inversus* (see Insight 1.2) to have this noted on a Medic Alert bracelet?

¹⁴*holo* = whole, entire

INSIGHT 1.2 Clinical Application

Situs Inversus and Other Unusual Anatomy

In most people, the spleen, pancreas, sigmoid colon, and most of the heart are on the left, while the appendix, gallbladder, and most of the liver are on the right. The normal arrangement of these and other internal organs is called *situs* (SITE-us) *solitus*. About 1 in 8,000 people, however, are born with an abnormality called *situs inversus*—the organs of the thoracic and abdominal cavities are reversed between right and left. A selective right-left reversal of the heart is called *dextrocardia*. In *situs perversus*, a single organ occupies an atypical position—for example, a kidney located low in the pelvic cavity instead of high in the abdominal cavity.

Conditions such as dextrocardia in the absence of complete *situs inversus* can cause serious medical problems. Complete *situs inversus*, however, usually causes no functional problems because all of the viscera, though reversed, maintain their normal relationships to one another. *Situs inversus* is often discovered in the fetus by sonography, but many people remain unaware of their condition for decades until it is discovered by medical imaging, on physical examination, or in surgery. You can easily imagine the importance of such conditions in diagnosing appendicitis, performing gallbladder surgery, interpreting an X-ray, auscultating the heart valves, or recording an electrocardiogram.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

10. In the hierarchy of human structure, what is the level between organ system and tissue? Between cell and molecule?
11. How are tissues relevant to the definition of an organ?
12. Why is reductionism a necessary but not sufficient point of view for fully understanding a patient’s illness?
13. Why should medical students observe multiple cadavers and not be satisfied to dissect only one?

1.6 Human Function

Objectives

When you have completed this section, you should be able to

- state the characteristics that distinguish living organisms from nonliving objects;
- explain the importance of defining a reference man and woman;
- define *homeostasis* and explain why this concept is central to physiology;

FIGURE 1.8 Variation in Anatomy of the Kidneys and Major Arteries Near the Heart.

- define *negative feedback*, give an example of it, and explain its importance to homeostasis; and
- define *positive feedback* and give examples of its beneficial and harmful effects.

Characteristics of Life

Why do we consider a growing child to be alive, but not a growing crystal? Is abortion the taking of a human life? If so, what about a contraceptive foam that kills only sperm? As a patient is dying, at what point does it become ethical to disconnect life-support equipment and remove organs for donation? If these organs are alive, as they must be to serve someone else, then why isn't the donor considered alive? Such questions have no easy answers, but they demand a concept of what life is—a concept that may differ with one's biological, medical, legal, or religious perspective.

From a biological viewpoint, life is not a single property. It is a collection of properties that help to distinguish living from nonliving things:

- **Organization.** Living things exhibit a far higher level of organization than the nonliving world around them. They expend a great deal of energy to maintain order, and a breakdown in this order is accompanied by disease and often death.
- **Cellular composition.** Living matter is always compartmentalized into one or more cells.
- **Metabolism.** Living things take in molecules from the environment and chemically change them into molecules that form their own structures, control their physiology, or provide them with energy. **Metabolism**¹⁵ is the sum of all this internal chemical change. It consists

¹⁵metabol = change + ism = process

of two classes of reactions: *anabolism*,¹⁶ in which relatively complex molecules are synthesized from simpler ones (for example, protein synthesis), and *catabolism*,¹⁷ in which relatively complex molecules are broken down into simpler ones (for example, protein digestion). Metabolism inevitably produces chemical wastes, some of which are toxic if they accumulate.

Metabolism therefore requires **excretion**, the separation of wastes from the tissues and their elimination from the body. There is a constant turnover of molecules in the body; few of the molecules now in your body have been there for more than a year. It is food for thought that although you sense a continuity of personality and experience from your childhood to the present, nearly all of your body has been replaced within the past year.

- **Responsiveness and movement.** The ability of organisms to sense and react to **stimuli** (changes in their environment) is called *responsiveness*, *irritability*, or *excitability*. It occurs at all levels from the single cell to the entire body, and it characterizes all living things from bacteria to you. Responsiveness is especially obvious in animals because of nerve and muscle cells that exhibit high sensitivity to environmental stimuli, rapid transmission of information, and quick reactions. Most living organisms are capable of self-propelled movement from place to place, and all organisms and cells are at least capable of moving substances internally, such as moving food along the digestive tract or moving molecules and organelles from place to place within a cell.
- **Homeostasis.** Although the environment around an organism changes, the organism maintains relatively stable internal conditions. This ability to maintain internal stability, called *homeostasis*, is explored in more depth shortly.
- **Development.** Development is any change in form or function over the lifetime of the organism. In most organisms, it involves two major processes: (1) **differentiation**, the transformation of cells with no specialized function into cells that are committed to a particular task, and (2) **growth**, an increase in size. Some nonliving things grow, but not in the way your body does. If you let a saturated sugar solution evaporate, crystals will grow from it, but not through a change in the composition of the sugar. They merely add more sugar molecules from the solution to the crystal surface. The growth of the body, by contrast, occurs through chemical change (metabolism); for the most part, your body is not composed of the molecules you ate but of molecules made by chemically altering your food.
- **Reproduction.** All living organisms can produce copies of themselves, thus passing their genes on to new, younger containers—their offspring.

- **Evolution.** All living species exhibit genetic change from generation to generation and therefore evolve. This occurs because *mutations* (changes in DNA structure) are inevitable and because environmental selection pressures endow some individuals with greater reproductive success than others. Unlike the other characteristics of life, evolution is a characteristic seen only in the population as a whole. No single individual evolves over the course of its life.

Clinical and legal criteria of life differ from these biological criteria. A person who has shown no brain waves for 24 hours, and has no reflexes, respiration, or heartbeat other than what is provided by artificial life support, can be declared legally dead. At such time, however, most of the body is still biologically alive and its organs may be useful for transplant.

Physiological Variation

Earlier we considered the clinical importance of variations in human anatomy, but physiology is even more variable. Physiological variables differ with sex, age, weight, diet, degree of physical activity, and environment, among other things. Failure to consider such variation leads to medical mistakes such as overmedication of the elderly or medicating women on the basis of research that was done on men. If an introductory textbook states a typical human heart rate, blood pressure, red blood cell count, or body temperature, it is generally assumed that such values are for a healthy young adult unless otherwise stated. The standards for such general values are the reference man and reference woman. The **reference man** is defined as a healthy male 22 years old, weighing 70 kg (154 lb), living at a mean ambient (surrounding) temperature of 20°C, engaging in light physical activity, and consuming 2,800 kilocalories (kcal) per day. The **reference woman** is the same except for a weight of 58 kg (128 lb) and an intake of 2,000 kcal/day.

Homeostasis and Negative Feedback

The human body has a remarkable capacity for self-restoration. Hippocrates commented that it usually returns to a state of equilibrium by itself, and people recover from most illnesses even without the help of a physician. This tendency results from **homeostasis**¹⁸ (HO-me-oh-STAY-sis), the body's ability to detect change, activate mechanisms that oppose it, and thereby maintain relatively stable internal conditions.

French physiologist **Claude Bernard** (1813–78) observed that the internal conditions of the body remain quite constant even when external conditions vary greatly. For example, whether it is freezing cold or swelteringly hot outdoors, the internal temperature of the body stays within a range of about 36° to 37°C (97°–99°F). American physiologist **Walter Cannon** (1871–1945) coined the term *homeostasis* for this tendency to maintain internal stability. Homeostasis has been one of the

¹⁶ana = up

¹⁷cata = down

¹⁸homeo = the same + stas = to place, stand, stay

FIGURE 1.9 Negative Feedback in a Home Heating System. (a) The negative-feedback loop that maintains room temperature. (b) Fluctuation of room temperature around the thermostatic set point.

What component of the heating system acts as the sensor? What component acts as the effector?

most enlightening theories in physiology. We now see physiology as largely a group of mechanisms for maintaining homeostasis, and the loss of homeostatic control as the cause of illness and death. Pathophysiology is essentially the study of unstable conditions that result when our homeostatic controls go awry.

Do not, however, overestimate the degree of internal stability. Internal conditions are not absolutely constant but fluctuate within a limited range, such as the range of body temperatures noted earlier. The internal state of the body is best described as a **dynamic equilibrium** (balanced change), in which there is a certain **set point** or average value for a given variable (such as 37°C for body temperature) and conditions fluctuate slightly around this point.

The fundamental mechanism that keeps a variable close to its set point is **negative feedback**—a process in which the body senses a change and activates mechanisms that negate or reverse it. By maintaining stability, negative feedback is the key mechanism for maintaining health.

These principles can be understood by comparison to a home heating system (fig. 1.9). Suppose it is a cold winter day and you have set your thermostat for 20°C (68°F)—the set point. If the room becomes too cold, a temperature-sensitive switch in the thermostat turns on the furnace. The temperature rises until it is slightly above the set point, and then the switch breaks the circuit and turns off the furnace. This is a negative-feedback process that reverses the falling temperature and restores it to something close to the set point. When the furnace turns off, the temperature slowly drops again until the switch is reactivated—thus, the furnace cycles on and off all day. The room temperature does not stay at exactly 20°C but *fluctuates* a few degrees either way—the system maintains a state of dynamic equilibrium in which the temperature averages 20°C and deviates only slightly from the set

point. Because feedback mechanisms alter the original changes that triggered them (temperature, for example), they are often called **feedback loops**.

Body temperature is similarly regulated by a “thermostat”—a group of nerve cells in the base of the brain that monitor the temperature of the blood. If you become overheated, the thermostat triggers heat-losing mechanisms (fig. 1.10). One of these is **vasodilation** (VAY-zo-dy-LAY-shun), the widening of blood vessels. When

FIGURE 1.10 Negative Feedback in Human Thermoregulation.

Negative feedback keeps the human body temperature homeostatically regulated within about 0.5°C of a 37°C set point. Sweating and cutaneous vasodilation lower the body temperature; shivering and cutaneous vasoconstriction raise it.

How does vasodilation reduce the body temperature?

blood vessels of the skin dilate, warm blood flows closer to the body surface and loses heat to the surrounding air. If this is not enough to return your temperature to normal, sweating occurs; the evaporation of water from the skin has a powerful cooling effect (see Insight 1.3). Conversely, if it is cold outside and your body temperature drops much below 37°C, these nerve cells activate heat-conserving mechanisms. The first to be activated is **vasoconstriction**, a narrowing of the blood vessels in the skin, which serves to retain warm blood deeper in your body and reduce heat loss. If this is not enough, the brain activates shivering—muscle tremors that generate heat.

Let's consider one more example—a case of homeostatic control of blood pressure. When you first rise from bed in the morning, gravity causes some of your blood to drain away from your head and upper torso, resulting in falling blood pressure in this region—a local imbalance in your homeostasis (fig. 1.11). This is detected by sensory nerve endings called *baroreceptors* in the large arteries near the heart. They transmit nerve signals to the brainstem, where we have a *cardiac center* that regulates the heart rate. The cardiac center responds by transmitting nerve signals to the heart, which speed it up. The faster heart rate quickly raises the blood pressure and restores normal homeostasis. In elderly people, this feedback loop is sometimes insufficiently responsive, and they may feel dizzy or faint as they rise from a reclining position and their cerebral blood pressure falls.

This reflexive correction of blood pressure (*baroreflex*) illustrates three common, although not universal, components of a feedback loop: a receptor, an integrating center, and an effector. The **receptor** is a structure that senses a change in the body, such as the stretch receptors that monitor blood pressure. The **integrating (control) center**, such as the cardiac center of the brain, is a mechanism that processes this information, relates it to other available information (for example, comparing what the blood pressure is with what it should be), and “makes a decision” about what the appropriate response should be. The

FIGURE 1.11 Homeostatic Compensation for a Postural Change in Blood Pressure.

effector is the cell or organ that carries out the final corrective action. In the foregoing example, it is the heart. The response, such as the restoration of normal blood pressure, is then sensed by the receptor, and the feedback loop is complete.

INSIGHT 1.3 Medical History

Men in the Oven

English physician Charles Blagden (1748–1820) staged a rather theatrical demonstration of homeostasis long before Cannon coined the word. In 1775, Blagden spent 45 minutes in a chamber heated to 127°C (260°F)—along with a dog, a beefsteak, and some research associates. Being dead and unable to maintain homeostasis, the beefsteak was cooked. But being alive and capable of evaporative cooling, the dog panted, the men sweated, and all of them survived. History does not record whether the men ate the beefsteak in celebration or shared it with the dog.

Positive Feedback and Rapid Change

Positive feedback is a self-amplifying cycle in which a physiological change leads to even greater change in the same direction, rather than producing the corrective effects of negative feedback. Positive feedback is often a normal way of producing rapid change. When a woman is giving birth, for example, the head of the fetus pushes against her cervix (the neck of the uterus) and stimulates its nerve endings (fig. 1.12). Nerve signals travel to the brain, which, in turn, stimulates the pituitary gland to secrete the hormone oxytocin. Oxytocin travels in the blood and stimulates the uterus to contract. This pushes the fetus downward, stimulating the cervix still more and causing the positive-feedback loop to be repeated. Labor

FIGURE 1.12 Positive Feedback in Childbirth.

contractions therefore become more and more intense until the fetus is expelled. Other cases of beneficial positive feedback are seen later in the book, for example in blood clotting, protein digestion, and the generation of nerve signals.

Frequently, however, positive feedback is a harmful or even life-threatening process. This is because its self-amplifying nature can quickly change the internal state of the body to something far from its homeostatic set point. Consider a high fever, for example. A fever triggered by infection is beneficial up to a point, but if the body temperature rises much above 40°C (104°F), it may create a dangerous positive-feedback loop. This high temperature raises the metabolic rate, which makes the body produce heat faster than it can get rid of it. Thus, temperature rises still further, increasing the metabolic rate and heat production still more. This “vicious circle” becomes fatal

at approximately 45°C (113°F). Thus, positive-feedback loops often create dangerously out-of-control situations that require emergency medical treatment.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

14. List four biological criteria of life and one clinical criterion. Explain how a person could be clinically dead but biologically alive.
15. What is meant by dynamic equilibrium? Why would it be wrong to say homeostasis prevents internal change?
16. Explain why stabilizing mechanisms are called negative feedback.
17. Explain why positive feedback is more likely than negative feedback to disturb homeostasis.

1.7 The Language of Medicine

Objectives

When you have completed this section, you should be able to

- explain why modern anatomical terminology is so heavily based on Greek and Latin;
- recognize eponyms when you see them;
- describe the efforts to achieve an internationally uniform anatomical terminology;
- break medical terms down into their basic word elements;
- state some reasons why the literal meaning of a word may not lend insight into its definition;
- relate singular noun forms to their plural and adjectival forms; and
- discuss why precise spelling is important in anatomy and physiology.

One of the greatest challenges faced by students of anatomy and physiology is the vocabulary. In this book, you will encounter such Latin terms as *corpus callosum* (a brain structure), *ligamentum arteriosum* (a small fibrous band near the heart), and *extensor carpi radialis longus* (a forearm muscle). You may wonder why structures aren't named in "just plain English," and how you will ever remember such formidable names. This section will give you some answers to these questions and some useful tips on mastering anatomical terminology.

The History of Anatomical Terminology

The major features of human gross anatomy have standard international names prescribed by a book titled the *Terminologia Anatomica (TA)*. The *TA* was codified in 1998 by an international body of anatomists, the Federative Committee on Anatomical Terminology, and approved by professional associations of anatomists in more than 50 countries.

About 90% of today's medical terms are formed from just 1,200 Greek and Latin roots. Why those two languages? Scientific investigation began in ancient Greece and soon spread to Rome. The Greeks and Romans coined many of the words still used in human anatomy today: *duodenum*, *uterus*, *prostate*, *cerebellum*, *diaphragm*, *sacrum*, *amnion*, and others. In the Renaissance, the fast pace of anatomical discovery required a profusion of new terms to describe things. Anatomists in different countries began giving different names to the same structures. Adding to the confusion, they often named new structures and diseases in honor of their esteemed teachers and predecessors, giving us such nondescriptive terms as *fallopian tube* and

duct of Santorini. Terms coined from the names of people, called **eponyms**,¹⁹ afford little clue as to what a structure or condition is.

In hopes of resolving this growing confusion, anatomists began meeting as early as 1895 to devise a uniform international terminology. After several false starts, they agreed on a list of terms titled the *Nomina Anatomica (NA)*, which rejected all eponyms and gave each structure a unique Latin name to be used worldwide. Even if you were to look at an anatomy atlas in Japanese or Arabic, the illustrations may be labeled with the same Latin terms as in an English-language atlas. The *NA* served for many decades until recently replaced by the *TA*, which prescribes both Latin names and accepted English equivalents. The terminology in this book conforms to the *TA* except where undue confusion would result from abandoning widely used, yet unofficial, terms.

Analyzing Medical Terms

The task of learning medical terminology seems overwhelming at first, but it is a simple skill to become more comfortable with the technical language of medicine. People who find scientific terms confusing and difficult to pronounce, spell, and remember usually feel more confident once they realize the logic of how terms are composed. A term such as *hyponatremia* is less forbidding once we recognize that it is composed of three common word elements: *hypo-* (below normal), *natr-* (sodium), and *-emia* (blood condition). Thus, hyponatremia is a deficiency of sodium in the blood. Those word elements appear over and over in many other medical terms: *hypothermia*, *natriuretic*, *anemia*, and so on. Once you learn the meanings of *hypo-*, *natri-*, and *-emia*, you already have the tools at least to partially understand hundreds of other biomedical terms. Inside the back cover, you will find a lexicon of the 400 word elements most commonly footnoted in this book.

Scientific terms are typically composed of one or more of the following elements:

- At least one *root (stem)* that bears the core meaning of the word. In *cardiology*, for example, the root is *cardi-* (heart). Many words have two or more roots. In *cardiomyopathy*, for example, the roots are *cardi-* (heart), *my-* (muscle), and *path-* (disease).
- *Combining vowels* that are often inserted to join roots and make the word easier to pronounce. In *cardiomyopathy*, each *o* is a combining vowel. Although *o* is the most common combining vowel, all vowels of the alphabet are used in this way, such as *a* in *ligament*, *e* in *vitreous*, *i* in *fusi-form*, *u* in *ovulation*, and *y* in *tachycardia*. Some words, such as *intervertebral*, have no combining vowels. A combination of a root and combining vowel is called a *combining form*; for example,

¹⁹*epo* = after, related to + *nym* = name

chrom- (color) + *o* (a combining vowel) make the combining form *chromo-*, as in *chromosome*.

- A *prefix* may be present to modify the core meaning of the word. For example, *gastric* (pertaining to the stomach or to the belly of a muscle) takes on a variety of new meanings when prefixes are added to it: *epigastric* (above the stomach), *hypogastric* (below the stomach), *endogastric* (within the stomach), and *digastric* (a muscle with two bellies).
- A *suffix* may be added to the end of a word to modify its core meaning. For example, *microscope*, *microscopy*, *microscopic*, and *microscopist* have different meanings because of their suffixes alone. Often two or more suffixes, or a root and suffix, occur together so often that they are treated jointly as a *compound suffix*; for example, *log* (study) + *y* (process) form the compound suffix *-logy* (the study of).

To summarize these basic principles, consider the word *gastroenterology*, a branch of medicine dealing with the stomach and small intestine. It breaks down into *gastro/entero/ology*:

gastro = a combining form meaning “stomach”

entero = a combining form meaning “small intestine”

logy = a compound suffix meaning “the study of”

“Dissecting” words in this way and paying attention to the word-origin footnotes throughout this book will help you become more comfortable with the language of anatomy. Knowing how a word breaks down and knowing the meaning of its elements make it far easier to pronounce a word, spell it, and remember its definition. There are a few unfortunate exceptions, however. The path from original meaning to current usage has often become obscured by history (see Insight 1.4). The foregoing approach also is no help with eponyms or **acronyms**—words composed of the first letter, or first few letters, of a series of words. For example, *calmodulin*, a calcium-binding protein found in many cells, is cobbled together from a few letters of the three words, *calcium modulating protein*.

Plural, Adjectival, and Possessive Forms

A point of confusion for many beginning students is how to recognize the plural forms of medical terms. Few people would fail to recognize that *ovaries* is the plural of *ovary*, but the connection is harder to make in other cases: for example, the plural of *cortex* is *cortices* (COR-ti-sees), the plural of *corpus* is *corpora*, and the plural of *epididymis* is *epididymides* (EP-ih-DID-ih-MID-eze). Table 1.2 will help you make the connection between common singular and plural noun terminals.

In some cases, what appears to the beginner to be two completely different words may be only the noun and adjectival forms of the same word. For example, *brachium* denotes the arm, and *brachii* (as in the muscle name *biceps*

INSIGHT 1.4 Medical History

Obscure Word Origins

The literal translation of a word doesn’t always provide great insight into its modern meaning. The history of language is full of twists and turns that are fascinating in their own right and say much about the history of human culture, but they can create confusion for students.

For example, the *amnion* is a transparent sac that forms around the developing fetus. The word is derived from *amnos*, from the Greek for “lamb.” From this origin, *amnos* came to mean a bowl for catching the blood of sacrificial lambs, and from there the word found its way into biomedical usage for the membrane that emerges (quite bloody) as part of the afterbirth. The *acetabulum*, the socket of the hip joint, literally means “vinegar cup.” Apparently the hip socket reminded an anatomist of the little cups used to serve vinegar as a condiment on dining tables in ancient Rome. The word *testicles* can be translated “little pots” or “little witnesses.” The history of medical language has several amusing conjectures as to why this word was chosen to name the male gonads.

TABLE 1.2

Singular and Plural Forms of Some Noun Terminals

Singular Ending	Plural Ending	Examples
-a	-ae	axilla, axillae
-ax	-aces	thorax, thoraces
-en	-ina	lumen, lumina
-ex	-ices	cortex, cortices
-is	-es	diagnosis, diagnoses
-is	-ides	epididymis, epididymides
-ix	-ices	appendix, appendices
-ma	-mata	carcinoma, carcinomata
-on	-a	ganglion, ganglia
-um	-a	septum, septa
-us	-era	viscus, viscera
-us	-i	villus, villi
-us	-ora	corpus, corpora
-x	-ges	phalanx, phalanges
-y	-ies	ovary, ovaries
-yx	-yces	calyx, calyces

brachii) means “of the arm.” *Carpus* denotes the wrist, and *carpi*, a word used in several muscle names, means “of the wrist.” Adjectives can also take different forms for the singular and plural and for different degrees of comparison. The *digits* are the fingers and toes. The word *digiti* in a muscle name means “of a single finger (or toe),” whereas *digitorum*

is the plural, meaning “of multiple fingers (or toes).” Thus the *extensor digiti minimi* muscle extends only the little finger, whereas the *extensor digitorum* muscle extends all fingers except the thumb.

The English words *large*, *larger*, and *largest* are examples of the positive, comparative, and superlative degrees of comparison. In Latin, these are *magnus*, *major* (from *maior*), and *maximus*. We find these in the muscle names *adductor magnus* (a *large* muscle of the thigh), the *pectoralis major* (the *larger* of two *pectoralis* muscles of the chest), and *gluteus maximus* (the *largest* of the three gluteal muscles of the buttock).

Some noun variations indicate the possessive, such as the *rectus abdominis*, a straight (*rectus*) muscle of the abdomen (*abdominis*, “of the abdomen”), and the *erector spinae*, a muscle that straightens (*erector*) the spinal column (*spinae*, “of the spine”).

Anatomical terminology also frequently follows the Greek and Latin practice of placing the adjective after the noun. Thus, we have such names as the *stratum lucidum* for a clear (*lucidum*) layer (*stratum*) of the epidermis, the *foramen magnum* for a large (*magnum*) hole (*foramen*) in the skull, and the aforementioned *pectoralis major* muscle of the chest.

This is not to say that you must be conversant in Latin or Greek grammar to proceed with your study of anatomy. These few examples, however, may alert you to some patterns to watch for in the terminology you study and, ideally, will make your encounters with anatomical terminology less confusing.

The Importance of Precision

A final word of advice for your study of anatomy and physiology: Be precise in your use of terms. It may seem trivial if you misspell *trapezius* as *trapezium*, but in doing so, you would be changing the name of a back muscle to the name of a wrist bone. Similarly, changing *occipitalis* to *occipital* or *zygomaticus* to *zygomatic* changes other muscle names to bone names. A “little” error such as misspelling *ileum* as *ilium* changes the name of the final portion of the small intestine to the name of the hip bone. Changing *malleus* to *malleolus* changes the name of a middle-ear bone to the name of a bony protuberance of your ankle.

The health professions demand the utmost attention to detail and precision—people’s lives may one day be in your hands. The habit of carefulness must extend to your use of language as well. Many patients have died because of miscommunication in the hospital.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

18. Explain why modern anatomical terminology is so heavily based on Greek and Latin.

19. Distinguish between an eponym and an acronym, and explain why both of these present difficulties for interpreting anatomical terms.
20. Break each of the following words down into its roots, prefixes, and suffixes, and state their meanings, following the example of gastroenterology analyzed earlier: pericardium, appendectomy, subcutaneous, phonocardiogram, otorhinolaryngology. Consult the list of word elements inside the back cover for help.
21. Write the singular form of each of the following words: pleurae, gyri, ganglia, fissures. Write the plural form of each of the following: villus, tibia, encephalitis, cervix, stoma.

1.8 Review of Major Themes

To close this chapter, let’s distill a few major points from it. These themes can provide you with a sense of perspective that will make the rest of the book more meaningful and not just a collection of disconnected facts. These are some key unifying principles behind all study of human anatomy and physiology:

- **Cell theory.** *All structure and function result from the activity of cells.* Every physiological concept in this book ultimately must be understood from the standpoint of how cells function. Even anatomy is a result of cellular function. If cells are damaged or destroyed, we see the results in disease symptoms of the whole person.
- **Homeostasis.** *The purpose of most normal physiology is to maintain stable conditions within the body.* Human physiology is essentially a group of homeostatic mechanisms that produce stable internal conditions favorable to cellular function. Any serious departure from these conditions can be harmful or fatal to cells and thus to the whole body.
- **Evolution.** *The human body is a product of evolution.* Like every other living species, we have been molded by millions of years of natural selection to function in a changing environment. Many aspects of human anatomy and physiology reflect our ancestors’ adaptations to their environment. Human form and function cannot be fully understood except in light of our evolutionary history.
- **Hierarchy of structure.** *Human structure can be viewed as a series of levels of complexity.* Each level is composed of a smaller number of simpler subunits than the level above it. These subunits are arranged in different ways to form diverse structures of higher complexity. For example, all the body’s organs are made of just four primary classes of tissue, and the thousands of proteins are made of various combinations of just 20 amino acids. Understanding these simpler components is the key to understanding higher levels of structure.
- **Unity of form and function.** *Form and function complement each other; physiology cannot be divorced*

from anatomy. This unity holds true even down to the molecular level. Our very molecules, such as DNA and proteins, are structured in ways that enable them to carry out their functions. Slight changes in molecular structure can destroy their activity and threaten life.

Think About It

Architect Louis Henri Sullivan coined the phrase, "Form ever follows function." What do you think he meant by this? Discuss how this idea could be applied to the human body and cite a specific example of human anatomy to support it.

INSIGHT 1.5 Clinical Application

Medical Imaging

The development of techniques for looking into the body without having to do exploratory surgery has greatly accelerated progress in medicine. A few of these techniques are described here.

Radiography

X-rays, a form of high-energy radiation, were discovered by William Roentgen in 1885. X-rays can penetrate soft tissues of the body and darken photographic film on the other side. They are absorbed, however, by dense tissues such as bone, teeth, tumors, and tuberculosis nodules, which leave the film lighter in these areas (fig. 1.13a). The process of examining the body with X-rays *continued*

(a) X-ray (radiograph)

(b) Cerebral angiogram

(c) Computed tomographic (CT) scan

(d) Positron emission tomographic (PET) scan

(e) Magnetic resonance image (MRI)

FIGURE 1.13 Radiologic Images of the Head. (a) X-ray (radiograph) showing the bones and teeth. (b) An angiogram of the cerebral blood vessels. The arteries are enhanced with false color. (c) A CT scan. The eyes and skin are shown in blue, bone in pink, and the brain in green. (d) A PET scan of the brain of an unmedicated schizophrenic patient. Red areas indicate regions of high metabolic rate. In this patient, the visual center of the brain at the rear of the head (bottom of photo) was especially active during the scan. (e) An MRI scan at the level of the eyes. The optic nerves appear in red and the muscles that move the eyes appear in green.

is called *radiography*. The term *X-ray* also applies to an image (*radiograph*) made by this method. Radiography is commonly used in dentistry, mammography, diagnosis of fractures, and examination of the chest. Hollow organs can be visualized by filling them with a *radiopaque* substance that absorbs X-rays. Barium sulfate is given orally for examination of the esophagus, stomach, and small intestine or by enema for examination of the large intestine. Other substances are given by injection for *angiography*, the examination of blood vessels (fig. 1.13b). Some disadvantages of radiography are that images of overlapping organs can be confusing and slight differences in tissue density are not easily detected. Nevertheless, radiography still accounts for over half of all clinical imaging. Until the 1960s, it was the only method widely available.

Computed Tomography (CT)

The *CT scan*, formerly called a computerized axial tomographic²⁰ (CAT) scan, is a more sophisticated application of X-rays developed in 1972. The patient is moved through a ring-shaped machine that emits low-intensity X-rays on one side and receives them with a detector on the opposite side. A computer analyzes signals from the detector and produces an image of a “slice” of the body about as thin as a coin (fig. 1.13c). The computer can “stack” a series of these images to construct a three-dimensional image of the body. CT scanning has the advantage of imaging thin sections of the body, so there is little overlap of organs and the image is much sharper than a conventional X-ray. It requires extensive knowledge of cross-sectional anatomy to interpret the images. CT scanning is useful for identifying tumors, aneurysms, cerebral hemorrhages, kidney stones, and other abnormalities. It has virtually eliminated exploratory surgery.

Positron Emission Tomography (PET)

The *PET scan*, developed in the 1970s, is used to assess the metabolic state of a tissue and to distinguish which tissues are most active at a given moment (fig. 1.13d). The procedure begins with an injection of radioactively labeled glucose, which emits positrons (electron-like particles with a positive charge). When a positron and electron meet, they annihilate each other and give off a pair of gamma rays that can be detected by sensors and analyzed by computer. The computer displays a color image that shows which tissues were using the most glucose at the moment. In cardiology, PET scans can show the extent of damaged heart tissue. Since it consumes little or no glucose, the damaged tissue appears dark. The PET scan is an example of *nuclear medicine*—the use of radioactive isotopes to treat disease or to form diagnostic images of the body.

Magnetic Resonance Imaging (MRI)

MRI was developed in the 1970s as a technique superior to CT scanning for visualizing soft tissues. The patient lies in a cylindrical chamber surrounded by a large electromagnet that creates a magnetic field 3,000 to 60,000 times as strong as the earth’s. Hydrogen atoms in the tissues align themselves with the magnetic field. The radiologic technologist then turns on a field of radio waves, causing the hydrogen atoms to absorb additional energy and align in a different direction. When the radio waves are turned off, the hydrogen atoms realign themselves to the magnetic field, giving off their excess energy at different rates

that depend on the type of tissue. A computer analyzes the emitted energy to produce an image of the body. MRI can “see” clearly through the skull and spinal column to produce images of the nervous tissue (fig. 1.13e). Moreover, it is better than CT for distinguishing between soft tissues such as the white and gray matter of the nervous system. MRI also eliminates exposure to harmful X-rays. *Functional MRI (fMRI)* is a variation of this technique that visualizes moment-to-moment changes in tissue function. fMRI scans of the brain, for example, show shifting patterns of activity as the brain applies itself to a specific task. fMRI has lately replaced the PET scan as the most important method for visualizing brain function. The use of fMRI in brain imaging is further discussed in chapter 14.

Sonography

*Sonography*²¹ is the second oldest and second most widely used method of imaging. It is an outgrowth of sonar technology developed in World War II. A handheld device held firmly to the skin produces high-frequency ultrasound waves and receives the signals that echo back from internal organs. Although sonography was first used medically in the 1950s, images of significant clinical value had to wait until computer technology had developed enough to analyze differences in the way tissues reflect ultrasound. Sonography is not very useful for examining bones or lungs, but it is the method of choice in obstetrics, where the image (*sonogram*) can be used to locate the placenta and evaluate fetal age, position, and development. Sonography avoids the harmful effects of X-rays, and the equipment is inexpensive and portable. Its primary disadvantage is that it does not produce a very sharp image (fig. 1.14).

CHAPTER REVIEW

Review of Key Concepts

1.1 The Scope of Anatomy and Physiology (p. 2)

1. Human *anatomy*, or structure, is studied at gross and microscopic (histological) levels.
2. The methods of anatomy include dissection, palpation, and imaging techniques such as X-rays; sonography; and CT, PET, and MRI scans.
3. Human *physiology*, or function, is studied by experimental methods, and often by comparison with other species.

1.2 The Origins of Biomedical Science (p. 3)

1. Hippocrates and Aristotle first put medicine on a scientific basis by distinguishing natural causes from the supernatural.
2. Galen wrote the first notable medical textbook, which dominated Western medicine for 1,500 years.
3. In the Middle Ages, medical science was preserved and advanced primarily in Muslim and Jewish culture, by such physicians as Avicenna and Maimonides.
4. In the sixteenth century, revolutionary work in anatomy by Vesalius and in physiology by Harvey created a foundation for modern medicine.
5. Improvements in the microscope by Hooke, Leeuwenhoek, and, later, Zeiss and Abbe opened the door to understanding anatomy, physiology, and disease at a cellular level.

1.3 Scientific Method (p. 7)

1. Philosophers Bacon and Descartes first established a systematic scientific way of thought in the seventeenth century.
2. The *inductive method*, common in anatomy, consists of generalizing about nature from numerous observations.
3. The *hypothetico-deductive method*, common in physiology, consists of formulating hypotheses and testing them by carefully crafted observational strategies.

4. The objectivity of medical science depends on experimental designs that include an adequate sample size, experimental controls such as placebos and the double-blind method, statistical analysis of the significance of the data, and peer review by other experts.
5. Science generates facts, laws, and theories. Theories are summations of our present knowledge of a natural phenomenon and are the basis of much of our study in anatomy and physiology.

1.4 Human Origins and Adaptations (p. 9)

1. Human form and function have been shaped by millions of years of *natural selection*.
2. Many aspects of anatomy and physiology today, such as stereoscopic vision and opposable thumbs, are *adaptations* to the environments in which our prehistoric ancestors lived, including the arboreal and grassland habitats of Africa.
3. *Evolutionary medicine* is the analysis of human form, function, and disease in light of the evolutionary history of the human body.

1.5 Human Structure (p. 12)

1. Human structure is organized around a hierarchy of complexity. Levels of human complexity from most complex to simplest are *organism, organ systems, organs, tissues, cells, organelles, molecules, and atoms*.
2. Introductory textbooks teach only the most common human structure, but there are many variations in both internal and external anatomy.

1.6 Human Function (p. 14)

1. Life can be defined only as a collection of properties including *organization, cellular composition, metabolism, excretion, responsiveness, movement, homeostasis, development, reproduction, and evolution*.

2. For clinical purposes, life and legal death are differentiated on the basis of brain waves, reflexes, respiration, and heartbeat.
3. Humans vary greatly in their physiology. Data given in introductory and general textbooks are typically based on a young adult *reference male* and *reference female*.
4. An important unifying theory in physiology is *homeostasis*, mechanisms of maintaining internal constancy in spite of environmental change. Homeostasis keeps such variables as blood pressure and body temperature within a narrow range of an average called the *set point*.
5. Homeostasis is maintained by self-correcting chain reactions called *negative feedback*. This often involves detection of a change by a *receptor*, processing of this information by an *integrating center*, and reversal of the change by an *effector*.
6. *Positive feedback* is a self-amplifying chain of events that tends to produce rapid change in the body. It can be valuable in such cases as childbirth and blood clotting, but is often a cause of dysfunction and death.

1.7 The Language of Medicine (p. 20)

1. Anatomists the world over adhere to a lexicon of standard international terms called the *Terminologia Anatomica (TA)*. Anatomy students must learn many Latin or English *TA* terms.
2. Biomedical terms can usually be simplified by breaking them down into familiar roots, prefixes, and suffixes. The habit of analyzing words in this way can greatly ease the difficulty of learning biomedical vocabulary, and is aided by footnotes throughout this book.
3. Precision in medical language is highly important. What may seem to be trivial spelling errors can radically change the meaning of a word, potentially causing dangerous medical errors.

1.8 Review of Major Themes (p. 22)

- Certain recurring themes help to unify the study of anatomy and physiology. The following five themes are particularly significant in this book.
- Cell theory* is the principle that all biological structure and function are based on cellular function.
- Homeostasis* is the tendency of the body to maintain internal stability in spite of changes in its environment.
- Evolution* is a history of adaptation to environmental change that accounts for the current structure and function of the body.
- Hierarchy of structure* refers to the composition of the body from a limited number of basic subunits combined in various ways and organized into a series of levels of complexity.
- Unity of form and function* refers to the dependence of structure and function on each other, hence the necessity to consider form when interpreting function and vice versa.

Testing Your Recall

- Structure that can be observed with the naked eye is called
 - gross anatomy.
 - ultrastructure.
 - microscopic anatomy.
 - histology.
 - cytology.
- The word root *homeo-* means
 - tissue.
 - metabolism.
 - change.
 - human.
 - same.
- The simplest structures considered to be alive are
 - organisms.
 - organs.
 - tissues.
 - cells.
 - organelles.
- Which of the following people revolutionized the teaching of gross anatomy?
 - Vesalius
 - Aristotle
 - Hippocrates
 - Leeuwenhoek
 - Cannon
- Which of the following embodies the greatest amount of scientific information?
 - a fact
 - a law of nature
 - a theory
 - a deduction
 - a hypothesis
- An informed, uncertain, but testable conjecture is
 - a natural law.
 - a scientific theory.
 - a hypothesis.
 - a deduction.
 - a scientific fact.
- A self-amplifying chain of physiological events is called
 - positive feedback.
 - negative feedback.
 - dynamic constancy.
 - homeostasis.
 - metabolism.
- Which of the following is *not* a human organ system?
 - integumentary
 - muscular
 - epithelial
 - nervous
 - endocrine
- _____ means studying anatomy by touch.
 - Gross anatomy
 - Auscultation
 - Osculation
 - Palpation
 - Percussion
- The prefix *hetero-* means
 - same.
 - different.
 - both.
 - solid.
 - below.
- Cutting and separating tissues to reveal structural relationships is called _____.
 - _____ invented many components of the compound microscope and named the cell.
 - By the process of _____, a scientist predicts what the result of a certain experiment will be if his or her hypothesis is correct.
 - Physiological effects of a person's mental state are called _____ effects.
 - The tendency of the body to maintain stable internal conditions is called _____.
 - Blood pH averages 7.4 but fluctuates from 7.35 to 7.45. A pH of 7.4 can therefore be considered the _____ for this variable.
 - Self-corrective mechanisms in physiology are called _____ loops.
 - A/an _____ is the simplest body structure to be composed of two or more types of tissue.
 - Depth perception, or the ability to form three-dimensional images, is also called _____ vision.
 - Our hands are said to be _____ because they can encircle an object such as a branch or tool. The presence of an _____ thumb is important to this ability.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. The technique for listening to the sounds of the heart valves is auscultation.
2. The inventions of Carl Zeiss and Ernst Abbe are necessary to the work of a modern histopathologist.
3. Abnormal skin color or dryness could be one piece of diagnostic information gained by auscultation.
4. There are more organelles than cells in the body.
5. The word *scuba*, derived from the words *self-contained underwater breathing apparatus*, is an acronym.
6. Leeuwenhoek was a biologist who invented the simple microscope in order to examine organisms in lake water.
7. A scientific theory is just a speculation until someone finds the evidence to prove it.
8. In a typical clinical research study, volunteer patients are in the treatment group and the physicians and scientists who run the study constitute the control group.
9. The great mobility of the primate shoulder joint is an adaptation to the arboreal habitat.
10. Negative feedback usually has a negative (harmful) effect on the body.

Answers in appendix B

Testing Your Comprehension

1. Ellen is pregnant and tells one of her coworkers that she is scheduled to get a fetal sonogram. Her coworker Janet expresses some alarm and warns Ellen about the danger of exposing a fetus to X-rays. Discuss why you think Janet's concern is warranted or unwarranted.
2. Which of the characteristics of living things are possessed by an automobile? What bearing does this have on our definition of life?
3. About 1 out of every 120 live-born infants has a structural defect in the heart such as a hole between two heart chambers. Such infants often suffer pulmonary congestion and heart failure, and about one-third of them die as a result. Which of the major themes in this chapter does this illustrate? Explain your answer.
4. How might human anatomy be different today if the forerunners of humans had never inhabited the forest canopy?
5. Suppose you have been doing heavy yard work on a hot day and sweating profusely. You become very thirsty, so you drink a tall glass of lemonade. Explain how your thirst relates to the concept of homeostasis. Which type of feedback—positive or negative—does this illustrate?

Atlas Review 49

A.1 General Anatomical Terminology

Anatomical Position

Anatomical position is a stance in which a person stands erect with the feet flat on the floor and close together, arms at the sides, and the palms and face directed forward (fig. A.1). This position provides a precise and standard frame of reference for anatomical description and dissection. Without such a frame of reference, to say that a structure such as the sternum, thyroid gland, or aorta is “above the heart” would be vague, since it would depend

FIGURE A.1 Anatomical Position. The feet are flat on the floor and close together, the arms are held downward and supine, and the face is directed forward.

on whether the subject was standing, lying face down, or lying face up. From the perspective of anatomical position, however, we can describe the thyroid as *superior* to the heart, the sternum as *anterior* to it, and the aorta as *posterior* to it. These descriptions remain valid regardless of the subject’s position.

Unless stated otherwise, assume that all anatomical descriptions refer to anatomical position. Bear in mind that if a subject is facing you, the subject’s left will be on your right and vice versa. In most anatomical illustrations, for example, the left atrium of the heart appears toward the right side of the page, and although the appendix is located in the right lower quadrant of the abdomen, it appears on the left side of most illustrations.

In anatomical position, the forearm is **supinated**—that is, rotated so the palm faces anteriorly. When the forearm is **pronated**, the palm faces posteriorly (fig. A.2). The difference is particularly important in descriptions of anatomy of this region. In the supinated position, the two forearm bones (radius and ulna) are parallel and the radius is lateral to the ulna. In the pronated position, the radius and ulna cross; the radius is lateral to the ulna at the elbow but medial to it at the wrist. Descriptions of nerves, muscles, blood vessels, and other structures of the upper limb assume that the forearm is supinated. The similar terms **supine** and **prone** refer to positions in which the body is lying face up and face down, respectively, or in which the hand is turned with the palm facing up or down.

FIGURE A.2 Positions of the Forearm. When the forearm is supinated, the palm faces forward; when pronated, it faces rearward. Note the differences in the relationship of the radius to the ulna.

Anatomical Planes

Many views of the body are based on real or imaginary “slices” called sections or planes. *Section* implies an actual cut or slice to reveal internal anatomy, whereas *plane* implies an imaginary flat surface passing through the body. The three major anatomical planes are *sagittal*, *frontal*, and *transverse* (fig. A.3).

A **sagittal**¹ (SADJ-ih-tul) **plane** passes vertically through the body or an organ and divides it into right and left portions. The sagittal plane that divides the body or organ into equal halves is also called the **median (midsagittal) plane**. The head and pelvic organs are commonly illustrated on the median plane (fig. A.4a). Other sagittal planes parallel to this (off center) divide the body into unequal right and left portions.

A **frontal (coronal) plane** also extends vertically, but it is perpendicular to the sagittal plane and divides the body into anterior (front) and posterior (back) portions. A frontal section of the head, for example, would divide it into one portion bearing the face and another bearing the back of the head. Contents of the thoracic and abdominal cavities are most commonly shown in the frontal section (fig. A.4b).

FIGURE A.3 Anatomical Planes of Reference.

• What is another name for the particular sagittal plane shown here?

¹sagitta = arrow

FIGURE A.4 Views of the Body in the Three Primary Anatomical Planes. (a) Sagittal section of the pelvic region. (b) Frontal section of the thoracic region. (c) Transverse section of the head at the level of the eyes.

A **transverse (horizontal) plane** passes across the body or an organ perpendicular to its long axis (fig. A.4c); it divides the body or organ into superior (upper) and inferior (lower) portions. CT scans are typically transverse sections (see fig. 1.13c, p. 23).

Directional Terms

Table A.1 summarizes frequently used terms that describe the position of one structure relative to another. Intermediate directions are often indicated by combinations of these terms. For example, one structure may be described as *posterolateral* to another (toward the back and side). The dorsal surface of a structure is also called the **dorsum**; for example, the dorsum of your hand is what most people call the “back” of the hand. The dorsum of the foot is its upper surface (see fig. A.5b). The dorsal surface of the hand or foot is the surface that bears the nails.

Because of the bipedal, upright stance of humans, some directional terms have different meanings for humans than they do for other animals. *Anterior*, for example, denotes the region of the body that leads the way in normal locomotion. For a four-legged animal such as a cat, this is the head end of the body; for a human, however, it is the front of the chest and abdomen. Thus, *anterior* has the same meaning as *ventral* for a human

TABLE A.1 Directional Terms in Human Anatomy

Term	Meaning	Examples of Usage
Ventral	Toward the front* or belly	The aorta is <i>ventral</i> to the vertebral column.
Dorsal	Toward the back or spine	The vertebral column is <i>dorsal</i> to the aorta.
Anterior	Toward the ventral side*	The sternum is <i>anterior</i> to the heart.
Posterior	Toward the dorsal side*	The esophagus is <i>posterior</i> to the trachea.
Cephalic	Toward the head or superior end	The <i>cephalic</i> end of the embryonic neural tube develops into the brain.
Rostral	Toward the forehead or nose	The forebrain is <i>rostral</i> to the brainstem.
Caudal	Toward the tail or inferior end	The spinal cord is <i>caudal</i> to the brain.
Superior	Above	The heart is <i>superior</i> to the diaphragm.
Inferior	Below	The liver is <i>inferior</i> to the diaphragm.
Medial	Toward the median plane	The heart is <i>medial</i> to the lungs.
Lateral	Away from the median plane	The eyes are <i>lateral</i> to the nose.
Proximal	Closer to the point of attachment or origin	The elbow is <i>proximal</i> to the wrist.
Distal	Farther from the point of attachment or origin	The fingernails are at the <i>distal</i> ends of the fingers.
Superficial	Closer to the body surface	The skin is <i>superficial</i> to the muscles.
Deep	Farther from the body surface	The bones are <i>deep</i> to the muscles.

*In humans only; definition differs for other animals.

but not for a cat. *Posterior* denotes the region of the body that comes last in normal locomotion—the tail end of a cat but the dorsal side (back) of a human. These differences must be kept in mind when dissecting other animals for comparison to human anatomy.

A.2 Body Regions

Knowledge of the external anatomy and landmarks of the body is important in performing a physical examination and many other clinical procedures. For purposes of study, the body is divided into two major regions called the *axial* and *appendicular* regions. Smaller areas within the major regions are described in the following paragraphs and illustrated in figure A.5.

Axial Region

The **axial region** consists of the **head**, **neck (cervical² region)**, and **trunk**. The trunk is further divided into the **thoracic region** above the diaphragm and the **abdominal region** below it.

One way of referring to the locations of abdominal structures is to divide the region into quadrants. Two perpendicular lines intersecting at the umbilicus (navel)

divide the abdomen into a **right upper quadrant (RUQ)**, **right lower quadrant (RLQ)**, **left upper quadrant (LUQ)**, and **left lower quadrant (LLQ)** (fig. A.6a, b). The quadrant scheme is often used to describe the site of an abdominal pain or abnormality.

The abdomen also can be divided into nine regions defined by four lines that intersect like a tic-tac-toe grid (fig. A.6c, d). Each vertical line is called a *midclavicular line* because it passes through the midpoint of the clavicle (collarbone). The superior horizontal line is called the *subcostal³ line* because it connects the inferior borders of the lowest costal cartilages (cartilage connecting the tenth rib on each side to the inferior end of the sternum). The inferior horizontal line is called the *intertubercular⁴ line* because it passes from left to right between the tubercles (*anterior superior spines*) of the pelvis—two points of bone located about where the front pockets open on most pants. The three lateral regions of this grid, from upper to lower, are the **hypochondriac⁵**, **lumbar**, and **inguinal⁶ (iliac) regions**. The three medial regions from upper to lower are the **epigastric⁷**, **umbilical**, and **hypogastric (pubic) regions**.

³*sub* = below + *cost* = rib

⁴*inter* = between + *tubercul* = little swelling

⁵*hypo* = below + *chondr* = cartilage

⁶*inguin* = groin

⁷*epi* = above, over + *gastr* = stomach

²*cervic* = neck

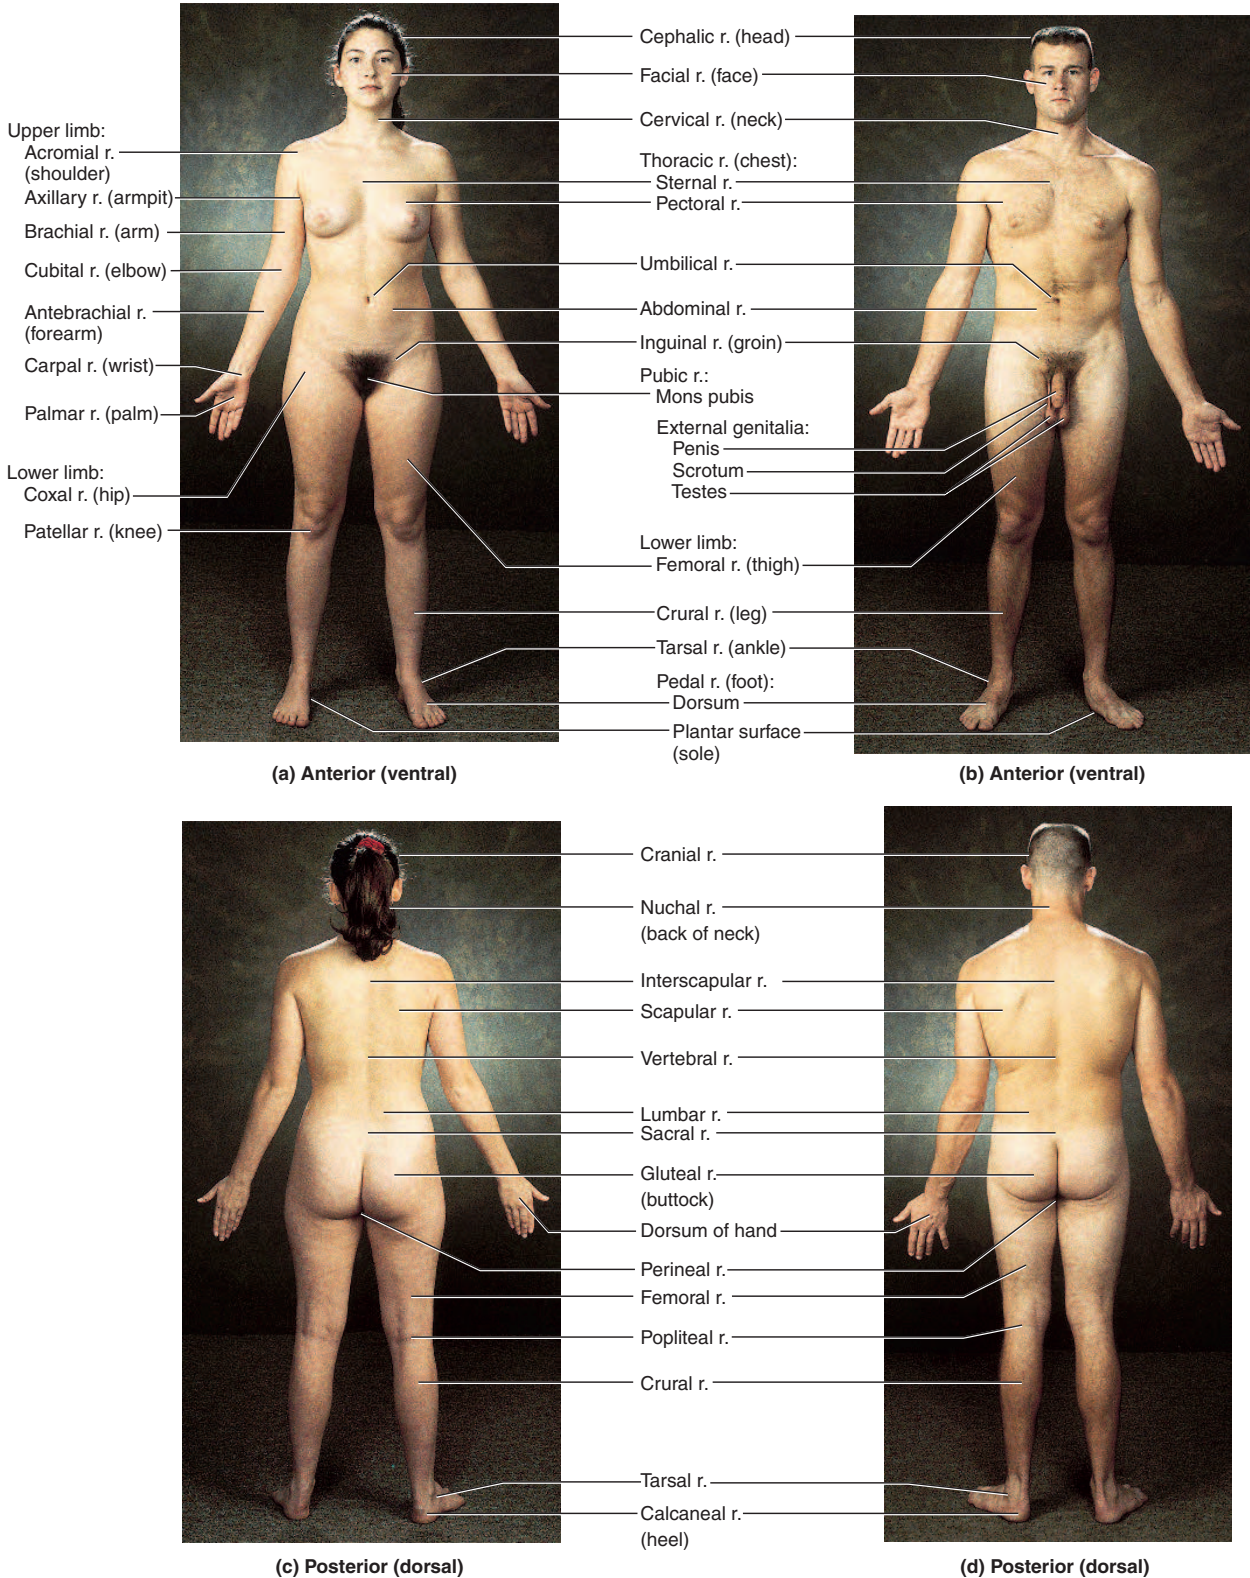

FIGURE A.5 The Adult Female and Male Bodies (r. = region).

FIGURE A.6 Four Quadrants and Nine Regions of the Abdomen. (a) External division into four quadrants. (b) Internal anatomy correlated with the four quadrants. (c) External division into nine regions. (d) Internal anatomy correlated with the nine regions.

Appendicular Region

The **appendicular** (AP-en-DIC-you-lur) **region** of the body consists of the **upper** and **lower limbs** (also called *appendages* or *extremities*). The upper limb includes the **arm (brachial region)** (BRAY-kee-ul), **forearm (antebrachial⁸ region)** (AN-teh-BRAY-kee-ul), **wrist (carpal region)**, **hand (manual region)**, and **fingers (digits)**. The lower limb includes the **thigh (femoral region)**, **leg (crural region)** (CROO-rul), **ankle (tarsal region)**, **foot (pedal region)**, and **toes (digits)**. In strict anatomical terms, *arm* refers only to that part of the upper limb between the shoulder and elbow. *Leg* refers only to that part of the lower limb between the knee and ankle.

The longitudinal portions of a limb between major joints are called **segments**. In the upper limb, the brachium is one segment, the antebrachium is another, and each finger is divided into three segments—proximal, middle, and distal (except that the thumb has only a proximal and a distal segment). The lower limb exhibits corresponding segments—the thigh, leg, and segments of the toes.

A.3 Body Cavities and Membranes

The body wall encloses multiple **body cavities**, each lined with a membrane and containing internal organs called **viscera** (VISS-er-uh) (singular, *viscus*⁹) (fig. A.7, table A.2).

FIGURE A.7 The Major Body Cavities.

The Cranial Cavity and Vertebral Canal

The **cranial** (CRAY-nee-ul) **cavity** is enclosed by the cranium (braincase) and contains the brain. The **vertebral canal** is enclosed by the vertebral column (backbone) and contains the spinal cord. The two are continuous with each other and are lined by three membrane layers called the **meninges** (meh-NIN-jeez). Among other functions, the meninges protect the delicate nervous tissue from the hard protective bone that encloses it.

The Thoracic Cavity

During embryonic development, a space called the **coelom** (SEE-loam) forms within the trunk. It subsequently becomes partitioned by a muscular sheet, the **diaphragm**, into a superior **thoracic cavity** and an inferior **abdominopelvic cavity**. Both cavities are lined with thin **serous membranes**, which secrete a lubricating film of moisture similar to blood serum (hence their name).

The thoracic cavity is divided by a thick wall called the **mediastinum**¹⁰ (ME-dee-ass-TY-num) (fig. A.7). This is the region between the lungs, extending from the base of the neck to the diaphragm. It is occupied by the heart, the major blood vessels connected to it, the esophagus, the trachea and bronchi, and a gland called the thymus.

⁸*ante* = fore, before + *brachi* = arm
⁹*viscus* = body organ

¹⁰*mediastinum* = in the middle

TABLE A.2 Body Cavities and Membranes		
Name of Cavity	Associated Viscera	Membranous Lining
Cranial cavity	Brain	Meninges
Vertebral canal	Spinal cord	Meninges
Thoracic cavity		
Pleural cavities (2)	Lungs	Pleurae
Pericardial cavity	Heart	Pericardium
Abdominopelvic cavity		
Abdominal cavity	Digestive organs, spleen, kidneys	Peritoneum
Pelvic cavity	Bladder, rectum, reproductive organs	Peritoneum

FIGURE A.8 Parietal and Visceral Layers of Double-Walled Membranes.

The heart is enfolded in a two-layered membrane called the **pericardium**.¹¹ The inner layer of the pericardium forms the surface of the heart itself and is called the **visceral** (VISS-er-ul) **pericardium**. The outer layer is called **parietal** (pa-RYE-eh-tul) **pericardium** (**pericardial sac**). It is separated from the visceral pericardium by a space called the **pericardial cavity** (fig. A.8a), which is lubricated by **pericardial fluid**.

The right and left sides of the thoracic cavity contain the lungs. Each is lined by a serous membrane called the **pleura**¹² (PLOOR-uh) (fig. A.8b). Like the pericardium,

the pleura has **visceral** (inner) and **parietal** (outer) layers. The **visceral pleura** forms the external surface of the lung, and the **parietal**¹³ **pleura** lines the inside of the rib cage. The narrow space between them is called the **pleural cavity** (see fig. A.19). It is lubricated by slippery **pleural fluid**.

Note that in both the pericardium and the pleura, the visceral layer of the membrane *covers* an organ surface and the parietal layer *lines* the inside of a body cavity. We will see this pattern elsewhere, including the abdominopelvic cavity.

¹¹peri = around + cardi = heart
¹²pleur = rib, side

¹³pariet = wall

FIGURE A.9 Transverse Section Through the Abdomen. Shows the peritoneum, peritoneal cavity (with most viscera omitted), and some retroperitoneal organs.

The Abdominopelvic Cavity

The abdominopelvic cavity consists of the **abdominal cavity** superiorly and the **pelvic cavity** inferiorly. These are separated by a bony landmark called the *brim* of the pelvis (see figs. A.16 and 8.35). The abdominal cavity contains most of the digestive organs as well as the kidneys and ureters. The pelvic cavity is markedly narrower and its lower end tilts posteriorly (see fig. A.7a). It contains the rectum, urinary bladder, urethra, and reproductive organs.

The abdominopelvic cavity contains a two-layered serous membrane called the **peritoneum**¹⁴ (PERR-ih-toe-NEE-um). Its outer layer, the **parietal peritoneum**, lines the cavity wall. The **visceral peritoneum** turns inward from the body wall, wraps around the abdominal viscera, binds them to the body wall or suspends them from it, and holds them in their proper place. The **peritoneal cavity** is the space between the parietal and visceral layers. It is lubricated by **peritoneal fluid**.

Some organs of the abdominal cavity lie against the posterior body wall and are covered by peritoneum only on the side facing the peritoneal cavity. They are said to have a **retroperitoneal**¹⁵ position (fig. A.9). These include the kidneys, ureters, adrenal glands, most of the pancreas, and abdominal portions of two major blood vessels—the aorta and inferior vena cava (see fig. A.15). Organs that are encircled by peritoneum and connected to the posterior body wall by peritoneal sheets are described as **intrapertoneal**.¹⁶

The intestines are suspended from the posterior (dorsal) abdominal wall by a translucent membrane called the **dorsal mesentery**¹⁷ (MESS-en-tare-ee), an infolding of the peritoneum. The dorsal mesentery of the large intestine is called the **mesocolon**. In some places, after wrapping around the intestines or other viscera, the mesentery continues toward the anterior body wall as the **ventral mesentery**. The most significant example of this is a fatty membrane called the **greater omentum**,¹⁸ which hangs like an apron from the inferolateral margin of the stomach and overlies the intestines (figs. A.10 and A.13). It is unattached at its inferior border and can be lifted to reveal the intestines. A smaller **lesser omentum** extends from the superomedial border of the stomach to the liver.

Where the visceral peritoneum meets an organ such as the stomach or small intestine, it divides and wraps around it, forming an outer layer of the organ called the **serosa** (seer-OH-sa) (fig. A.10). The visceral peritoneum thus consists of the mesenteries and serosae.

Potential Spaces

Some of the spaces between body membranes are considered to be **potential spaces**, so named because under normal conditions, the membranes are pressed firmly together and there is no actual space between them. The membranes are not physically attached, however, and under unusual conditions, they may separate and create a space filled with fluid or other matter. Thus there is

¹⁴*peri* = around + *tone* = stretched

¹⁵*retro* = behind

¹⁶*intra* = within

¹⁷*mes* = in the middle + *enter* = intestine

¹⁸*omentum* = covering

FIGURE A.10 Serous Membranes of the Abdominal Cavity. Sagittal section, left lateral view.

❖ Is the urinary bladder in the peritoneal cavity?

normally no actual space, but only a potential for membranes to separate and create one.

The pleural cavity is one example. Normally the parietal and visceral pleurae are pressed together without a gap between them, but under pathological conditions, air or serous fluid can accumulate between the membranes and open up a space. The internal cavity (*lumen*) of the uterus is another. In a nonpregnant uterus, the mucous membranes of opposite walls are pressed together so that there is no open space in the organ. In pregnancy, of course, a growing fetus occupies this space and pushes the mucous membranes apart.

A.4 Organ Systems

The human body has 11 **organ systems** (fig. A.11) and an immune system, which is better described as a population of cells than as an organ system. These systems are

classified in the following list by their principal functions, but this is an unavoidably flawed classification. Some organs belong to two or more systems—for example, the male urethra is part of both the urinary and reproductive systems; the pharynx is part of the respiratory and digestive systems; and the mammary glands can be considered part of the integumentary and female reproductive systems.

Protection, support, and movement

Integumentary system
Skeletal system
Muscular system

Internal communication and integration

Nervous system
Endocrine system

Fluid transport

Circulatory system
Lymphatic system

Defense

Immune system

Input and output

Respiratory system
Urinary system
Digestive system

Reproduction

Reproductive system

Some medical terms combine the names of two systems—for example, the *musculoskeletal system*, *cardiopulmonary system*, and *urogenital (genitourinary) system*. These terms serve to call attention to the close anatomical or physiological relationships between two systems, but these are not literally individual organ systems.

A.5 A Visual Survey of the Body

Figures A.12 through A.16 provide an overview of the anatomy of the trunk and internal organs of the thoracic and abdominopelvic cavities. Figures A.17 through A.22 are photographs of the cadaver showing the major organs of the dorsal and ventral body cavities.

ATLAS REVIEW

Review of Key Concepts

A.1 General Anatomical Terminology (p. 29)

1. Anatomical position provides a standard frame of reference so that directional terms remain consistent regardless of the orientation of the subject's body relative to the observer.
2. In anatomical position, the forearm is *supinated* (palms forward) rather than *pronated* (palms rearward). The feet are close together and flat on the floor, arms to the sides, and the head and eyes directed forward.
3. Three mutually perpendicular planes through the body are the *sagittal*, *frontal*, and *transverse planes*. The sagittal plane that divides the body or an organ into equal halves is called the median plane.
4. The positions of structures relative to each other are described by standard directional terms defined in table A.1. Some of these definitions are different for a human than for four-legged animals. Such differences must be kept in mind when doing laboratory animal dissections for comparison to humans.

A.2 Body Regions (p. 31)

1. The *axial region* of the body consists of the head, neck, and trunk. The trunk is divided into the *thoracic* and *abdominal regions*, separated by the diaphragm.
2. The abdomen can be divided into four quadrants (right and left, upper and lower) or nine smaller regions (the *hypochondriac*, *lumbar*, and *inguinal* regions on each side, and the *epigastric*, *umbilical*, and *hypogastric* regions medially). These divisions are useful for anatomical and clinical descriptions of the locations of organs, pain, or other abnormalities.
3. The *appendicular regions* are the upper and lower limbs. From proximal to distal, the upper limb is divided into the arm proper (*brachium*), forearm (*antebrachium*), wrist (*carpus*), hand (*manus*), and fingers (*digits*). The lower limb is divided, from proximal to distal, into the thigh (*femoral region*), leg proper (*crus*), ankle (*tarsus*), foot (*pes*),

and toes (*digits*). Each limb is divided along its length into *segments* separated by joints such as the elbow, knee, and knuckles.

A.3 Body Cavities and Membranes (p. 34)

1. The major body cavities are the cranial cavity, vertebral canal, thoracic cavity, and abdominopelvic cavity. Each is lined by a membrane and contains organs collectively called the *viscera*.
2. The *cranial cavity* is enclosed in the cranium and contains the brain. The *vertebral canal* is enclosed by the vertebral column and contains the spinal cord. These cavities are lined by three membranes called the *meninges*.
3. The *thoracic cavity* develops from the embryonic *coelom* and lies superior to the diaphragm. Its median portion, from the base of the neck to the diaphragm, is the *mediastinum*, which contains the heart; some major blood vessels; and the esophagus, trachea, bronchi, and thymus.
4. The heart is enfolded in a double-walled serous membrane, the *pericardium*. Its inner layer, the *visceral pericardium*, forms the heart surface. This is separated from the outer layer, the *parietal pericardium*, by the *pericardial cavity*. The cavity is lubricated by *pericardial fluid*.
5. Each lung is enfolded in a double-walled serous membrane, the *pleura*. The *visceral pleura* forms the lung surface, and the *parietal pleura* lines the inside of the rib cage. The *pleural cavity* between these layers is lubricated by *pleural fluid*.
6. The *abdominopelvic cavity* consists of the abdominal cavity above the pelvic brim and the pelvic cavity below it. It is lined by a serous membrane called the *peritoneum*. The *parietal peritoneum* forms the inner lining of the body wall, and the *visceral peritoneum* wraps around the abdominal viscera, suspends them from the wall, and holds them in place. The cavity is lubricated by *peritoneal fluid*.

7. *Retroperitoneal* organs lie against the dorsal body wall and are covered by peritoneum on only one side. *Intraperitoneal* organs lie more loosely within the abdominal cavity. They are encircled on all sides by peritoneum and are suspended from the body wall by peritoneal sheets.
8. The *dorsal mesentery* is a peritoneal sheet that turns inward from the posterior body wall and extends to the abdominal viscera. The dorsal mesentery of the colon is the *mesocolon*. The *ventral mesentery* continues beyond the viscera toward the anterior body wall. The major ventral mesenteries are the *greater omentum* and *lesser omentum*.
9. Where it wraps around viscera such as the stomach and intestines, the peritoneum forms the outer surface of the organ, called the *serosa*.
10. Some body membranes are pressed closely together and enclose only a *potential space* between them. Potential spaces can open up and create actual spaces when air, liquid, or other matter accumulates in them. The pleural cavity and lumen of the uterus are examples of potential spaces.

A.4 Organ Systems (p. 37)

1. The body has 11 organ systems. Some organs play roles in two or more of these systems.
2. The *integumentary*, *skeletal*, and *muscular* systems provide protection, support, and movement.
3. The *nervous* and *endocrine* systems provide internal communication and integration.
4. The *circulatory* and *lymphatic* systems provide fluid transport.
5. The *respiratory*, *urinary*, and *digestive* systems provide for the input of gases and nutrients and the output of metabolic wastes.
6. The *reproductive* system produces offspring and thus serves for continuity of the species.
7. The *immune system* is not an organ system but a population of cells that colonize the various organ systems and provide defense against pathogens.

Testing Your Recall

- Which of the following is *not* an essential part of anatomical position?
 - feet together
 - feet flat on the floor
 - forearms supinated
 - mouth closed
 - arms down to the sides
- A ring-shaped section of the small intestine would be a _____ section.
 - sagittal
 - coronal
 - transverse
 - frontal
 - median
- The tarsal region is _____ to the popliteal region.
 - medial
 - superficial
 - superior
 - dorsal
 - distal
- The greater omentum is _____ to the small intestine.
 - posterior
 - parietal
 - deep
 - superficial
 - proximal
- A _____ line passes through the sternum, umbilicus, and mons pubis.
 - central
 - proximal
 - midclavicular
 - midsagittal
 - intertubercular
- The _____ region is immediately medial to the coxal region.
 - inguinal
 - hypochondriac
 - umbilical
 - popliteal
 - cubital
- Which of the following regions is not part of the upper limb?
 - plantar
 - carpal
 - cubital
 - brachial
 - palmar
- Which of these organs is within the peritoneal cavity?
 - urinary bladder
 - kidneys
 - heart
 - liver
 - brain
- In which area do you think pain from the gallbladder would be felt?
 - umbilical region
 - right upper quadrant
 - hypogastric region
 - left hypochondriac region
 - left lower quadrant
- Which organ system regulates blood volume, controls acid–base balance, and stimulates red blood cell production?
 - digestive system
 - lymphatic system
 - nervous system
 - urinary system
 - circulatory system
- The forearm is said to be _____ when the palms are facing forward.
- The superficial layer of the pleura is called the _____ pleura.
- The right and left pleural cavities are separated by a thick wall called the _____.
- The back of the neck is the _____ region.
- The manus is more commonly known as the _____ and the pes is more commonly known as the _____.
- The cranial cavity is lined by membranes called the _____.
- Organs that lie within the abdominal cavity but not within the peritoneal cavity are said to have a _____ position.
- The sternal region is _____ to the pectoral region.
- The pelvic cavity can be described as _____ to the abdominal cavity in position.
- The anterior pit of the elbow is the _____ region, and the corresponding (but posterior) pit of the knee is the _____ fossa.

Answers in appendix B

True or False?

Determine which five of the following statements are false, and briefly explain why.

- A single sagittal section of the body can pass through one lung but not through both.
- It would be possible to see both eyes in one frontal section of the head.
- The knee is both superior and proximal to the tarsal region.
- The diaphragm is posterior to the lungs.
- The esophagus is inferior to the stomach.
- The liver is in the lumbar region.
- The heart is in the mediastinum.
- Both kidneys could be shown in a single coronal section of the body.
- The peritoneum lines the inside of the stomach and intestines.
- The sigmoid colon is in the lower right quadrant of the abdomen.

Answers in appendix B

Testing Your Comprehension

- Identify which anatomical plane—sagittal, frontal, or transverse—is the only one that could *not* show (a) both the brain and tongue, (b) both eyes, (c) both the hypogastric and gluteal regions, (d) both kidneys, (e) both the sternum and vertebral column, and (f) both the heart and uterus.
- Laypeople often misunderstand anatomical terminology. What do you think people really mean when they say they have “planter’s warts”?
- Name one structure or anatomical feature that could be found in each of the following locations relative to the ribs: medial, lateral, superior, inferior, deep, superficial, posterior, and anterior. Try not to use the same example twice.
- Based on the illustrations in this atlas, identify an internal organ that is (a) in the upper left quadrant and retroperitoneal; (b) in the lower right quadrant of the peritoneal cavity; (c) in the hypogastric region; (d) in the right hypochondriac region; and (e) in the pectoral region.
- Why do you think people with imaginary illnesses came to be called hypochondriacs?

INSIGHTS

2.1 Medical History: Radiation and Madame Curie 55

2.2 Clinical Application: pH and Drug Action 64

2.3 Clinical Application: “Good” and “Bad” Cholesterol 75

2.4 Clinical Application: The Diagnostic Use of Isoenzymes 78

2.5 Clinical Application: Anabolic-Androgenic Steroids 83

Why is too much sodium or cholesterol harmful? Why does an iron deficiency cause anemia and an iodine deficiency cause a goiter? Why does a pH imbalance make some drugs less effective? Why do some pregnant women suffer convulsions after several days of vomiting? How can radiation cause cancer as well as cure it?

None of these questions can be answered, nor would the rest of this book be intelligible, without understanding the chemistry of life. A little knowledge of chemistry can help you choose a healthy diet, use medications more wisely, avoid worthless health fads and frauds, and explain treatments and procedures to your patients or clients. Thus, we begin our study of the human body with basic chemistry, the simplest level of the body's structural organization.

We will progress from general chemistry to **biochemistry**, study of the molecules that compose living organisms—especially molecules unique to living things, such as carbohydrates, fats, proteins, and nucleic acids. Most people have at least heard of these and it is common knowledge that we need proteins, fats, carbohydrates, vitamins, and minerals in our diet, and that we should avoid consuming too much saturated fat and cholesterol. But most people have only a vague concept of what these molecules are, much less how they function in the body. Such knowledge is very helpful in matters of personal fitness and patient education and is essential to the comprehension of the rest of this book.

The Chemical Elements

A chemical **element** is the simplest form of matter to have unique chemical properties. Water, for example, has unique properties, but it can be broken down into two elements, hydrogen and oxygen, that have unique chemical properties of their own. If we carry this process any further, however, we find that hydrogen and oxygen are made of protons, neutrons, and electrons—and none of these are unique. A proton of gold is identical to a proton of oxygen. Hydrogen and oxygen are the simplest chemically unique components of water and are thus elements.

Each element is identified by an *atomic number*, the number of protons in its nucleus. The atomic number of carbon is 6 and that of oxygen is 8, for example. The periodic table of the elements (see appendix C) arranges the elements in order by their atomic numbers. The elements are represented by one- or two-letter symbols, usually based on their English names: C for carbon, Mg for magnesium, Cl for chlorine, and so forth. A few symbols are based on Latin names, such as K for potassium (*kali*um), Na for sodium (*na*trium), and Fe for iron (*fer*rum).

There are 91 naturally occurring elements on earth, 24 of which play normal physiological roles in humans. Table 2.1 groups these 24 according to their abundance in the body. Six of them account for 98.5% of the body's weight: oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus. The next 0.8% consists of another 6 elements: sulfur, potassium, sodium, chlorine, magnesium, and iron. The remaining 12 account for 0.7% of body weight, and no one of them accounts for more than 0.02%; thus they are known as **trace elements**. Despite their minute quantities, trace elements play vital roles in physiology. Other elements without natural physiological roles can contaminate the body and severely disrupt its functions, as in heavy-metal poisoning with lead or mercury.

Several of these elements are classified as **minerals**—inorganic elements that are extracted from the soil by plants and passed up the food chain to humans and other organisms. Minerals constitute about 4% of the human body by weight. Nearly three-quarters of this is Ca and P; the rest is mainly Cl, Mg, K, Na, and S. Minerals contribute significantly to body structure. The bones and teeth consist partly of crystals of calcium, phosphate, magnesium, fluoride, and sulfate ions. Many proteins include sulfur, and phosphorus is a major component of nucleic acids, ATP, and cell membranes. Minerals also enable enzymes and other organic molecules to function. Iodine is a component of thyroid hormone; iron is a component of hemoglobin; and some enzymes function only when manganese, zinc, copper, or other minerals are bound to them. The electrolytes needed for nerve and muscle function are mineral salts. The biological roles of minerals are discussed in more detail in chapters 24 and 26.

2.1 Atoms, Ions, and Molecules

Objectives

When you have completed this section, you should be able to

- name the chemical elements of the body from their chemical symbols;
- distinguish between chemical elements and compounds;
- state the functions of minerals in the body;
- explain the basis for radioactivity and the types and hazards of ionizing radiation;
- distinguish between ions, electrolytes, and free radicals; and
- define the types of chemical bonds.

TABLE 2.1		Elements of the Human Body	
Name	Symbol	Percentage of Body Weight	
Major Elements (Total 98.5%)			
Oxygen	O	65.0	
Carbon	C	18.0	
Hydrogen	H	10.0	
Nitrogen	N	3.0	
Calcium	Ca	1.5	
Phosphorus	P	1.0	
Lesser Elements (Total 0.8%)			
Sulfur	S	0.25	
Potassium	K	0.20	
Sodium	Na	0.15	
Chlorine	Cl	0.15	
Magnesium	Mg	0.05	
Iron	Fe	0.006	
Trace Elements (Total 0.7%)			
Chromium	Cr	Molybdenum	Mo
Cobalt	Co	Selenium	Se
Copper	Cu	Silicon	Si
Fluorine	F	Tin	Sn
Iodine	I	Vanadium	V
Manganese	Mn	Zinc	Zn

Atomic Structure

In the fifth century BCE, the Greek philosopher Democritus reasoned that we can cut matter such as a gold nugget into smaller and smaller pieces, but there must ultimately be particles so small that nothing could cut them. He called these imaginary particles atoms¹ (“indivisible”). Atoms were only a philosophical concept until 1803, when English chemist John Dalton began to develop an atomic theory based on experimental evidence. In 1913, Danish physicist Niels Bohr proposed a model of atomic structure similar to planets orbiting the sun (figs. 2.1 and 2.2). Although this *planetary model* is too simple to account for many of the properties of atoms, it remains useful for elementary purposes.

At the center of an atom is the *nucleus*, composed of protons and neutrons. **Protons (p⁺)** have a single positive charge and **neutrons (n⁰)** have no charge. Each proton or neutron weighs approximately 1 *atomic mass unit (amu)*, defined as one-twelfth the mass of an atom of carbon-12. The *atomic mass* of an element is approximately equal to its total number of protons and neutrons.

Around the nucleus are one or more concentric clouds of **electrons (e⁻)**, tiny particles with a single negative charge and very low mass. It takes 1,836 electrons to equal 1 amu, so for most purposes we can disregard their mass. A person who weighs 64 kg (140 lb) contains less than 24 g (1 oz) of electrons. This hardly means that we can ignore electrons, however. They determine the chemical properties of an atom, thereby governing what molecules can exist and what chemical reactions can occur. The number of electrons equals the number of protons, so their charges cancel each other and an atom is electrically neutral.

¹a = not + tom = cut

FIGURE 2.1 Bohr Planetary Models of Four Representative Elements. Note the filling of electron shells as atomic number increases (p⁺ = protons; e⁻ = electrons; n⁰ = neutrons).

Will potassium have a greater tendency to give up an electron or to take one away from another atom?

54 PART ONE Organization of the Body

FIGURE 2.2 Isotopes of Hydrogen. The three isotopes differ only in the number of neutrons present (p^+ = protons; n^0 = neutrons; e^- = electrons).

Electrons swarm about the nucleus in concentric regions called *electron shells* (*energy levels*). The more energy an electron has, the farther away from the nucleus its orbit lies. Each shell holds a limited number of electrons (fig. 2.1). The one closest to the nucleus holds a maximum of 2 electrons, the second one holds a maximum of 8, and the third holds a maximum of 18. The outermost shell never holds more than 8 electrons, but a shell can acquire more electrons after another one, farther out, begins to fill. Thus, the third shell will hold 18 electrons only in atoms with four or more shells. The elements known to date have up to seven electron shells, but those ordinarily involved in human physiology do not exceed four.

The electrons of the outermost shell, called **valence electrons**, determine the chemical bonding properties of an atom. An atom tends to bond with other atoms that will fill its outer shell and produce a stable number of valence electrons. A hydrogen atom, with only one electron shell and one electron (fig. 2.2), tends to react with other atoms that provide another electron and fill this shell with a stable number of two electrons. All other atoms react in ways that produce eight electrons in the valence shell. This tendency is called the *octet rule* (*rule of eights*).

Isotopes and Radioactivity

Dalton believed that every atom of an element was identical. We now know, however, that all elements have varieties called **isotopes**,² which differ from one another

only in number of neutrons and therefore in atomic mass. Most hydrogen atoms, for example, have only one proton; this isotope is symbolized ${}^1\text{H}$. Hydrogen has two other isotopes: *deuterium* (${}^2\text{H}$) with one proton and one neutron, and *tritium* (${}^3\text{H}$) with one proton and two neutrons (fig. 2.2). Over 99% of carbon atoms have an atomic mass of 12 (6p^+ , 6n^0) and are called carbon-12 (${}^{12}\text{C}$), but a small percentage of carbon atoms are ${}^{13}\text{C}$, with seven neutrons, and ${}^{14}\text{C}$, with eight. All isotopes of a given element behave the same chemically. Deuterium (${}^2\text{H}$), for example, reacts with oxygen the same way ${}^1\text{H}$ does to produce water.

The *atomic weight* of an element accounts for the fact that an element is a mixture of isotopes. If all carbon were ${}^{12}\text{C}$, the atomic weight of carbon would be the same as its atomic mass, 12.000. But since a sample of carbon also contains small amounts of the heavier isotopes ${}^{13}\text{C}$ and ${}^{14}\text{C}$, the atomic weight is slightly higher, 12.011.

Although different isotopes of an element exhibit identical chemical behavior, they differ in physical behavior. Many of them are unstable and *decay* (break down) to more stable isotopes by giving off radiation. Unstable isotopes are therefore called **radioisotopes**, and the process of decay is called **radioactivity** (see Insight 2.1). Every element has at least one radioisotope. Oxygen, for example, has three stable isotopes and five radioisotopes. All of us contain radioisotopes such as ${}^{14}\text{C}$ and ${}^{40}\text{K}$ —that is, we are all mildly radioactive!

Many forms of radiation, such as light and radio waves, have low energy and are harmless. High-energy radiation, however, ejects electrons from atoms, converting atoms to ions; thus it is called **ionizing radiation**. It destroys molecules and produces dangerous free radicals and ions in human tissues. In high doses, ionizing radiation is quickly fatal. In lower doses, it can be *mutagenic* (causing mutations in DNA) and *carcinogenic* (triggering cancer as a result of mutation).

Examples of ionizing radiation include ultraviolet rays, X-rays, and three kinds of radiation produced by nuclear decay: *alpha* (α) *particles*, *beta* (β) *particles*, and *gamma* (γ) *rays*. An alpha particle is composed of two protons and two neutrons (equivalent to a helium nucleus), and a beta particle is a free electron. Alpha particles are too large to penetrate the skin, and beta particles can penetrate only a few millimeters. They are relatively harmless when emitted by sources outside the body, but they are very dangerous when emitted by radioisotopes that have gotten into the body. Strontium-90 (${}^{90}\text{Sr}$), for example, has been released by nuclear accidents and the atmospheric testing of nuclear weapons. It settles onto pastures and contaminates cow's milk. In the body, it behaves chemically like calcium, becoming incorporated into the bones, where it emits beta particles for years. Uranium and plutonium emit electromagnetic gamma rays, which have high energy and penetrating power. Gamma rays are very dangerous even when emitted by sources outside the body.

²*iso* = same + *top* = place (same position in the periodic table)

INSIGHT 2.1 Medical History**Radiation and Madame Curie**

In 1896, French scientist Henri Becquerel (1852–1908) discovered that uranium darkened photographic plates through several thick layers of paper. Marie Curie (1867–1934) and Pierre Curie (1859–1906), her husband, discovered that polonium and radium did likewise. Marie Curie coined the term *radioactivity* for the emission of energy by these elements. Becquerel and the Curies shared a Nobel Prize in 1903 for this discovery.

Marie Curie (fig. 2.3) was not only the first woman in the world to receive a Nobel Prize but also the first woman in France even to receive a Ph.D. She received a second Nobel Prize in 1911 for further work in radiation. Curie crusaded to train women for careers in science, and in World War I, she and her daughter, Irène Joliot-Curie (1897–1956), trained physicians in the use of X-ray machines. Curie pioneered radiation therapy for breast and uterine cancer.

In the wake of such discoveries, radium was regarded as a wonder drug. Unaware of its danger, people drank radium tonics and flocked to health spas to bathe in radium-enriched waters. Marie herself suffered extensive damage to her hands from handling radioactive minerals and died of radiation poisoning at age 67. The following year, Irène and her husband, Frédéric Joliot (1900–1958), were awarded a Nobel Prize for work in artificial radioactivity and synthetic radioisotopes. Apparently also a martyr to her science, Irène died of leukemia, possibly induced by radiation exposure.

FIGURE 2.3 Marie Curie (1867–1934). This portrait was made in 1911, when Curie received her second Nobel Prize.

Each radioisotope has a characteristic **physical half-life**, the time required for 50% of its atoms to decay to a more stable state. One gram of ^{90}Sr , for example, would be half gone in 28 years. In 56 years, there would still be 0.25 g left, in 84 years 0.125 g, and so forth. Many radioisotopes are much longer-lived. The half-life of ^{40}K , for example, is 1.3 billion years. Nuclear power plants produce hundreds of radioisotopes that will be intensely radioactive for at least 10,000 years—longer than the life of any disposal container yet conceived.

The **biological half-life** of a radioisotope is the time required for half of it to disappear from the body. Some of it is lost by radioactive decay and even more of it by excretion from the body. Cesium-137, for example, has a physical half-life of 30 years but a biological half-life of only 17 days. Chemically, it behaves like potassium; it is quite mobile and rapidly excreted by the kidneys.

There are several ways to measure the intensity of ionizing radiation, the amount absorbed by the body, and its biological effects. To understand the units of measurement requires a grounding in physics beyond the scope of this book, but the standard international (SI) unit of radiation exposure is the *sievert*³ (*Sv*), which takes into account the type and intensity of radiation and its biological effect.

Doses of 5 Sv or more are usually fatal. The average American receives about 3.6 millisieverts (mSv) per year in *background radiation* from natural sources and another 0.6 mSv from artificial sources. The most significant natural source is *radon*, a gas that is produced by the decay of uranium in the earth and that may accumulate in buildings to unhealthy levels. Artificial sources of radiation exposure include medical X-rays, radiation therapy, and consumer products such as color televisions, smoke detectors, and luminous watch dials. Such voluntary exposure must be considered from the standpoint of its risk-to-benefit ratio. The benefits of a smoke detector or mammogram far outweigh the risk from the low levels of radiation involved. Radiation therapists and radiologists face a greater risk than their patients, however, and astronauts and airline flight crews receive more than average exposure. U.S. federal standards set a limit of 50 mSv/year as acceptable occupational exposure to ionizing radiation.

Ions, Electrolytes, and Free Radicals

Ions are charged particles with unequal numbers of protons and electrons. Elements with one to three valence electrons tend to give them up, and those with four to seven electrons tend to gain more. If an atom of the first kind is exposed to an atom of the second, electrons may transfer from one to the other and turn both of them into

³Rolf Maximillian Sievert (1896–1966), Swedish radiologist

ions. This process is called *ionization*. The particle that gains electrons acquires a negative charge and is called an **anion** (AN-eye-on). The one that loses electrons acquires a positive charge (because it then has a surplus of protons) and is called a **cation** (CAT-eye-on).

Consider, for example, what happens when sodium and chlorine meet (fig. 2.4). Sodium has three electron shells with a total of 11 electrons: 2 in the first shell, 8 in the second, and 1 in the third. If it gives up the electron in the third shell, its second shell becomes the valence shell and has the stable configuration of 8 electrons. Chlorine has 17 electrons: 2 in the first shell, 8 in the second, and 7 in the third. If it can gain one more electron, it can fill the third shell with 8 electrons and become stable. Sodium and chlorine seem “made for each other”—one needs to lose an electron and the other needs to gain one. This is just what they do. When they interact, an electron transfers from sodium to chlorine. Now, sodium has 11 protons in its nucleus but only 10 electrons. This imbalance gives it a positive charge, so we symbolize the

② The charged sodium ion (Na⁺) and chloride ion (Cl⁻) that result

FIGURE 2.4 Ionization.

sodium ion Na⁺. Chlorine has been changed to the chloride ion with a surplus negative charge, symbolized Cl⁻.

Some elements exist in two or more ionized forms. Iron, for example, has ferrous (Fe²⁺) and ferric (Fe³⁺) ions. Note that some ions have a single positive or negative charge, whereas others have charges of ± 2 or ± 3 because they gain or lose more than one electron. The charge on an ion is called its *valence*. Ions are not always single atoms that have become charged; some are groups of atoms—phosphate (PO₄³⁻) and bicarbonate (HCO₃⁻) ions, for example.

Ions with opposite charges are attracted to each other and tend to follow each other through the body. Thus, when Na⁺ is excreted in the urine, Cl⁻ tends to follow it. The attraction of cations and anions to each other is important in maintaining the excitability of muscle and nerve cells, as we shall see in chapters 11 and 12.

Electrolytes are salts that ionize in water and form solutions capable of conducting electricity (table 2.2). We can detect electrical activity of the muscles, heart, and brain with electrodes on the skin because electrolytes in the body fluids conduct electrical currents from these organs to the skin surface. Electrolytes are important for their chemical reactivity (as when calcium phosphate becomes incorporated into bone), osmotic effects (influence on water content and distribution in the body), and electrical effects (which are essential to nerve and muscle function). Electrolyte balance is one of the most important considerations in patient care. Electrolyte imbalances have effects ranging from muscle cramps and brittle bones to coma and cardiac arrest.

Free radicals are chemical particles with an odd number of electrons. For example, oxygen normally exists as a stable molecule composed of two oxygen atoms, O₂; but if an additional electron is added, it becomes a free radical called the *superoxide anion*, O₂^{-•}. Free radicals are represented with a dot to symbolize the odd electron.

Free radicals are produced by some normal metabolic reactions of the body (such as the ATP-producing oxidation reactions in mitochondria, and a reaction that some white blood cells use to kill bacteria); by radiation (such as ultraviolet radiation and X-rays); and by chemicals (such as carbon tetrachloride, a cleaning solvent, and nitrites, present as preservatives in some wine, meat, and other foods). They are

TABLE 2.2

Major Electrolytes and the Ions Released by their Dissociation

Electrolyte		Cation	Anion
Calcium chloride (CaCl ₂)	→	Ca ²⁺	2 Cl ⁻
Disodium phosphate (Na ₂ HPO ₄)	→	2 Na ⁺	HPO ₄ ²⁻
Magnesium chloride (MgCl ₂)	→	Mg ²⁺	2 Cl ⁻

Sodium bicarbonate (NaHCO ₃)	→	Na ⁺	HCO ₃ ⁻
Sodium chloride (NaCl)	→	Na ⁺	Cl ⁻

short-lived and combine quickly with molecules such as fats, proteins, and DNA, converting them into free radicals and triggering chain reactions that destroy still more molecules. Among the damages caused by free radicals are some forms of cancer and myocardial infarction, the death of heart tissue. One theory of aging is that it results in part from life-long cellular damage by free radicals.

Because free radicals are so common and destructive, we have multiple mechanisms for neutralizing them. An **antioxidant** is a chemical that neutralizes free radicals. The body produces an enzyme called *superoxide dismutase (SOD)*, for example, that converts superoxide into oxygen and hydrogen peroxide. Selenium, vitamin E (α -tocopherol), vitamin C (ascorbic acid), and carotenoids (such as β -carotene) are some antioxidants obtained from the diet. Dietary deficiencies of antioxidants have been associated with increased incidence of heart attacks, sterility, muscular dystrophy, and other disorders.

Molecules and Chemical Bonds

Molecules are chemical particles composed of two or more atoms united by a chemical bond. The atoms may be identical, as in nitrogen (N_2), or different, as in glucose ($C_6H_{12}O_6$). Molecules composed of two or more different elements are called **compounds**. Oxygen (O_2) and carbon dioxide (CO_2) are both molecules, because they consist of at least two atoms; but only CO_2 is a compound, because it has atoms of two different elements.

Molecules can be represented by *molecular formulae* that identify their constituent elements and show how many atoms of each are present. Molecules with identical molecular formulae but different arrangements of their atoms are called **isomers**⁴ of each other. For example, both ethanol (grain alcohol) and ethyl ether have the molecular formula C_2H_6O , but they are certainly not interchangeable! To show the difference between them, we use *structural formulae* that show the location of each atom (fig. 2.5).

The **molecular weight (MW)** of a compound is the sum of the atomic weights of its atoms. Rounding the atomic mass units (amu) to whole numbers, we can calculate the approximate MW of glucose ($C_6H_{12}O_6$), for example, as

$$\begin{array}{rclcl} 6 & \text{C atoms} & \times & 12 \text{ amu each} & = & 72 \text{ amu} \\ 12 & \text{H atoms} & \times & 1 \text{ amu each} & = & 12 \text{ amu} \\ 6 & \text{O atoms} & \times & 16 \text{ amu each} & = & 96 \text{ amu} \\ \hline & \text{Molecular weight (MW)} & & & = & 180 \text{ amu} \end{array}$$

Molecular weight is needed to compute some measures of concentration, as we shall see later.

A molecule is held together, and molecules are attracted to one another, by forces called **chemical bonds**. The bonds of greatest physiological interest are *ionic bonds*, *covalent bonds*, *hydrogen bonds*, and *van der Waals forces* (table 2.3).

	Structural formulae	Condensed structural formulae	Molecular formulae
Ethanol	$\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ \text{H}-\text{C}-\text{C}-\text{OH} \\ \quad \\ \text{H} \quad \text{H} \end{array}$	CH_3CH_2OH	C_2H_6O
Ethyl ether	$\begin{array}{c} \text{H} \quad \quad \text{H} \\ \quad \quad \\ \text{H}-\text{C}-\text{O}-\text{C}-\text{H} \\ \quad \quad \\ \text{H} \quad \quad \text{H} \end{array}$	CH_3OCH_3	C_2H_6O

FIGURE 2.5 Structural Isomers, Ethanol and Ethyl Ether.

The molecular formulae are identical, but the structures and chemical properties are different.

An **ionic bond** is the attraction of a cation to an anion. Sodium (Na^+) and chloride (Cl^-) ions, for example, are attracted to each other and form the compound sodium chloride ($NaCl$), common table salt. Ionic compounds can be composed of more than two ions. Calcium has two

TABLE 2.3		Types of Chemical Bonds
Bond Type	Definition and Remarks	
Ionic bond	Relatively weak attraction between an anion and a cation. Easily disrupted in water, as when salt dissolves.	
Covalent bond	Sharing of one or more pairs of electrons between nuclei.	
Single covalent	Sharing of one electron pair.	
Double covalent	Sharing of two electron pairs. Often occurs between carbon atoms, between carbon and oxygen, and between carbon and nitrogen.	
Nonpolar covalent	Covalent bond in which electrons are equally attracted to both nuclei. May be single or double. Strongest type of chemical bond.	
Polar covalent	Covalent bond in which electrons are more attracted to one nucleus than to the other, resulting in slightly positive and negative regions in one molecule. May be single or double.	
Hydrogen bond	Weak attraction between polarized molecules or between polarized regions of the same molecule. Important in the three-dimensional folding and coiling of large molecules. Easily disrupted by temperature and pH changes.	
Van der Waals force	Weak, brief attraction due to random disturbances in the electron clouds of adjacent atoms. Weakest of all bonds.	

⁴iso = same + mer = part

valence electrons. It can become stable by donating one electron to one chlorine atom and the other electron to another chlorine, thus producing a calcium ion (Ca^{2+}) and two chloride ions. The result is calcium chloride, CaCl_2 . Ionic bonds are weak and easily dissociate (break up) in the presence of something more attractive, such as water. The ionic bonds of NaCl break down easily as salt dissolves in water, because both Na^+ and Cl^- are more attracted to water molecules than they are to each other.

Think About It

Do you think ionic bonds are common in the human body? Explain your answer.

Covalent bonds form by the sharing of electrons. For example, two hydrogen atoms share valence electrons to form a hydrogen molecule, H_2 (fig. 2.6a). The two electrons, one donated by each atom, swarm around both nuclei in a dumbbell-shaped cloud. A *single covalent bond* is the sharing of a single pair of electrons. It is symbolized by a single line between atomic symbols, for example $\text{H}-\text{H}$. A *double covalent bond* is the sharing of two pairs of electrons. In carbon dioxide, for example, a central carbon atom shares two electron pairs with each oxygen atom. Such bonds are symbolized by two lines—for example, $\text{O}=\text{C}=\text{O}$ (fig. 2.6b).

When shared electrons spend approximately equal time around each nucleus, they form a *nonpolar covalent*

FIGURE 2.6 Covalent Bonding. (a) Two hydrogen atoms share a single pair of electrons to form a hydrogen molecule. (b) A carbon dioxide molecule, in which a carbon atom shares two pairs of electrons with each oxygen atom, forming double covalent bonds.

How is the octet rule illustrated by the CO_2 molecule?

FIGURE 2.7 Nonpolar and Polar Covalent Bonds.

(a) A nonpolar covalent bond between two carbon atoms, formed by electrons that spend an equal amount of time around each nucleus, as represented by the symmetric blue cloud. (b) A polar covalent bond, in which electrons orbit one nucleus significantly more than the other, as represented by the asymmetric cloud. This results in a slight negative charge (δ^-) in the region where the electrons spend most of their time, and a slight positive charge (δ^+) at the other pole.

bond (fig. 2.7a), the strongest of all chemical bonds. Carbon atoms bond to each other with nonpolar covalent bonds. If shared electrons spend significantly more time orbiting one nucleus than they do the other, they lend their negative charge to the region where they spend the most time, and they form a *polar covalent bond* (fig. 2.7b). When hydrogen bonds with oxygen, for example, the electrons are more attracted to the oxygen nucleus and orbit it more than they do the hydrogen. This makes the oxygen region of the molecule slightly negative and the hydrogen regions slightly positive. The Greek delta (δ) is used to symbolize a charge less than that of one electron or proton. A slightly negative region of a molecule is represented δ^- and a slightly positive region is represented δ^+ .

A **hydrogen bond** is a weak attraction between a slightly positive hydrogen atom in one molecule and a slightly negative oxygen or nitrogen atom in another. Water molecules, for example, are weakly attracted to each other by hydrogen bonds (fig. 2.8). Hydrogen bonds also form between different regions of the same molecule, especially in very large molecules such as proteins and DNA. They cause such molecules to fold or coil into precise three-dimensional shapes. Hydrogen bonds are represented by dotted or broken lines between atoms: $-\text{C}=\text{O}\cdots\text{H}-\text{N}-$. Hydrogen bonds are relatively weak, but they are enormously important to physiology.

FIGURE 2.8 Hydrogen Bonding of Water. The polar covalent bonds of water molecules enable each oxygen to form a hydrogen bond with a hydrogen of a neighboring molecule. Thus, the water molecules are weakly attracted to each other.

❖ Why would this behavior raise the boiling point of water above that of a nonpolar liquid?

Van der Waals⁵ forces are weak, brief attractions between neutral atoms. When electrons orbit an atom's nucleus, they do not maintain a uniform distribution but show random fluctuations in density. If the electrons briefly crowd toward one side of an atom, they render that side slightly negative and the other side slightly positive for a moment. If another atom is close enough to this one, the second atom responds with disturbances in its own electron cloud. Oppositely charged regions of the two atoms then attract each other for a very short instant in time.

A single van der Waals attraction is only about 1% as strong as a covalent bond, but when two surfaces or large molecules meet, the van der Waals attractions between large numbers of atoms can create a very strong attraction. This is how plastic wrap clings to food and dishes; flies and spiders walk across a ceiling; and even a 100-g lizard, the Tokay gecko, can run up a windowpane. Van der Waals forces also have a significant effect on the boiling points of liquids. In human structure, they are especially important in protein folding, the binding of proteins to each other and to other molecules such as hormones, and the association

of lipid molecules with each other. Some of these molecular behaviors are described later in this chapter.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Consider iron (Fe), hydrogen gas (H_2), and ammonia (NH_3). Which of these is or are atoms? Which of them is or are molecules? Which of them is or are compounds? Explain each answer.
2. Why is the biological half-life of a radioisotope shorter than its physical half-life?
3. Where do free radicals come from? What harm do they do? How is the body protected from free radicals?
4. How does an ionic bond differ from a covalent bond?
5. What is a hydrogen bond? Why do hydrogen bonds depend on the existence of polar covalent bonds?

2.2 Water and Mixtures

Objectives

When you have completed this section, you should be able to

- define *mixture* and distinguish between mixtures and compounds;
- describe the biologically important properties of water;
- show how three kinds of mixtures differ from each other;
- discuss some ways in which the concentration of a solution can be expressed, and explain why different expressions of concentration are used for different purposes; and
- define *acid* and *base* and interpret the pH scale.

Our body fluids are complex mixtures of chemicals. A **mixture** consists of substances that are physically blended but not chemically combined. Each substance retains its own chemical properties. To contrast a mixture with a compound, consider sodium chloride again. Sodium is a lightweight metal that bursts into flame if exposed to water, and chlorine is a yellow-green poisonous gas that was used for chemical warfare in World War I. When these elements chemically react, they form common table salt. Clearly, the compound has properties much different from the properties of its elements. But if you were to put a little salt on your watermelon, the watermelon would taste salty and sweet because the sugar of the melon and the salt you added would merely form a mixture in which each compound retained its individual properties.

⁵Johannes Diderik van der Waals (1837–1923), Dutch physicist

FIGURE 2.9 Water and Hydration Spheres. (a) A water molecule showing its bond angle and polarity. (b) Water molecules aggregate around a sodium ion with their negatively charged oxygen poles facing the Na^+ and aggregate around a chloride ion with their positively charged hydrogen poles facing the Cl^- .

Water

Most mixtures in our bodies consist of chemicals dissolved or suspended in water. Water constitutes 50% to 75% of your body weight, depending on age, sex, fat content, and other factors. Its structure, simple as it is, has profound biological effects. Two aspects of its structure are particularly important: (1) its atoms are joined by polar covalent bonds, and (2) the molecule is V-shaped, with a 105° bond angle (fig. 2.9a). This makes the molecule as a whole polar, with a slight negative charge (δ^-) on the oxygen and a slight positive charge (δ^+) on each hydrogen. Like little magnets, water molecules are attracted to one another by hydrogen bonds (see fig. 2.8). This gives water a set of properties that account for its ability to support life: *solvency*, *cohesion*, *adhesion*, *chemical reactivity*, and *thermal stability*.

Solvency is the ability to dissolve other chemicals. Water is sometimes called the *universal solvent* because it dissolves a broader range of substances than any other liquid. Substances that dissolve in water, such as sugar, are said to be **hydrophilic**⁶ (HY-dro-FILL-ic); the relatively few substances that do not, such as fats, are **hydrophobic**⁷ (HY-dro-FOE-bic). Virtually all metabolic reactions depend on the solvency of water. Biological molecules must be dissolved in water to move freely, come together, and react. The solvency of water also makes it the body's primary means of transporting substances from place to place.

To be soluble in water, a molecule must be polarized or charged so that its charges can interact with those

of water. When NaCl is dropped into water, for example, the ionic bonds between Na^+ and Cl^- are overpowered by the attraction of each ion to water molecules. Water molecules form a cluster, or *hydration sphere*, around each sodium ion with the $\text{O}^{\delta-}$ pole of each water molecule facing the sodium ion. They also form a hydration sphere around each chloride ion, with the $\text{H}^{\delta+}$ poles facing it. This isolates the sodium ions from the chloride ions and keeps them dissolved (fig. 2.9b).

Adhesion is the tendency of one substance to cling to another, whereas *cohesion* is the tendency of molecules of the same substance to cling to each other. Water adheres to the body's tissues and forms a lubricating film on membranes such as the pleura and pericardium. This helps reduce friction as the lungs and heart contract and expand and rub against these membranes. Water also is a very cohesive liquid because of its hydrogen bonds. This is why, when you spill water on the floor, it forms a puddle and evaporates slowly. By contrast, if you spill a nonpolar substance such as liquid nitrogen, it dances about and evaporates in seconds, like a drop of water in a hot dry skillet. This is because nitrogen molecules have no attraction for each other, so the little bit of heat provided by the floor is enough to disperse them into the air. The cohesion of water is especially evident at its surface, where it forms an elastic layer called the *surface film* held together by a force called *surface tension*. This force causes water to hang in drops from a leaky faucet and travel in rivulets down a window.

The *chemical reactivity* of water is its ability to participate in chemical reactions. Not only does water ionize many other chemicals such as acids and salts, but water itself ionizes into H^+ and OH^- . These ions can be incorporated into other molecules, or released from them, in

⁶hydro = water + philic = loving, attracted to

⁷phobic = fearing, avoiding

the course of chemical reactions such as *hydrolysis* and *dehydration synthesis*, described later in this chapter.

The *thermal stability* of water helps to stabilize the internal temperature of the body. It results from the high *heat capacity* of water—the amount of heat required to raise the temperature of 1 g of a substance by 1°C. The base unit of heat is the **calorie⁸ (cal)**—1 cal is the amount of heat that raises the temperature of 1 g of water 1°C. The same amount of heat would raise the temperature of a nonpolar substance such as nitrogen about four times as much. The difference stems from the presence or absence of hydrogen bonding. To increase in temperature, the molecules of a substance must move around more actively. The hydrogen bonds of water molecules inhibit their movement, so water can absorb a given amount of heat without changing temperature (molecular motion) as much.

The high heat capacity of water also makes it a very effective coolant. When it changes from a liquid to a vapor, water carries a large amount of heat with it. One milliliter of perspiration evaporating from the skin removes about 500 cal of heat from the body. This effect is very apparent when you are sweaty and stand in front of a fan.

Think About It

Why are heat and temperature not the same thing?

Solutions, Colloids, and Suspensions

Mixtures of other substances in water can be classified as *solutions*, *colloids*, and *suspensions*.

A **solution** consists of particles of matter called the **solute** mixed with a more abundant substance (usually water) called the **solvent**. The solute can be a gas, solid, or liquid—as in a solution of oxygen, sodium chloride, or alcohol in water, respectively. Solutions are defined by the following properties:

- The solute particles are under 1 nanometer (nm) in size. The solute and solvent therefore cannot be visually distinguished from each other, even with a microscope.
- Such small particles do not scatter light noticeably, so solutions are usually transparent (fig. 2.10a).
- The solute particles will pass through most selectively permeable membranes, such as dialysis tubing and cell membranes.
- The solute does not separate from the solvent when the solution is allowed to stand.

The most common **colloids⁹** in the body are mixtures of protein and water, such as the albumin in blood plasma. Many colloids can change from liquid to gel states—gelatin desserts, agar culture media, and the fluids

FIGURE 2.10 A Solution, a Colloid, and a Suspension.

Top row: Photographs of a representative solution, colloid, and suspension. Bottom row: Symbolic representation of the particle sizes in each mixture. (a) In a copper sulfate solution, the solute particles are so small they remain permanently mixed and the solution is transparent. (b) In milk, the protein molecules are small enough to remain permanently mixed, but large enough to scatter light, so the mixture is opaque. (c) In blood, the red blood cells scatter light and make the mixture opaque. (d) Red blood cells are too large to remain evenly mixed, so they settle to the bottom as in this blood specimen that stood overnight.

⁸calor = heat

⁹collo = glue + oid = like, resembling

within and between our cells, for example. Colloids are defined by the following physical properties:

- The colloidal particles range from 1 to 100 nm in size.
- Particles this large scatter light, so colloids are usually cloudy (fig. 2.10b).
- The particles are too large to pass through most selectively permeable membranes.
- The particles are still small enough, however, to remain permanently mixed with the solvent when the mixture stands.

The blood cells in our blood plasma exemplify a **suspension**. Suspensions are defined by the following properties:

- The suspended particles exceed 100 nm in size.
- Such large particles render suspensions cloudy or opaque.
- The particles are too large to penetrate selectively permeable membranes.
- The particles are too heavy to remain permanently suspended, so suspensions separate on standing. If allowed to stand, blood cells settle to the bottom of a tube, for example (fig. 2.10c, d).

An **emulsion** is a suspension of one liquid in another, such as oil-and-vinegar salad dressing. The fat in breast milk is an emulsion, as are medications such as Kaopectate and milk of magnesia.

A single mixture can fit into more than one of these categories. Blood is a perfect example—it is a solution of sodium chloride, a colloid of protein, and a suspension of cells. Milk is a solution of calcium, a colloid of protein, and an emulsion of fat. Table 2.4 summarizes the types of mixtures and provides additional examples.

Measures of Concentration

Solutions are often described in terms of their concentration—how much solute is present in a given volume of solution. Concentration is expressed in different ways for different purposes, some of which are explained here.

The table of symbols and measures in appendix D may be helpful as you study this section.

Weight per Volume

A simple way to express concentration is the weight of solute in a given volume of solution. For example, intravenous (I.V.) saline typically contains 8.5 grams of NaCl per liter of solution (8.5 g/L). For many biological purposes, however, we deal with smaller quantities such as milligrams per deciliter (mg/dL; 1 dL = 100 mL). For example, a typical serum cholesterol concentration may be 200 mg/dL, also expressed 200 mg/100 mL or 200 milligram-percent (mg-%).

Percentages

Percentage concentrations are also simple to compute, but it is necessary to specify whether the percentage refers to the weight or to the volume of solute in a given volume of solution. For example, if we begin with 5 g of dextrose (an isomer of glucose) and add enough water to make 100 mL of solution, the resulting concentration will be 5% weight per volume (w/v). A common intravenous fluid is D5W, which stands for 5% w/v dextrose in distilled water. If the solute is a liquid, such as ethanol, percentages refer to volume of solute per volume of solution. Thus, 70 mL of ethanol diluted with water to 100 mL of solution produces 70% volume per volume (70% v/v) ethanol.

Molarity

Percentage concentrations are easy to prepare, but that unit of measurement is inadequate for many purposes. The physiological effect of a chemical depends on how many molecules of it are present in a given volume, not the weight of the chemical. Five percent glucose, for example, contains almost twice as many glucose molecules as the same volume of 5% sucrose (fig. 2.11a). Each solution contains 50 g of sugar per liter, but glucose has a molecular weight (MW) of 180 and sucrose has a MW of 342. Since each molecule of glucose is lighter, 50 g of glucose contains more molecules than 50 g of sucrose.

TABLE 2.4

Types of Mixtures

	Solution	Colloid	Suspension
<i>Particle Size</i>	< 1 nm	1-100 nm	> 100 nm
<i>Appearance</i>	Clear	Often cloudy	Cloudy-opaque
<i>Will particles settle out?</i>	No	No	Yes
<i>Will particles pass through a selectively permeable membrane?</i>	Yes	No	No
<i>Examples</i>	Glucose in blood O ₂ in water Saline solutions Sugar in coffee	Proteins in blood Intracellular fluid Milk protein Gelatin	Blood cells Cornstarch in water Fats in blood Kaopectate

(a) Solutions of equal percentage concentration

(b) Solutions of equal molar concentration

FIGURE 2.11 Comparison of Percentage and Molar Concentrations. (a) Solutions with the same percentage concentrations can differ greatly in the number of molecules per volume because of differences in molecular weights of the solutes. Fifty grams of sucrose has about half as many molecules as 50 g of glucose, for example. (b) Solutions with the same molarity have the same number of molecules per volume because molarity takes differences in molecular weight into account.

To produce solutions with a known number of molecules per volume, we must factor in the molecular weight. If we know the MW and weigh out that many grams of the substance, we have a quantity known as its gram molecular weight, or 1 *mole*. One mole of glucose is 180 g and 1 mole of sucrose is 342 g. Each quantity contains the same number of molecules of the respective sugar—a number known as the Avogadro¹⁰ number, 6.023×10^{23} . Such a large number is hard to imagine. If each molecule were the size of a pea, 6.023×10^{23} molecules would cover 60 earth-size planets 3 m (10 ft) deep!

Molarity (M) is the number of moles of solute per liter of solution. A *one-molar* (1.0 M) solution of glucose contains 180 g/L, and 1.0 M solution of sucrose contains

342 g/L. Both have the same number of solute molecules in a given volume (fig. 2.11b). Body fluids and laboratory solutions usually are less concentrated than 1 M, so biologists and clinicians more often work with *millimolar* (mM) and *micromolar* (μM) concentrations— 10^{-3} and 10^{-6} M, respectively.

Electrolyte Concentrations

Electrolytes are important for their chemical, physical (osmotic), and electrical effects on the body. Their electrical effects, which determine such things as nerve, heart, and muscle actions, depend not only on their concentration but also on their electrical charge. A calcium ion (Ca^{2+}) has twice the electrical effect of a sodium ion (Na^+), for example, because it carries twice the charge. When we measure electrolyte concentrations, we must therefore take the charges into account.

One *equivalent* (Eq) of an electrolyte is the amount that would electrically neutralize 1 mole of hydrogen ions (H^+) or hydroxide ions (OH^-). For example, 1 mole (58.4 g) of NaCl yields 1 mole, or 1 Eq, of Na^+ in solution. Thus, an NaCl solution of 58.4 g/L contains 1 equivalent of Na^+ per liter (1 Eq/L). One mole (98 g) of sulfuric acid (H_2SO_4) yields 2 moles of positive charges (H^+). Thus, 98 g of sulfuric acid per liter would be a solution of 2 Eq/L.

The electrolytes in our body fluids have concentrations less than 1 Eq/L, so we more often express their concentrations in **milliequivalents per liter (mEq/L)**. If you know the millimolar concentration of an electrolyte, you can easily convert this to mEq/L by multiplying it by the valence of the ion:

$$1 \text{ mM Na}^+ = 1 \text{ mEq/L}$$

$$1 \text{ mM Ca}^{2+} = 2 \text{ mEq/L}$$

$$1 \text{ mM Fe}^{3+} = 3 \text{ mEq/L}$$

Acids, Bases, and pH

Most people have some sense of what acids and bases are. Advertisements are full of references to excess stomach acid and pH-balanced shampoo. We know that drain cleaner (a strong base) and battery acid can cause serious chemical burns. But what exactly do “acidic” and “basic” mean, and how can they be quantified?

An **acid** is any *proton donor*, a molecule that releases a proton (H^+) in water. A **base** is a proton acceptor. Since hydroxide ions (OH^-) accept H^+ , many bases are substances that release hydroxide ions—sodium hydroxide (NaOH), for example. A base does not have to be a hydroxide donor, however. Ammonia (NH_3) is also a base. It does not release hydroxide ions, but it readily accepts hydrogen ions to become the ammonium ion (NH_4^+).

Acidity is expressed in terms of **pH**, a measure derived from the molarity of H^+ . Molarity is represented by square brackets, so the molarity of H^+ is symbolized $[\text{H}^+]$. pH is the negative logarithm of hydrogen ion molarity—that is,

¹⁰Amedeo Avogadro (1776–1856), Italian chemist

FIGURE 2.12 The pH scale. The pH is shown within the colored bar. H^+ molarity increases 10-fold for every step down the scale.

$pH = -\log [H^+]$. In pure water, 1 in 10 million molecules ionizes into hydrogen and hydroxide ions: $H_2O \rightleftharpoons H^+ + OH^-$. Pure water has a neutral pH because it contains equal amounts of H^+ and OH^- . Since 1 in 10 million molecules ionize, the molarity of H^+ and the pH of water are

$$[H^+] = 0.0000001 \text{ molar} = 10^{-7} \text{ M}$$

$$\log [H^+] = -7$$

$$pH = -\log [H^+] = 7$$

The pH scale (fig. 2.12) was invented in 1909 by Danish biochemist and brewer Søren Sørensen to measure the acidity of beer. The scale extends from 0.0 to 14.0. A solution with a pH of 7.0 is **neutral**; solutions with pH below 7 are **acidic**; and solutions with pH above 7 are **basic** (alkaline). The lower the pH value, the more hydrogen ions a solution has and the more acidic it is. Since the pH scale is logarithmic, a change of one whole number on the scale represents a 10-fold change in H^+ concentration. In other words, a solution with pH 4 is 10 times as acidic as one with pH 5 and 100 times as acidic as one with pH 6.

Slight disturbances of pH can seriously disrupt physiological functions and alter drug actions (see Insight 2.2), so it is important that the body carefully control its pH. Blood, for example, normally has a pH ranging from 7.35 to 7.45. Deviations from this range cause tremors, fainting, paralysis, or even death. Chemical solutions that resist changes in pH are called **buffers**. Buffers and pH regulation are considered in detail in chapter 24.

Think About It

A pH of 7.20 is slightly alkaline, yet a blood pH of 7.20 is called acidosis. Why do you think it is called this?

INSIGHT 2.2 Clinical Application

pH and Drug Action

The pH of our body fluids has a direct bearing on how we react to drugs. Depending on pH, drugs such as aspirin, phenobarbital, and penicillin can exist in charged (ionized) or uncharged forms. Whether a drug is charged or not can determine whether it will pass through cell membranes. When aspirin is in the acidic environment of the stomach, for example, it is uncharged and passes easily through the stomach lining into the bloodstream. Here it encounters a basic pH, whereupon it ionizes. In this state, it is unable to pass back through the membrane, so it accumulates in the blood. This effect, called *ion trapping* or *pH partitioning*, can be controlled to help clear poisons from the body. The pH of the urine, for example, can be manipulated so that poisons become trapped there and thus rapidly excreted from the body.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- What is the difference between a mixture and a compound?
- What are hydrophilic and hydrophobic substances? Give an example of each.
- Why would the cohesion and thermal stability of water be less if water did not have polar covalent bonds?
- How do solutions, colloids, and suspensions differ from each other? Give an example of each in the human body.

10. What is one advantage of percentage over molarity as a measure of solute concentration? What is one advantage of molarity over percentage?
11. If solution A had an H^+ concentration of $10^{-8} M$, what would be its pH? If solution B had 1,000 times this H^+ concentration, what would be its pH? Would solution A be acidic or basic? What about solution B?

2.3 Energy and Chemical Reactions

Objectives

When you have completed this section, you should be able to

- define *energy* and *work*, and describe some types of energy;
- understand how chemical reactions are symbolized by chemical equations;
- list and define the fundamental types of chemical reactions;
- identify the factors that govern the speed and direction of a reaction;
- define *metabolism* and its two subdivisions; and
- define *oxidation* and *reduction* and relate these to changes in the energy content of a molecule.

Energy and Work

Energy is the capacity to do work. To do **work** means to move something, whether it is a muscle or a molecule. Some examples of physiological work are breaking chemical bonds, building molecules, pumping blood, and contracting skeletal muscles. All of the body's activities are forms of work.

Energy is broadly classified as *potential* or *kinetic energy*. *Potential energy* is energy contained in an object because of its position or internal state but that is not doing work at the time. *Kinetic energy* is energy of motion, energy that is doing work. It is observed in musculoskeletal movements, the flow of ions into a cell, and vibration of the eardrum, for example. The water behind a dam has potential energy because of its position. Let the water flow through, and it exhibits kinetic energy that can be tapped for generating electricity. Like water behind a dam, ions concentrated on one side of a cell membrane have potential energy that can be released by opening gates in the membrane. As the ions flow through the gates, their kinetic energy can be tapped to create a nerve signal or make the heart beat.

Within the two broad categories of potential and kinetic energy, several forms of energy are relevant to human physiology. *Chemical energy* is potential energy

stored in the bonds of molecules. Chemical reactions release this energy and make it available for physiological work. *Heat* is the kinetic energy of molecular motion. The temperature of a substance is a measure of rate of this motion, and adding heat to a substance increases this rate. *Electromagnetic energy* is the kinetic energy of moving “packets” of radiation called *photons*. The most familiar form of electromagnetic energy is light. *Electrical energy* has both potential and kinetic forms. It is potential energy when charged particles have accumulated at a point such as a battery terminal or on one side of a cell membrane; it becomes kinetic energy when these particles begin to move and create an electrical current—for example, when electrons move through your household wiring or sodium ions move through a cell membrane.

Free energy is the potential energy available in a system to do useful work. In human physiology, the most relevant free energy is the energy stored in the chemical bonds of organic molecules.

Classes of Chemical Reactions

A **chemical reaction** is a process in which a covalent or ionic bond is formed or broken. The course of a chemical reaction is symbolized by a **chemical equation** that typically shows the *reactants* on the left, the *products* on the right, and an arrow pointing from the reactants to the products. For example, consider this common occurrence: If you open a bottle of wine and let it stand for several days, it turns sour. Wine “turns to vinegar” because oxygen gets into the bottle and reacts with ethanol to produce acetic acid and water. Acetic acid gives the tart flavor to vinegar and spoiled wine. The equation for this reaction is

Ethanol and oxygen are the reactants, and acetic acid and water are the products of this reaction. Not all reactions are shown with the arrow pointing from left to right. In complex biochemical equations, reaction chains are often written vertically or even in circles.

Chemical reactions can be classified as *decomposition*, *synthesis*, or *exchange reactions*. In **decomposition reactions**, a large molecule breaks down into two or more smaller ones (fig. 2.13a); symbolically, $AB \rightarrow A + B$. When you eat a potato, for example, digestive enzymes decompose its starch into thousands of glucose molecules, and most cells further decompose glucose to water and carbon dioxide. Starch, a very large molecule, ultimately yields about 36,000 molecules of H_2O and CO_2 .

Synthesis reactions are just the opposite—two or more small molecules combine to form a larger one; symbolically, $A + B \rightarrow AB$ (fig. 2.13b). When the body synthesizes proteins, for example, it combines several hundred amino acids into one protein molecule.

FIGURE 2.13 Decomposition, Synthesis, and Exchange Reactions. (a) In a decomposition reaction, large molecules are broken down into simpler ones. (b) In a synthesis reaction, smaller molecules are joined to form larger ones. (c) In an exchange reaction, two molecules exchange atoms.

• To which of these categories does the digestion of food belong?

In **exchange reactions**, two molecules exchange atoms or groups of atoms; $AB + CD \rightarrow AC + BD$ (fig. 2.13c). For example, when stomach acid (HCl) enters the small intestine, the pancreas secretes sodium bicarbonate (NaHCO_3) to neutralize it. The reaction between the two is $\text{NaHCO}_3 + \text{HCl} \rightarrow \text{NaCl} + \text{H}_2\text{CO}_3$. We could say the sodium atom has exchanged its bicarbonate group ($-\text{HCO}_3$) for a chlorine atom.

Reversible reactions can go in either direction under different circumstances and are represented with paired arrows. For example, carbon dioxide combines with water to produce carbonic acid, which in turn decomposes into bicarbonate ions and hydrogen ions:

This reaction appears in this book more often than any other, especially as we discuss respiratory, urinary, and digestive physiology.

The direction in which a reversible reaction goes is determined by the relative abundance of substances on each side of the equation. If there is a surplus of CO_2 , this reaction proceeds to the right and produces bicarbonate and hydrogen ions. If bicarbonate and hydrogen ions are present in excess, the reaction proceeds to the left and generates CO_2 and H_2O . Reversible reactions follow the **law of mass action**: they proceed from the side with the greater quantity of reactants to the side

with the lesser quantity. This law will help to explain processes discussed in later chapters, such as why hemoglobin binds oxygen in the lungs yet releases it to muscle tissue.

In the absence of upsetting influences, reversible reactions exist in a state of **equilibrium**, in which the ratio of products to reactants is stable. The carbonic acid reaction, for example, normally maintains a 20:1 ratio of bicarbonate ions to carbonic acid molecules. This equilibrium can be upset, however, by a surplus of hydrogen ions, which drive the reaction to the left, or adding carbon dioxide and driving it to the right.

Reaction Rates

The basis for chemical reactions is molecular motion and collisions. All molecules are in constant motion, and reactions occur when mutually reactive molecules collide with sufficient force and the right orientation. The rate of a reaction depends on the nature of the reactants and on the frequency and force of these collisions. Some factors that affect reaction rates are

- **Concentration.** Reaction rates increase when the reactants are more concentrated. This is because the molecules are more crowded and collide more frequently.
- **Temperature.** Reaction rate increases as the temperature rises. This is because heat causes molecules to move more rapidly and collide with greater force and frequency.

TABLE 2.5

Energy-Transfer Reactions in the Human Body

Exergonic Reactions	Reactions in which there is a net release of energy. The products have less total free energy than the reactants did.
Oxidation	An exergonic reaction in which electrons are removed from a reactant. Electrons may be removed one or two at a time and may be removed in the form of hydrogen atoms (H or H ₂). The product is then said to be oxidized.
Decomposition	A reaction such as digestion and cell respiration, in which larger molecules are broken down into smaller ones.
Catabolism	The sum of all decomposition reactions in the body.
Endergonic Reactions	Reactions in which there is a net input of energy. The products have more total free energy than the reactants did.
Reduction	An endergonic reaction in which electrons are donated to a reactant. The product is then said to be reduced.
Synthesis	A reaction such as protein and glycogen synthesis, in which two or more smaller molecules are combined into a larger one.
Anabolism	The sum of all synthesis reactions in the body.

- **Catalysts** (CAT-uh-lists). These are substances that temporarily bind to reactants, hold them in a favorable position to react with each other, and may change the shapes of reactants in ways that make them more likely to react. By reducing the element of chance in molecular collisions, a catalyst speeds up a reaction. It then releases the products and is available to repeat the process with more reactants. The catalyst itself is not permanently consumed or changed by the reaction. The most important biological catalysts are enzymes, discussed later in this chapter.

Metabolism, Oxidation, and Reduction

All the chemical reactions in the body are collectively called **metabolism**. Metabolism has two divisions: *catabolism* and *anabolism*. **Catabolism**¹¹ (ca-TAB-oh-lizm) consists of energy-releasing decomposition reactions. Such reactions break covalent bonds, produce smaller molecules from larger ones, and release energy that can be used for other physiological work. Energy-releasing reactions are called *exergonic*¹² reactions. If you hold a beaker of water in your hand and pour sulfuric acid into it, for example, the beaker will get so hot you may have to put it down. If you break down energy-storage molecules to run a race, you too will get hot. In both cases, the heat signifies that exergonic reactions are occurring.

Anabolism¹³ (ah-NAB-oh-lizm) consists of energy-storing synthesis reactions, such as the production of protein or fat. Reactions that require an energy input, such as these, are called *endergonic*¹⁴ reactions. Anabolism is driven by the energy that catabolism releases, so endergonic and exergonic processes, anabolism and catabolism, are inseparably linked.

Oxidation is any chemical reaction in which a molecule gives up electrons and releases energy. A molecule is

oxidized by this process, and whatever molecule takes the electrons from it is an **oxidizing agent** (electron acceptor). The term *oxidation* stems from the fact that oxygen is often involved as the electron acceptor. Thus, we can sometimes recognize an oxidation reaction from the fact that oxygen has been added to a molecule. The rusting of iron, for example, is a slow oxidation process in which oxygen is added to iron to form iron oxide (Fe₂O₃). Many oxidation reactions, however, do not involve oxygen at all. For example, when yeast ferments glucose to alcohol, no oxygen is required; indeed, the alcohol *contains less oxygen* than the sugar originally did, but it is *more oxidized* than the sugar:

Reduction is a chemical reaction in which a molecule gains electrons and energy. When a molecule accepts electrons, it is said to be *reduced*; a molecule that donates electrons to another is therefore called a **reducing agent** (electron donor). The oxidation of one molecule is always accompanied by the reduction of another, so these electron transfers are known as *oxidation–reduction (redox) reactions*.

It is not necessary that *only* electrons be transferred in a redox reaction. Often, the electrons are transferred in the form of hydrogen atoms. The fact that a proton (the hydrogen nucleus) is also transferred is immaterial to whether we consider a reaction oxidation or reduction.

Table 2.5 summarizes these energy-transfer reactions. We can symbolize oxidation and reduction as follows, letting A and B symbolize arbitrary molecules and letting e[−] represent one or more electrons:

Ae[−] is a reducing agent because it reduces B, and B is an oxidizing agent because it oxidizes Ae[−].

¹¹*cato* = down, to break down

¹²*ex, exo* = out + *erg* = work

¹³*ana* = up, to build up

¹⁴*end, endo* = in + *erg* = work

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Define energy. Distinguish potential energy from kinetic energy.
- Define metabolism, catabolism, and anabolism.
- What does oxidation mean? What does reduction mean? Which of them is endergonic and which is exergonic?
- When sodium chloride forms, which element—sodium or chlorine—is oxidized? Which one is reduced?

2.4 Organic Compounds

Objectives

When you have completed this section, you should be able to

- explain why carbon is especially well suited to serve as the structural foundation of many biological molecules;
- identify some common functional groups of organic molecules from their formulae;
- discuss the relevance of polymers to biology and explain how they are formed and broken by dehydration synthesis and hydrolysis;
- discuss the types and functions of carbohydrates;
- discuss the types and functions of lipids;
- discuss protein structure and function;
- explain how enzymes function;
- describe the structure, production, and function of ATP;
- identify other nucleotide types and their functions; and
- identify the principal types of nucleic acids.

Carbon Compounds and Functional Groups

Organic chemistry is the study of compounds of carbon. By 1900, biochemists had classified the organic molecules of life into four primary categories: *carbohydrates*, *lipids*, *proteins*, and *nucleic acids*. We examine the first three in this chapter but describe the details of nucleic acids, which are concerned with genetics, in chapter 4.

Carbon is an especially versatile atom that serves as the basis of a wide variety of structures. It has four valence electrons, so it bonds with other atoms that can provide it with four more to complete its valence shell. Carbon atoms readily bond with each other and can form long chains, branched molecules, and rings—an enormous variety of **carbon backbones** for organic molecules.

Carbon also forms covalent bonds with hydrogen, oxygen, nitrogen, sulfur, and other elements.

Carbon backbones carry a variety of **functional groups**—small clusters of atoms that determine many of the properties of an organic molecule. For example, organic acids bear a **carboxyl** (car-BOC-sil) **group**, and ATP is named for its three **phosphate groups**. Other common functional groups include **hydroxyl**, **methyl**, and **amino groups** (fig. 2.14).

Monomers and Polymers

Since carbon can form long chains, some organic molecules are gigantic *macromolecules* with molecular weights that range from the thousands (as in starch and

Name and Symbol	Structure	Occurs in
Hydroxyl (—OH)		Sugars, alcohols
Methyl (—CH ₃)		Fats, oils, steroids, amino acids
Carboxyl (—COOH)		Amino acids, sugars, proteins
Amino (—NH ₂)		Amino acids, proteins
Phosphate (—H ₂ PO ₄)		Nucleic acids, ATP

FIGURE 2.14 Functional Groups of Organic Molecules.

FIGURE 2.15 Synthesis and Hydrolysis Reactions. (a) In dehydration synthesis, a hydrogen atom is removed from one monomer and a hydroxyl group is removed from another. These combine to form water as a by-product. The monomers become joined by a covalent bond to form a dimer. (b) In hydrolysis, a covalent bond between two monomers is broken. Water donates a hydrogen atom to one monomer and a hydroxyl group to the other.

proteins) to the millions (as in DNA). Most macromolecules are **polymers**¹⁵—molecules made of a repetitive series of identical or similar subunits called **monomers** (MON-oh-murs). Starch, for example, is a polymer of about 3,000 glucose monomers. In starch, the monomers are identical, whereas in other polymers they have a basic structural similarity but differ in detail. DNA, for example, is made of 4 different kinds of monomers (nucleotides), and proteins are made of 20 kinds (amino acids).

The joining of monomers to form a polymer is called **polymerization**. Living cells achieve this by means of a reaction called **dehydration synthesis (condensation)** (fig. 2.15a). A hydroxyl (—OH) group is removed from one monomer and a hydrogen (—H) from another, producing water as a by-product. The two monomers become joined by a covalent bond, forming a **dimer**. This is repeated for each monomer added to the chain, potentially leading to a chain long enough to be considered a polymer.

The opposite of dehydration synthesis is **hydrolysis**¹⁶ (fig. 2.15b). In hydrolysis, a water molecule ionizes into OH^- and H^+ . A covalent bond linking one monomer to another is broken, the OH^- is added to one monomer, and the H^+ is added to the other one. All digestion consists of hydrolysis reactions.

Carbohydrates

A **carbohydrate**¹⁷ is a hydrophilic organic molecule with the general formula $(\text{CH}_2\text{O})_n$, where n represents the number of carbon atoms. In glucose, for example, $n = 6$ and the formula is $\text{C}_6\text{H}_{12}\text{O}_6$. As the generic formula shows, carbohydrates have a 2:1 ratio of hydrogen to oxygen.

Think About It

Why is carbohydrate an appropriate name for this class of compounds? Relate this name to the general formula of carbohydrates.

The names of individual carbohydrates are often built on the word root *sacchar-* or the suffix *-ose*, both of which mean “sugar” or “sweet.” The most familiar carbohydrates are the sugars and starches.

The simplest carbohydrates are monomers called **monosaccharides**¹⁸ (MON-oh-SAC-uh-rides), or simple sugars. The three of primary importance are **glucose**, **fructose**, and **galactose**, all with the molecular formula $\text{C}_6\text{H}_{12}\text{O}_6$; they are isomers of each other (fig. 2.16). We obtain these sugars mainly by the digestion of more complex carbohydrates. Glucose is the “blood sugar” that provides energy to most of our cells. Two other monosaccharides, ribose and deoxyribose, are important components of DNA and RNA.

Disaccharides are sugars composed of two monosaccharides. The three of greatest importance are **sucrose** (made of glucose + fructose), **lactose** (glucose + galactose), and **maltose** (glucose + glucose) (fig. 2.17). Sucrose is produced by sugarcane and sugar beets and used as common table sugar. Lactose is milk sugar. Maltose is a product of starch digestion and is present in a few foods such as germinating wheat and malt beverages.

Polysaccharides (POL-ee-SAC-uh-rides) are long chains of glucose. Some polysaccharides have molecular weights of 500,000 or more (compared with 180 for a single glucose). Three polysaccharides of interest to human physiology are glycogen, starch, and cellulose. Animals, including ourselves, make glycogen, while starch and cellulose are plant products.

¹⁵poly = many + mer = part

¹⁶hydro = water + lysis = splitting apart

¹⁷carbo = carbon + hydr = water

¹⁸mono = one + sacchar = sugar

FIGURE 2.16 The Three Major Monosaccharides. All three have the molecular formula $C_6H_{12}O_6$. Each angle in the rings represents a carbon atom except the one where oxygen is shown. This is a conventional way of representing carbon in the structural formulae of organic compounds.

Glycogen¹⁹ is an energy-storage polysaccharide made by cells of the liver, muscles, brain, uterus, and vagina. It is a long branched glucose polymer (fig. 2.18). The liver produces glycogen after a meal, when the blood glucose level is high, and then breaks it down between meals to maintain blood glucose levels when there is no food intake. Muscle stores glycogen for its own energy needs, and the uterus uses it in pregnancy to nourish the embryo.

Starch is the corresponding energy-storage polysaccharide of plants. They store it when sunlight and nutrients are available and draw from it when photosynthesis is not possible (for example, at night and in winter, when a plant has shed its leaves). Starch is the only significant digestible polysaccharide in the human diet.

Cellulose is a structural polysaccharide that gives strength to the cell walls of plants. It is the principal component of wood, cotton, and paper. It consists of a few thousand glucose monomers joined together, with every other monomer “upside down” relative to the next.

FIGURE 2.17 The Three Major Disaccharides.

(The CH_2OH groups all face in the same direction in glycogen and starch, but alternate between facing up and down in cellulose.) Cellulose is the most abundant organic compound on earth and it is a common component of the diets of humans and other animals—yet we have no enzymes to digest it and thus derive no energy or nutrition from it. Nevertheless, it is important as dietary “fiber,” “bulk,” or “roughage.” It swells with water in the digestive tract and helps move other materials through the intestine.

Carbohydrates are, above all, a source of energy that can be quickly mobilized. All digested carbohydrate is ultimately converted to glucose, and glucose is oxidized to make ATP, a high-energy compound discussed later. But carbohydrates have other functions as well (table 2.6). They are often **conjugated**²⁰ with (covalently bound to) proteins and lipids. Many of the lipid and protein molecules at the external surface of the cell membrane have chains of up to 12 sugars attached to them, thus forming

¹⁹glyco = sugar + gen = producing

²⁰con = together + jug = join

FIGURE 2.18 Glycogen. This is the only polysaccharide found in human tissues. (a) Part of a glycogen molecule showing the chain of glucose monomers and branching pattern. (b) Detail of the molecule at a branchpoint.

TABLE 2.6		Carbohydrate Functions
Type	Function	
<i>Monosaccharides</i>		
Glucose	Blood sugar—energy source for most cells	
Galactose	Converted to glucose and metabolized	
Fructose	Fruit sugar—converted to glucose and metabolized	
<i>Disaccharides</i>		
Sucrose	Cane sugar—digested to glucose and fructose	
Lactose	Milk sugar—digested to glucose and galactose; important in infant nutrition	
Maltose	Malt sugar—product of starch digestion, further digested to glucose	
<i>Polysaccharides</i>		
Cellulose	Structural polysaccharide of plants; dietary fiber	
Starch	Energy storage in plant cells	
Glycogen	Energy storage in animal cells (liver, muscle, brain, uterus, vagina)	
<i>Conjugated Carbohydrates</i>		
Glycoprotein	Component of the cell surface coat and mucus, among other roles	
Glycolipid	Component of the cell surface coat	
Proteoglycan	Cell adhesion; lubrication; supportive filler of some tissues and organs	

glycolipids and **glycoproteins**, respectively. Among other functions, glycoproteins are a major component of mucus, which traps particles in the respiratory system, resists infection, and protects the digestive tract from its own acid and enzymes.

Proteoglycans (once called *mucopolysaccharides*) are macromolecules in which the carbohydrate component is dominant and a peptide or protein forms a smaller component. Proteoglycans form gels that help hold cells and tissues together, form a gelatinous filler in the umbilical cord and eye, lubricate the joints of the skeletal system, and account for the tough rubbery texture of cartilage. Their structure and functions are further considered in chapter 5.

When discussing conjugated macromolecules, it is convenient to refer to each chemically different component as a **moiety**²¹ (MOY-eh-tee). Proteoglycans have a protein moiety and a carbohydrate moiety, for example.

Lipids

A **lipid** is a hydrophobic organic molecule, usually composed only of carbon, hydrogen, and oxygen, with a high ratio of hydrogen to oxygen. A fat called *tristearin* (tri-STEE-uh-rin), for example, has the molecular formula C₅₇H₁₁₀O₆—more than 18 hydrogens for every oxygen. Lipids are less oxidized than carbohydrates, and thus have more calories per gram. Beyond these criteria, it is difficult to generalize about lipids; they are much more variable in structure than the other macromolecules we are considering. We consider here the five primary types of lipids in humans—*fatty acids*, *triglycerides*, *phospholipids*, *icosanoids*, and *steroids* (table 2.7).

A **fatty acid** is a chain of usually 4 to 24 carbon atoms with a carboxyl group at one end and a methyl group at the other. Fatty acids and the fats made from them are classified as *saturated* or *unsaturated*. A **saturated fatty acid** such as palmitic acid has as much hydrogen as it can carry. No more could be added without exceeding four covalent bonds per carbon atom; thus it is “saturated”

²¹moiety = half

Type	Function
Bile acids	Steroids that aid in fat digestion and nutrient absorption
Cholesterol	Component of cell membranes; precursor of other steroids
Eicosanoids	Chemical messengers between cells
Fat-soluble vitamins	Involved in a variety of functions including blood clotting, wound healing, vision, and calcium absorption
Fatty acids	Precursor of triglycerides; source of energy
Phospholipids	Major component of cell members; aid in fat digestion
Steroid hormones	Chemical messengers between cells
Triglycerides	Energy storage: thermal insulation; filling space; binding organs together; cushioning organs

with hydrogen. In **unsaturated fatty acids** such as linoleic acid, however, some carbon atoms are joined by double covalent bonds (fig. 2.19). Each of these could potentially share one pair of electrons with another hydrogen atom instead of the adjacent carbon, so hydrogen could be added to this molecule. **Polyunsaturated fatty acids** are those with many C=C bonds. Most fatty acids can be synthesized by the human body, but a few, called **essential fatty acids**, must be obtained from the diet because we cannot synthesize them (see chapter 26).

A **triglyceride** (try-GLISS-ur-ide) is a molecule consisting of three fatty acids covalently bonded to a three-carbon alcohol called **glycerol**; triglycerides are more correctly, although less widely, also known as *triacylglycerols*. Each bond between a fatty acid and glycerol is formed by dehydration synthesis (fig. 2.19). Once joined to glycerol, a fatty acid can no longer donate a proton to solution and is therefore no longer an acid. For this reason, triglycerides are also called *neutral fats*. Triglycerides are broken down by hydrolysis reactions, which split each of these bonds apart by the addition of water.

Triglycerides that are liquid at room temperature are also called *oils*, but the difference between a fat and oil is fairly arbitrary. Coconut oil, for example, is solid at room temperature. Animal fats are usually made of saturated fatty acids, so they are called *saturated fats*. They are solid at room or body temperature. Most plant triglycerides are *polyunsaturated fats*, which generally remain liquid at room temperature. Examples include peanut, olive, corn, and linseed oils. Saturated fats contribute more to cardiovascular disease than unsaturated fats, and for this reason it is healthier to cook with vegetable oils than with lard, bacon fat, or butter.

The primary function of fat is energy storage, but when concentrated in *adipose tissue*, it also provides thermal insulation and acts as a shock-absorbing cushion for vital organs (see chapter 5).

Phospholipids are similar to neutral fats except that, in place of one fatty acid, they have a phosphate group that, in turn, is linked to other functional groups. Lecithin is a common phospholipid in which the phosphate is bonded to a nitrogenous group called *choline* (CO-leen) (fig. 2.20). Phospholipids have a dual nature. The two fatty acid “tails” of the molecule are hydrophobic, but the phosphate “head” is hydrophilic. Thus, phospholipids are said to be **amphiphilic**²² (AM-fih-FIL-ic). Together, the head and the two tails of a phospholipid give it a shape like a clothespin. The most important function of phospholipids is to serve as the structural foundation of cell membranes (see chapter 3).

Eicosanoids²³ (eye-CO-sah-noyds) are 20-carbon compounds derived from a fatty acid called *arachidonic* (ah-RACK-ih-DON-ic) *acid*. They function primarily as hormonelike chemical signals between cells. The most functionally diverse eicosanoids are the **prostaglandins**, in which five of the carbon atoms are arranged in a ring (fig. 2.21). They were originally found in the secretions of bovine prostate glands, hence their name, but they are now known to be produced in almost all tissues. They play a variety of signaling roles in inflammation, blood clotting, hormone action, labor contractions, control of blood vessel diameter, and other processes (see chapter 17).

A **steroid** is a lipid with 17 of its carbon atoms arranged in four rings (fig. 2.22). **Cholesterol** is the “parent” steroid from which the other steroids are synthesized. The others include cortisol, progesterone, estrogens, testosterone, and bile acids. These differ from each other in the location of C=C bonds within the rings and in the functional groups attached to the rings.

Cholesterol is synthesized only by animals (especially in liver cells) and is not present in vegetable oils or other plant products. The average adult contains over 200 g (half a pound) of cholesterol. Cholesterol has a bad reputation as a factor in cardiovascular disease (see Insight 2.3), and it is true that hereditary and dietary factors can elevate blood cholesterol to dangerously high levels. Nevertheless, cholesterol is a natural product of the body. Only about 15% of our cholesterol comes from the diet; the other 85% is internally synthesized. In addition to being the precursor of the other steroids, cholesterol is an important component of cell membranes and is required for proper nervous system function.

The primary lipids and their functions are summarized in table 2.7.

²²*amphi* = both + *philic* = loving

²³*eicosa* = 20

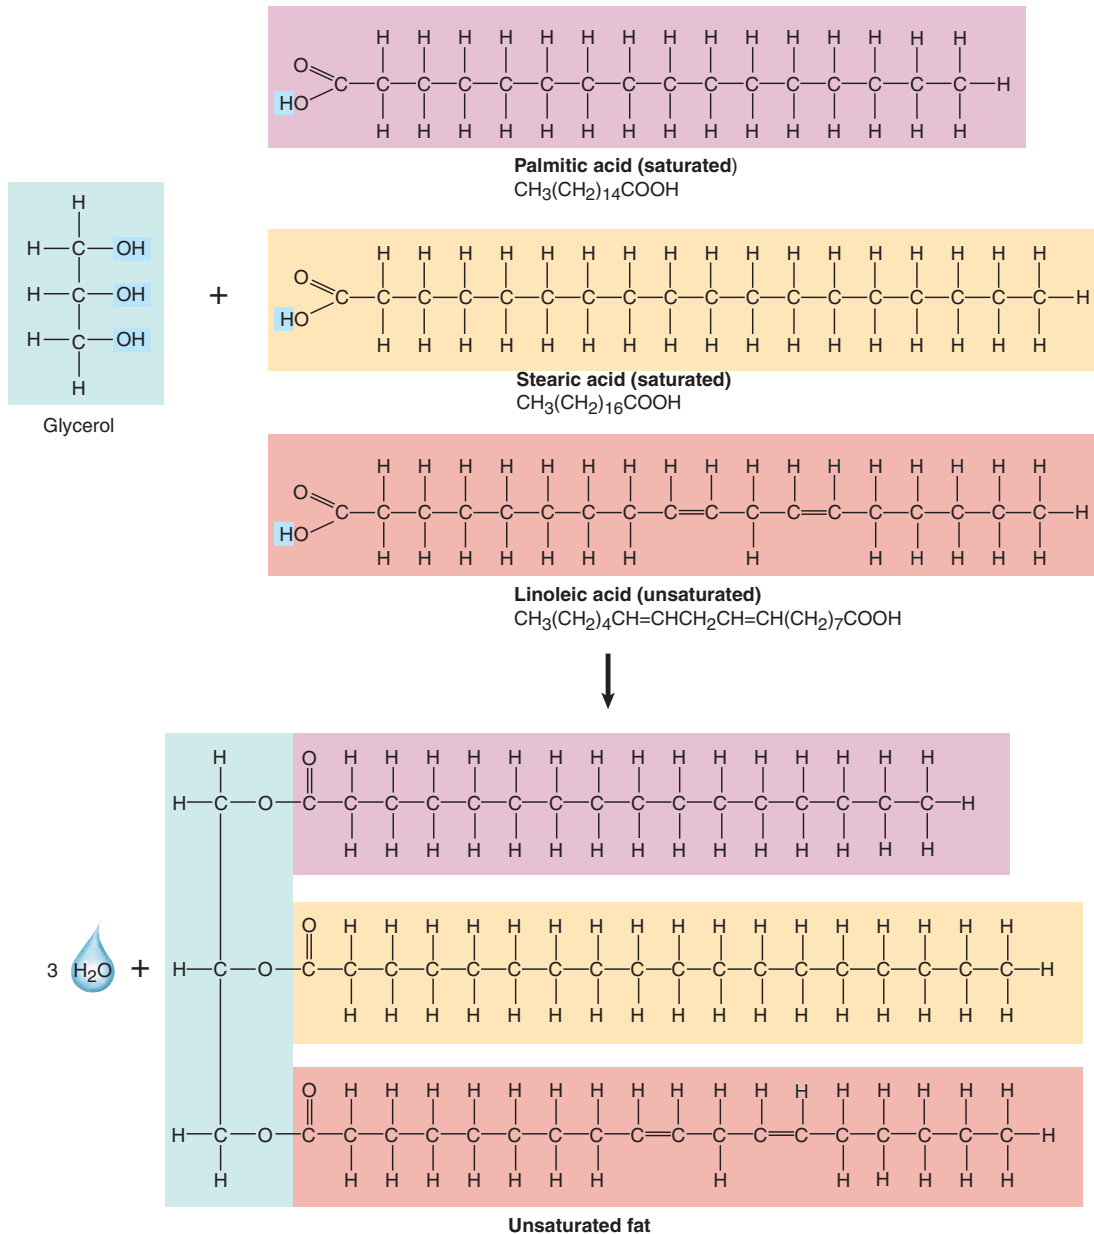

FIGURE 2.19 Triglyceride (Fat) Synthesis. Note the difference between saturated and unsaturated fatty acids and the production of 3 H_2O as a by-product of this dehydration synthesis reaction.

Proteins

The word *protein* is derived from the Greek word *pro-teios*, meaning “of first importance.” Proteins are the most versatile molecules in the body, and many discussions in this book will draw on your understanding of protein structure and behavior.

Amino Acids and Peptides

A **protein** is a polymer of **amino acids**. An amino acid has a central carbon atom with an amino ($-\text{NH}_2$) and a carboxyl ($-\text{COOH}$) group bound to it (fig. 2.23a). The 20 amino acids used to make proteins are identical except for a third functional group called the *radical*

FIGURE 2.20 Lecithin, a Representative Phospholipid. (a) Structural formula. (b) A space-filling model that gives some idea of the actual shape of the molecule. (c) A simplified representation of the phospholipid molecule used in diagrams of cell membranes.

FIGURE 2.22 Cholesterol. All steroids have this basic four-ringed structure, with variations in the functional groups and locations of double bonds within the rings.

INSIGHT 2.3 Clinical Application

“Good” and “Bad” Cholesterol

There is only one kind of cholesterol, and it does far more good than harm. When the popular press refers to “good” and “bad” cholesterol, it is actually referring to droplets in the blood called *lipoproteins*, which are a complex of cholesterol, fat, phospholipids, and protein. So-called bad cholesterol refers to low-density lipoprotein (LDL), which has a high ratio of lipid to protein and contributes to cardiovascular disease. So-called good cholesterol refers to high-density lipoprotein (HDL), which has a lower ratio of lipid to protein and may help to prevent cardiovascular disease. Even when food products are advertised as cholesterol-free, they may be high in saturated fat, which stimulates the body to produce more cholesterol. Palmitic acid seems to be the greatest culprit in stimulating elevated cholesterol levels, while linoleic acid has a cholesterol-lowering effect. Both are shown in figure 2.19. Cardiovascular disease is further discussed at the end of chapter 19, and LDLs and HDLs are more fully explained in chapter 26.

(R-group) attached to the central carbon. In the simplest amino acid, glycine, R is merely a hydrogen atom, whereas in the largest amino acids it includes rings of carbon. Some radicals are hydrophilic and some are hydrophobic. Being composed of many amino acids, proteins as a whole are therefore often amphiphilic. The 20 amino acids involved in proteins are listed in table 2.8 along with their abbreviations.

A **peptide** is any molecule composed of two or more amino acids joined by **peptide bonds**. A peptide bond, formed by dehydration synthesis, joins the amino group of one amino acid to the carboxyl group of the next (fig. 2.23b). Peptides are named for the number of amino acids they have—for example, dipeptides have two and tripeptides have three. Chains of fewer than 10 or 15 amino acids are called **oligopeptides**,²⁴ and chains larger than that are called **polypeptides**. An example of an oligopeptide is the childbirth-inducing hormone oxytocin, composed of 9 amino acids. A representative polypeptide is adrenocorticotropic hormone (ACTH), which is 39 amino acids long. A protein is a polypeptide of 50 amino acids or more. A typical amino acid has a molecular weight of about 80 amu, and the molecular weights of the smallest proteins are around 4,000 to 8,000 amu. The average protein weighs in at about 30,000 amu, and some of them have molecular weights in the hundreds of thousands.

Protein Structure

Proteins have complex coiled and folded structures that are critically important to the roles they play. Even slight changes in their **conformation** (three-dimensional shape)

Some nonpolar amino acids

Some polar amino acids

can destroy protein function. Protein molecules have three to four levels of complexity, from primary through quaternary structure (fig. 2.24).

Primary structure is the protein’s sequence of amino acids, which is encoded in the genes (see chapter 4).

Secondary structure is a coiled or folded shape held together by hydrogen bonds between the slightly negative $C=O$ group of one peptide bond and the slightly positive $N-H$ group of another one some distance away. The most common secondary structures are a springlike shape called the **alpha (α) helix** and a pleated, ribbonlike shape,

²⁴oligo = a few

TABLE 2.8

The 20 Amino Acids
and Their Abbreviations

Alanine	Ala	Leucine	Leu
Arginine	Arg	Lysine	Lys
Asparagine	Asn	Methionine	Met
Aspartic acid	Asp	Phenylalanine	Phe
Cysteine	Cys	Proline	Pro
Glutamine	Gln	Serine	Ser
Glutamic acid	Glu	Threonine	Thr
Glycine	Gly	Tryptophan	Trp
Histidine	His	Tyrosine	Tyr
Isoleucine	Ile	Valine	Val

the **beta (β) sheet** (or β -pleated sheet). Many proteins have multiple α -helical and β -pleated regions joined by short segments with a less orderly geometry. A single protein molecule may fold back on itself and have two or more β -pleated regions linked to one other by hydrogen bonds. Separate, parallel protein chains also may be hydrogen-bonded to each other through their β -pleated regions.

Tertiary²⁵ (TUR-she-air-ee) **structure** is formed by the further bending and folding of proteins into various globular and fibrous shapes. It results from hydrophobic radicals associating with each other and avoiding water, while the hydrophilic radicals are attracted to the surrounding water. Van der Waals forces play a significant role in stabilizing tertiary structure. *Globular proteins*, somewhat resembling a wadded ball of yarn, have a compact tertiary structure well suited for proteins embedded in cell membranes and proteins that must move around freely in the body fluids, such as enzymes and antibodies. *Fibrous proteins* such as myosin, keratin, and collagen are slender filaments better suited for such roles as muscle contraction and providing strength to skin, hair, and tendons.

The amino acid cysteine (Cys), whose radical is $-\text{CH}_2-\text{SH}$ (see fig. 2.23), often stabilizes a protein's tertiary structure by forming covalent **disulfide bridges**. When two cysteines align with each other, each can release a hydrogen atom, leaving the sulfur atoms to form a disulfide ($-\text{S}-\text{S}-$) bridge. Disulfide bridges hold separate polypeptide chains together in such molecules as antibodies and insulin (fig. 2.25).

Quaternary²⁶ (QUA-tur-nare-ee) **structure** is the association of two or more polypeptide chains by noncovalent forces such as ionic bonds and hydrophilic-hydrophobic interactions. It occurs in only some proteins. Hemoglobin, for example, consists of four polypeptides: two identical

alpha chains and two identical, slightly longer beta chains (see fig. 2.24).

One of the most important properties of proteins is their ability to change conformation, especially tertiary structure. This can be triggered by such influences as voltage changes on a cell membrane during the action of nerve cells, the binding of a hormone to a protein, or the dissociation of a molecule from a protein. Subtle, reversible changes in conformation are important to processes such as enzyme function, muscle contraction, and the opening and closing of pores in cell membranes. **Denaturation** is a more drastic conformational change in response to conditions such as extreme heat or pH. It is seen, for example, when you cook an egg and the egg white (albumen) turns from clear and runny to opaque and stiff. Denaturation is sometimes reversible, but often it permanently destroys protein function.

Conjugated proteins have a non-amino acid moiety called a **prosthetic**²⁷ **group** covalently bound to them. Hemoglobin, for example, not only has the four polypeptide chains described earlier, but each chain also has a complex iron-containing ring called a *heme* moiety attached to it (see fig. 2.24). Hemoglobin cannot transport oxygen unless this group is present. In glycoproteins, as described earlier, the carbohydrate moiety is a prosthetic group.

Protein Functions

Proteins have more diverse functions than other macromolecules. These include

- **Structure.** *Keratin*, a tough structural protein, gives strength to the nails, hair, and skin surface. Deeper layers of the skin, as well as bones, cartilage, and teeth, contain an abundance of the durable protein *collagen*.
- **Communication.** Some hormones and other cell-to-cell signals are proteins, as are the receptors to which the signal molecules bind in the receiving cell. Any hormone or other molecule that reversibly binds to a protein is called a **ligand**²⁸ (LIG-and).
- **Membrane transport.** Some proteins form channels in cell membranes that govern what passes through the membranes and when. Others act as carriers that briefly bind to solute particles and transport them to the other side of the membrane. Among their other roles, such proteins turn nerve and muscle activity on and off.
- **Catalysis.** Most metabolic pathways of the body are controlled by enzymes, which are globular proteins that function as catalysts.

²⁵ *tert* = third²⁶ *quater* = fourth²⁷ *prosth*e = appendage, addition²⁸ *lig* = to bind

Primary structure

Sequence of amino acids joined by peptide bonds

Secondary structure

Alpha helix or beta sheet formed by hydrogen bonding

Tertiary structure

Folding and coiling due to interactions among R groups and between R groups and surrounding water

Quaternary structure

Association of two or more polypeptide chains with each other

- Recognition and protection.** The role of glycoproteins in immune recognition was mentioned earlier. Antibodies and other proteins attack and neutralize organisms that invade the body. Clotting proteins protect the body against blood loss.
- Movement.** Movement is fundamental to all life, from the intracellular transport of molecules to the galloping of a racehorse. Proteins, with their special ability to change shape repeatedly, are the basis for all such movement. Some proteins are called *molecular motors* (*motor proteins*) for this reason.
- Cell adhesion.** Proteins bind cells to each other, which enables sperm to fertilize eggs, enables immune cells to bind to enemy cancer cells, and keeps tissues from falling apart.

Enzymes and Metabolism

Enzymes are proteins that function as biological catalysts. They permit biochemical reactions to occur rapidly at normal body temperatures. Enzymes were initially given somewhat arbitrary names, some of which are still with us, such as *pepsin* and *trypsin*. The modern system of naming enzymes, however, is more uniform and informative. It identifies the substance the enzyme acts upon, called its **substrate**; sometimes refers to the enzyme's action; and adds the suffix *-ase*.

FIGURE 2.24 Four Levels of Protein Structure. The molecule shown for quaternary structure is hemoglobin, which is composed of four polypeptide chains. The heme groups are iron-containing nonprotein moieties.

FIGURE 2.25 Primary Structure of Insulin. Insulin is composed of two polypeptide chains joined by disulfide bridges.

Thus, *amylase* digests starch (*amyl-* = starch) and *carbonic anhydrase* removes water (*anhydr-*) from carbonic acid. Enzyme names may be further modified to distinguish different forms of the same enzyme found in different tissues (see Insight 2.4).

To appreciate the effect of an enzyme, think of what happens when paper burns. Paper is composed mainly of glucose (in the form of cellulose). The burning of glucose can be represented by the equation

Paper does not spontaneously burst into flame because few of its molecules have enough kinetic energy to react. Lighting the paper with a match, however, raises the kinetic energy enough to initiate combustion (rapid oxidation). The energy needed to get the reaction started, supplied by the match, is called the **activation energy** (fig. 2.26a).

In the body, we carry out the same reaction and oxidize glucose to water and carbon dioxide to extract its energy. We could not tolerate the heat of combustion in our bodies, however, so we must oxidize glucose in a more controlled way at a biologically feasible and safe

INSIGHT 2.4 Clinical Application

The Diagnostic Use of Isoenzymes

A given enzyme may exist in slightly different forms, called *isoenzymes*, in different cells. Isoenzymes catalyze the same chemical reactions but have enough structural differences that they can be distinguished by standard laboratory techniques. This is useful in the diagnosis of disease. When organs are diseased, some of their cells break down and release specific isoenzymes that can be detected in the blood. Normally, these isoenzymes would not be present in the blood or would have very low concentrations. An elevation in blood levels can help pinpoint what cells in the body have been damaged.

For example, *creatine kinase* (*CK*) occurs in different forms in different cells. An elevated serum level of CK-1 indicates a breakdown of skeletal muscle and is one of the signs of muscular dystrophy. An elevated CK-2 level indicates heart disease, because this isoenzyme comes only from cardiac muscle. There are five isoenzymes of *lactate dehydrogenase* (*LDH*). High serum levels of LDH-1 may indicate a tumor of the ovaries or testes, whereas LDH-5 may indicate liver disease or muscular dystrophy. Different isoenzymes of *phosphatase* in the blood may indicate bone or prostate disease.

temperature. Enzymes make this happen by lowering the activation energy—that is, by reducing the barrier to glucose oxidation (fig. 2.26b)—and by releasing the energy in small steps rather than a single burst of heat.

Enzyme Structure and Action

Figure 2.27 illustrates the action of an enzyme, using the example of *sucrase*, an enzyme that breaks sucrose down to glucose and fructose. The process occurs in three principal steps:

- 1 A substrate molecule approaches a pocket on the enzyme surface called the **active site**. Amino acid side groups in this region of the enzyme are arranged so as to bind functional groups on the substrate molecule. Many enzymes have two active sites, enabling them to bind two different substrates so that they can react with each other.
- 2 The substrate binds to the enzyme, forming an **enzyme-substrate complex**. The fit between a particular enzyme and its substrate is often compared to a lock and key. Just as only one key fits a particular lock, sucrose is the only substrate that fits the active site of sucrase. Sucrase cannot digest other disaccharides such as maltose or lactose. This selectivity is called **enzyme-substrate specificity**.

FIGURE 2.26 Effect of an Enzyme on Activation Energy. (a) Without catalysts, some chemical reactions proceed slowly because of the high activation energy needed to get molecules to react. (b) A catalyst facilitates molecular interaction, thus lowering the activation energy and making the reaction proceed more rapidly.

❖ Does an enzyme release more energy from its substrate than an uncatalyzed reaction would release?

FIGURE 2.27 The Three Steps of an Enzymatic Reaction.

- Sucrase breaks the covalent bond between the two sugars of sucrose, adding H^+ and OH^- groups from water (see fig. 2.15b; not illustrated in fig. 2.27). This hydrolyzes sucrose to two monosaccharides, glucose and fructose, which are then released by the enzyme as its **reaction products**. The enzyme remains unchanged and is ready to repeat the process if another sucrose is available.

Since an enzyme is not consumed by the reaction it catalyzes, one enzyme molecule can consume millions of substrate molecules, and at astonishing speed. A single molecule of carbonic anhydrase, for example, breaks carbonic acid (H_2CO_3) down to H_2O and CO_2 at a rate of 36 million molecules per minute.

Factors that change the shape of an enzyme—notably temperature and pH—tend to alter or destroy the ability of the enzyme to bind its substrate. They disrupt the hydrogen bonds and other weak forces that hold the enzyme in its proper conformation, essentially changing the shape of the “lock” (active site) so that the “key” (substrate) no longer fits. Enzymes vary in optimum pH according to where in the body they normally function. Thus salivary amylase, which digests starch in the mouth, functions best at pH 7 and is inactivated when it is exposed to stomach acid; pepsin, which works in the acidic environment of the stomach, functions best around pH 2; and trypsin, a digestive enzyme that works in the alkaline environment of the small intestine, has an optimum pH of 9.5. Our internal body temperature is nearly

the same everywhere, however, and all human enzymes have a temperature optimum (that is, they produce their fastest reaction rates) near 37°C.

Think About It

Why is homeostasis important for enzyme function?

Cofactors

About two-thirds of human enzymes require a nonprotein partner called a **cofactor**. Inorganic cofactors include iron, copper, zinc, magnesium, and calcium ions. Some of these work by binding to the enzyme and inducing it to fold into a shape that activates its active site. **Coenzymes** are organic cofactors usually derived from niacin, riboflavin, and other water-soluble vitamins. They accept electrons from an enzyme in one metabolic pathway and transfer them to an enzyme in another. For example, cells partially oxidize glucose through a pathway called *glycolysis*. A coenzyme called NAD^+ ,²⁹ derived from niacin, shuttles electrons from this pathway to another one called *aerobic respiration*, which uses energy from the electrons to make ATP (fig. 2.28). If NAD^+ is unavailable, the glycolysis pathway shuts down.

Metabolic Pathways

A **metabolic pathway** is a chain of reactions with each step usually catalyzed by a different enzyme. A simple metabolic pathway can be symbolized

where A is the initial *reactant*, B and C are *intermediates*, and D is the *end product*. The Greek letters above the reaction arrows represent enzymes that catalyze each step of the reaction. A is the substrate for enzyme α , B is the substrate for enzyme β , and C for enzyme γ . Such a pathway can be turned on or off by altering the conformation of any of these enzymes, thereby activating or deactivating them. This can be done by such means as the binding or dissociation of a cofactor, or by an end product of the pathway binding to an enzyme at an earlier step (product D binding to enzyme α and shutting off the reaction chain at that step, for example). In these and other ways, cells are able to turn on metabolic pathways when their end products are needed and shut them down when the end products are not needed.

ATP, Other Nucleotides, and Nucleic Acids

Nucleotides are organic compounds with three principal components: a single or double carbon-nitrogen ring called a *nitrogenous base*, a monosaccharide, and one or more

FIGURE 2.28 The Action of a Coenzyme. A coenzyme such as NAD^+ acts as a shuttle that picks up electrons from one metabolic pathway (in this case, glycolysis) and delivers them to another (in this case, aerobic respiration).

phosphate groups. One of the best-known nucleotides is ATP (fig. 2.29a), in which the nitrogenous base is a double ring called *adenine*, the sugar is *ribose*, and there are three phosphate groups.

Adenosine Triphosphate

Adenosine triphosphate (ATP) is the body's most important energy-transfer molecule. It briefly stores energy gained from exergonic reactions such as glucose oxidation and releases it within seconds for physiological work such as polymerization reactions, muscle contraction, and pumping ions through cell membranes. The second and third phosphate groups of ATP are attached to the rest of the molecule by high-energy covalent bonds traditionally indicated by a wavy line (~) in the structural formula. Since phosphate groups are negatively charged, they repel each other. It requires a high-energy bond to overcome that repellent force and hold them together—especially to add the third phosphate group to a chain that already has two negatively charged phosphates. Most energy transfers to and from ATP involve adding or removing that third phosphate.

Enzymes called **adenosine triphosphatases (ATPases)** are specialized to hydrolyze the third high-energy phosphate bond, producing **adenosine diphosphate (ADP)** and an inorganic phosphate group (P_i). This reaction releases 7.3 kilocalories (kcal) of energy for every mole (505 g) of ATP. Most of this energy escapes as heat, but we live on the portion of it that does useful work. We can summarize this as follows:

The free phosphate groups released by ATP hydrolysis are often added to enzymes or other molecules to activate them. This addition of P_i , called **phosphorylation**,

²⁹nicotinamide adenine dinucleotide

FIGURE 2.29 Adenosine Triphosphate (ATP) and Cyclic Adenosine Monophosphate (cAMP). The last two P~O bonds in ATP, indicated by wavy lines, are high-energy bonds.

is carried out by enzymes called **kinases (phosphokinases)**. The phosphorylation of an enzyme is sometimes the “switch” that turns a metabolic pathway on or off.

ATP is a short-lived molecule, usually consumed within 60 seconds of its formation. The entire amount in the body would support life for less than 1 minute if it were not continually replenished. At a moderate rate of physical activity, a full day’s supply of ATP would weigh twice as much as you do. Even if you never got out of bed, you would need about 45 kg (99 lb) of ATP to stay alive for a day. The reason cyanide is so lethal is that it halts ATP synthesis.

ATP synthesis is explained in detail in chapter 26, but you will find it necessary to become familiar with the general idea of it before you reach that chapter—especially in understanding muscle physiology (chapter 11). Much of the energy for ATP synthesis comes from glucose oxidation (fig. 2.30). The first stage in glucose oxidation (fig. 2.31) is the reaction pathway known as **glycolysis** (gly-COLL-ih-sis). This literally means “sugar splitting,” and indeed its major effect is to split the six-carbon glucose molecule into two three-carbon molecules of *pyruvic acid*. A little ATP is produced in this stage (a net yield of 2 ATP per glucose), but most of the chemical energy of the glucose is still in the pyruvic acid.

What happens to pyruvic acid depends on whether oxygen is available. If not, pyruvic acid is converted to lactic acid by a pathway called **anaerobic**³⁰ (AN-err-OH-bic)

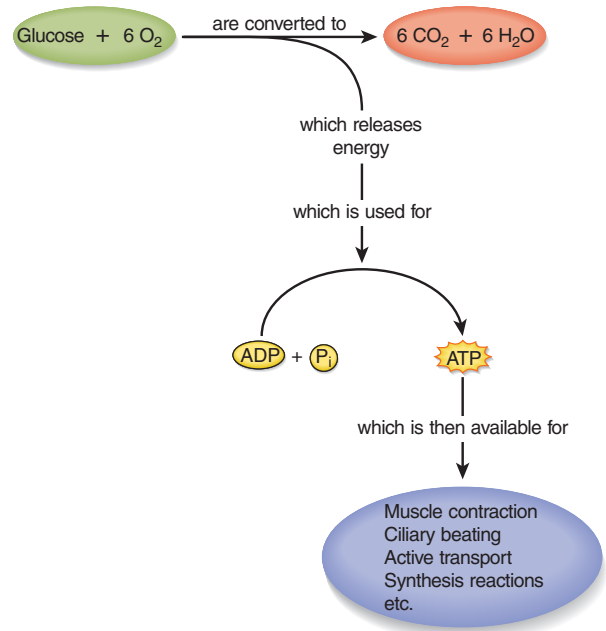

FIGURE 2.30 The Source and Uses of ATP.

³⁰an = without + aer = air + obic = pertaining to life

FIGURE 2.31 ATP Production. Glycolysis produces pyruvic acid and a net gain of two ATPs. In the absence of oxygen, anaerobic fermentation is necessary to keep glycolysis running and producing a small amount of ATP. In the presence of oxygen, aerobic respiration occurs in the mitochondria and produces a much greater amount of ATP.

fermentation. This pathway has two noteworthy disadvantages: First, it does not extract any more energy from pyruvic acid; second, the lactic acid it produces is toxic, so most cells can use anaerobic fermentation only as a temporary measure. The only advantage to this pathway is that it enables glycolysis to continue (for reasons explained in chapter 26) and thus enables a cell to continue producing a small amount of ATP.

If oxygen is available, a more efficient pathway called **aerobic respiration** occurs. This breaks pyruvic acid down to carbon dioxide and water and generates up to 36 more molecules of ATP for each of the original glucose molecules. The reactions of aerobic respiration are carried out in the cell's *mitochondria* (described in the chapter 3), so mitochondria are regarded as a cell's principal "ATP factories."

Other Nucleotides

Guanosine (GWAH-no-seen) **triphosphate (GTP)** is another nucleotide involved in energy transfers. In some reactions, it donates phosphate groups to other molecules.

For example, it can donate its third phosphate group to ADP to regenerate ATP.

Cyclic adenosine monophosphate (cAMP) (see fig. 2.29b) is a nucleotide formed by the removal of both the second and third phosphate groups from ATP. In some cases, when a hormone or other chemical signal ("first messenger") binds to a cell surface, it triggers an internal reaction that converts ATP to cAMP. The cAMP then acts as a "second messenger" to activate metabolic effects within the cell.

Nucleic Acids

Nucleic (new-CLAY-ic) **acids** are polymers of nucleotides. The largest of them, **deoxyribonucleic acid (DNA)**, is typically 100 million to 1 billion nucleotides long. It constitutes our genes, gives instructions for synthesizing all of the body's proteins, and transfers hereditary information from cell to cell when cells divide and from generation to generation when organisms reproduce. Three forms of **ribonucleic acid (RNA)**, which range from 70 to 10,000 nucleotides long, carry out those instructions and synthesize the proteins, assembling amino acids in the right order to produce each protein "described" by the DNA. The detailed structure of DNA and RNA and the mechanisms of protein synthesis and heredity are described in chapter 4.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Which reaction—dehydration synthesis or hydrolysis—converts a polymer to its monomers? Which one converts monomers to a polymer? Explain your answer.
- What is the chemical name of blood sugar? What carbohydrate is polymerized to form starch and glycogen?
- What is the main chemical similarity between carbohydrates and lipids? What are the main differences between them?
- Explain the statement, All proteins are polypeptides but not all polypeptides are proteins.
- Which is more likely to be changed by heating a protein, its primary structure or its tertiary structure? Explain.
- Use the lock-and-key analogy to explain why excessively acidic body fluids (acidosis) could destroy enzyme function.
- How does ATP change structure in the process of releasing energy?
- What advantage and disadvantage does anaerobic fermentation have compared with aerobic respiration?
- How is DNA related to nucleotides?

INSIGHT 2.5 Clinical Application**Anabolic-Androgenic Steroids**

The sex hormone testosterone stimulates muscular growth and aggressive behavior, especially in males. In Nazi Germany, testosterone was given to SS troops in an effort to make them more aggressive, but with no proven success. In the 1950s, pharmaceutical companies developed compounds related to testosterone, called *anabolic-androgenic*³¹ *steroids*, to treat anemia, breast cancer, osteoporosis, and some muscle diseases and to prevent the shrinkage of muscles in immobilized patients. By the early 1960s, athletes were using anabolic-androgenic steroids to stimulate muscle growth, accelerate the repair of tissues damaged in training or competition, and stimulate the aggressiveness needed to excel in some contact sports such as football and boxing.

The doses used by athletes, however, are 10 to 1,000 times higher than the doses prescribed for medical purposes, and they can have devastating effects on one's health. They raise cholesterol levels, which promotes fatty degeneration of the arteries (*atherosclerosis*). This can lead to coronary artery disease, heart and kidney failure, and stroke. Deteriorating blood circulation also sometimes results in gangrene, which may require amputation of the extremities. As the liver attempts to dispose of the high concentration of steroids, liver cancer and other liver diseases may ensue. In addition, steroids suppress the immune system, so the user is more subject to infection and cancer. They cause a premature end to bone elongation, so people who use anabolic steroids in adolescence may never attain normal adult height.

Anabolic-androgenic steroids have the same effect on the brain as natural testosterone. Thus, when steroid levels are high, the brain and pituitary gland stop producing the hormones that stimulate sperm production and testosterone secretion. In men,

this leads to atrophy of the testes, impotence (inability to achieve or maintain an erection), low sperm count, and infertility. Ironically, anabolic-androgenic steroids have feminizing effects on men and masculinizing effects on women. Men may develop enlarged breasts (*gynecomastia*), whereas in some female users the breasts and uterus atrophy, the clitoris enlarges, and ovulation and menstruation become irregular. Female users may develop excessive facial and body hair and a deeper voice, and both sexes show an increased tendency toward baldness.

Especially in men, steroid abuse can be linked to severe emotional disorders. The steroids themselves stimulate heightened aggressiveness and unpredictable mood swings, so the abuser may vacillate between depression and violence ("roid rage"). It surely doesn't help matters that impotence, shrinkage of the testes, infertility, and enlargement of the breasts are so incongruous with the self-image of a male athlete who abuses steroids.

Partly because of the well-documented adverse health effects, the use of anabolic-androgenic steroids in sports has been condemned by the American Medical Association and American College of Sports Medicine and banned by the International Olympic Committee, National Football League, Major League Baseball Players' Association, and National Collegiate Athletic Association. But in spite of such warnings and bans, many athletes continue to use steroids and related performance-enhancing drugs, which remain available through unscrupulous coaches, physicians, Internet sources, and foreign mail-order suppliers. By some estimates, as many as 80% of weight lifters, 30% of college and professional athletes, and 20% of male high school athletes now use anabolic-androgenic steroids. The National Institutes of Health find increasing usage among high school students in recent years, and increasing denial that anabolic-androgenic steroids present a significant health hazard.

³¹*andro* = male + *genic* = producing

CHAPTER REVIEW

Review of Key Concepts

2.1 Atoms, Ions, and Molecules (p. 52)

- The simplest form of matter with unique chemical properties is the *element*. Twenty-four elements play normal physiological roles in humans. Those called *trace elements* are needed in only tiny amounts.
- An *atom* consists of a central positively charged nucleus of protons and usually neutrons, orbited by a usually multilayered cloud of negatively charged electrons.
- The outermost electrons, called *valence electrons*, determine the chemical behavior of an element.
- Isotopes* are variations of an element that differ only in the number of neutrons. Some are unstable *radioisotopes*, which give off radioactivity as they change to a more stable isotope.
- Ions* are particles with one or more excess electrons or protons, and thus a negative charge (*anions*) or positive charge (*cations*). Oppositely charged ions are attracted to each other and tend to follow each other in the body.
- Electrolytes* are salts that ionize in water to form solutions that conduct electricity. These include salts of sodium, potassium, chlorine, phosphate, and bicarbonate (table 2.2).
- Free radicals* are highly reactive particles with an odd number of electrons. They have very destructive effects on cells and may contribute to aging and cancer, but the body has *antioxidant* chemicals that provide some protection from them.
- A *molecule* consists of two or more atoms joined by chemical bonds. If the elements are nonidentical, the molecule is a *compound*.
- Isomers* are molecules with the same number and kinds of elements, but different arrangements of them and different chemical properties.
- A molecule's *molecular weight* is the sum of the atomic weights of its elements.
- Molecules are held together by *ionic*, *covalent*, or *hydrogen bonds*; *van der Waals forces*; or a combination of these.

2.2 Water and Mixtures (p. 59)

- The polarity and bond angle of water result in the hydrogen bonding of water molecules to one another. Hydrogen bonding is responsible for the diverse biologically important properties of water.
- A *mixture* is a combination of substances that are physically blended but not chemically combined. Most mixtures in the body are a combination of water and various solutes.
- Mixtures can be classified as *solutions*, *colloids*, or *suspensions* based on the size of their particles.
- The concentration of a mixture is expressed for differing purposes as weight per volume, percentage, molarity, or (for electrolytes) milliequivalents per liter.
- The concentration of hydrogen ions in a solution is expressed as pH, with a range from 1 to 14. A pH of 7 is neutral (with equal quantities of H⁺ and OH⁻), a pH < 7.0 is acidic, and a pH > 7.0 is basic.
- Buffers* are chemical solutions that resist changes in pH when acid or base is added to them.

2.3 Energy and Chemical Reactions (p. 65)

- Energy*, the capacity to do work, exists in *potential* and *kinetic* forms.
- Chemical reactions can be *decomposition*, *synthesis*, or *exchange* reactions.
- Some chemical reactions are *reversible*; their direction depends on the relative amounts of reactants and products present. Such reactions tend to achieve an *equilibrium* state unless disrupted by the addition of new reactants or removal of products.
- The rate of a chemical reaction is influenced by concentration, temperature, and catalysts.
- Metabolism* is the sum of all chemical reactions in the body. It consists of *catabolism* (breakdown of larger molecules into smaller ones) and *anabolism* (synthesis of larger molecules).

- Oxidation* is the removal of electrons from a molecule; *reduction* is the addition of electrons.

2.4 Organic Compounds (p. 68)

- Organic* molecules contain carbon. They often have carbon atoms arranged in a *backbone* with attached *functional groups* (carboxyl and amino groups, for example) that determine the chemical behavior of the molecule.
- Many biologically important molecules are *polymers*—large molecules composed of a chain of identical or similar subunits called *monomers*.
- The joining of monomers to form a polymer, called *polymerization*, is achieved by a *dehydration synthesis* reaction that removes water from the reactants. Polymers are broken up into monomers by *hydrolysis* reactions, which consume water to add —H and —OH to the molecules.
- Carbohydrates* are organic molecules of carbon and a 2:1 ratio of H:O. The major carbohydrates are the *monosaccharides* (glucose, fructose, galactose), *disaccharides* (sucrose, lactose, maltose), and *polysaccharides* (starch, cellulose, glycogen).
- Carbohydrates are good sources of quickly mobilized energy but also play structural and other roles (table 2.6).
- Lipids* are hydrophobic compounds of carbon and a high ratio of H:O. Major classes of lipids are *fatty acids*, *triglycerides*, *phospholipids*, *icosanoids*, and *steroids*.
- Lipids serve for energy storage, as chemical signals, and as structural components of cells, among other roles (table 2.7).
- Proteins* are polymers of amino acids.
- An *amino acid* is a small organic molecule with an amino (—NH₂) and a carboxyl (—COOH) group. They can join together through *peptide bonds* to form *peptides* from two to thousands of amino acids long. Proteins are generally regarded as peptides of 50 or more amino acids.

10. Proteins have four levels of structure: *primary* (amino acid sequence), *secondary* (an alpha helix or beta sheet), *tertiary* (further bending and folding), and sometimes *quaternary* (attraction of two or more polypeptide chains to each other).
11. Protein function depends strongly on three-dimensional shape, or *conformation*. *Denaturation* is a destructive change in conformation, usually caused by temperature or pH changes.
12. *Conjugated* proteins require a nonprotein component such as a carbohydrate or an inorganic ion attached to them in order to function. The nonprotein moiety is called the *prosthetic group*.
13. Proteins have a wide range of structural, communication, transport, catalytic, and other functions
14. *Enzymes* are proteins that function as biological catalysts. The substances they act upon are called their *substrates*, and bind to an enzyme at specific locations called *active sites*.
15. Enzymes accelerate chemical reactions by lowering their *activation energy*.
16. An enzyme generally reacts only with specific substrates that fit its active site.
17. Enzymatic reactions are often linked together to form *metabolic pathways*.
18. *Adenosine triphosphate (ATP)* is a universal energy-transfer molecule composed of adenine, ribose, and three phosphate groups. It is essential to many physiological processes, and life ends in seconds in the absence of ATP.
19. Small amounts of ATP are generated by glycolysis linked, in the absence of oxygen, to anaerobic fermentation. Much larger amounts are generated when oxygen is available and glycolysis is linked to aerobic respiration.
20. The *nucleic acids*, DNA and RNA, are polymers of ATP-like nucleotides. They are responsible for heredity and the control of protein synthesis.

Testing Your Recall

1. A substance that _____ is considered to be a chemical compound.
 - a. contains at least two different elements
 - b. contains at least two atoms
 - c. has a chemical bond
 - d. has a stable valence shell
 - e. has covalent bonds
2. An ionic bond is formed when
 - a. two anions meet.
 - b. two cations meet.
 - c. an anion meets a cation.
 - d. electrons are unequally shared between nuclei.
 - e. electrons transfer completely from one atom to another.
3. The ionization of a sodium atom to produce Na^+ is an example of
 - a. oxidation.
 - b. reduction.
 - c. catabolism.
 - d. anabolism.
 - e. a decomposition reaction.
4. The weakest and most temporary of the following chemical bonds are
 - a. polar covalent bonds.
 - b. nonpolar covalent bonds.
 - c. hydrogen bonds.
 - d. ionic bonds.
 - e. double covalent bonds.
5. A substance capable of dissolving freely in water is
 - a. hydrophilic.
 - b. hydrophobic.
 - c. hydrolyzed.
 - d. hydrated.
 - e. amphiphilic.
6. A carboxyl group is symbolized
 - a. $-\text{OH}$.
 - b. $-\text{NH}_2$.
 - c. $-\text{CH}_3$.
 - d. $-\text{CH}_2\text{OH}$.
 - e. $-\text{COOH}$.
7. The only polysaccharide synthesized in the human body is
 - a. cellulose.
 - b. glycogen.
 - c. cholesterol.
 - d. starch.
 - e. prostaglandin.
8. The arrangement of a polypeptide into a fibrous or globular shape is called its
 - a. primary structure.
 - b. secondary structure.
 - c. tertiary structure.
 - d. quaternary structure.
 - e. conjugated structure.
9. Which of the following functions is more characteristic of carbohydrates than of proteins?
 - a. contraction
 - b. energy storage
 - c. catalyzing reactions
 - d. immune defense
 - e. intercellular communication
10. The feature that most distinguishes a lipid from a carbohydrate is that a lipid has
 - a. more phosphate.
 - b. more sulfur.
 - c. a lower ratio of carbon to oxygen.
 - d. a lower ratio of oxygen to hydrogen.
 - e. a greater molecular weight.
11. When an atom gives up an electron and acquires a positive charge, it is called a/an _____.
12. Dietary antioxidants are important because they neutralize _____.
13. Any substance that increases the rate of a reaction without being consumed by it is a/an _____. In the human body, _____ serve this function.
14. All the synthesis reactions in the body form a division of metabolism called _____.
15. A chemical reaction that joins two organic molecules into a larger one and produces water as a by-product is called _____.
16. The suffix _____ denotes a sugar, while the suffix _____ denotes an enzyme.
17. The amphiphilic lipids of cell membranes are called _____.
18. A chemical named _____ is derived from ATP and widely employed as a "second messenger" in cellular signaling.
19. When oxygen is unavailable, cells employ a metabolic pathway called _____ to produce ATP.
20. A substance acted upon and changed by an enzyme is called the enzyme's _____.

True or False

Determine which five of the following statements are false, and briefly explain why.

- The monomers of a polysaccharide are called amino acids.
- An emulsion is a mixture of two liquids that separate from each other on standing.
- Two molecules with the same atoms arranged in a different order are called isotopes.
- If a pair of shared electrons are more attracted to one nucleus than to the other, they form a polar covalent bond.
- Amino acids are joined by a unique type of bond called a peptide bond.
- A saturated fat is defined as a fat to which no more carbon can be added.
- Organic compounds get their unique chemical characteristics more from their functional groups than from their carbon backbones.
- The higher the temperature is, the faster an enzyme works.
- Two percent sucrose and 2% sodium bicarbonate have the same number of molecules per liter of solution.
- A solution of pH 8 has one-tenth the hydrogen ion concentration of a solution with pH 7.

Answers in appendix B

Testing Your Comprehension

- Suppose a pregnant woman with severe morning sickness has been vomiting steadily for several days. How will her loss of stomach acid affect the pH of her body fluids? Explain.
- Suppose a person with a severe anxiety attack hyperventilates and exhales CO₂ faster than his body produces it. Consider the carbonic acid reaction on page 66 and explain what effect this hyperventilation will have on his blood pH. (*Hint: Remember the law of mass action.*)
- In one form of nuclear decay, a neutron breaks down into a proton and electron and emits a gamma ray. Is this an endergonic or exergonic reaction, or neither? Is it an anabolic or catabolic reaction, or neither? Explain both answers.
- How would the body's metabolic rate be affected if there were no such thing as enzymes? Explain.
- Some metabolic conditions such as diabetes mellitus cause disturbances in the acid–base balance of the body, which gives the body fluids an abnormally low pH. Explain how this could affect enzyme–substrate reactions and metabolic pathways in the body.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Glycolipids and glycoproteins (p. 71)
- Phospholipids and their amphiphilic nature (p. 72)
- The relationship of protein function to tertiary structure (p. 76)
- Protein functions (p. 76)

All organisms, from the simplest to the most complex, are composed of cells—whether the single cell of a bacterium or the trillions of cells that constitute the human body. These cells are responsible for all structural and functional properties of a living organism. A knowledge of cells is therefore indispensable to any true understanding of the workings of the human body, the mechanisms of disease, and the rationale of therapy. Thus, this chapter and the next one introduce the basic cell biology of the human body, and subsequent chapters expand upon this information as we examine the specialized cellular structure and function of specific organs.

3.1 Concepts of Cellular Structure

Objectives

When you have completed this section, you should be able to

- discuss the development and modern tenets of the cell theory;
- describe cell shapes from their descriptive terms;
- state the size range of human cells and discuss factors that limit cell size;
- discuss the way that developments in microscopy have changed our view of cell structure; and
- outline the major components of a cell.

Development of the Cell Theory

Cytology,¹ the scientific study of cells, was born in 1665 when Robert Hooke observed the empty cell walls of cork and coined the word *cellulae* (“little cells”) to describe them. Soon he studied thin slices of fresh wood and saw living cells “filled with juices”—a fluid later named *protoplasm*.² Two centuries later, Theodor Schwann studied a wide range of animal tissues and concluded that all animals are made of cells.

Schwann and other biologists originally believed that cells came from nonliving body fluid that somehow congealed and acquired a membrane and nucleus. This idea of *spontaneous generation*—that living things arise from nonliving matter—was rooted in the scientific thought of

the times. For centuries, it seemed to be simple common sense that decaying meat turned into maggots, stored grain into rodents, and mud into frogs. Schwann and his contemporaries merely extended this idea to cells. The idea of spontaneous generation wasn’t discredited until some classic experiments by French microbiologist Louis Pasteur in 1859. By the end of the nineteenth century, it was established beyond all reasonable doubt that cells arise only from other cells.

The development of biochemistry from the late nineteenth to the twentieth century made it further apparent that all physiological processes of the body are based on cellular activity and that the cells of all species exhibit remarkable biochemical unity. Thus emerged the generalizations that constitute the modern cell theory:

1. All organisms are composed of cells and cell products.
2. The cell is the simplest structural and functional unit of life. There are no smaller subdivisions of a cell or organism that, in themselves, are alive. An enzyme molecule, for example, is not alive, although the life of a cell depends on the activity of numerous enzymes.
3. An organism’s structure and all of its functions are ultimately due to the activities of its cells.
4. Cells come only from preexisting cells, not from nonliving matter. All life, therefore, traces its ancestry to the same original cells.
5. Because of this common ancestry, the cells of all species have many fundamental similarities in their chemical composition and metabolic mechanisms.

Cell Shapes and Sizes

There are about 200 types of cells in the human body, and they vary greatly in appearance (fig. 3.1). **Squamous**³ (SQUAY-mus) cells are thin, flat, and often have a bulge where the nucleus is—much like the shape of a fried egg “sunny side up.” Such cells line the esophagus and cover the skin. **Polygonal**⁴ cells have irregularly angular shapes with four, five, or more sides. Some nerve cells have multiple extensions that give them a starlike, or **stellate**,⁵ shape. **Cuboidal**⁶ cells are squarish and approximately as tall as they are wide; liver cells are a good example. **Columnar** cells, such as those lining the intestines, are markedly taller than wide. Egg cells and fat cells are **spheroid** to **ovoid** (round to oval). Red blood cells are **discoid** (disc-shaped). Smooth muscle cells are **fusiform**⁷ (FEW-zih-form)—thick in the middle and tapered toward the ends. Skeletal muscle cells are described as **fibrous**

³squam = scale + ous = characterized by

⁴poly = many + gon = angles

⁵stell = star + ate = characterized by

⁶cub = cube + oidal = like, resembling

⁷fusi = spindle + form = shape

¹cyto = cell + logy = study of

²proto = first + plasm = formed

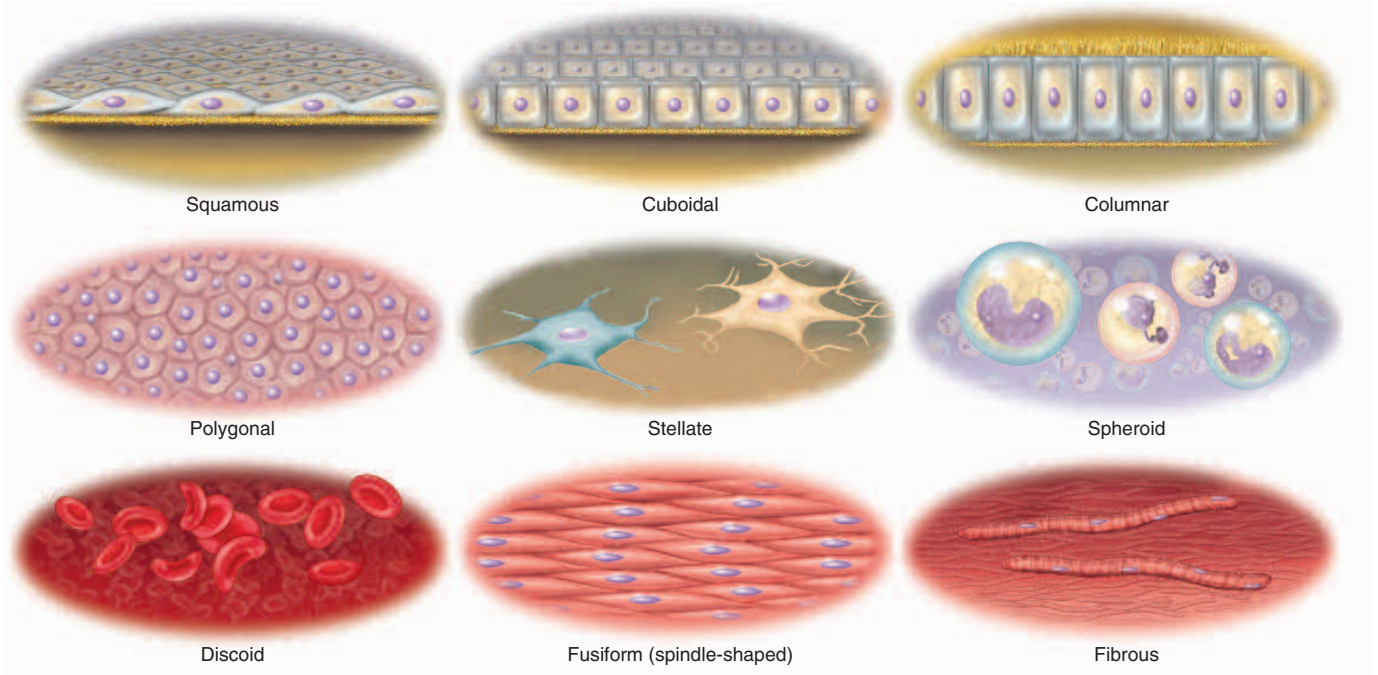

FIGURE 3.1 Common Cell Shapes.

because of their threadlike shape. Some of these shapes refer to the way a cell looks in typical tissue sections, not to the complete three-dimensional shape of the cell. A cell that looks squamous, cuboidal, or columnar in a tissue section, for example, usually looks polygonal if viewed from its upper surface.

Most human cells range from 10 to 15 micrometers (μm) in diameter. (See appendix D for units of measurement.) The human egg cell, an exceptionally large $100 \mu\text{m}$ in diameter, is barely visible to the naked eye. The longest human cells are nerve cells (sometimes over a meter long) and muscle cells (up to 30 cm long), but both are too slender to be seen with the naked eye.

There is a limit to how large a cell can be, partly due to the relationship between its volume and surface area. The surface area of a cell is proportional to the square of its diameter, while volume is proportional to the cube of its diameter. Thus, for a given increase in diameter, volume increases much more than surface area. Picture a cuboidal cell $10 \mu\text{m}$ on each side (fig 3.2). It would have a surface area of $600 \mu\text{m}^2$ ($10 \mu\text{m} \times 10 \mu\text{m} \times 6$ sides) and a volume of $1,000 \mu\text{m}^3$ ($10 \times 10 \times 10 \mu\text{m}$). Now, suppose it grew by another $10 \mu\text{m}$ on each side. Its new surface area would be $20 \mu\text{m} \times 20 \mu\text{m} \times 6 = 2,400 \mu\text{m}^2$, and its volume would be $20 \times 20 \times 20 \mu\text{m} = 8,000 \mu\text{m}^3$.

FIGURE 3.2 The Relationship Between Cell Surface Area and Volume. As a cell doubles in diameter, its volume increases eightfold, but its surface area increases only fourfold. A cell that is too large may have too little plasma membrane to serve the metabolic needs of its increased volume of cytoplasm.

Effect of cell growth:
 Diameter (D) increased by a factor of 2
 Surface area increased by a factor of 4 ($= D^2$)
 Volume increased by a factor of 8 ($= D^3$)

The 20 μm cell has eight times as much protoplasm needing nourishment and waste removal, but only four times as much membrane surface through which wastes and nutrients can be exchanged. A cell that is too big cannot support itself. In addition, an overly large cell is at risk of rupturing like an overfilled water balloon.

Think About It

Can you conceive of some other reasons for an organ to consist of many small cells rather than fewer larger ones?

General Cell Structure

In Schwann's time, little was known about cells except that they were enclosed in a membrane and contained a nucleus. The fluid between the nucleus and surface membrane, called **cytoplasm**, was thought to be little more than a gelatinous mixture of chemicals and vaguely defined particles. The **transmission electron microscope (TEM)**, invented in the mid-twentieth century, radically changed this concept. Using a beam of electrons in place of light, the TEM enabled biologists to see a cell's *ultrastructure* (fig. 3.3), a fine degree of detail extending even to the molecular level. The most important thing about a good

microscope is not magnification but **resolution**—the ability to reveal detail. Any image can be photographed and enlarged as much as we wish, but if enlargement fails to reveal any more useful detail, it is *empty magnification*. A big fuzzy image is not nearly as informative as one that is small and sharp. The TEM reveals far more detail than the light microscope (LM), even at the same magnification (fig. 3.4). A later invention, the **scanning electron microscope (SEM)**, produces dramatic three-dimensional images at high magnification and resolution (see fig. 3.11a), but can only view surface features.

Table 3.1 gives the sizes of some cells and subcellular objects relative to the resolution of the naked eye, light microscope, and TEM. You can see why the very existence of cells was unsuspected until the light microscope was invented, and why little was known about their internal components until the TEM became available.

FIGURE 3.3 Ultrastructure of a White Blood Cell (TEM).

(a) Light microscope (LM)

(b) Transmission electron microscope (TEM)

FIGURE 3.4 Magnification Versus Resolution.

These cells were photographed at the same magnification (about $\times 750$) through (a) a light microscope and (b) a transmission electron microscope.

TABLE 3.1 Sizes of Biological Structures in Relation to the Resolution of the Eye, Light Microscope, and Transmission Electron Microscope

Object	Size
Visible to the Naked Eye (Resolution 70–100 μm)	
Human egg, diameter	100 μm
Visible with the Light Microscope (Resolution 200 nm)	
Most human cells, diameter	10–15 μm
Cilia, length	7–10 μm
Mitochondria, width \times length	0.2 \times 4 μm
Bacteria (<i>Escherichia coli</i>), length	1–3 μm
Microvilli, length	1–2 μm
Lysosomes, diameter	0.5 μm = 500 nm
Visible with the Transmission Electron Microscope (Resolution 0.5 nm)	
Nuclear pores, diameter	30–100 nm
Centriole, diameter \times length	20 \times 50 nm
Polio virus, diameter	30 nm
Ribosomes, diameter	15 nm
Globular proteins, diameter	5–10 nm
Plasma membrane, thickness	7.5 nm
DNA molecule, diameter	2.0 nm
Plasma membrane channels, diameter	0.8 nm

Figure 3.5 shows some major constituents of a typical cell. The cell is surrounded by a **plasma (cell) membrane** made of proteins and lipids. The composition and functions of this membrane can differ significantly from one region of a cell to another, especially among the basal, lateral, and apical (upper) surfaces of cells like the one pictured.

The cytoplasm is crowded with fibers, tubules, passageways, and compartments (see photograph on p. 87 and fig. 3.26). It includes several kinds of **organelles** and a supportive framework called the **cytoskeleton**—all of which we will study in this chapter. A cell may have 10 billion protein molecules, including potent enzymes with the potential to destroy the cell if they are not contained and isolated from other cellular components. You can imagine the enormous problem of keeping track of all this material, directing molecules to the correct destinations, and maintaining order against the incessant trend toward disorder. Cells maintain order partly by compartmentalizing their contents in the organelles.

The organelles and cytoskeleton are embedded in a clear gel called the **cytosol** or **intracellular fluid (ICF)**. The fluid outside the cell is **extracellular fluid (ECF)**.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What are the basic principles of the cell theory?
2. What does it mean to say a cell is squamous, stellate, columnar, or fusiform?
3. Why can cells not grow to unlimited size?
4. What is the difference between cytoplasm and cytosol?
5. Define intracellular fluid (ICF) and extracellular fluid (ECF).

3.2 The Cell Surface

Objectives

When you have completed this section, you should be able to

- describe the structure of a plasma membrane;
- explain the functions of the lipid, protein, and carbohydrate components of the plasma membrane;
- describe a second-messenger system and discuss its importance in human physiology;
- describe the composition and functions of the glycocalyx that coats cell surfaces; and
- describe the structure and functions of microvilli, cilia, and flagella.

Throughout this book, you will find that many of the most physiologically important processes occur at the surface of a cell—such events as immune responses, the binding of egg and sperm, cell-to-cell signaling by hormones, and the detection of tastes and smells, for example. A substantial part of this chapter is therefore concerned with the cell surface. Before we venture into the interior of the cell, we will examine the structure of the plasma membrane, surface features such as cilia and microvilli, and methods of transport through the membrane.

The Plasma Membrane

The electron microscope reveals that the cell and many of the organelles within it are bordered by a *unit membrane*, which appears as a pair of dark parallel lines with a total thickness of about 7.5 nm (fig. 3.6a). The *plasma membrane* is the unit membrane at the cell surface. It defines the boundaries of the cell, governs its interactions with other cells, and controls the passage of materials into and out of the cell. The side that faces the cytoplasm is the *intracellular face* of the membrane, and the side that faces outward is the *extracellular face*.

FIGURE 3.5 Structure of a Representative Cell.

Membrane Lipids

Figure 3.6b shows our current concept of the molecular structure of the plasma membrane—an oily film of lipids with diverse proteins embedded in it. Typically about 98% of the molecules in the membrane are lipids, and about 75% of the lipids are phospholipids. These amphiphilic molecules arrange themselves into a bilayer, with their hydrophilic phosphate-containing heads facing the water on each side of the membrane and their hydrophobic tails directed toward the center, avoiding the water. The phospholipids drift laterally from place to place, spin on their axes, and flex their tails. These movements keep the membrane fluid.

Think About It

What would happen if the plasma membrane were made primarily of a hydrophilic substance such as carbohydrate? Which of the major themes at the end of chapter 1 does this point best exemplify?

Cholesterol molecules, found near the membrane surfaces amid the phospholipids, constitute about 20% of the membrane lipids. By interacting with the phospholipids and holding them still, cholesterol can stiffen the membrane (make it less fluid) in spots. Higher concentrations of cholesterol, however, can increase membrane fluidity by preventing phospholipids from becoming packed closely together.

The remaining 5% of the membrane lipids are glycolipids—phospholipids with short carbohydrate chains on the extracellular face of the membrane. They help to form the *glycocalyx*, a carbohydrate coating on the cell surface with multiple functions described shortly.

Membrane Proteins

Although proteins are only about 2% of the molecules of the plasma membrane, they are larger than lipids and constitute about 50% of the membrane weight. Some of them, called **transmembrane proteins**, pass through the membrane. They have hydrophilic regions in contact with the cytoplasm and extracellular fluid, and hydrophobic regions that pass back and forth through the lipid of the membrane (fig. 3.7). Most transmembrane proteins are glycoproteins, which are conjugated with oligosaccharides on the extracellular side of the membrane. Many of the transmembrane proteins drift about freely in the phospholipid film, like ice cubes floating in a bowl of water. Others are anchored to the *cytoskeleton*—an intracellular system of tubules and filaments discussed later. **Peripheral proteins** do not protrude into the phospholipid layer but adhere to one face of the membrane. A peripheral protein is typically associated with a transmembrane protein and tethered to the cytoskeleton.

FIGURE 3.6 The Plasma Membrane. (a) Plasma membranes of two adjacent cells (TEM). (b) Molecular structure of the plasma membrane.

FIGURE 3.7 Transmembrane Proteins. A transmembrane protein has hydrophobic regions embedded in the phospholipid bilayer and hydrophilic regions projecting into the intracellular and extracellular fluids. The protein may cross the membrane once (left) or multiple times (right). The intracellular regions are often anchored to the cytoskeleton by peripheral proteins.

The functions of membrane proteins include the following:

- **Receptors** (fig. 3.8a). Many of the chemical signals by which cells communicate (epinephrine, for example) cannot enter the target cell but bind to surface proteins called receptors. Receptors are usually specific for one particular messenger, much like an enzyme that is specific for one substrate.
- **Second-messenger systems.** When a messenger binds to a surface receptor, it may trigger changes within the cell that produce a second messenger in the cytoplasm. This process involves both transmembrane proteins (the receptors) and peripheral proteins. Second-messenger systems are discussed later in more detail.
- **Enzymes** (fig. 3.8b). Enzymes in the plasma membrane carry out the final stages of starch and protein digestion in the small intestine, help produce second messengers, and break down hormones and other signaling molecules whose job is done, thus stopping them from excessively stimulating a cell.
- **Ion channels** (fig. 3.8c). Ion channels are transmembrane proteins or protein clusters with pores that allow water and dissolved ions to pass through the membrane. Some channels are always open, while others are **gates** that open and close under different circumstances, thus determining when solutes can pass (fig. 3.8d). These gates respond to three types of stimuli: **ligand-regulated gates** respond to chemical messengers, **voltage-regulated gates** to changes in electrical potential (voltage) across the plasma membrane, and **mechanically regulated gates** to physical stress on a cell, such as stretch and pressure.

By controlling the movement of electrolytes through the plasma membrane, gated channels play an important role in the timing of nerve signals and muscle contraction (see Insight 3.1).

- **Carriers** (see figs. 3.18 and 3.19). Carriers are transmembrane proteins that bind to glucose, electrolytes, and other solutes and transfer them to the other side of the membrane. Some carriers, called **pumps**, consume ATP in the process.
- **Cell-identity markers** (fig. 3.8e). Glycoproteins contribute to the *glycocalyx*, a carbohydrate surface coating discussed shortly. Among other functions, this acts like an “identification tag” that enables our bodies to tell which cells belong to it and which are foreign invaders.
- **Cell-adhesion molecules** (fig. 3.8f). Cells adhere to one another and to extracellular material through membrane proteins called cell-adhesion molecules (CAMs). With few exceptions (such as blood cells and metastasizing cancer cells), cells do not grow or survive normally unless they are mechanically linked to the extracellular material. Special events such as sperm–egg binding and the binding of an immune cell to a cancer cell also require CAMs.

Second Messengers

Second messengers are of such importance that they require a closer look. You will find this information essential for your later understanding of hormone and neurotransmitter action. Let’s consider how the hormone epinephrine stimulates a cell. Epinephrine, the “first messenger,” cannot pass through the plasma membrane, so it binds to a surface receptor. The receptor is linked on

FIGURE 3.8 Some Functions of Membrane Proteins.

INSIGHT 3.1 Clinical Application

Calcium Channel Blockers

Calcium channel blockers are a class of drugs that show the therapeutic relevance of understanding gated membrane channels. The walls of the arteries contain smooth muscle that contracts or relaxes to change their diameter. These changes modify the blood flow and strongly influence blood pressure. Blood pressure rises when the arteries constrict and falls when they relax and dilate. Excessive, widespread vasoconstriction can cause hypertension (high blood pressure), and vasoconstriction in the coronary blood vessels of the heart can cause pain (angina) due to inadequate blood flow to the cardiac muscle. In order to contract, a smooth muscle cell must open calcium channels in its plasma membrane and allow calcium to enter from the extracellular fluid. Calcium channel blockers prevent these channels from opening, thereby relaxing the arteries, relieving angina, and lowering blood pressure.

the intracellular side to a peripheral protein called a **G protein** (fig. 3.9). G proteins are named for the ATP-like chemical, guanosine triphosphate (GTP), from which they get their energy. When activated by the receptor, a G protein relays the signal to another membrane protein, **adenylate cyclase** (ah-DEN-ih-late SY-clase). Adenylate cyclase removes two phosphate groups from ATP and converts it to **cyclic AMP (cAMP)**, the second messenger (see fig. 2.29b). Cyclic AMP then activates enzymes called

kinases (KY-nace-es) in the cytosol. Kinases add phosphate groups to other cellular enzymes. This activates some enzymes and deactivates others, but either way, it triggers a great variety of physiological changes within the cell. Up to 60% of currently used drugs work by altering the activity of G proteins.

The Glycocalyx

External to the plasma membrane, all animal cells have a fuzzy coat called the **glycocalyx**⁸ (GLY-co-CAY-licks) (fig. 3.10), which consists of the carbohydrate moieties of membrane glycolipids and glycoproteins. It is chemically unique in everyone but identical twins, and acts like an identification tag that enables the body to distinguish its own healthy cells from transplanted tissues, invading organisms, and diseased cells. Human blood types and transfusion compatibility are determined by glycolipids. The glycocalyx includes the cell-adhesion molecules that enable cells to adhere to each other and guide the movement of cells in embryonic development. The functions of the glycocalyx are summarized in table 3.2.

Microvilli, Cilia, and Flagella

Many cells have surface extensions called *microvilli*, *cilia*, and *flagella*. These aid in absorption, movement, and sensory processes.

⁸glyco = sugar + calyx = cup, vessel

FIGURE 3.9 A Second-Messenger System.

• Is adenylate cyclase a transmembrane protein or a peripheral protein? What about the G protein?

Microvilli

Microvilli⁹ (MY-cro-VIL-eye; singular, *microvillus*) are extensions of the plasma membrane that serve primarily to increase a cell's surface area (figs. 3.10 and 3.11a, c). They are best developed in cells specialized for absorption, such as the epithelial cells of the intestines and

kidney tubules. They give such cells 15 to 40 times as much absorptive surface area as they would have if their apical surfaces were flat.

Individual microvilli cannot be distinguished very well with the light microscope because they are only 1 to 2 μm long. On some cells, they are very dense and appear as a fringe called the **brush border** at the apical cell surface. With the scanning electron microscope, they resemble a deep-pile carpet. With the transmission electron

⁹micro = small + villi = hairs

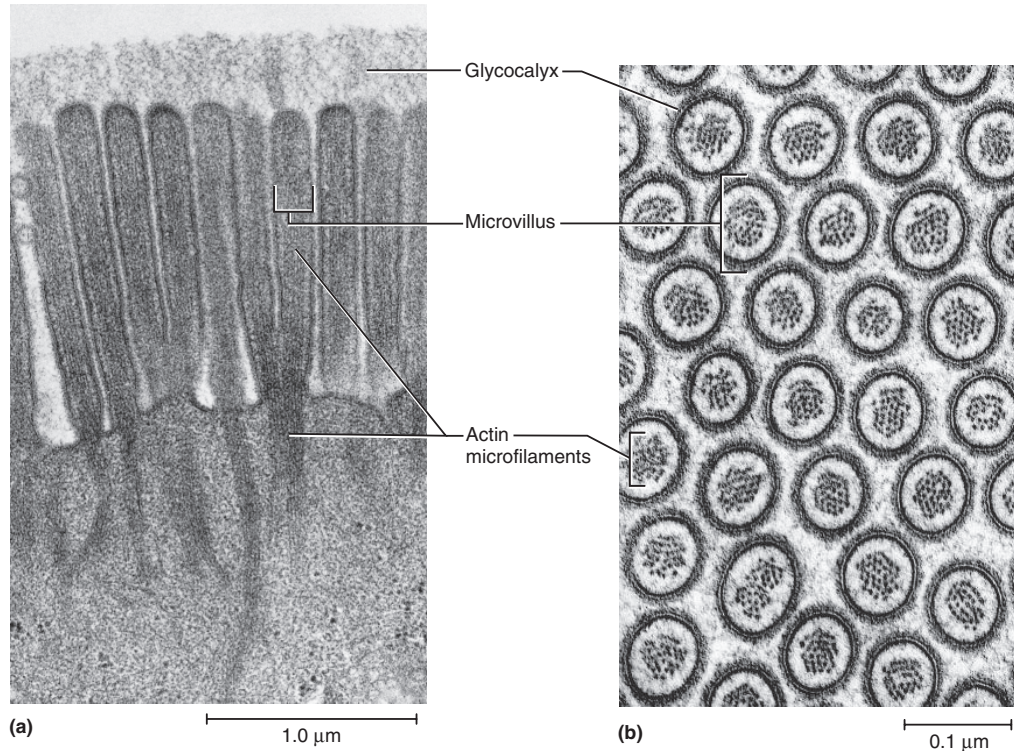

FIGURE 3.10 Microvilli and the Glycocalyx (TEM). The microvilli are anchored by microfilaments of actin, which occupy the core of each microvillus and project into the cytoplasm. (a) Longitudinal section, perpendicular to the cell surface. (b) Cross section.

TABLE 3.2	Functions of the Glycocalyx
Protection	Cushions the plasma membrane and protects it from physical and chemical injury
Immunity to infection	Enables the immune system to recognize and selectively attack foreign organisms
Defense against cancer	Changes in the glycocalyx of cancerous cells enable the immune system to recognize and destroy them
Transplant compatibility	Forms the basis for compatibility of blood transfusions, tissue grafts, and organ transplants
Cell adhesion	Binds cells together so tissues do not fall apart
Fertilization	Enables sperm to recognize and bind to eggs
Embryonic development	Guides embryonic cells to their destinations in the body

microscope, microvilli typically look like finger-shaped projections of the cell surface. They show little internal structure, but some have a bundle of stiff filaments of a protein called *actin*. Actin filaments attach to the inside of the plasma membrane at the tip of the microvillus, and at its base they extend a little way into the cell and anchor the microvillus to a protein mesh called the *terminal web*. When tugged by another protein in the cytoplasm, actin can shorten a microvillus to milk its absorbed contents downward into the cell.

In contrast to the long, shaggy microvilli of absorptive cells, those on many other cells are little more than tiny bumps on the surface. On cells of the taste buds and inner ear, they are well developed but serve sensory rather than absorptive functions.

Cilia

Cilia (SIL-ee-uh; singular, *cilium*¹⁰) (fig. 3.11) are hairlike processes about 7 to 10 μm long. Nearly every human cell has a single, nonmotile *primary cilium* a few micrometers long. Its function in some cases is still a mystery, but

¹⁰*cilium* = eyelash

FIGURE 3.11 Cilia. (a) Inner surface of the trachea (SEM). Several nonciliated, mucus-secreting goblet cells are visible among the ciliated cells. The goblet cells have short microvilli on their surface. (b) Three-dimensional structure of a cilium. (c) Cross section of a few cilia and microvilli (TEM). (d) Cross-sectional structure of a cilium. Note the relative sizes of cilia and microvilli in parts (a) and (c).

apparently many of them are sensory, serving as the cell's “antenna” for monitoring nearby conditions. In the inner ear, they play a role in the sense of balance; in the retina of the eye, they are highly elaborate and form the light-absorbing part of the receptor cells; and in the kidney,

they are thought to monitor the flow of fluid as it is processed into urine. In some cases, they open calcium gates in the plasma membrane, activating an informative signal in the cell. Sensory cells in the nose have multiple non-motile cilia that bind odor molecules.

FIGURE 3.12 Ciliary Action. (a) Cilia of an epithelium moving mucus along a surface layer of saline. (b) Power and recovery strokes of an individual cilium.

Motile cilia are less widespread, occurring in the respiratory tract, uterine (fallopian) tubes, internal cavities (*ventricles*) of the brain, and short ducts (*efferent ductules*) associated with the testes. There may be 50 to 200 cilia on the surface of one cell. They beat in waves that sweep across the surface of an epithelium, always in the same direction (fig. 3.12), propelling such materials as mucus, an egg cell, or cerebrospinal fluid. Each cilium bends stiffly forward and produces a *power stroke* that pushes along the mucus or other matter. Shortly after a cilium begins its power stroke, the one just ahead of it begins, and the next and the next—collectively producing a wavelike motion. After a cilium completes its power stroke, it is pulled limply back by a *recovery stroke* that restores it to the upright position, ready to flex again.

Think About It

How would the movement of mucus in the respiratory tract be affected if cilia were equally stiff on both their power and recovery strokes?

Cilia could not beat freely if they were embedded in sticky mucus (see Insight 3.2). Instead, they beat within a saline (saltwater) layer at the cell surface. *Chloride pumps* in the apical plasma membrane produce this layer by pumping Cl^- into the extracellular fluid. Sodium ions follow by electrical attraction and water follows by osmosis. Mucus essentially floats on the surface of this layer and is pushed along by the tips of the cilia.

The structural basis for ciliary movement is a core called the **axoneme**¹¹ (ACK-so-neem), which consists of an array of thin protein cylinders called *microtubules*. There are two central microtubules surrounded by a ring of nine microtubule pairs—an arrangement called the *9 + 2 structure* (fig. 3.11d). The central microtubules stop

INSIGHT 3.2

Clinical Application

Cystic Fibrosis

The significance of chloride pumps becomes especially evident in *cystic fibrosis* (CF), a hereditary disease affecting primarily white children of European descent. CF is usually caused by a defect in which cells make chloride pumps but fail to install them in the plasma membrane. Consequently, there is an inadequate saline layer on the cell surface and the mucus is dehydrated and overly sticky. This thick mucus plugs the ducts of the pancreas and prevents it from secreting digestive enzymes into the small intestine, so digestion and nutrition are compromised. In the respiratory tract, the mucus clogs the cilia and prevents them from beating freely. The respiratory tract becomes congested with thick mucus, often leading to chronic infection and pulmonary collapse. The mean life expectancy of people with CF is about 30 years.

at the cell surface, but the peripheral microtubules continue a short distance into the cell as part of a **basal body** that anchors the cilium. In each pair of peripheral microtubules, one tubule has two little **dynein**¹² (DINE-een) **arms**. Dynein, a motor protein, uses energy from ATP to “crawl” up the adjacent pair of microtubules. When microtubules on the front of the cilium crawl up the microtubules behind them, the cilium bends toward the front.

Flagella

There is only one functional **flagellum**¹³ (fla-JEL-um) in humans—the whiplike tail of a sperm. It is much longer than a cilium and has an identical axoneme, but between the axoneme and plasma membrane it also has a complex

¹¹axo = axis + neme = thread

¹²dyn = power, energy + in = protein

¹³flagellum = whip

sheath of coarse fibers that stiffen and support the tail. It does not beat with power and recovery strokes like those of a cilium, but in a more undulating, snakelike fashion. It is described in further detail on page 1066.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- How does the structure of a plasma membrane depend on the amphiphilic nature of phospholipids?
- Distinguish between transmembrane and peripheral proteins.
- Explain the differences between a receptor, pump, and cell-adhesion molecule.
- How does a gate differ from other channel proteins? What three factors open and close membrane gates?
- What roles do cAMP, adenylate cyclase, and kinases play in cellular function?
- Identify several reasons why the glycocalyx is important to human survival.
- How do microvilli and cilia differ in structure and function?

3.3 Membrane Transport

Objectives

When you have completed this section, you should be able to

- explain what is meant by a selectively permeable membrane;
- describe the various mechanisms for transporting material through the plasma membrane; and
- define *osmolarity* and *tonicity* and explain their importance.

The plasma membrane is both a barrier and gateway between the cytoplasm and ECF. It is **selectively permeable**—it allows some things through, such as nutrients and wastes, but usually prevents other things, such as proteins and phosphates, from entering or leaving the cell.

The methods of moving substances through the membrane can be classified in two overlapping ways: as *passive* or *active* mechanisms and as *carrier-mediated* or not. Passive mechanisms require no energy (ATP) expenditure by the cell. In most cases, the random molecular motion of the particles themselves provides the necessary energy. Passive mechanisms include filtration, diffusion, and osmosis. Active mechanisms, however, consume ATP. These include active transport and vesicular transport. Carrier-mediated mechanisms use a membrane protein to transport substances from one side of the membrane to the other. We will first consider the mechanisms that

are not carrier-mediated (filtration, simple diffusion, and osmosis) and then the carrier-mediated mechanisms (facilitated diffusion and active transport).

Filtration

Filtration is a process in which particles are driven through a selectively permeable membrane by **hydrostatic pressure**, the force exerted on a membrane by water. A coffee filter provides an everyday example. The weight of the water drives water and dissolved matter through the filter, while the filter holds back larger particles (the coffee grounds). In physiology, the most important case of filtration is seen in the blood capillaries, where blood pressure forces fluid through gaps in the capillary wall (fig. 3.13). This is how water, salts, nutrients, and other solutes are transferred from the bloodstream to the tissue fluid and how the kidneys filter wastes from the blood. Capillaries hold back larger particles such as blood cells and proteins. Unlike the other processes discussed here, this entails movement of materials between cells rather than through the plasma membrane.

Simple Diffusion

Simple diffusion is the net movement of particles from a place of high concentration to a place of lower concentration as a result of their constant, spontaneous motion. It can be observed by dropping a dye crystal in a dish of still water. As the crystal dissolves, it forms a colored zone in the water that gets larger and larger with time (fig. 3.14). The dye molecules exhibit net movement from the point of origin, where their concentration is high, toward the

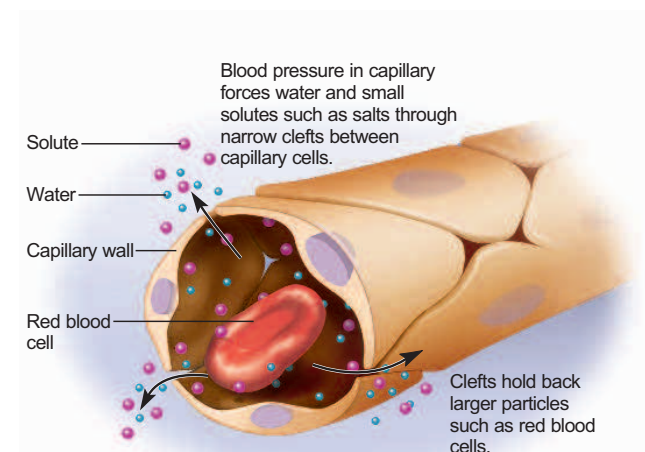

FIGURE 3.13 Filtration Through the Wall of a Blood Capillary. Water and small solutes pass through gaps between cells, while blood cells and other large particles are held back.

FIGURE 3.14 Diffusion in a Concentration Gradient.

Dye molecules diffusing away from a crystal dissolving in water. The direction from high concentration (near the crystal) to low concentration is described as “down the concentration gradient”; the opposite direction is described as “up the concentration gradient.”

edges of the dish, where their concentration is low. When the concentration of a substance differs from one point to another, we say it exhibits a **concentration gradient**. Particle movement from a region of high concentration toward a region of lower concentration is said to go *down*, or *with*, the gradient, and movement in the other direction is said to go *up*, or *against*, the gradient.

Diffusion occurs readily in air or water and doesn't necessarily need a membrane. However, if there is a membrane in the path of the diffusing molecules, and if it is permeable to that substance, the molecules will pass from one side of the membrane to the other. This is how oxygen passes from the air we inhale into the bloodstream. Dialysis treatment for kidney patients is based on diffusion of solutes through artificial *dialysis membranes*.

Diffusion rates are very important to cell survival because they determine how quickly a cell can acquire nutrients or rid itself of wastes. Some factors that affect the rate of diffusion through a membrane are as follows:

- **Temperature.** Diffusion is driven by the kinetic energy of the particles, and temperature is a measure of that kinetic energy. The warmer a substance is, the more rapidly its particles diffuse. This is why sugar diffuses more quickly through hot tea than through iced tea.
- **Molecular weight.** Heavy molecules such as proteins move more sluggishly and diffuse more slowly than light particles such as electrolytes and gases. Small molecules also pass through membrane pores more easily than large ones.
- **“Steepness” of the concentration gradient.** The steepness of a gradient refers to the concentration difference between two points. Particles diffuse more

rapidly if there is a greater concentration difference. For example, we can increase the rate of oxygen diffusion into a patient's blood by using an oxygen mask, thus increasing the difference in oxygen concentration between the air and blood.

- **Membrane surface area.** As noted earlier, the apical surface of cells specialized for absorption (for example, in the small intestine) is often extensively folded into microvilli. This makes more membrane available for particles to diffuse through.
- **Membrane permeability.** Diffusion through a membrane depends on how permeable it is to the particles. For example, potassium ions diffuse more rapidly than sodium ions through a plasma membrane. Nonpolar, hydrophobic, lipid-soluble substances such as oxygen, nitric oxide, alcohol, and steroids diffuse through the phospholipid regions of a plasma membrane. Water and small charged, hydrophilic solutes such as electrolytes do not mix with lipids but diffuse primarily through channel proteins in the membrane. Cells can adjust their permeability to such a substance by adding channel proteins to the membrane, by taking them away, or by opening and closing membrane gates.

Osmosis

Osmosis¹⁴ (oz-MO-sis) is the net flow of water from one side of a selectively permeable membrane to the other. It occurs through nonliving membranes, such as cellophane and dialysis membranes, and through the plasma membranes of cells. The usual direction of net movement is from the side with the higher concentration of water molecules (less dissolved matter) to the side with the lower water concentration (more dissolved matter)—that is, down the water concentration gradient. The reason for this is that when water molecules encounter a solute particle, they tend to associate with it to form a *hydration sphere* (see fig. 2.9, p. 60). Even though this is a loose, reversible attraction, it does make those water molecules less available to diffuse back across the membrane to the side from which they came. In essence, solute particles on one side of the membrane draw water away from the other side. Thus, water accumulates on the side with the most solute.

An exception to this is *reverse osmosis*, in which mechanical pressure applied to one side of the system can drive water through a membrane against its concentration gradient. This principle is used to create highly purified water for laboratory use and to desalinate seawater, converting it to drinkable fresh water—very handy for arid countries and ships at sea.

¹⁴osm = push, thrust + osis = condition, process

Significant amounts of water diffuse even through the hydrophobic, phospholipid regions of a plasma membrane, but it diffuses more easily through the channels of transmembrane proteins called **aquaporins**, specialized for the passage of water. Cells can increase the rate of osmosis by installing more aquaporins in the membrane or decrease the rate by removing them. Certain cells of the kidney, for example, regulate the rate of urinary water loss by adding or removing aquaporins.

A cell can exchange a tremendous amount of water by osmosis. In red blood cells, for example, the amount of water passing through the plasma membrane every second is a hundred times the volume of the cell.

Figure 3.15 is a conceptual model of osmosis. Imagine a chamber divided by a selectively permeable membrane. Side A contains a solution of large particles that cannot pass through the membrane pores—a *nonpermeating* solute such as albumin (egg white protein). Side B contains distilled water. Water passes down its concentration gradient from B to A (fig. 3.15a) and associates with the albumin

molecules in A, hindering their movement back to side B. The rate and direction of osmosis depend on the relative concentration of nonpermeating solutes on the two sides of the membrane.

Under the conditions illustrated, the water level in side B would fall and the level in side A would rise. It might seem as if this would go on indefinitely until side B dried up. This would not happen, however, because as water accumulated in side A, it would become heavier and exert more hydrostatic pressure on that side of the membrane. This would cause some filtration (reverse osmosis) of water from A back to B. At some point, the rate of filtration would equal the rate of “forward” osmosis, water would pass through the membrane equally in both directions, and net osmosis would slow down and stop. At this point, an equilibrium (balance between opposing forces) would exist. The hydrostatic pressure required on side A to halt osmosis is called **osmotic pressure**. The more nonpermeating solute there is in A, the greater the osmotic pressure.

Think About It

If the albumin concentration on side A were half what it was in the original experiment, would the fluid on that side reach a higher or lower level than before? Explain.

FIGURE 3.15 Osmosis. The dashed line represents a selectively permeable membrane dividing the chamber in half. The large particles on side A represent any solute, such as albumin, too large to pass through the membrane. The small particles are water molecules. (a) Water diffuses from side B, where it is relatively concentrated, to side A, where it is less concentrated. Fluid level rises in side A and falls in side B. (b) Net diffusion stops when the weight (hydrostatic pressure) of the fluid in side A balances the osmotic pressure. At this point, water passes at equal rates from A to B by filtration and from B to A by osmosis. The two processes are then in equilibrium.

Osmotic pressure, generated by the solutes, is one of the forces that drives osmosis. As seen in the case of reverse osmosis, however, osmosis can also be driven by mechanical pressure, such as that generated by the pumps of a desalination plant. The body’s principal pump is the heart, which drives water out of the smallest blood vessels (the capillaries) by reverse osmosis—a process called *capillary filtration*. The equilibrium between osmosis and filtration will be an important consideration when we study fluid exchange by the capillaries in chapter 20. Blood plasma also contains albumins. In the preceding discussion, side A is analogous to the bloodstream and side B is analogous to the tissue fluid surrounding the capillaries. Water leaves the capillaries by filtration, but this is approximately balanced by water moving back into the capillaries by osmosis.

Osmolarity and Tonicity

The osmotic concentration of body fluids has such a great effect on cellular function that it is important to understand the units in which it is measured. One **osmole** is 1 mole of dissolved particles. If a solute does not ionize in water, then 1 mole of the solute yields 1 osmole (osm) of dissolved particles. A solution of 1 molar (1 M) glucose, for example, is also 1 osm/L. If a solute does ionize, it yields two or more dissolved particles in solution. A 1 M solution of NaCl, for example, contains 1 mole of sodium ions and 1 mole of chloride ions per liter. Both ions affect osmosis and must be separately counted in a measure of osmotic concentration.

Thus, 1 M NaCl = 2 osm/L. Calcium chloride (CaCl_2) would yield three ions if it dissociated completely (one Ca^{2+} and two Cl^-), so 1 M CaCl_2 = 3 osm/L.

Osmolality is the number of osmoles of solute *per kilogram of water*, and **osmolarity** is the number of osmoles *per liter of solution*. Most clinical calculations are based on osmolarity, since it is easier to measure the volume of a solution than the weight of water it contains. At the concentrations of human body fluids, there is less than 1% difference between osmolality and osmolarity, and the two terms are nearly interchangeable. All body fluids and many clinical solutions are mixtures of many chemicals. The osmolarity of such a solution is the total osmotic concentration of all of its dissolved particles.

A concentration of 1 osm/L is substantially higher than we find in most body fluids, so physiological concentrations are usually expressed in terms of **milliosmoles per liter** (mOsm/L) ($1 \text{ mOsm/L} = 10^{-3} \text{ osm/L}$). Blood plasma, tissue fluid, and intracellular fluid measure about 300 mOsm/L.

Tonicity is the ability of a solution to affect the fluid volume and pressure in a cell. If a solute cannot pass through a plasma membrane but remains more concentrated on one side of the membrane than on the other, it causes osmosis. A **hypotonic**¹⁵ solution has a lower concentration of nonpermeating solutes than the intracellular fluid (ICF). Cells in a hypotonic solution absorb water,

swell, and may burst (*lyse*) (fig. 3.16a). Distilled water is the extreme example; a sufficient quantity given to a person intravenously would lyse the blood cells. A **hypertonic**¹⁶ solution is one with a higher concentration of nonpermeating solutes than the ICF. It causes cells to lose water and shrivel (*crenate*) (fig. 3.16c). Such cells may die of torn membranes and cytoplasmic loss. In **isotonic**¹⁷ solutions, the total concentration of nonpermeating solutes is the same as in the ICF—hence, isotonic solutions cause no change in cell volume or shape (fig. 3.16b).

It is essential for cells to be in a state of osmotic equilibrium with the fluid around them, and this requires that the ECF have the same concentration of nonpermeating solutes as the ICF. Intravenous fluids given to patients are usually isotonic solutions, but hypertonic or hypotonic fluids are given for special purposes. A 0.9% solution of NaCl, called *normal saline*, is isotonic to human blood cells.

It is important to note that osmolarity and tonicity are not the same. Urea, for example, is a small organic molecule that easily penetrates plasma membranes. If cells are placed in 300 mOsm/L urea, urea diffuses into them (down its concentration gradient), water follows by osmosis, and the cells swell and burst. Thus, 300 mOsm/L urea is not isotonic to the cells. Sodium chloride, by contrast, penetrates plasma membranes poorly. In 300 mOsm/L NaCl, there is little change in cell volume; this solution is isotonic to cells.

¹⁵hypo = less + ton = tension

¹⁶hyper = more + ton = tension

(a) Hypotonic

(b) Isotonic

(c) Hypertonic

FIGURE 3.16 Effects of Tonicity on Red Blood Cells (RBCs). (a) In a hypotonic medium such as distilled water, RBCs absorb water, swell, and may burst. (b) In an isotonic medium such as 0.9% NaCl, RBCs gain and lose water at equal rates and maintain their normal, concave disc shape. (c) In a hypertonic medium such as 2% NaCl, RBCs lose more water than they gain and become shrunken and spiky (crenated).

Carrier-Mediated Transport

The processes of membrane transport described up to this point do not necessarily require a cell membrane; they can occur just as well through artificial membranes. Now, however, we come to processes for which a cell membrane is essential, because they employ transport proteins to get through. Thus, the next two processes are cases of **carrier-mediated transport**.

The carriers act like enzymes in some ways: the solute is a ligand that binds to a specific receptor site on the carrier, like a substrate binding to the active site of an enzyme. The carrier exhibits **specificity** for a certain ligand, just as an enzyme does for its substrate. A glucose carrier, for example, cannot transport fructose. Carriers also exhibit **saturation**; as the solute concentration rises, its rate of transport through a membrane increases but only up to a point. When every carrier is occupied, adding more solute cannot make the process go any faster. The carriers are saturated—no more are available to handle the increased demand, and transport levels off at a rate called the **transport maximum (T_m)** (fig. 3.17). As we'll see later in the book, the T_m explains why glucose appears in the urine of people with diabetes mellitus. An important difference between a membrane carrier and an enzyme is that carriers do not chemically change their ligands; they simply pick them up on one side of the membrane and release them, unchanged, on the other.

There are three kinds of carriers: uniports, symports, and antiports. A **uniport**¹⁸ carries one solute at a time. For example, most cells pump out calcium by means of a uniport, maintaining a low intracellular calcium concentration so that calcium salts don't crystallize in the

FIGURE 3.17 Carrier Saturation and Transport Maximum.

Up to a point, increasing the solute concentration increases the rate of transport through a membrane. At the transport maximum (T_m), however, all carrier proteins are busy and cannot transport the solute any faster, even if more solute is added.

cytoplasm. A **symport**¹⁹ carries two or more solutes through a membrane simultaneously in the same direction; this process is called **cotransport**.²⁰ As an example, absorptive cells of the small intestine and kidneys take up sodium and glucose simultaneously by means of a symport. An **antiport**²¹ carries two or more solutes in opposite directions; this process is called **countertransport**. Nearly all cells have an antiport called the *sodium-potassium pump* that continually removes Na^+ from the cell and brings in K^+ .

These carriers employ two mechanisms of transport called facilitated diffusion and active transport. (Any carrier type—uniport, symport, or antiport—can use either of these transport mechanisms.) **Facilitated diffusion** is the carrier-mediated transport of a solute through a membrane *down its concentration gradient*. It is a passive transport process; that is, it does not consume ATP. It transports solutes, such as glucose, that cannot pass through the membrane unaided. The solute attaches to a binding site on the carrier, then the carrier changes conformation and releases the solute on the other side of the membrane (fig. 3.18).

Active transport is the carrier-mediated transport of a solute through a membrane *up its concentration gradient*, using energy provided by ATP. The calcium pumps mentioned previously use active transport. Even though Ca^{2+} is already more concentrated in the ECF than within the cell, these carriers pump still more of it out of the cell. Active transport also enables cells to absorb amino acids that are already more concentrated in the cytoplasm than in the ECF.

A prominent example of active transport is the **sodium-potassium ($\text{Na}^+\text{-K}^+$) pump**, also known as $\text{Na}^+\text{-K}^+$ *ATPase* because the carrier is an enzyme that hydrolyzes ATP. The $\text{Na}^+\text{-K}^+$ pump binds three Na^+ simultaneously on the cytoplasmic side of the membrane, releases these to the ECF, binds two K^+ simultaneously from the ECF, and releases these into the cell (fig. 3.19). Each cycle of the pump consumes one ATP and exchanges three Na^+ for two K^+ . This keeps the K^+ concentration higher and the Na^+ concentration lower within the cell than they are in the ECF. These ions continually leak through the membrane, and the $\text{Na}^+\text{-K}^+$ pump compensates like bailing out a leaky boat.

Lest you question the importance of the $\text{Na}^+\text{-K}^+$ pump, about half of the calories you use each day go to this purpose alone. Beyond compensating for a leaky plasma membrane, the $\text{Na}^+\text{-K}^+$ pump has at least four functions:

1. **Regulation of cell volume.** Certain anions are confined to the cell and cannot penetrate the plasma membrane. These “fixed anions,” such as proteins and phosphates, attract and retain cations. If there

¹⁹*sym* = together + *port* = carry

²⁰*co* = together + *trans* = across + *port* = carry

²¹*anti* = opposite + *port* = carry

²²*facil* = easy

¹⁸*uni* = one + *port* = carry

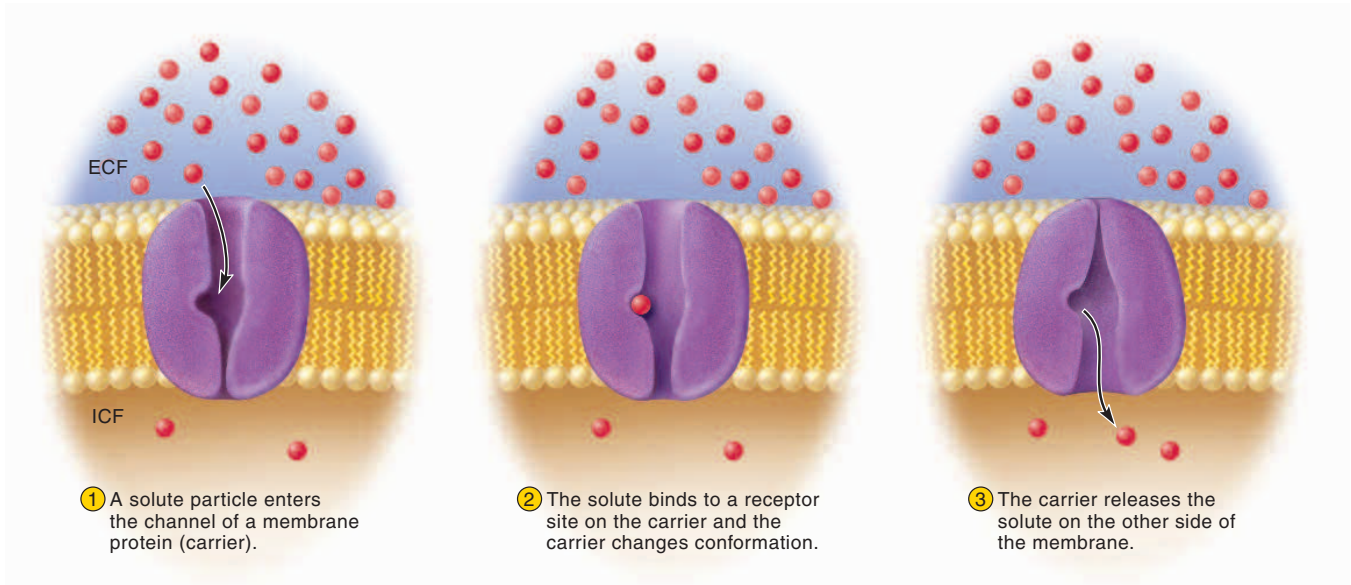

FIGURE 3.18 Facilitated Diffusion. Note that the solute moves down its concentration gradient.

were nothing to correct for it, the retention of these ions would cause osmotic swelling and possibly lysis of the cell. Cellular swelling, however, stimulates the $\text{Na}^+\text{-K}^+$ pumps. Since each cycle of the pump

FIGURE 3.19 The Sodium-Potassium Pump ($\text{Na}^+\text{-K}^+$ ATPase). In each cycle of action, this membrane carrier removes three sodium ions (Na^+) from the cell, brings two potassium ions (K^+) into the cell, and hydrolyzes one molecule of ATP.

Why would the $\text{Na}^+\text{-K}^+$ pump, but not osmosis, cease to function after a cell dies?

removes one ion more than it brings in, the pumps are part of a negative feedback loop that reduces ion concentration, osmolarity, and cellular swelling.

- Secondary active transport.** The $\text{Na}^+\text{-K}^+$ pump maintains a steep concentration gradient of Na^+ and K^+ between one side of the membrane and the other. Like water behind a dam that can be tapped to generate electricity, this gradient has a high potential energy that can drive other processes. Since Na^+ has a high concentration outside the cell, it tends to diffuse back in. Some cells exploit this to move other solutes into the cell. In kidney tubules, for example, the cells have $\text{Na}^+\text{-K}^+$ pumps in the basal membrane that remove Na^+ from the cytoplasm and maintain a low intracellular Na^+ concentration. In the apical membrane, the cells have a facilitated diffusion carrier, the **sodium-glucose transport protein (SGLT)**, which simultaneously binds Na^+ and glucose and carries both into the cell at once (fig. 3.20). By exploiting the tendency of Na^+ to diffuse down its concentration gradient into these cells, the SGLT absorbs glucose and prevents it from being wasted in the urine. The SGLT in itself does not consume ATP, but it does depend on the ATP-consuming $\text{Na}^+\text{-K}^+$ pumps at the base of the cell. We say that glucose is absorbed by *secondary active transport*, as opposed to the *primary active transport* carried out by the $\text{Na}^+\text{-K}^+$ pump.

- Heat production.** When the weather turns chilly, we turn up not only the furnace in our home but also the “furnace” in our body. Thyroid hormone stimulates cells to produce more $\text{Na}^+\text{-K}^+$ pumps. As these pumps consume ATP, they release heat, compensating for the body heat we lose to the cold air around us.

4. **Maintenance of a membrane potential.** All living cells have an electrical charge difference called the *resting membrane potential* across the plasma membrane. Like the two poles of a battery, the inside of the membrane is negatively charged and the outside is positively charged. This difference stems from the unequal distribution of ions on the two sides of the membrane, maintained by the $\text{Na}^+ - \text{K}^+$ pump. The membrane potential is essential to the function of nerve and muscle cells, as we will study in later chapters.

Think About It

An important characteristic of proteins is their ability to change conformation in response to the binding or dissociation of a ligand (chapter 2). Explain how this characteristic is essential to carrier-mediated transport.

FIGURE 3.20 Secondary Active Transport. At the basal surface of the cell, an $\text{Na}^+ - \text{K}^+$ pump removes sodium ions (Na^+) from the cytoplasm, maintaining a low sodium concentration within the cell. At the apical surface, Na^+ enters the cell by facilitated diffusion, following its concentration gradient. It can gain entry to the cell only by binding to a carrier, the sodium-glucose transport protein (SGLT), which simultaneously binds and transports glucose. The SGLT does not consume ATP, but does depend on the ATP-consuming pump at the base of the cell.

Vesicular Transport

So far, we have considered processes that move one or a few ions or molecules at a time through the plasma membrane. **Vesicular transport** processes, by contrast, move large particles, droplets of fluid, or numerous molecules at once through the membrane, contained in bubblelike **vesicles** of membrane. Vesicular processes that bring matter into a cell are called **endocytosis**²³ (EN-doe-sy-TOE-sis) and those that release material from a cell are called **exocytosis**²⁴ (EC-so-sy-TOE-sis). These processes employ motor proteins whose movements are energized by ATP.

There are three forms of endocytosis: phagocytosis, pinocytosis, and receptor-mediated endocytosis. **Phagocytosis**²⁵ (FAG-oh-sy-TOE-sis), or “cell eating,” is the process of engulfing particles such as bacteria, dust, and cellular debris—particles large enough to be seen with a microscope. For example, neutrophils (a class of white blood cells) protect the body from infection by phagocytizing and killing bacteria. A neutrophil spends most of its life crawling about in the connective tissues by means of blunt footlike extensions called **pseudopods**²⁶ (SOO-doe-pods). When a neutrophil encounters a bacterium, it surrounds it with pseudopods and traps it in a **phagosome**²⁷—a vesicle in the cytoplasm surrounded by a unit membrane (fig. 3.21). A lysosome merges with the vacuole, converting it to a *phagolysosome*, and contributes enzymes that destroy the invader. Several other kinds of phagocytic cells are described in chapter 21. In general, phagocytosis is a way of keeping the tissues free of debris and infectious microbes. Some cells called *macrophages* (literally, “big eaters”) phagocytize the equivalent of 25% of their own volume per hour.

Pinocytosis²⁸ (PIN-oh-sy-TOE-sis), or “cell drinking,” is the process of taking in droplets of ECF containing molecules of some use to the cell. While phagocytosis occurs in only a few specialized cells, pinocytosis occurs in all human cells. The process begins as the plasma membrane becomes dimpled, or caved in, at points. These pits soon separate from the surface membrane and form small membrane-bounded **pinocytotic vesicles** in the cytoplasm. The vesicles contain droplets of the ECF with whatever molecules happened to be there.

Receptor-mediated endocytosis (fig. 3.22) is a more selective form of either phagocytosis or pinocytosis. It enables a cell to take in specific molecules from the ECF with a minimum of unnecessary matter. Particles in the ECF bind to specific receptors on the plasma membrane. The receptors then cluster together and the membrane sinks in at this point, creating a pit coated with a

FIGURE 3.21 Phagocytosis, Intracellular Digestion, and Exocytosis.

peripheral membrane protein called *clathrin*.²⁹ The pit soon pinches off to form a *clathrin-coated vesicle* in the cytoplasm. Clathrin may serve as an “address label” on the coated vesicle that directs it to an appropriate destination in the cell, or it may inform other structures in the cell what to do with the vesicle.

One example of receptor-mediated endocytosis is the uptake of *low-density lipoproteins (LDLs)*—protein-coated droplets of cholesterol and other lipids in the blood (see chapter 26). The thin endothelial cells that line our blood vessels have LDL receptors on their surfaces and absorb LDLs in clathrin-coated vesicles. Inside the cell, the LDL is freed from the vesicle and metabolized, and the membrane with its receptors is recycled to the cell surface. Much of what we know about receptor-mediated endocytosis comes from studies of a hereditary disease called *familial hypercholesterolemia*, which dramatically illustrates the significance of this process to our cardiovascular health (see Insight 3.3).

Endothelial cells also imbibe insulin by receptor-mediated endocytosis. Insulin is too large a molecule to pass through channels in the plasma membrane, yet it must

somehow get out of the blood and reach the surrounding cells if it is to have any effect. Endothelial cells take up insulin by receptor-mediated endocytosis, transport the vesicles across the cell, and release the insulin on the other side, where tissue cells await it. Such transport of material

INSIGHT 3.3 Clinical Application

Familial Hypercholesterolemia

The significance of LDL receptors and receptor-mediated endocytosis is dramatically illustrated by a hereditary disease called *familial hypercholesterolemia*.³⁰ People with this disease have an abnormally low number of LDL receptors. Their cells therefore absorb less cholesterol than normal, and the cholesterol remains in the blood. Their blood cholesterol levels may be as high as 1,200 mg/dL, compared with a normal level of about 200 mg/dL. People who inherit the gene from both parents typically have heart attacks before the age of 20 (sometimes even in infancy) and seldom survive beyond the age of 30.

²⁹*clathr* = lattice + *in* = protein

³⁰*familial* = running in the family; *hyper* = above normal + *cholesterol* + *emia* = blood condition

FIGURE 3.22 Receptor-Mediated Endocytosis.

across a cell (capture on one side and release on the other side) is called **transcytosis**³¹ (fig. 3.23). This process is especially active in muscle capillaries and transfers a significant amount of blood albumin into the tissue fluid.

Receptor-mediated endocytosis is not always to our benefit; hepatitis, polio, and AIDS viruses trick our cells into engulfing them by receptor-mediated endocytosis.

Exocytosis (fig. 3.24) is the process of discharging material from a cell. It occurs, for example, when endothelial cells release insulin to the tissue fluid, mammary gland cells secrete milk, other gland cells release hormones, and sperm cells release enzymes for penetrating an egg. It bears a superficial resemblance to endocytosis in reverse. A secretory vesicle in the cell migrates to the surface and “docks” on peripheral proteins of the plasma membrane. These proteins pull the membrane inward and create a dimple that eventually fuses with the vesicle and allows it to release its contents.

The question might occur to you, If endocytosis continually takes away bits of plasma membrane to form intracellular vesicles, why doesn't the membrane grow smaller and smaller? Another purpose of exocytosis, however, is to replace plasma membrane that has been removed by endocytosis or become damaged or worn out. Plasma membrane is continually recycled from the cell surface into the cytoplasm and back to the surface.

Table 3.3 summarizes the mechanisms of transport we have discussed.

FIGURE 3.23 Transcytosis. An endothelial cell of a capillary imbibes droplets of blood plasma at sites indicated by arrows along the right. This forms pinocytotic vesicles, which the cell transports to the other side. Here, it releases the contents by exocytosis at sites indicated by arrows along the left side of the cell. This process is especially active in muscle capillaries and transfers a significant amount of blood albumin into the tissue fluid.

Why isn't transcytosis listed as a separate means of membrane transport, in addition to pinocytosis and the others?

³¹trans = across + cyt = cell + osis = process

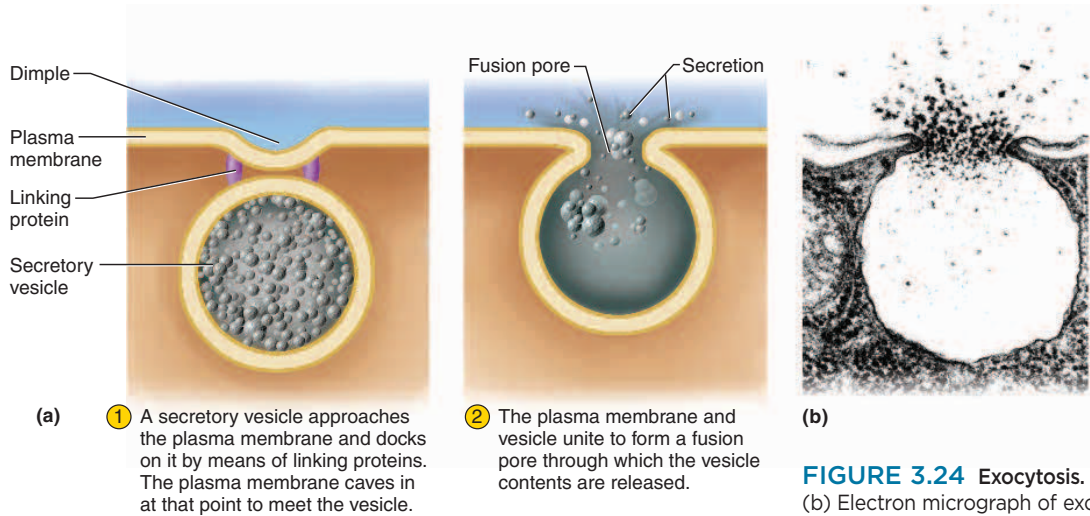

FIGURE 3.24 Exocytosis. (a) Stages of exocytosis. (b) Electron micrograph of exocytosis.

TABLE 3.3

Methods of Membrane Transport

Transport Without Carriers	Movement of material without the aid of carrier proteins
Filtration	Movement of water and solutes through a selectively permeable membrane as a result of hydrostatic pressure
Simple diffusion	Diffusion of particles through water or air or through a living or artificial membrane, down their concentration gradient, without the aid of membrane carriers
Osmosis	Net flow of water through a selectively permeable membrane, driven by either a difference in solute concentration or a mechanical force
Carrier-Mediated Transport	Movement of material through a cell membrane with the aid of carrier proteins
Facilitated diffusion	Transport of particles through a selectively permeable membrane, down their concentration gradient, by a carrier that does not directly consume ATP
Active transport	Transport of particles through a selectively permeable membrane, up their concentration gradient, with the aid of a carrier that consumes ATP
Primary active transport	Direct transport of solute particles by an ATP-using membrane pump
Secondary active transport	Transport of solute particles by a carrier that does not in itself use ATP but depends on concentration gradients produced by primary active transport
Cotransport	Transport of two or more solutes simultaneously in the same direction through a membrane by either facilitated diffusion or active transport
Countertransport	Transport of two or more different solutes in opposite directions through a membrane by either facilitated diffusion or active transport
Uniport	A carrier that transports only one solute, using either facilitated diffusion or active transport
Symport	A carrier that performs cotransport
Antiport	A carrier that performs countertransport
Vesicular (Bulk) Transport	Movement of fluid and particles through a plasma membrane by way of membrane vesicles; consumes ATP
Endocytosis	Vesicular transport of particles into a cell
Phagocytosis	Process of engulfing large particles by means of pseudopods; "cell eating"
Pinocytosis	Process of imbibing extracellular fluid in which the plasma membrane sinks in and pinches off small vesicles containing droplets of fluid
Receptor-mediated endocytosis	Phagocytosis or pinocytosis in which specific solute particles bind to receptors on the plasma membrane, and are then taken into the cell in clathrin-coated vesicles with a minimal amount of extraneous matter
Exocytosis	Process of eliminating material from a cell by means of a vesicle approaching the cell surface, fusing with the plasma membrane, and expelling its contents; used to release cell secretions, replace worn-out plasma membrane, and replace membrane that has been internalized by endocytosis

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

13. What is the importance of filtration to human physiology?
14. What does it mean to say a solute moves down its concentration gradient?
15. How does osmosis help to maintain blood volume?
16. Define osmolarity and tonicity, and explain the difference between them.
17. Define hypotonic, isotonic, and hypertonic, and explain why these concepts are important in clinical practice.
18. What do facilitated diffusion and active transport have in common? How are they different?
19. How does the $\text{Na}^+ - \text{K}^+$ pump exchange sodium ions for potassium ions across the plasma membrane? What are some purposes served by this pump?
20. How does phagocytosis differ from pinocytosis?
21. Describe the process of exocytosis. What are some of its purposes?

3.4 The Cell Interior

Objectives

When you have completed this section, you should be able to

- list the main organelles of a cell, describe their structure, and explain their functions;
- describe the cytoskeleton and its functions; and
- give some examples of cell inclusions and explain how inclusions differ from organelles.

We now probe more deeply into the cell to study the structures in the cytoplasm. These are classified into three groups—*organelles*, *cytoskeleton*, and *inclusions*—all embedded in the clear, gelatinous cytosol.

Organelles

Organelles are internal structures of a cell that carry out specialized metabolic tasks. Some are surrounded by one or two layers of unit membrane and are therefore referred to as *membranous organelles*. These are the nucleus, mitochondria, lysosomes, peroxisomes, endoplasmic reticulum, and Golgi complex. Organelles that are not surrounded by membranes include the ribosomes, centrosome, centrioles, and basal bodies.

The Nucleus

The **nucleus** is the largest organelle and usually the only one visible with the light microscope. It is usually spheroid

to elliptical in shape and typically about 5 μm in diameter. Most cells have a single nucleus, but there are exceptions. Mature red blood cells have none; they are **anuclear**. A few cell types are **multinucleate**, having 2 to 50 nuclei. Examples include skeletal muscle cells, some liver cells, and certain bone-dissolving and platelet-producing cells.

With the TEM, the nucleus can be distinguished by the two unit membranes surrounding it, which together form the **nuclear envelope** (fig. 3.25). The envelope is perforated with **nuclear pores**, about 30 to 100 nm in diameter, formed by a ring of proteins. These proteins regulate molecular traffic through the envelope and act like a rivet to hold the two unit membranes together. Hundreds of molecules pass through the nuclear pores every minute. Coming into the nucleus are raw materials for DNA and RNA synthesis, enzymes that are made in the cytoplasm but function in the nucleus, and hormones that activate certain genes. Going the other way, RNA is made in the nucleus but leaves to perform its job in the cytoplasm.

Immediately inside the nuclear envelope is a narrow but densely fibrous zone called the **nuclear lamina**. This is composed of a web of protein filaments. It supports the nuclear envelope and pores, provides points of attachment and organization for the chromatin inside the nucleus, and plays a role in regulation of the cell life cycle. Abnormalities of its structure or function are associated with certain genetic diseases and premature cell death.

The material in the nucleus is called **nucleoplasm**. This includes **chromatin**³² (CRO-muh-tin)—fine thread-like matter composed of DNA and protein—and one or more dark-staining masses called **nucleoli** (singular, *nucleolus*), where ribosomes are produced. The genetic function of the nucleus is described in chapter 4.

Endoplasmic Reticulum

Endoplasmic reticulum (ER) literally means “little network within the cytoplasm.” It is a system of interconnected channels called **cisternae**³³ (sis-TUR-nee) enclosed by a unit membrane (fig. 3.26). Parts of it called **rough endoplasmic reticulum** are composed of parallel, flattened sacs covered with granules called *ribosomes*. The rough ER is continuous with the outer membrane of the nuclear envelope, and adjacent cisternae are often connected by perpendicular bridges. The parts called **smooth endoplasmic reticulum** lack ribosomes, have more tubular cisternae, and branch more extensively. The cisternae of the smooth ER are thought to be continuous with those of the rough ER, so the two are functionally different parts of the same network.

The ER synthesizes steroids and other lipids, detoxifies alcohol and other drugs, and manufactures all membranes of the cell. Rough ER produces the phospholipids and proteins of the plasma membrane and synthesizes

³²chromat = color

³³cistern = reservoir

FIGURE 3.25 The Nucleus. These photomicrographs were made by different TEM methods to show the internal structure of the nucleus and surface of the nuclear envelope.

Why do these nuclear pores have to be larger in diameter than the channels in the cell's plasma membrane? (See table 3.1.)

proteins that are either packaged in other organelles such as lysosomes or secreted from the cell. Rough ER is most abundant in cells that synthesize large amounts of protein, such as antibody-producing cells and cells of the digestive glands. This role is discussed further in chapter 4.

Most cells have only a scanty smooth ER, but it is relatively abundant in cells that engage extensively in detoxification, such as liver and kidney cells. Long-term abuse of alcohol, barbiturates, and other drugs leads to tolerance partly because the smooth ER proliferates and detoxifies the drugs more quickly. Smooth ER is also abundant in cells of the testes and ovaries that synthesize steroid hormones. Skeletal and cardiac muscle contain extensive networks of smooth ER that store calcium and release it to trigger muscle contraction.

Ribosomes

Ribosomes are small granules of protein and RNA found in the nucleoli, in the cytosol, and on the outer surfaces of the rough ER and nuclear envelope. They “read” coded genetic messages (messenger RNA) and assemble amino acids into proteins specified by the code. This process is detailed in chapter 4.

Golgi Complex

The **Golgi**³⁴ (GOAL-jee) **complex** is a small system of cisternae that synthesize carbohydrates and put the finishing

touches on protein and glycoprotein synthesis. The complex resembles a stack of pita bread. Typically, it consists of about six cisternae, slightly separated from each other; each cisterna is a flattened, often curved sac with swollen edges (fig. 3.27; see also fig. 3.3). The Golgi complex receives newly synthesized proteins from the rough ER. It sorts them, cuts and splices some of them, adds carbohydrate moieties to some, and finally packages the proteins in membrane-bounded **Golgi vesicles**. These vesicles bud off the swollen rim of a cisterna and are seen in abundance in the neighborhood of the Golgi complex. Some vesicles become *lysosomes*, the organelle discussed next; some migrate to the plasma membrane and fuse with it, contributing fresh protein and phospholipid to the membrane; and some become **secretory vesicles** that store a cell product, such as breast milk or digestive enzymes, for later release. The role of the Golgi complex in protein synthesis and secretion is detailed in chapter 4.

Lysosomes

A **lysosome**³⁵ (LY-so-some) (fig. 3.28a) is a package of enzymes bounded by a single unit membrane. Although often round or oval, lysosomes are extremely variable in shape. When viewed with the TEM, they often exhibit dark gray contents devoid of structure, but sometimes show crystals or parallel layers of protein. At least 50 lysosomal enzymes have been identified. They hydrolyze proteins, nucleic acids, complex carbohydrates, phospholipids,

³⁴Camillo Golgi (1843–1926), Italian histologist

³⁵*lyso* = loosen, dissolve + *some* = body

FIGURE 3.26 Endoplasmic Reticulum (ER). (a) Rough ER. (b) Smooth ER and an inclusion (oil droplet). (c) Structure of the endoplasmic reticulum, with rough and smooth regions.

and other substrates. In the liver, lysosomes break down stored glycogen to release glucose into the bloodstream. White blood cells use their lysosomes to digest phagocytized bacteria. Lysosomes also digest and dispose of worn-out mitochondria and other organelles; this process is called **autophagy**³⁶ (aw-TOFF-uh-jee). They also aid in a process of “cell suicide.” Some cells are meant to do a certain job and then destroy themselves. The uterus, for example, weighs about 900 g at full-term pregnancy and

shrinks to 60 g within 5 or 6 weeks after birth. This shrinkage is due to **autolysis**,³⁷ the digestion of surplus cells by their own lysosomal enzymes. Such *programmed cell death* is further discussed in chapter 5.

Peroxisomes

Peroxisomes (fig. 3.28b) resemble lysosomes but contain different enzymes and are not produced by the Golgi complex. Their general function is to use molecular oxygen (O_2)

³⁶auto = self + phagy = eating

³⁷auto = self + lysis = dissolving

FIGURE 3.27 The Golgi Complex.

FIGURE 3.28 Lysosomes and Peroxisomes.

to oxidize organic molecules. These reactions produce hydrogen peroxide (H_2O_2)—hence, the name of the organelle. H_2O_2 is then used to oxidize other molecules, and the excess is broken down to water and oxygen by an enzyme called *catalase*.

Peroxisomes occur in nearly all cells but are especially abundant in liver and kidney cells. They neutralize free radicals and detoxify alcohol, other drugs, and a variety of blood-borne toxins. Peroxisomes also decompose fatty acids into two-carbon acetyl groups, which the mitochondria then use as an energy source for ATP synthesis.

Mitochondria

Mitochondria³⁸ (MY-toe-CON-dree-uh) (fig. 3.29) are organelles specialized for synthesizing ATP. They have a variety of shapes: spheroid, rod-shaped, kidney bean-shaped, or threadlike. Like the nucleus, a mitochondrion is surrounded by a double unit membrane. The inner membrane usually has folds called **cris**tae³⁹ (CRIS-tee), which project like shelves across the organelle. The space

between the cristae, called the **matrix**, contains ribosomes; enzymes used in ATP synthesis; and a small, circular DNA molecule called *mitochondrial DNA (mtDNA)*. Mitochondria are the “powerhouses” of the cell. Energy is not *made* here, but it is extracted from organic compounds and transferred to ATP, primarily by enzymes located on the cristae. The role of mitochondria in ATP synthesis is explained in detail in chapter 26, and some evolutionary and clinical aspects of mitochondria are discussed at the end of this chapter (see Insight 3.4).

Centrioles

A **centriole** (SEN-tree-ole) is a short cylindrical assembly of microtubules, arranged in nine groups of three microtubules each (fig. 3.30). Two centrioles lie perpendicular to each other within a small clear area of cytoplasm called the **centrosome**⁴⁰ (see fig. 3.5). They play a role in cell division described in chapter 4. Each basal body of a flagellum or cilium is a single centriole oriented perpendicular to the plasma membrane. Basal bodies originate in a *centriolar*

³⁸*mito* = thread + *chondr* = grain

³⁹*crista* = crest

⁴⁰*centro* = central + *some* = body

FIGURE 3.29 A Mitochondrion.

FIGURE 3.30 Centrioles. (a) Electron micrograph of a centriole as seen in cross section. (b) A pair of perpendicular centrioles.

How does a centriole resemble the axoneme of a cilium? How does it differ?

organizing center and migrate to the plasma membrane. Two microtubules of each triplet then elongate to form the nine pairs of peripheral microtubules of the axoneme. A cilium can grow to its full length in less than an hour.

The Cytoskeleton

The **cytoskeleton** is a collection of protein filaments and cylinders that determine the shape of a cell, lend it structural support, organize its contents, direct the movement of substances through the cell, and contribute to movements of the cell as a whole. It can form a very dense supportive scaffold in the cytoplasm (fig. 3.31). It is connected to transmembrane proteins of the plasma membrane, and they in turn are connected to protein fibers external to the cell, so there is a strong structural continuity from extracellular material to the cytoplasm. Cytoskeletal elements may even connect to chromosomes in the nucleus, enabling physical tension on a cell to move nuclear contents and mechanically stimulate genetic function.

The cytoskeleton is composed of *microfilaments*, *intermediate filaments*, and *microtubules*. **Microfilaments** are about 6 nm thick and are made of the protein *actin*. They form a network on the cytoplasmic side of the plasma membrane called the **terminal web (membrane skeleton)**. The phospholipids of the plasma membrane spread out

over the membrane skeleton like butter on a slice of bread. Like butter acting as a moisture barrier in a sandwich, the phospholipids of the plasma membrane act as a permeability barrier at the cell surface, whereas the terminal web, like the bread, provides physical support. It is thought that the phospholipids would break up into little droplets without this cytoskeletal bed.

The roles of actin in supporting microvilli and producing cell movements were discussed earlier. Through its role in cell motility, actin plays a crucial role in embryonic development, muscle contraction, immune function, wound healing, cancer metastasis, and other processes that involve cell migration.

Intermediate filaments (8–10 nm in diameter) are thicker and stiffer than microfilaments. They resist stresses placed on a cell and participate in junctions that attach some cells to their neighbors. In epidermal cells, they are made of the tough protein *keratin* and occupy most of the cytoplasm. They are responsible for the strength of hair and fingernails. Intermediate filaments also line the inside of the nuclear envelope and form the cage-like nuclear lamina that encloses the DNA.

A **microtubule** (25 nm in diameter) is a cylinder made of 13 parallel strands called *protofilaments*. Each protofilament is a long chain of globular proteins called *tubulin* (fig. 3.32). Microtubules radiate from the centrosome and

FIGURE 3.31 The Cytoskeleton. (a) Components of the cytoskeleton. Few organelles are shown in order to emphasize the cytoskeleton. Note that all microtubules radiate from the centrosome; they often serve as trackways for motor proteins (kinesin) transporting organelles. (b) Cells with their cytoskeletons labeled with fluorescent antibodies, photographed through a fluorescence microscope. The density of a typical cytoskeleton far exceeds even that shown in part (a).

FIGURE 3.32 Microtubules. (a) A microtubule is composed of 13 protofilaments. Each protofilament is a helical chain of globular proteins called tubulin. (b) One of the nine microtubule pairs that form the axonemes of cilia and flagella. (c) One of the nine microtubule triplets that form a centriole.

hold organelles in place, form bundles that maintain cell shape and rigidity, and act somewhat like railroad tracks. Motor proteins “walk” along these tracks carrying organelles and macromolecules to specific destinations in the cell. Microtubules form the axonemes of cilia and flagella and are responsible for their beating movements, and form

the mitotic spindle that guides chromosome movement during cell division. Microtubules are not permanent structures. They come and go moment by moment as tubulin molecules assemble into a tubule and then suddenly break apart again to be used somewhere else in the cell. The double and triple sets of microtubules in cilia, flagella, basal bodies, and centrioles, however, are more stable.

Inclusions

Inclusions are of two kinds: stored cellular products such as glycogen granules, pigments, and fat droplets (see fig. 3.26b), and foreign bodies such as viruses, intracellular bacteria, and dust particles and other debris phagocytized by a cell. Inclusions are never enclosed in a unit membrane; and unlike the organelles and cytoskeleton, they are not essential to cell survival.

The major features of a cell are summarized in table 3.4.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

22. Distinguish between organelles and inclusions. State two examples of each.
23. Briefly state how each of the following cell components can be recognized in electron micrographs: the nucleus, a mitochondrion, a lysosome, and a centriole. What is the primary function of each?
24. What three organelles are involved in protein synthesis?
25. In what ways do rough and smooth endoplasmic reticulum differ?
26. Define centriole, microtubule, cytoskeleton, and axoneme. How are these structures related to one another?

TABLE 3.4 Summary of Organelles and Other Cellular Structures

Structure	Appearance to TEM	Function
Plasma membrane (figs. 3.3 and 3.6)	Two dark lines at cell surface, separated by a narrow light space	Prevents escape of cell contents; regulates exchange of materials between cytoplasm and extracellular fluid; involved in intercellular communication
Microvilli (fig. 3.10)	Short, densely spaced, hairlike processes or scattered bumps on cell surface; interior featureless or with bundle of microfilaments	Increase absorptive surface area; widespread sensory roles (hearing, equilibrium, taste)
Cilia (fig. 3.11)	Long hairlike projections of apical cell surface; axoneme with 9 + 2 array of microtubules	Move substances along cell surface; widespread sensory roles (hearing, equilibrium, smell, vision)
Flagellum	Long, single, whiplike process with axoneme	Sperm motility
Nucleus (figs. 3.3 and 3.25)	Largest organelle in most cells, surrounded by double unit membrane with nuclear pores	Genetic control center of cell; directs protein synthesis; shelters the DNA
Rough ER (fig. 3.26a)	Extensive sheets of parallel unit membranes with ribosomes on outer surface	Protein synthesis and manufacture of cellular membranes
Smooth ER (fig. 3.26b)	Branching network of tubules with smooth surface (no ribosomes); usually broken into numerous small segments in TEM photos	Lipid synthesis, detoxification, calcium storage
Ribosomes (fig. 3.26a)	Small dark granules free in cytosol or on surface of rough ER and nuclear envelope	Interpret the genetic code and synthesize polypeptides
Golgi complex (fig. 3.27)	Several closely spaced, parallel cisternae with thick edges, usually near nucleus, often with many Golgi vesicles nearby	Receives and modifies newly synthesized polypeptides, synthesizes carbohydrates, adds carbohydrates to glycoproteins; packages cell products into Golgi vesicles
Golgi vesicles (fig. 3.27)	Round to irregular sacs near Golgi complex, usually with light, featureless contents	Become secretory vesicles and carry cell products to apical surface for exocytosis, or become lysosomes
Lysosomes (fig. 3.28a)	Round to oval sacs with single unit membrane, often a dark featureless interior but sometimes with protein layers or crystals	Contain enzymes for intracellular digestion, autophagy, programmed cell death, and glucose mobilization
Peroxisomes (fig. 3.28b)	Similar to lysosomes; often lighter in color	Contain enzymes for detoxification of free radicals, alcohol, and other drugs; oxidize fatty acids
Mitochondria (fig. 3.29)	Round, rod-shaped, bean-shaped, or threadlike structures with double unit membrane and shelflike infoldings called cristae	ATP synthesis
Centrioles (fig. 3.30)	Short cylindrical bodies, each composed of a circle of nine triplets of microtubules	Form mitotic spindle during cell division; unpaired centrioles form basal bodies of cilia and flagella
Centrosome (fig. 3.5)	Clear area near nucleus containing a pair of centrioles	Organizing center for formation of microtubules of cytoskeleton and mitotic spindle
Basal body (fig. 3.11b)	Unpaired centriole at the base of a cilium or flagellum	Point of origin, growth, and anchorage of a cilium or flagellum; produces axoneme
Microfilaments (figs. 3.10 and 3.31)	Thin protein filaments (6 nm diameter), often in parallel bundles or dense networks in cytoplasm	Support microvilli and plasma membrane; involved in muscle contraction and other cell motility, endocytosis, and cell division
Intermediate filaments (fig. 3.31a)	Thicker protein filaments (8–10 nm diameter) extending throughout cytoplasm or concentrated at cell-to-cell junctions	Give shape and physical support to cell; anchor cells to each other and to extracellular material; compartmentalize cell contents
Microtubules (figs. 3.31 and 3.32)	Hollow protein cylinders (25 nm diameter) radiating from centrosome	Form axonemes of cilia and flagella, centrioles, basal bodies, and mitotic spindles; enable motility of cell parts; form trackways that direct organelles and macromolecules to their destinations within a cell
Inclusions (fig. 3.26b)	Highly variable—fat droplets, glycogen granules, protein crystals, dust, bacteria, viruses; never enclosed in unit membranes	Storage products or other products of cellular metabolism, or foreign matter retained in cytoplasm

INSIGHT 3.4 Evolutionary Medicine**Mitochondria—Evolution and Clinical Significance**

It is virtually certain that mitochondria evolved from bacteria that invaded another primitive cell, survived in its cytoplasm, and became permanent residents. Certain modern bacteria called *rickettsii* live in the cytoplasm of other cells, showing that this mode of life is feasible. The two unit membranes around the mitochondrion suggest that the original bacterium provided the inner membrane, and the host cell's phagosome provided the outer membrane when the bacterium was phagocytized.

Several comparisons show the apparent relationship of mitochondria to bacteria. Their ribosomes are more like bacterial ribosomes than those of eukaryotic (nucleated) cells. Mitochondrial DNA (mtDNA) is a small, circular molecule that resembles the circular DNA of bacteria, not the linear DNA of the cell nucleus. It replicates independently of nuclear DNA. Mitochondrial DNA codes for some of the enzymes employed in ATP synthesis. It consists of 16,569 *base pairs* (explained in chapter 4), comprising 37 genes, compared with over 3 billion base pairs and about 25,000 to 35,000 genes in nuclear DNA.

When a sperm fertilizes an egg, any mitochondria introduced by the sperm are usually destroyed and only those provided by the egg are passed on to the developing embryo. Therefore, mitochondrial DNA is inherited almost exclusively through the mother. While nuclear DNA is reshuffled in every generation by sexual reproduction, mtDNA remains unchanged except by random mutation. Biologists and anthropologists have used mtDNA as a “molecular clock” to trace evolutionary lineages in humans

and other species. Mitochondrial DNA has also been used as evidence in criminal law and to identify the remains of soldiers killed in combat. It was used in 2001 to identify the remains of the famed bandit Jesse James, who was killed in 1882. Anthropologists have gained evidence that of all the women who lived in Africa 200,000 years ago, only one has any descendants still living today. This “mitochondrial Eve” is ancestor to us all.

Mitochondrial DNA is very exposed to damage from free radicals normally generated in mitochondria by aerobic respiration. Yet unlike nuclear DNA, mtDNA has no effective mechanism for repairing damage. Therefore, it mutates about 10 times as rapidly as nuclear DNA. Some of these mutations are responsible for various rare hereditary diseases and death in early childhood. Tissues and organs with the highest energy demands are the most vulnerable to mitochondrial dysfunctions—nervous tissue, the heart, the kidneys, and skeletal muscles, for example.

Mitochondrial myopathy is a degenerative muscle disease in which the muscle displays “ragged red fibers,” cells with abnormal mitochondria that stain red with a particular histological stain. *Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS)* is a mitochondrial syndrome involving seizures, paralysis, dementia, muscle deterioration, and a toxic accumulation of lactic acid in the blood. *Leber hereditary optic neuropathy (LHON)* is a form of blindness that usually appears in young adulthood as a result of damage to the optic nerve. *Kearns-Sayre syndrome (KSS)* involves paralysis of the eye muscles, degeneration of the retina, heart disease, hearing loss, diabetes, and kidney failure. Damage to mtDNA has also been implicated as a possible factor in Alzheimer disease, Huntington disease, and other degenerative diseases of old age.

CHAPTER REVIEW

Review of Key Concepts

3.1 Concepts of Cellular Structure (p. 88)

1. Cytology is the study of cellular structure and function.
2. All human structure and function are the result of cellular activity.
3. Cell shapes are described as squamous, polygonal, stellate, cuboidal, columnar, spheroid, ovoid, discoid, fusiform, and fibrous.
4. Most human cells are 10 to 15 μm in diameter. Cell size is limited in part by the ratio of surface area to volume.
5. A cell is enclosed in a *plasma membrane* and contains usually one nucleus.
6. The *cytoplasm* is everything between the plasma membrane and nucleus. It consists of a clear fluid, the *cytosol* or *intracellular fluid (ICF)*, and embedded organelles and other structures. Fluid external to the cell is *extracellular fluid (ECF)*.

3.2 The Cell Surface (p. 91)

1. The plasma membrane is made of lipid and protein.
2. The most abundant lipid molecules in the membrane are phospholipids, which form a bilayer with their hydrophilic heads facing the ICF and ECF. Other membrane lipids include cholesterol and glycolipids.
3. Membrane proteins are called *transmembrane proteins* if they are embedded in the lipid bilayer and extend all the way through it, and *peripheral proteins* if they cling to only one face of the lipid bilayer.
4. Membrane proteins serve as receptors, second-messenger systems, enzymes, ion channels, carriers, cell-identity markers, and cell-adhesion molecules.
5. Channel proteins are called *gates* if they can open and close. Gates are called *ligand-regulated*, *voltage-regulated*, or *mechanically regulated* depending on whether they open and close in response to chemicals, voltage changes across the membrane, or mechanical stress.
6. Second-messenger systems are systems for generating an internal cellular signal in response to an

external one. One of the best-known examples results in the formation of a second messenger, *cyclic AMP (cAMP)*, within the cell when certain extracellular signaling molecules bind to a membrane receptor.

7. All cells are covered with a *glycocalyx*, a layer of carbohydrate molecules bound to membrane lipids and proteins. The glycocalyx functions in immunity and other forms of protection, cell adhesion, fertilization, and embryonic development, among other roles.
8. *Microvilli* are tiny surface extensions of the plasma membrane that increase a cell's surface area. They are especially well developed on absorptive cells, as in the kidney and small intestine. On some cells, they play a sensory role.
9. *Cilia* are longer, hairlike surface extensions with a central axoneme, composed of a 9 + 2 arrangement of microtubules. Some cilia are stationary and sensory in function, and some are motile and propel substances across epithelial surfaces.
10. A *flagellum* is a long, solitary, whiplike extension of the cell surface. The only functional flagellum in humans is the sperm tail.

3.3 Membrane Transport (p. 100)

1. The plasma membrane is *selectively permeable*—it allows some substances to pass through it but prevents others from entering or leaving a cell. There are several methods of passage through plasma membranes and other membranes.
2. *Filtration* is the movement of fluid through a membrane under a physical force such as blood pressure, while the membrane holds back relatively large particles.
3. *Simple diffusion* is the spontaneous net movement of particles from a place of high concentration to a place of low concentration, such as respiratory gases moving between the pulmonary air sacs and the blood. It can occur with or without a membrane. The speed of diffusion

depends on temperature, molecular weight, concentration differences, and the surface area and permeability of the membrane.

4. *Osmosis* is the net flow of water through a selectively permeable membrane. Channel proteins called *aquaporins* allow passage of water through plasma membranes.
5. The speed of osmosis depends on the relative concentrations, on the two sides of a membrane, of solute molecules that cannot penetrate the membrane. *Osmotic pressure*, the physical force that would be required to stop osmosis, is proportional to the concentration of nonpermeating solutes on the side to which water is moving.
6. An *osmole* is one mole of dissolved particles in a solution. *Osmolarity* is the number of osmoles of solute per liter of solution. The osmolarity of body fluids is usually expressed in milliosmoles per liter (mOsm/L).
7. *Tonicity* is the ability of a solution to affect the fluid volume and pressure in a cell. A solution is *hypotonic*, *isotonic*, or *hypertonic* to a cell if it contains, respectively, a lower, equal, or greater concentration of nonpermeating solutes than the cell cytoplasm does. Cells swell and burst in hypotonic solutions and shrivel in hypertonic solutions.
8. *Carrier-mediated transport* employs membrane proteins to move solutes through a membrane. A given carrier is usually specific for a particular solute.
9. Membrane carriers can become *saturated* with solute molecules and then unable to work any faster. The maximum rate of transport is the *transport maximum (T_m)*.
10. A *uniport* is a carrier that transports only one solute at a time; a *symport* carries two or more solutes through the membrane in the same direction (a process called *cotransport*); and an *antiport* carries two or more solutes in opposite directions (a process called *countertransport*).
11. *Facilitated diffusion* is a form of carrier-mediated transport that moves

solutes through a membrane down a concentration gradient, without an expenditure of ATP.

12. *Active transport* is a form of carrier-mediated transport that moves solutes through a membrane up (against) a concentration gradient, with the expenditure of ATP.
13. The $\text{Na}^+ - \text{K}^+$ pump is an antiport that moves Na^+ out of a cell and K^+ into it. It serves for control of cell volume, secondary active transport, heat production, and maintenance of an electrical membrane potential.
14. *Vesicular transport* is the movement of substances in bulk through a membrane in membrane-enclosed vesicles.
15. *Endocytosis* is any form of vesicular transport that brings material into a cell, including *phagocytosis*, *pinocytosis*, and *receptor-mediated endocytosis*.
16. *Exocytosis* is a form of vesicular transport that discharges material from a cell. It functions in the release of cell products and in replacement of plasma membrane removed by endocytosis.

3.4 The Cell Interior (p. 110)

1. The cytoplasm is composed of a clear gelatinous cytosol in which are embedded organelles, the cytoskeleton, and inclusions (table 3.4).
2. *Organelles* are internal structures in the cytoplasm that carry out specialized tasks for a cell.

3. *Membranous* organelles are enclosed in one or two layers of unit membrane similar to the plasma membrane. These include the nucleus, endoplasmic reticulum (which has rough and smooth portions), ribosomes, the Golgi complex, lysosomes, peroxisomes, and mitochondria. The ribosomes, centrosome, centrioles, and basal bodies are nonmembranous organelles.
4. The *nucleus* contains most of the cell's DNA and is its genetic control center.
5. The *endoplasmic reticulum (ER)* is a network of cisternae. It has areas of *rough ER* that are flattened cisternae covered with ribosomes, and areas of *smooth ER* that are ribosome-free and more tubular and branched. The ER in general synthesizes phospholipids and steroids, detoxifies alcohol and other drugs, and produces a cell's membranes. The rough ER is also a major site of protein synthesis, and the smooth ER acts as a calcium-storage reservoir in some cells.
6. *Ribosomes* are small protein-RNA granules found in the cytosol and on the rough ER and nuclear envelope. They synthesize proteins.
7. The *Golgi complex* synthesizes carbohydrates and processes many new proteins into their final form. It buds off *Golgi vesicles*, which can become secretory vesicles bound for exocytosis or lysosomes retained in the cell.

8. *Lysosomes* are membrane-bounded packets of enzymes that degrade ingested matter, glycogen and other stored biochemicals, and expired organelles and that sometimes bring about programmed cell death.
9. *Peroxisomes* are membrane-bounded packets of enzymes that oxidize various organic molecules.
10. *Mitochondria* are organelles specialized for ATP synthesis.
11. *Centrioles* are short cylindrical arrays of microtubules. A centriole pair in the centrosome functions in cell division, and solitary centrioles form the basal bodies of cilia and flagella.
12. The *cytoskeleton* is a supportive framework of protein filaments and tubules in a cell. It gives a cell its shape, organizes the cytoplasmic contents, and functions in movements of cell contents and the cell as a whole. It is composed of *microfilaments* of the protein *actin*; *intermediate filaments* of *keratin* or other proteins; and cylindrical *microtubules* of the protein *tubulin*.
13. *Inclusions* are either stored cellular products such as glycogen, pigments, and fat, or foreign bodies such as bacteria, viruses, and dust. Inclusions are not vital to cell survival.

Testing Your Recall

1. The clear, structureless gel in a cell is its
 - a. nucleoplasm.
 - b. protoplasm.
 - c. cytoplasm.
 - d. neoplasm.
 - e. cytosol.
2. The $\text{Na}^+ - \text{K}^+$ pump is
 - a. a peripheral protein.
 - b. a transmembrane protein.
 - c. a G protein.
 - d. a glycolipid.
 - e. a phospholipid.
3. Which of the following processes could occur *only* in the plasma membrane of a living cell?
 - a. facilitated diffusion
 - b. simple diffusion
 - c. filtration
 - d. active transport
 - e. osmosis
4. Cells specialized for absorption of matter from the ECF are likely to show an abundance of
 - a. lysosomes.
 - b. microvilli.
 - c. mitochondria.
 - d. secretory vesicles.
 - e. ribosomes.
5. Aquaporins are transmembrane proteins that promote
 - a. pinocytosis.
 - b. carrier-mediated transport.
 - c. active transport.
 - d. facilitated diffusion.
 - e. osmosis.
6. Membrane carriers resemble enzymes except for the fact that carriers
 - a. are not proteins.
 - b. do not have binding sites.
 - c. are not selective for particular ligands.
 - d. change conformation when they bind a ligand.
 - e. do not chemically change their ligands.
7. The cotransport of glucose derives energy from
 - a. an Na^+ concentration gradient.
 - b. the glucose being transported.
 - c. a Ca^{2+} gradient.
 - d. the membrane voltage.
 - e. body heat.
8. The function of cAMP in a cell is
 - a. to activate a G protein.
 - b. to remove phosphate groups from ATP.
 - c. to activate kinases.
 - d. to bind to the first messenger.
 - e. to add phosphate groups to enzymes.

122 PART ONE Organization of the Body

9. Most cellular membranes are made by
 - a. the nucleus.
 - b. the cytoskeleton.
 - c. enzymes in the peroxisomes.
 - d. the endoplasmic reticulum.
 - e. replication of existing membranes.
10. Matter can leave a cell by any of the following means *except*
 - a. active transport.
 - b. pinocytosis.
 - c. an antiport.
 - d. simple diffusion.
 - e. exocytosis.
11. Most human cells are 10 to 15 _____ in diameter.
12. When a hormone cannot enter a cell, it activates the formation of a/an _____ inside the cell.
13. _____ gates in the plasma membrane open or close in response to changes in the electrical charge difference across the membrane.
14. The force exerted on a membrane by water is called _____.
15. A concentrated solution that causes a cell to shrink is _____ to the cell.
16. Fusion of a secretory vesicle with the plasma membrane, and release of the vesicle's contents, is called _____.
17. Two organelles that are surrounded by a double unit membrane are the _____ and the _____.
18. Liver cells can detoxify alcohol with two organelles, the _____ and _____.
19. An ion gate in the plasma membrane that opens or closes when a chemical binds to it is called a/an _____.
20. The space enclosed by the unit membrane of the Golgi complex and endoplasmic reticulum is called the _____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. If a cell were poisoned so it could not make ATP, osmosis through its membrane would cease.
2. Material can move either into a cell or out by means of active transport.
3. A cell's second messengers serve mainly to transport solutes through the membrane.
4. The Golgi complex makes lysosomes but not peroxisomes.
5. Some membrane channels are peripheral proteins.
6. The plasma membrane consists primarily of protein molecules.
7. The brush border of a cell is composed of cilia.
8. Human cells swell or shrink in any solution other than an isotonic one.
9. Osmosis is not limited by the transport maximum (T_m).
10. It is very unlikely for a cell to have more centrosomes than ribosomes.

Answers in appendix B

Testing Your Comprehension

1. If someone bought a saltwater fish in a pet shop and put it in a freshwater aquarium at home, what would happen to the fish's cells? What would happen if someone put a freshwater fish in a saltwater aquarium? Explain.
2. A farmer's hand and forearm are badly crushed in a hay bailer. When examined at the hospital, his blood potassium level is found to be abnormal. Would you expect it to be higher or lower than normal? Explain.
3. Many children worldwide suffer from a severe deficiency of dietary protein. As a result, they have very low levels of blood albumin. How do you think this affects the water content and volume of their blood? Explain.
4. It is often said that mitochondria make energy for a cell. Why is this statement false?
5. Kartagener syndrome is a hereditary disease in which dynein arms are lacking from the axonemes of cilia and flagella. Predict the effect of Kartagener syndrome on a man's ability to father a child. Predict its effect on his respiratory health. Explain both answers.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Levels of protein structure (pp. 75–76)
- Functions of proteins (pp. 76–77)
- Exocytosis (p. 108)
- Rough endoplasmic reticulum, ribosomes, and Golgi complex (pp. 110–111)
- Centrioles (p. 114)
- Microtubules (p. 115)

Several chapters in this book discuss hereditary traits such as blood types and hair color and genetic disorders such as color blindness, cystic fibrosis, diabetes mellitus, and hemophilia. To understand such conditions, it is necessary to have some familiarity with DNA and genes. This chapter is intended to provide such preparation.

Heredity has been a matter of human interest dating even to biblical writings, but a scientific understanding of how traits pass from parent to offspring began with the Austrian monk Gregor Mendel (1822–1884) and his famous experiments on garden peas. By the late nineteenth century, biologists had observed chromosomes and their behavior during cell division. In the early twentieth century, they rediscovered Mendel's work and realized the correlation between chromosome behavior and his laws of heredity. From that simple but insightful beginning, genetics has grown into a highly diverse science with several subdisciplines and is arguably the most dynamic of all natural sciences in these early years of the twenty-first century. *Mendelian genetics* deals with parent-offspring and larger family relationships to discern and predict patterns of inheritance within a family line. *Cytogenetics* uses the techniques of cytology and microscopy to study chromosomes and their relationship to hereditary traits. *Molecular genetics* uses the techniques of biochemistry to study the structure and function of DNA. *Genomic medicine* comprehensively studies the entire DNA endowment of an individual (the *genome*), how it influences health and disease, and how this knowledge can be used to prevent, treat, or cure diseases. We will examine all four of these perspectives in this chapter.

With improvements in the microscope, biologists of the late nineteenth century saw that cell division is immediately preceded by nuclear division, and during nuclear division, the chromosomes split neatly in two and distribute their halves to the two daughter cells. They came to suspect that the nucleus was the center of heredity and cellular control, and they began probing it for the biochemical secrets of heredity. Swiss biochemist Johann Friedrich Miescher (1844–95) studied the nuclei of white blood cells extracted from pus in used hospital bandages, and later the nuclei of salmon sperm, since both cell types offered large nuclei with minimal amounts of contaminating cytoplasm. In 1869, he discovered an acidic, phosphorus-rich substance he named *nuclein*. He correctly believed this to be the cell's hereditary matter, although he was never able to convince other scientists of this. We now call this substance **deoxyribonucleic acid (DNA)** and know it to be the repository of our genes.

By 1900, biochemists knew the basic components of DNA—sugar, phosphate groups, and organic rings called nitrogenous bases—but they didn't have the technology to determine how these were put together. That understanding didn't come until 1953, in one of the century's most dramatic and important stories of scientific discovery (see Insight 4.1). The following description of DNA is largely the outcome of that work.

DNA Structure and Function

DNA is a long threadlike molecule with a uniform diameter of 2 nm, although its length varies greatly from the smallest to the largest chromosomes. Most human cells have 46 molecules of DNA totaling 2 m in length. This makes the average DNA molecule about 43 mm (almost 2 in.) long. To put this in perspective, imagine that an average DNA molecule was scaled up to the diameter of a telephone pole (about 20 cm, or 8 in.). At this diameter, a pole proportionate to DNA would rise about 4,400 km (2,700 mi.) into space—far higher than the orbits of space shuttles (320–390 km) and the Hubble Space Telescope (600 km).

At the molecular level, DNA and other nucleic acids are polymers of **nucleotides** (NEW-lee-oh-tides). A nucleotide consists of a sugar, a phosphate group, and a single- or double-ringed **nitrogenous** (ny-TRODJ-eh-nus) **base** (fig. 4.1a). Two of the bases in DNA—**cytosine (C)** and **thymine (T)**—have a single carbon–nitrogen ring and are classified as *pyrimidines* (py-RIM-ih-deens). The other two bases—**adenine (A)** and **guanine (G)**—have double rings and are classified as *purines* (fig. 4.1b). The bases of RNA are somewhat different, as explained later, but still fall into the purine and pyrimidine classes.

The structure of DNA, commonly described as a *double helix*, resembles a spiral staircase (fig. 4.2). Each sidepiece is a backbone composed of phosphate groups alternating with the sugar *deoxyribose*. The steplike connections between the backbones are pairs of nitrogenous bases. The bases face

4.1 DNA and RNA—The Nucleic Acids

Objectives

When you have completed this section, you should be able to

- describe the structure of DNA and relate this to its function;
- explain how DNA and proteins are organized to form the chromosomes; and
- describe the types of RNA, their structural and functional differences, and how they compare with DNA.

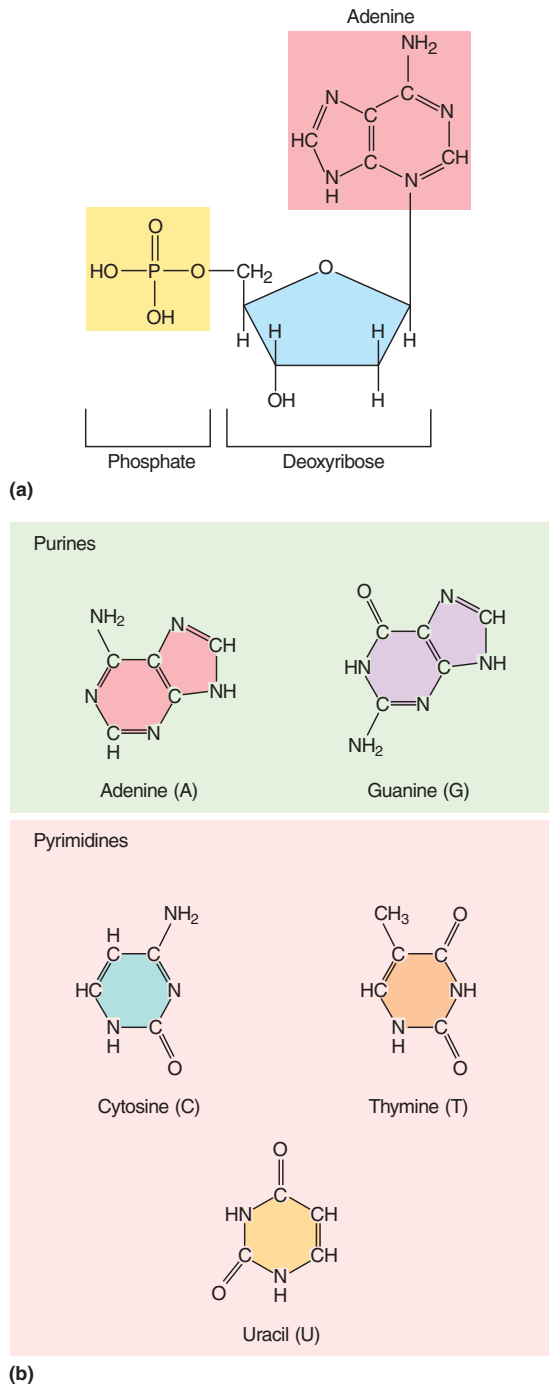

FIGURE 4.1 Nucleotides and Nitrogenous Bases.

(a) The structure of a nucleotide, one of the monomers of DNA and RNA. In RNA, the sugar is ribose. (b) The five nitrogenous bases found in DNA and RNA.

How would the uniform 2 nm diameter of DNA be affected if two purines or two pyrimidines could pair with each other?

FIGURE 4.2 DNA Structure. (a) A molecular space-filling model of DNA giving some impression of its molecular geometry. (b) The “twisted ladder” structure. The two sugar-phosphate backbones twine around each other while complementary bases (colored bars) face each other on the inside of the double helix. (c) A small segment of DNA showing the composition of the backbone and complementary pairing of the nitrogenous bases.

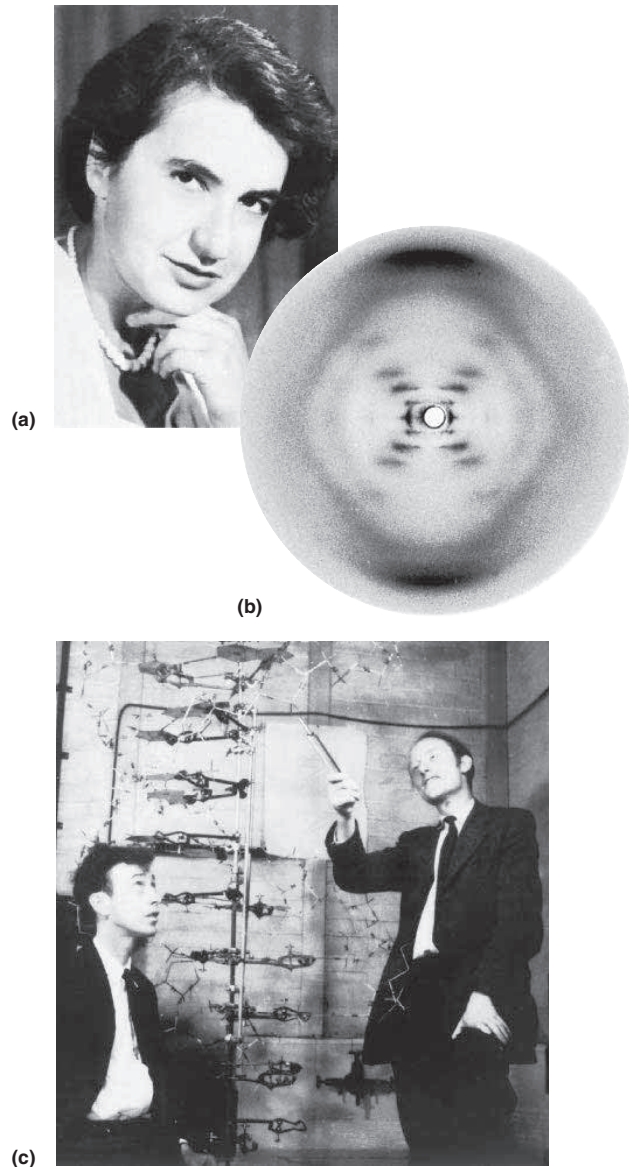

INSIGHT 4.1 Medical History**Discovery of the Double Helix**

Credit for determining the double-helical structure of DNA has gone mainly to James Watson and Francis Crick (fig. 4.3). The events surrounding their discovery form one of the most dramatic stories of modern science—the subject of many books and at least one movie. When Watson and Crick came to share a laboratory at Cambridge University in 1951, both had barely begun their careers. Watson, age 23, had just completed his Ph.D. in the United States, and Crick, 11 years older, was a doctoral candidate in England. Yet the two were about to become the most famous molecular biologists of the twentieth century, and the discovery that won them such acclaim came without a single laboratory experiment of their own.

Others were fervently at work on DNA, including Rosalind Franklin and Maurice Wilkins at King's College in London. Using a technique called X-ray diffraction, Franklin had determined that DNA had a repetitious helical structure with sugar and phosphate on the outside of the helix. Without her permission, Wilkins showed one of Franklin's best X-ray photographs to Watson. Watson said, "The instant I saw the picture my mouth fell open and my pulse began to race." It provided a flash of insight that allowed the Watson and Crick team to beat Franklin to the goal. They were quickly able to piece together a scale model from cardboard and sheet metal that fully accounted for the known geometry of DNA. They rushed a paper into print in 1953 describing the double helix, barely mentioning the importance of Franklin's 2 years of painstaking X-ray diffraction work in unlocking the mystery of life's most important molecule. Franklin published her findings in a separate paper back to back with theirs.

For this discovery, Watson, Crick, and Wilkins shared the Nobel Prize for Physiology or Medicine in 1962. Nobel Prizes are awarded only to the living, and in the final irony of her career, Rosalind Franklin had died in 1958, at the age of 37, of a cancer possibly induced by the X-rays that were her window on DNA architecture.

FIGURE 4.3 Discoverers of the Double Helix. (a) Rosalind Franklin (1920–58), whose painstaking X-ray diffraction photographs revealed important information about the molecular geometry of DNA. (b) One of Franklin's X-ray photographs. (c) James Watson (1928–) (left) and Francis Crick (1916–2004), with their model of the double helix.

the inside of the helix and hold the two backbones together with hydrogen bonds. Across from a purine on one backbone, there is a pyrimidine on the other. The pairing of each small, single-ringed pyrimidine with a large, double-ringed purine gives the DNA molecule its uniform 2 nm width.

A given purine cannot arbitrarily bind to just any pyrimidine. Adenine and thymine form two hydrogen bonds with each other, and guanine and cytosine form three, as shown in figure 4.2b. Therefore, where there is an A on one backbone, there is normally a T across from it, and every C is normally paired with a G. A–T and C–G

are called the **base pairs**. The fact that one strand governs the base sequence of the other is called the **law of complementary base pairing**. It enables us to predict the base sequence of one strand if we know the sequence of the complementary strand.

Think About It

What would be the base sequence of the DNA strand across from ATTGACTCG? If a DNA molecule were known to be 20% adenine, predict its percentage of cytosine and explain your answer.

The essential function of DNA is to carry instructions, called *genes*, for the synthesis of proteins. At this point in the chapter, we will provisionally regard a gene as a segment of DNA that codes for a protein. Later, we shall have to confront the fact that this is an inadequate definition, and we'll examine the meaning of the word more deeply.

Humans are estimated to have 25,000 to 35,000 genes. These constitute only about 2% of the DNA. The other 98% is noncoding DNA, which plays various roles in chromosome structure and regulation of gene activity, and some of which may have no function at all. Some of the noncoding DNA is sometimes thought of as “junk DNA” to suggest that it might be merely harmless debris accumulated by mutation over eons of evolutionary time.

Chromatin and Chromosomes

DNA does not exist as a naked double helix in the nucleus of a cell, but is complexed with proteins to form a fine

filamentous material called **chromatin**. In most cells, the chromatin occurs as 46 long filaments called **chromosomes**. There is a stupendous amount of DNA in one nucleus—about 2 m (6 ft) of it in the first half of a cell's life cycle and twice as much when a cell has replicated its DNA in preparation for cell division. It is a prodigious feat to pack this much DNA into a nucleus only about 5 μm in diameter—and in such an orderly fashion that it does not become tangled, broken, and damaged beyond use. Here, we will examine how this is achieved.

In nondividing cells, the chromatin is so slender that it usually cannot be seen with the light microscope. With a high-resolution electron microscope, however, it has a granular appearance, like beads on a string (fig. 4.4a). Each “bead” is a disc-shaped cluster of eight proteins called **histones**. A DNA molecule winds around the cluster for a little over one and a half turns, like a ribbon around a spool, and then continues on its way until it reaches the next histone cluster and winds around that

FIGURE 4.4 Chromatin Structure. (a) Nuclear contents of a germ cell from an 8-week-old human embryo (colorized SEM). The center mass is the nucleolus. It is surrounded by granular fibers of chromatin. Each granule represents one nucleosome. (b) The coiling of chromatin and its relationship to the nucleosomes.

(b)

one (fig. 4.4b). The average chromatin thread repeats this pattern almost 800,000 times, and thus appears divided into segments called **nucleosomes**. Each nucleosome consists of a *core particle* (the spool of histones with the DNA ribbon around them) and a short segment of *linker DNA* leading to the next core particle. Winding the DNA around the histones makes the chromatin thread more than five times as thick (11 nm) and one-third shorter than the DNA alone.

But even at this degree of compaction, a single chromosome would cross the entire nucleus hundreds of times. There are higher orders of structure that make the chromosome still more compact. First, the nucleosomes are arranged in a zigzag pattern, folding the chromatin like an accordion. This produces a strand 30 nm wide, but still 100 times as long as the nuclear diameter. Then, the 30 nm strand is thrown into complex, irregular loops and coils that make the chromosome 300 nm thick and 1,000 times shorter than the DNA molecule. Finally, each chromosome is packed into its own spheroidal region of the nucleus, called a *chromosome territory*. A chromosome territory is permeated with channels that allow regulatory chemicals to have access to the genes.

This is the state of the DNA in a nondividing cell. It is not a static structure, but changes from moment to moment according to the genetic activity of the cell as individual genes are turned on and off. Whole chromosomes migrate to new territories as a cell develops—for example, moving from the edge to the core of a nucleus as its genes are activated for a certain developmental task. This allows genes on different chromosomes to partner with each other in bringing about developmental changes in the cell.

When a cell is preparing to divide, it makes an exact copy of all its nuclear DNA by a process described later, increasing its allotment to about 4 m of DNA. Each chromosome then consists of two parallel filaments called **sister chromatids**. In the early stage of cell division (*prophase*), these chromatids coil some more until each one becomes another 10 times shorter and about 700 nm wide. Thus, at its most compact, each thread of chromatin is 10,000 times shorter but 350 times thicker than the DNA double helix. Only now are the chromosomes thick enough to be seen with a light microscope. This compaction not only allows the 4 m of DNA to be packed into the nucleus, but also enables the two sister chromatids to be pulled apart and carried to separate daughter cells without damage to the DNA.

Figure 4.5 shows the structure of a chromosome in early cell division, when it is compacted to its maximum extent. It consists of two genetically identical, rodlike sister chromatids joined together at a pinched spot called the **centromere**. On each side of the centromere, there is a protein plaque called a **kinetochore**¹ (kih-NEE-to-core), which has a role in cell division explained later.

FIGURE 4.5 Chromosome Structure at Metaphase. (a) Drawing of a metaphase chromosome. (b) Scanning electron micrograph.

RNA Structure and Function

Before we leave this section, we mustn't forget those smaller cousins of DNA, the ribonucleic acids (RNAs). There are several forms of RNA in a cell, but we will focus on the three that are directly involved in producing proteins: *messenger RNA (mRNA)*, *ribosomal RNA (rRNA)*, and *transfer RNA (tRNA)*. DNA cannot produce proteins without their help. The other RNA types play various regulatory roles that we will not consider.

The individual roles of mRNA, rRNA, and tRNA are described later, but for now we consider what they have in common and how they differ from DNA (table 4.1). The most significant difference is that RNA is much smaller, ranging from about 70 to 90 bases in tRNA to slightly over 10,000 bases in the largest mRNA. DNA, by contrast, averages more than 100 million base pairs long. Also, whereas DNA is a double helix, RNA consists of only one nucleotide chain, not held together by complementary base pairs except in certain short regions where the molecule folds back on itself. The sugar in RNA is ribose instead of deoxyribose. RNA contains three of the same nitrogenous bases as DNA—adenine, cytosine, and guanine—but it has no thymine; a base called **uracil (U)** takes its place (see fig. 4.1b). Transfer RNA has more than 50 different nitrogenous bases, but for our purposes, we don't need to consider any except A, U, C, and G.

The essential function of the three principal RNAs is to interpret the code in DNA and use those instructions to synthesize proteins. RNA is a disposable molecule that works mainly in the cytoplasm, while DNA is irreplaceable and remains safely behind in the nucleus, "giving orders" from there. This process is described in the next section of the chapter.

¹kineto = motion + chore = place

TABLE 4.1 Comparison of DNA and RNA

Feature	DNA	RNA
Sugar	Deoxyribose	Ribose
Types of nitrogenous bases	A, T, C, G	A, U, C, G
Number of nitrogenous bases	Averages 10^8 base pairs	70–10,000 bases, mostly unpaired
Number of nucleotide chains	Two (double helix)	One
Site of action	Functions in nucleus; cannot leave	Leaves nucleus; functions mainly in cytoplasm
Function	Codes for synthesis of RNA and protein	Carries out the instructions in DNA; assembles proteins

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What are the three components of a nucleotide? Which component varies from one nucleotide to another in DNA?
2. What governs the pattern of base pairing in DNA?
3. What is the difference between DNA and chromatin?
4. Summarize the structural and functional differences between DNA and RNA.

4.2 Genes and Their Action

Objectives

When you have completed this section, you should be able to

- give a working definition of the *gene* and explain why new discoveries in genetics have changed our concept of what a gene is;
- explain what the human genome is and what relationship it has to the health sciences;
- define *genetic code* and describe how DNA codes for protein structure;
- describe the process of assembling amino acids to form a protein;
- explain what happens to a protein after its amino acid sequence has been synthesized;
- describe some ways that a gene can be turned on or off; and
- explain how DNA indirectly regulates the synthesis of nonprotein molecules.

What Is a Gene?

As much as biologists take interest in genes, the term is devilishly difficult to define. The classical concept of the gene, rooted in Mendel's studies of heredity in peas, was that it is an abstract "unit of heredity" by which a trait

passes from parent to offspring. Following discovery of the double helix, molecular biologists worked out the *genetic code* contained in the four bases of DNA and considered a gene to be a segment of the DNA that carries the code for a particular protein. Now, however, we know that the human body has millions of different proteins but only 30,000 genes or so; obviously there isn't a separate gene for every protein. In addition, we know now that several percent of the human genes produce only RNA molecules that never go on to direct the synthesis of a protein; thus, RNA is their final product. Several other recent discoveries have complicated our concept of the gene still more—genes overlapping each other, so some segments of DNA belong to two different genes; short genes embedded within longer ones; cases where a single gene codes for multiple related proteins; and other unexpected arrangements. As molecular biologists have learned more and more about DNA, the definition of the gene has become more and more frayed around the edges. It has lately become virtually impossible for geneticists to agree on what the word means.

For the purposes of an introductory book such as this one, however, we can settle for an approximate meaning. We will define **gene** as an information-containing segment of DNA that codes for the production of a molecule of RNA, which in most cases goes on to play a role in the synthesis of one or more proteins. The amino acid sequence of a protein is determined by a nucleotide sequence in the DNA.

The Human Genome

The 46 human chromosomes come in two sets of 23 each, one set from each parent. Each pair of chromosomes has the same genes, although pairs may have different versions of a given gene (*alleles*, discussed later in the chapter). All the DNA, both coding and noncoding, in one 23-chromosome set is called the **genome**. The human genome consists of about 3.1 billion nucleotide pairs. Owing to a massive multinational undertaking called the **Human Genome Project (HGP)**, carried out from 1990 to 2003, biologists now know the base sequence (A, T, C, G) of more than 99% of the genome. The only unknown portions are some short,

dense regions of the chromosomes inaccessible to present technology, but apparently containing very few (if any) genes.

Sequencing the human genome has been hailed as a technological accomplishment as momentous as splitting the atom and landing explorers on the moon. It has opened a new field of biology called **genomics**, the comprehensive study of the whole genome and how its genes and noncoding DNA interact to affect the structure and function of the whole organism. Among the revolutionary findings to come from the Human Genome Project are these:

- *Homo sapiens* has only about 25,000 to 35,000 genes, not the 100,000 formerly believed.
- These genes generate millions of different proteins, so gone is the old idea of one gene for each protein. In its place is the realization that a single gene can code for many different proteins through alternative splicing of mRNA (see p. 131) and other means.
- Genes average about 3,000 bases long, but range up to 2.4 million bases.
- All humans, worldwide, are at least 99.99% genetically identical, but even the 0.01% variation means that we can differ from one another in more than 3 million base pairs. Various combinations of these **single-nucleotide polymorphisms**² account for all human genetic variation.

²*poly* = multiple + *morph* = form

- Some chromosomes are gene-rich (17, 19, and 22) and some are gene-poor (4, 8, 13, 18, 21, and Y; see fig. 4.17).
- Before the HGP, we knew the chromosomal locations of fewer than 100 disease-producing mutations; we now know more than 1,400, and this number is sure to rise as the genome is further analyzed. This opens the door to a new branch of medical diagnosis and therapy called **genomic medicine** (see Insight 4.2).

The Genetic Code

It seems remarkable that the body can make millions of different proteins, all from the same 20 amino acids and all encoded by genes made of just 4 nucleotides (A, T, C, G). This is a striking illustration of how a great variety of complex structures can be made from a small variety of simpler components. The **genetic code** is a system that enables these 4 nucleotides to code for the amino acid sequences of all proteins.

It is not unusual for simple codes to represent complex information. Computers store and transmit complex information, including pictures and sounds, in a binary code with only the symbols 1 and 0. Thus, it should not be surprising that a mere 20 amino acids can be represented by a code of 4 nucleotides; all that is required is to combine these symbols in varied ways. It requires more than 2 nucleotides to code for each amino acid, because A, U, C, and G can combine in only 16 different pairs (AA, AU, AC, AG, UA, UU, and so on). The minimum code to symbolize 20 amino acids is 3 nucleotides

INSIGHT 4.2 Clinical Application

Genomic Medicine

Genomic medicine is the application of our knowledge of the genome to the prediction, diagnosis, and treatment of disease. It is relevant to disorders as diverse as cancer, Alzheimer disease, schizophrenia, obesity, and even a person's susceptibility to nonhereditary diseases such as AIDS and tuberculosis.

As the technology of gene sequencing continues to be improved, geneticists expect that we may soon be able to sequence any person's entire genome for less than \$1,000. Why would we want to? Because knowing one's genome could dramatically change clinical care. It may allow clinicians to forecast a person's risk of disease and to predict its course; mutations in a single gene can affect the severity of such diseases as hemophilia, muscular dystrophy, and cystic fibrosis. Genomics should also allow for earlier detection of diseases and for earlier, more effective clinical intervention. Drugs that are safe for most people can have serious side effects in others, owing to genetic variations in drug metabolism. Genomics may therefore provide a basis for choosing the safest or most effective drug and for

adjusting dosages for different patients on the basis of their genetic makeup.

Knowing the sites of disease-producing mutations expands the potential for *gene-substitution therapy*. This is a procedure in which cells are removed from a patient with a genetic disorder, supplied with a normal gene in place of the defective one, and reintroduced to the body. The hope is that these genetically modified cells will proliferate and provide the patient with a gene product that he or she was lacking—perhaps insulin for a patient with diabetes or a blood-clotting factor for a patient with hemophilia. Attempts at gene therapy have been marred by some tragic setbacks, however, and still face great technical difficulties that have not yet been surmounted.

Genomics is introducing new problems in medical ethics and law. Should your genome be a private matter between you and your physician? Or should an insurance company be entitled to know your genome before issuing health or life insurance to you so they can know your risk of contracting a catastrophic illness, adjust the cost of your coverage, or even deny coverage? Should a prospective employer have the right to know your genome before offering employment? These are areas in which biology, politics, and law converge to shape public policy.

per amino acid, and indeed this is the case in DNA. A sequence of 3 DNA nucleotides that stands for 1 amino acid is called a **base triplet**. When messenger RNA is produced from these DNA instructions, it contains more or less a “mirror image” of these triplets. A 3-base sequence in mRNA is called a **codon**. The genetic code is expressed in terms of codons.

For the purpose of this book, it isn’t necessary to tabulate the entire genetic code, but sufficient to see a few illuminating examples of how the DNA triplets relate to the mRNA codons and how they relate to the amino acids of a protein (table 4.2). You can see from the table that sometimes two or more codons represent the same amino acid. The reason for this is easy to explain mathematically. Four symbols (N) taken three at a time (x) can be combined in N^x different ways; that is, there are $4^3 = 64$ possible codons available to represent the 20 amino acids.

Only 61 of these, however, code for amino acids. The other 3—UAG, UGA, and UAA—are called **stop codons**; they signal “end of message,” like the period at the end of a sentence. A stop codon enables the cell’s protein-synthesizing machinery to sense that it has reached the end of the instruction for a particular protein. The codon AUG plays two roles: It serves as a code for methionine and as a **start codon**. This dual function is explained shortly.

Protein Synthesis

We can now move on to an understanding of how DNA and RNA collaborate to produce proteins. Before studying the details, however, it will be helpful to consider the big picture. In brief, the genetic code in DNA specifies which proteins a cell can make. All the body’s cells except the sex cells and some immune cells contain identical genes. However, different genes are activated in different cells; for example, the genes for digestive enzymes are active in

stomach cells but not in muscle cells. Any given cell uses only one-third to two-thirds of its genes; the rest remain dormant in that cell, but may be functional in other types of cells.

When a gene is activated, a molecule of **messenger RNA (mRNA)**, a sort of mirror-image copy of the gene, is made. Most mRNA migrates from the nucleus to the cytoplasm, where its code is “read” by a ribosome. Ribosomes are cytoplasmic granules composed of **ribosomal RNA (rRNA)** and enzymes. **Transfer RNA (tRNA)** delivers amino acids to the ribosome, and the ribosome chooses from among these to assemble amino acids in the order directed by the codons of mRNA.

In summary, you can think of the process of protein synthesis as DNA → mRNA → protein, with each arrow reading as “codes for the production of.” The step from DNA to mRNA is called *transcription*, and the step from mRNA to protein is called *translation*. Transcription occurs in the nucleus, where the DNA is, and most translation occurs in the cytoplasm. Recent research has shown, however, that 10% to 15% of proteins are synthesized in the nucleus, with both steps occurring there.

Transcription

DNA is too large to leave the nucleus and participate directly in cytoplasmic protein synthesis. It is necessary, therefore, to make a small mRNA copy that can migrate through a nuclear pore into the cytoplasm. Just as we might transcribe (copy) a document, **transcription** in genetics means the process of copying genetic instructions from DNA to RNA. An enzyme called **RNA polymerase** (po-LIM-ur-ase) binds to the DNA and assembles the RNA. Certain distinctive base sequences (often TATATA or TATAAA) inform the polymerase where to begin.

RNA polymerase opens up the DNA helix about 17 base pairs at a time. It reads the bases from one strand of the DNA and makes a corresponding RNA. Where it finds a C on the DNA, it adds a G to the RNA; where it finds an A, it adds a U; and so forth. The enzyme then rewinds the DNA helix behind it. Another RNA polymerase may follow closely behind the first one; thus, a gene may be transcribed by several polymerase molecules at once, and numerous copies of the same RNA are made. At the end of the gene is a base sequence that serves as a terminator, which signals the polymerase to stop.

The RNA produced by transcription is an “immature” form called *pre-mRNA*. This molecule contains “sense” portions called *exons* that will be translated into a protein, and “nonsense” portions called *introns* that must be removed before translation. Enzymes remove the introns and splice the exons together into a functional mRNA molecule. Through a mechanism called *alternative splicing*, one gene can code for more than one protein. Suppose a gene produced a pre-mRNA containing six exons

TABLE 4.2 Examples of the Genetic Code

Base Triplet of DNA	Codon of mRNA	Name of Amino Acid	Abbreviation for Amino Acid
CCT	GGA	Glycine	Gly
CCA	GGU	Glycine	Gly
CCC	GGG	Glycine	Gly
CTC	GAG	Glutamic acid	Glu
CGC	GCG	Alanine	Ala
CGT	GCA	Alanine	Ala
TGG	ACC	Threonine	Thr
TGC	ACG	Threonine	Thr
GTA	CAU	Histidine	His
TAC	AUG	Methionine	Met

FIGURE 4.6 Alternative Splicing of mRNA. By splicing together different combinations of exons from a single pre-mRNA, a cell can generate multiple proteins from a single gene.

separated by noncoding introns. As shown in figure 4.6, these exons can be spliced together in various combinations to yield codes for two or more proteins. This is a partial explanation of how the body can produce millions of different proteins with 30,000 genes.

Translation

Just as we might translate a work from Spanish into English, genetic **translation** converts the language of nucleotides into the language of amino acids (fig. 4.7). This job is done by ribosomes, which occur mainly in the cytosol and on the outside of the rough ER and nuclear envelope. A ribosome consists of two granular subunits, large and small, each made of several rRNA and enzyme molecules.

The mRNA molecule begins with a *leader sequence* of bases that serve only as a binding site for the ribosome. The small ribosomal subunit binds to it, the large subunit joins the complex, and the ribosome begins pulling the mRNA through it like a ribbon, reading bases as it goes. When it reaches the start codon, AUG, it begins making protein. Since AUG codes for methionine, all proteins begin with methionine when first synthesized, although this may be removed later.

Translation also requires the participation of transfer RNA (tRNA). This is a small RNA molecule that turns back and coils on itself to form an angular L shape (fig. 4.8). One end of the L includes three nucleotides called an **anticodon**, and the other end has a binding site specific for one

amino acid. Each tRNA picks up a specific amino acid from a pool of free amino acids in the cytosol. One ATP molecule is used in binding the amino acid to this site and provides the energy that is used later to join that amino acid to the growing protein. Thus, protein synthesis consumes one ATP for each peptide bond formed.

When the small ribosomal subunit reads a codon such as GCA, it must find an activated tRNA with the corresponding anticodon; in this case, CGU would do nicely. Codon-anticodon pairing, however, tolerates some mismatches, especially at the third base of the codon. Therefore, CGU isn't necessarily the only anticodon that can pair with GCA. Due to this imprecision or "wobble" in the system, it takes only 48 different tRNAs to pair up with the 61 different codons that represent the amino acids.

A tRNA with anticodon CGU would have the amino acid alanine at its other end. The ribosome binds and holds this tRNA and then reads the next codon—say, GGU. Here, it would bind a tRNA with anticodon CCA, which carries glycine. The large ribosomal subunit contains an enzyme that forms peptide bonds, and now that alanine and glycine are side by side, it links them together. The first tRNA is no longer needed, so it is released from the ribosome. The second tRNA is used, temporarily, to anchor the growing peptide to the ribosome. Now the ribosome reads the third codon—say, ACG. It finds the tRNA with the anticodon UGC, which carries the amino acid threonine. The large subunit adds threonine to the growing chain, now three amino acids long. By repetition of

FIGURE 4.7 Translation of mRNA.

Why would translation not work if ribosomes could bind only one tRNA at a time?

FIGURE 4.8 Transfer RNA (tRNA).

(a) The shape of tRNA. tRNA has an amino acid-accepting end that binds to one specific amino acid, and an anticodon at the other end that binds to a complementary codon of mRNA. (b) tRNA laid out in a schematic to show its structure more clearly. The three loops in the molecule are color-coded for correlation between the two figures. Black bars represent areas of complementary A-T, C-G base pairing between different regions of the nucleotide chain.

FIGURE 4.9 Several Ribosomes Attached to a Single mRNA Molecule, Forming a Polyribosome.

this process, the entire protein is assembled. Eventually, the ribosome reaches a stop codon and is finished translating this mRNA. The protein is turned loose, and the ribosome dissociates into its two subunits.

One ribosome can assemble a protein of 400 amino acids in about 20 seconds, but it does not work at the task alone. After the mRNA leader sequence passes through one ribosome, a neighboring ribosome often takes it up and begins translating the mRNA before the first ribosome has finished. One mRNA can hold 10 or 20 ribosomes together in a cluster called a **polyribosome** (fig. 4.9). Not only is each mRNA translated by all these ribosomes at once, but a cell may have 300,000 identical mRNA molecules undergoing simultaneous translation. Thus, a cell may produce over 150,000 protein molecules per second—a remarkably productive protein factory! As much as 25% of the dry weight of liver cells, which are highly active in protein synthesis, is composed of ribosomes.

Figure 4.10 summarizes transcription and translation and shows how a nucleotide sequence translates to a hypothetical peptide of 6 amino acids. An average protein is about 400 amino acids long; it would have to be represented, at a minimum, by a sequence of 1,203 nucleotides (3 for each amino acid, plus a stop codon).

Protein Processing and Secretion

Protein synthesis is not finished when its amino acid sequence (primary structure) has been assembled. To be functional, it must coil or fold into precise secondary and tertiary structures; in some cases, it associates with other protein chains (quaternary structure) or binds with a nonprotein such

as a vitamin or carbohydrate. As a new protein is assembled by a ribosome, it is often picked up by an older protein called a **chaperone**. The chaperone guides the new protein in folding into the proper shape and helps to prevent improper associations between different proteins. As in the colloquial sense of the word, a chaperone is an older protein that escorts and regulates the behavior of the “youngsters.” Some chaperones are also called *stress proteins* or *heat-shock proteins* because they are produced in response to heat or other stress on a cell and help damaged proteins fold back into their correct functional shapes.

If a protein is going to be used in the cytosol (for example, the enzymes of glycolysis), it is likely to be made by free ribosomes in the cytosol. If it is going to be packaged into a lysosome or secreted from the cell, however, the entire polyribosome migrates to the rough ER and docks on its surface. Assembly of the amino acid chain is then completed on the rough ER and the protein is sent to the Golgi complex for final modification. Thus, we turn to the functions of the ER and Golgi in the processing and secretion of a protein. Compare the following description to figure 4.11.

- As a protein is assembled on the ER surface, it threads itself through a pore in the ER membrane and into the cisterna. Enzymes in the cisterna modify the new protein in a variety of ways—removing some amino acid segments, folding

FIGURE 4.10 Relationship of a DNA Base Sequence to Peptide Structure.

the protein and stabilizing it with disulfide bridges, adding carbohydrates, and so forth. Such changes are called **posttranslational modification**. Insulin, for example, is first synthesized as a protein 83 amino acids long. In posttranslational modification, the chain folds back on itself, three disulfide bridges are formed, and 32 amino acids are removed from the middle of the protein. The final insulin molecule is therefore made of two chains of 21 and 30 amino acids held together by disulfide bridges (see fig. 2.25, p. 78).

- ② When the rough ER is finished with a protein, it pinches off bubblelike **transport vesicles** coated with a protein called *clathrin*. Clathrin apparently helps to select the proteins to be transported in the vesicles, and as a basketlike cage, it helps to mold the forming vesicles. Soon after the vesicles detach from the ER, they fuse into irregularly shaped clusters that carry their cargo to the nearest cisterna of the Golgi complex.
- ③ Upon contact with the Golgi complex, the cluster fuses with it and unloads its protein cargo into the Golgi cisterna.

FIGURE 4.11 Protein Processing and Secretion. Some proteins are synthesized by ribosomes on the rough ER and carried in transport vesicles to the nearest cisterna of the Golgi complex. The Golgi complex modifies the structure of the protein, transferring it from one cisterna to the next, and finally packages it in Golgi vesicles. Some Golgi vesicles may remain within the cell and become lysosomes, while others migrate to the plasma membrane and release the cell product by exocytosis.

- ④ The Golgi complex further modifies the protein, often by adding carbohydrate chains. This is where the *glycoproteins* mentioned in chapter 2 are assembled. There is still some disagreement about how the Golgi cisternae behave. Some say the maturing protein is passed by transport vesicles from one cisterna to the next, as shown in the figure. Others say the whole cisterna migrates from one side of the complex to the other and then breaks up into vesicles.
- ⑤ The final Golgi cisterna, farthest from the ER, either buds off new coated **Golgi vesicles** containing the finished protein, or may simply break up into vesicles, to be replaced by a younger cisterna behind it.
- ⑥ Some of the Golgi vesicles become lysosomes, while others become **secretory vesicles** that migrate to the plasma membrane and fuse with it, releasing the cell product by exocytosis. This is how a cell of a salivary gland, for example, secretes mucus and digestive enzymes.

Table 4.3 summarizes the diverse destinations and functions of newly synthesized proteins.

Gene Regulation

Genes don't simply produce their products at a steady, incessant pace, like a 24-hour nonstop manufacturing plant. They are turned on and off from day to day, even hour to hour, as their products are needed or not, and many genes are permanently turned off in any given cell. The genes for hemoglobin and digestive enzymes, for example, are present but inactive in liver cells.

TABLE 4.3

Some Destinations and Functions of Newly Synthesized Proteins

Destination or Function	Proteins (Examples)
Deposited as a structural protein within cells	Actin of cytoskeleton; keratin of epidermis
Used in the cytosol as a metabolic enzyme	ATPase; kinases
Returned to the nucleus for use in nuclear metabolism	Histones of chromatin; RNA polymerase
Packaged in lysosomes for autophagy, intracellular digestion, and other functions	Numerous lysosomal enzymes
Delivered to other organelles for intracellular use	Catalase of peroxisomes; mitochondrial enzymes
Delivered to plasma membrane to serve transport and other functions	Hormone receptors; sodium-potassium pumps
Secreted by exocytosis for extracellular functions	Digestive enzymes; casein of breast milk

There are several ways to turn genes on or off. We cannot consider all of them here, but an example can convey the general principle. Consider a woman who has just given birth to her first baby. In the ensuing days, the hormone *prolactin* stimulates cells of her mammary glands to begin synthesizing the various components of breast milk, including the protein *casein*—something her body has never synthesized before. How is the gene for casein turned on at this point in her life? Figure 4.12 shows the steps leading from prolactin stimulation to casein secretion.

- ① Prolactin binds to its receptors, a pair of proteins in the plasma membrane of the mammary cell.
- ② The receptors trigger the activation of a **regulatory protein** (transcription activator) in the cytoplasm.
- ③ The regulatory protein moves into the nucleus and binds to the DNA near the casein gene.
- ④ This binding enables RNA polymerase to bind to the gene and transcribe it, producing the mRNA for casein.

FIGURE 4.12 A Mechanism of Gene Activation. The hormone prolactin triggers intracellular reactions that activate a regulatory protein. This protein binds to the DNA near the casein gene, enabling RNA polymerase to produce mRNA for casein. The mRNA is then translated to synthesize the casein itself. See the text for further explanation of the numbered steps.

- 5 The casein mRNA moves into the cytoplasm and is translated by ribosomes on the rough endoplasmic reticulum.
- 6 The Golgi complex packages casein into secretory vesicles.
- 7 The secretory vesicles release the casein by exocytosis, and it becomes part of the breast milk.

At step 4, there are multiple ways that regulatory proteins can activate gene transcription. Some of them attract and position RNA polymerase so it can begin transcription of the gene. Others modify the coiling of DNA in a nucleosome in a way that makes specific genes more accessible to RNA polymerase. To turn off a gene, a regulatory protein can coil the chromatin in a different way that makes the gene less accessible, thus preventing transcription. There are several additional ways, beyond the scope of this book, for inducing or halting the production of a gene product, but the casein example shows how a certain gene may lie dormant in a person until, only a few times in one's life (and only if one bears children), it is activated by a stimulus such as a hormonal signal.

Synthesizing Compounds Other Than Proteins

Cells, of course, make more than proteins—they also synthesize glycogen, fat, steroids, phospholipids, pigments, and many other compounds. There are no genes for these cell products, and yet their synthesis is under indirect genetic control. How? They are produced by enzymatic reactions, and enzymes are proteins encoded by genes.

Consider the production of testosterone, for example (fig. 4.13). This is a steroid; there is no gene for testosterone. But to make it, a cell of the testis takes in cholesterol and enzymatically converts it to testosterone. This can occur only if the genes for the enzymes are active. Yet a further implication of this is that genes may greatly affect such complex outcomes as behavior, since testosterone strongly influences such behaviors as aggression and sex drive. In short, DNA codes only for RNA and protein synthesis, yet it indirectly controls the synthesis of a much wider range of substances concerned with all aspects of anatomy, physiology, and behavior.

FIGURE 4.13 Indirect Control of Testosterone Synthesis by DNA. There is no gene for testosterone, but DNA regulates its production by coding for enzymes that convert cholesterol to testosterone.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Define gene, genetic code, codon, and anticodon.
2. Describe the roles of RNA polymerase, ribosomes, and tRNA in producing a protein.
3. What is the difference between genetic transcription and translation?
4. Summarize the processing of a protein from the time a ribosome finishes its work to the time a protein is secreted from the cell. What roles do the endoplasmic reticulum and Golgi complex play in this?
5. Describe a way that a gene can be turned on or off at different times in a person's life.
6. Considering that genes can code only for RNA or proteins, how can the synthesis of nonprotein substances such as carbohydrates or steroids be under genetic control?

4.3 DNA Replication and the Cell Cycle

Objectives

When you have completed this section, you should be able to

- describe how DNA is replicated;
- discuss the consequences of replication errors;
- describe the life history of a cell, including the events of mitosis; and
- explain how the timing of cell division is regulated.

Before a cell divides, it must duplicate its DNA so it can give a complete copy of all of its genes to each daughter cell. Since DNA controls all cellular function, this replication process must be very exact. We now examine how it is accomplished and consider the consequences of mistakes.

DNA Replication

The law of complementary base pairing shows that we can predict the base sequence of one DNA strand if we know the sequence of the other. More importantly, it enables a cell to reproduce one strand based on information in the other. The fundamental steps of the replication process are as follows (fig. 4.14):

1. The double helix unwinds from the histones.
2. Like a zipper, an enzyme called **DNA helicase** opens up one short segment of the helix at a time, exposing its nitrogenous bases. The point where the DNA is

opened up, like the two halves of a zipper separating, is called the **replication fork**.

3. Molecules of the enzyme **DNA polymerase** move along each strand; read the exposed bases; and like a matchmaker, arrange “marriages” with complementary free nucleotides. If the polymerase finds the sequence TCG, for example, it assembles AGC across from it. The two separated strands of DNA are copied by separate polymerase molecules, proceeding in opposite directions. On one strand (top of figure 4.14), the DNA polymerase moves toward the replication fork and makes a long, continuous, new strand of DNA to complement the old one. On the other strand (bottom of the figure), DNA polymerase moves away from the replication fork and copies only a short segment of DNA at a time. The segments are then joined together by another enzyme called **DNA ligase**. Ultimately, from the old *parental DNA* molecule, two new *daughter DNA* molecules are made. Each daughter DNA consists of one new helix synthesized from free nucleotides and one old helix conserved from the parental DNA. The process is therefore called **semiconservative replication**.
4. While DNA is synthesized in the nucleus, new histones are synthesized in the cytoplasm. Millions of histones are transported into the nucleus within a few minutes after DNA replication, and each new DNA helix wraps around them to make new nucleosomes.

Despite the complexity of this process, each DNA polymerase works at an impressive rate of about 100 base pairs per second. Even at this rate, however, it would take weeks for one polymerase molecule to replicate even one chromosome. But in reality, thousands of polymerase molecules work simultaneously on each DNA molecule, and all 46 chromosomes are replicated in a mere 6 to 8 hours.

Errors and Mutations

DNA polymerase is fast and accurate, but it makes mistakes. For example, it might read A and place a C across from it where it should have placed a T. If nothing were done to correct such errors, each generation of cells would have thousands of faulty proteins, coded for by DNA that had been miscopied. To prevent such catastrophic damage to the cell, there are multiple modes of correcting replication errors. The DNA polymerase itself double-checks the new base pair and tends to replace incorrect, biochemically unstable pairs with more stable, correct pairs—for example, removing C and replacing it with T. As a result, only one mistake remains for every billion base pairs replicated—a very high degree of replication accuracy, if not completely flawless.

FIGURE 4.14 Semiconservative DNA Replication. (a) At the replication fork, DNA helicase unwinds the double helix and exposes the bases. DNA polymerases begin assembling new bases across from the existing ones. (b) On one strand, DNA polymerase moves toward the replication fork and makes one long, continuous new DNA strand. (c) On the other strand, DNA polymerases begin at the fork and move away from it, replicating the DNA in short segments with gaps between them. (d) DNA ligase closes the gaps to join the segments into a continuous double helix. (e) The ultimate result is two DNA double helices, each composed of one strand of the original DNA and one newly synthesized strand.

Changes in DNA structure, called **mutations**,³ can result from replication errors or from environmental factors such as radiation, chemicals, and viruses. Uncorrected mutations can be passed on to the descendants of that cell, but many of them have no adverse effect. One reason is that a new base sequence sometimes codes for the same thing as the old one. For example, TGG and TGC both code for threonine (see table 4.2), so a mutation from G to C in the third place would not necessarily change protein structure. Another reason is that a change in protein structure is not always critical to its function. For example, the beta chain of hemoglobin is 146 amino acids long in both humans and horses, but 25 of these amino acids differ between the two species. Nevertheless, the hemoglobin is fully functional in both species. Furthermore, since 98% of the DNA does not code for any proteins, the great majority of mutations do not affect protein structure at all. Other mutations,

however, may kill a cell, turn it cancerous, or cause genetic defects in future generations. When a mutation changes the sixth amino acid of β -hemoglobin from glutamic acid to valine, for example, the result is a crippling disorder called sickle-cell disease. Clearly some amino acid substitutions are more critical than others, and this affects the severity of a mutation.

The Cell Cycle

Most cells periodically divide into two daughter cells, so a cell has a life cycle extending from one division to the next. This **cell cycle** is divided into four main phases: G_1 , S , G_2 , and M (fig. 4.15).

G_1 is the **first gap phase**, an interval between cell division and DNA replication. During this time, a cell synthesizes proteins, grows, and carries out its preordained tasks for the body. Almost all of the discussion in this book relates to what cells do in the G_1 phase. Cells in G_1 also accumulate the materials needed to replicate their DNA in

³muta = change

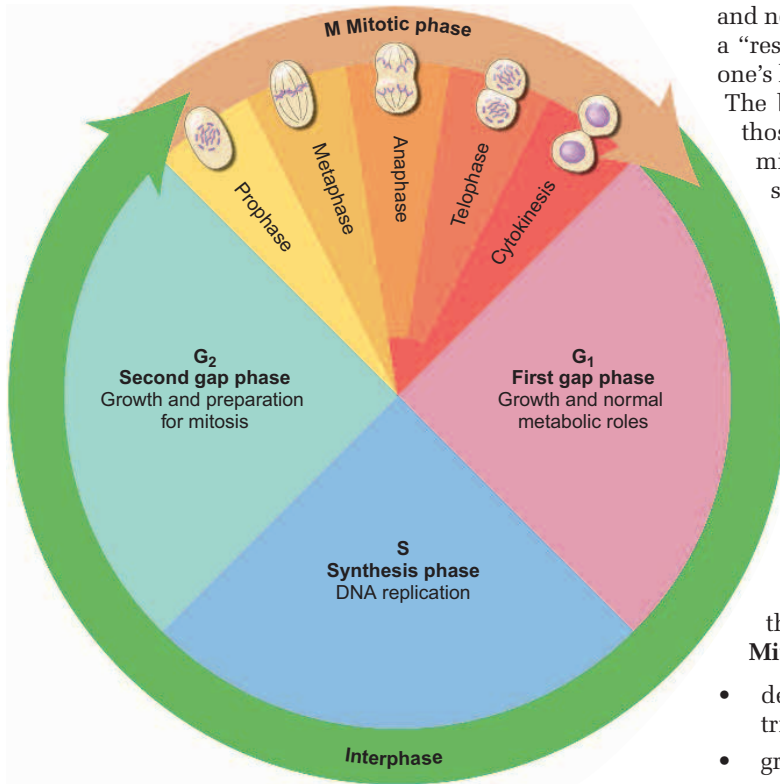

FIGURE 4.15 The Cell Cycle.

the next phase. In cultured cells called fibroblasts, which divide every 18 to 24 hours, G_1 lasts 8 to 10 hours.

S is the **synthesis phase**, in which a cell makes a duplicate copy of its centrioles and all of its nuclear DNA. The two identical sets of DNA molecules are then available to be divided up between daughter cells at the next cell division. This phase takes 6 to 8 hours in cultured fibroblasts.

G_2 , the **second gap phase**, is a relatively brief interval (4–6 hours) between DNA replication and cell division. In G_2 , a cell finishes replicating its centrioles and synthesizes enzymes that control cell division. It also checks the fidelity of DNA replication and usually repairs any errors that are detected.

M is the **mitotic phase**, in which a cell replicates its nucleus and then pinches in two to form two new daughter cells. In cultured fibroblasts, the M phase takes 1 to 2 hours. The details of this phase are considered in the next section. Phases G_1 , S, and G_2 are collectively called **interphase**—the time between M phases.

The length of the cell cycle varies greatly from one cell type to another. Stomach and skin cells divide rapidly, bone and cartilage cells slowly, and skeletal muscle cells

and nerve cells not at all. Some cells leave the cell cycle for a “rest” and cease to divide for days, years, or the rest of one’s life. Such cells are said to be in the **G_0 (G-zero) phase**. The balance between cells that are actively cycling and those standing by in G_0 is an important factor in determining the number of cells in the body. An inability to stop cycling and enter G_0 is characteristic of cancer cells (see Insight 4.3).

Think About It

What is the maximum number of DNA molecules ever contained in a cell over the course of its life cycle? (Assume the cell has only one nucleus, and disregard mitochondrial DNA.)

Mitosis

Cells divide by two mechanisms called mitosis and meiosis. Meiosis, however, is restricted to one purpose, the production of eggs and sperm, and is therefore treated in chapter 27 on reproduction. **Mitosis** serves all the other functions of cell division:

- development of an individual, composed of some 40 trillion cells, from a one-celled fertilized egg;
- growth of all tissues and organs after birth;
- replacement of cells that die; and
- repair of damaged tissues.

Four phases of mitosis are recognizable: *prophase*, *metaphase*, *anaphase*, and *telophase* (fig. 4.16).

① **Prophase.**⁴ At the outset of mitosis, the chromosomes shorten and thicken, eventually coiling into compact rods that are easier to distribute to daughter cells than the long, delicate chromatin of interphase. There are 46 chromosomes, two chromatids per chromosome, and one molecule of DNA in each chromatid. The nuclear envelope disintegrates during prophase and releases the chromosomes into the cytosol. The centrioles begin to sprout elongated microtubules called **spindle fibers**, which push the centrioles apart as they grow. Eventually, a pair of centrioles comes to lie at each pole of the cell. Some spindle fibers grow toward the chromosomes and become attached to the kinetochore on each side of the centromere (see fig. 4.5). The spindle fibers then tug the chromosomes back and forth until they line up along the midline of the cell.

② **Metaphase.**⁵ The chromosomes are aligned on the cell equator, oscillating slightly and awaiting a signal that stimulates each of them to split in two at the

⁴pro = first

⁵meta = next in a series

FIGURE 4.16 Mitosis. The photographs show mitosis in whitefish eggs, where chromosomes are relatively easy to observe. The drawings show a hypothetical cell with only two chromosome pairs; in humans, there are 23 pairs.

centromere. The spindle fibers now form a lemon-shaped array called the **mitotic spindle**. Long microtubules reach out from each centriole to the chromosomes, and shorter microtubules form a star-like *aster*,⁶ which anchors the assembly to the inside of the plasma membrane at each end of the cell.

③ **Anaphase.**⁷ This phase begins with activation of an enzyme that cleaves the two sister chromatids from each other at the centromere. Each chromatid is now regarded as a separate, single-stranded *daughter chromosome*. One daughter chromosome migrates to each pole of the cell, with its centromere leading the way and the arms trailing behind. Migration is achieved by means of motor proteins in the kinetochore crawling along the spindle fiber as the fiber itself is “chewed up” and disassembled at the chromosomal end. Since sister chromatids are genetically identical, and since each daughter cell receives one chromatid from each chromosome, the daughter cells of mitosis are genetically identical.

④ **Telophase.**⁸ The chromatids cluster on each side of the cell. The rough ER produces a new nuclear envelope around each cluster, and the chromatids begin to uncoil and return to the thinly dispersed chromatin form. The mitotic spindle breaks up and vanishes. Each new nucleus forms nucleoli, indicating it has already begun making RNA and preparing for protein synthesis.

Telophase is the end of nuclear division but overlaps with **cytokinesis**⁹ (SY-toe-kih-NEE-sis), division of the cytoplasm into two cells. Early traces of cytokinesis are visible even at anaphase. It is achieved by the motor protein myosin pulling on microfilaments of actin in the terminal web of the cytoskeleton. This creates a crease called the *cleavage furrow* around the equator of the cell, and the cell eventually pinches in two. Interphase has now begun for these new cells.

The Timing of Cell Division

One of the most important questions in biology is what signals cells when to divide and when to stop. The activation and inhibition of cell division are subjects of intense research for obvious reasons such as management of cancer and tissue repair. Cells divide when (1) they grow large enough to have enough cytoplasm to distribute to their two daughter cells; (2) they have replicated their DNA, so they can give each daughter cell a duplicate set of genes; (3) they receive an adequate supply of nutrients;

(4) they are stimulated by **growth factors**, chemical signals secreted by blood platelets, kidney cells, and other sources; or (5) neighboring cells die, opening up space in a tissue to be occupied by new cells. Cells stop dividing when they snugly contact neighboring cells or when nutrients or growth factors are withdrawn. The cessation of cell division in response to contact with other cells is called **contact inhibition**.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

11. Describe the genetic roles of DNA helicase and DNA polymerase. Contrast the function of DNA polymerase with that of RNA polymerase.
12. Explain why DNA replication is called semiconservative.
13. Define mutation. Explain why some mutations are harmless and others can be lethal.
14. List the stages of the cell cycle and summarize what occurs in each one.
15. List the stages of mitosis and the main processes that occur in each one.

4.4 Chromosomes and Heredity

Objectives

When you have completed this section, you should be able to

- describe the paired arrangement of chromosomes in the human karyotype;
- define *allele* and discuss how alleles affect the traits of an individual; and
- discuss the interaction of heredity and environment in producing individual traits.

Heredity is the transmission of genetic characteristics from parent to offspring. In the following discussion, we will examine a few basic principles of normal heredity, thus establishing a basis for understanding hereditary traits in later chapters. Hereditary defects are described in chapter 29 along with nonhereditary birth defects.

The Karyotype

As we have seen, the agents of heredity are the genes, and the genes are carried on the chromosomes. Nearly all human cells—with the exception of eggs, sperm, and a few others—have 46 chromosomes. When we lay the chromosomes out in order by size and other physical features, we get a chart called a **karyotype** (fig. 4.17). These chromosomes occur in 23 pairs; the two members of each pair are

⁶aster = star

⁷ana = apart

⁸telo = end, final

⁹cyto = cell + kinesis = action, motion

FIGURE 4.17 Karyotype of a Normal Human Male. This is a false-color micrograph of chromosomes stained to accentuate their banding patterns. The two chromosomes of each homologous pair exhibit similar size, shape, and banding.

❏ How would this karyotype differ if it were from a female?

called **homologous**¹⁰ (ho-MOLL-uh-gus) **chromosomes**. One member of each pair is inherited from the individual's mother and one from the father. Except for the X and Y chromosomes, two homologous chromosomes look alike and carry the same genes, although they may have different varieties of those genes. Chromosomes X and Y are called the **sex chromosomes** because they determine the individual's sex; all the others are called **autosomes**. A female normally has a homologous pair of X chromosomes, whereas a male has one X and a much smaller Y.

Think About It

Why would a cell in metaphase be more useful than a cell in interphase for producing a karyotype?

Any cell with 23 pairs of chromosomes is said to be **diploid**.¹¹ Sperm and egg cells, however, are **haploid**,¹²

meaning they contain half as many chromosomes as the somatic cells. Sperm and eggs, and cells on their way to becoming sperm and eggs, are called **germ cells**. All other cells of the body are called **somatic cells**. In meiosis (see chapter 27), the two homologous chromosomes of each pair become *segregated* into separate daughter cells leading to the haploid germ cells. At fertilization, one set of *paternal* (sperm) chromosomes unites with a set of *maternal* (egg) chromosomes, restoring the diploid number to the fertilized egg and the somatic cells that arise from it.

Genes and Alleles

Considering that each haploid chromosome set consists of 23 chromosomes and carries about 30,000 genes, it is obvious that each chromosome carries many genes. The location of a particular gene on a chromosome is called its **locus**. Homologous chromosomes have the same gene at the same locus, although they may carry different forms of that gene, called **alleles**¹³ (ah-LEELS), which produce alternative forms of a particular trait. Frequently, one allele is **dominant** and the other one **recessive**. If at least one chromosome carries the dominant allele, the corresponding trait is usually detectable in the individual. A dominant allele masks the effect of any recessive allele that may be present. Recessive alleles are therefore expressed only when present on both of the homologous chromosomes—that is, when the individual has no dominant allele at that locus. Typically, but not always, dominant alleles code for a normal, functional protein and recessive alleles for a nonfunctional variant of the protein.

A feature of the chin presents an example of dominant and recessive genetic effects. Some people have a *cleft chin*, with a deep dimple in the middle, whereas most people do not (fig. 4.18a). The allele for cleft chin is dominant; we will represent it with a capital *C*. Those who inherit this from one or both parents will normally have a cleft chin. The allele for an uncleft chin is recessive, here represented with a lowercase *c*. (It is customary to represent a dominant allele with a capital letter and a recessive allele with its lowercase equivalent.) One must inherit the recessive allele from both parents to have an uncleft chin (fig. 4.18b).

Individuals with two identical alleles, such as *CC* or *cc*, are said to be **homozygous**¹⁴ (HO-mo-ZY-gus) for that trait. If the homologous chromosomes have different alleles for that gene (*Cc*), the individual is **heterozygous**¹⁵ (HET-er-oh-ZY-gus). The alleles that an individual possesses for a particular trait constitute the **genotype** (JEE-no-type). An observable trait such as cleft or uncleft chin is called the **phenotype**¹⁶ (FEE-no-type).

We say that an allele is **expressed** if it shows in the phenotype of an individual. Chin allele *c* is expressed only when it is present in a homozygous state (*cc*); allele *C* is

¹⁰*homo* = same + *log* = relation

¹¹*diplo* = double

¹²*haplo* = half

¹³*allo* = different

¹⁴*homo* = same + *zygo* = union, joined

¹⁵*hetero* = different

¹⁶*pheno* = showing, evident

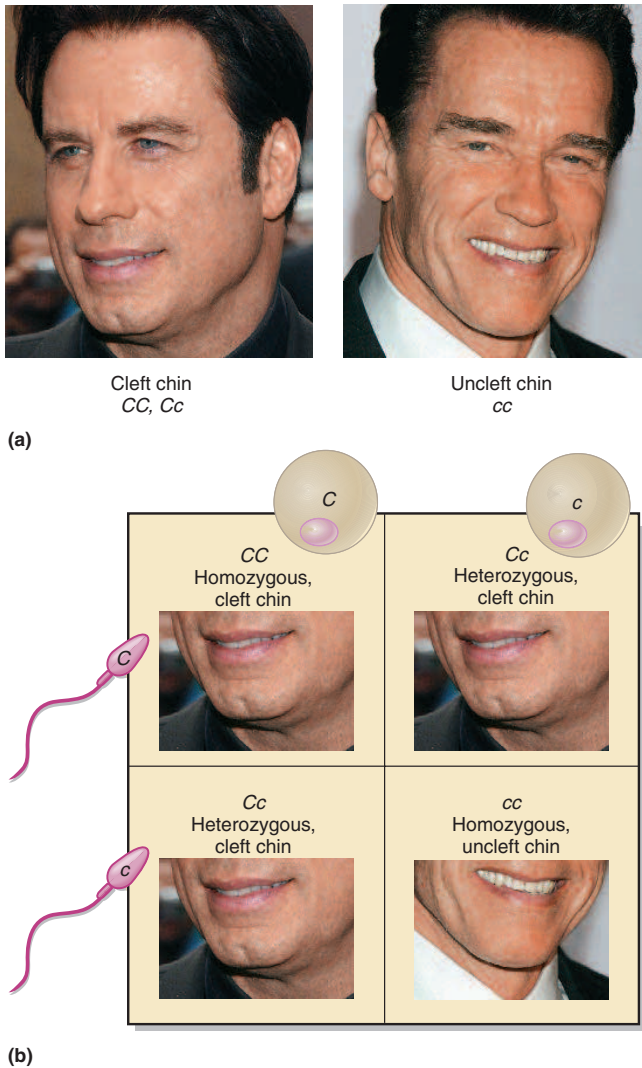

FIGURE 4.18 Genetics of Cleft Chin. (a) A cleft chin occurs if even one allele of the pair is dominant (C). The more common uncleft chin occurs only when both alleles are recessive (c). (b) A Punnett square shows why such a trait can “skip a generation.” Both parents in this case have heterozygous genotypes (Cc) and cleft chins. An egg from the mother can carry either allele C or c (top), as can a sperm from the father (left). This gives their offspring a one-in-four chance of having an uncleft chin (cc).

expressed whether it is homozygous (CC) or heterozygous (Cc). The only way most recessive alleles can be expressed is for an individual to inherit them from both parents.

Recessive traits can “skip” one or more generations. A diagram called a *Punnett square* (fig. 4.18b) shows how two heterozygous parents with cleft chins can produce a child with an uncleft chin. Across the top are the two genetically possible types of eggs the mother could produce, and on the left side are the possible types of sperm from the father. The four cells of the square show the genotypes and phenotypes that would result from each

possible combination of sperm and egg. You can see that three of the possible combinations would produce a child with cleft chin (genotypes CC and Cc), but one combination (cc) would produce a child with an uncleft chin. Therefore, the uncleft chin trait skipped the parental generation in this case but could be expressed in their child.

This phenomenon becomes more significant when parents are heterozygous **carriers** of hereditary diseases such as cystic fibrosis—individuals who carry a recessive allele and may pass it on, but do not phenotypically express it in themselves. For some hereditary diseases, tests are available to detect carriers and allow couples to weigh their risk of having children with genetic disorders. *Genetic counselors* perform genetic testing or refer clients for tests, advise couples on the probability of transmitting genetic diseases, and assist people in coping with genetic disease.

Think About It

Would it be possible for a woman with an uncleft chin to have children with cleft chins? Use a Punnett square and one or more hypothetical genotypes for the father to demonstrate your point.

Multiple Alleles, Codominance, and Incomplete Dominance

Some genes exist in more than two allelic forms—that is, there are **multiple alleles** within the collective genetic makeup, or **gene pool**, of the population as a whole. For example, there are over 100 alleles responsible for cystic fibrosis, and there are 3 alleles for ABO blood types. Two of the ABO blood type alleles are dominant and symbolized with a capital I (for *immunoglobulin*) and a superscript: I^A and I^B . There is one recessive allele, symbolized with a lowercase i . Which two alleles one inherits determine the blood type, as follows:

Genotype	Phenotype
$I^A I^A$	Type A
$I^A i$	Type A
$I^B I^B$	Type B
$I^B i$	Type B
$I^A I^B$	Type AB
ii	Type O

Think About It

Why can't one person have all three of the ABO alleles?

Some alleles are equally dominant, or **codominant**. When both of them are present, both are phenotypically expressed. For example, a person who inherits allele I^A from one parent and I^B from the other has blood type AB. These alleles code for enzymes that produce the surface glycolipids of red blood cells. Type AB means that both A and B glycolipids are present, and type O means that neither of them is present.

Other alleles exhibit **incomplete dominance**. When two different alleles are present, the phenotype is intermediate between the traits that each allele would produce alone. Familial hypercholesterolemia, the disease discussed in Insight 3.3 (p. 107), is a good example. Individuals with two abnormal alleles die of heart attacks in childhood, those with only one abnormal allele typically die as young adults, and those with two normal alleles have normal life expectancies. Thus, the heterozygous individuals suffer an effect between the two extremes.

Polygenic Inheritance and Pleiotropy

Polygenic (multiple-gene) inheritance (fig. 4.19) is a phenomenon in which genes at two or more loci, or even on different chromosomes, contribute to a single phenotypic trait. Human eye and skin colors are normal polygenic traits, for example. They result from the combined expression of all the genes for each trait. Several diseases are also thought to stem from polygenic inheritance, including some forms of alcoholism, mental illness, cancer, and heart disease.

Pleiotropy (ply-OT-roe-pee) is a phenomenon in which one gene produces multiple phenotypic effects. For example, about 1 in 200,000 people has a genetic disorder called *alkaptonuria*, caused by a mutation on chromosome 3. The mutation blocks the normal breakdown of an amino acid named tyrosine, resulting in the accumulation of an intermediate breakdown product, homogentisic acid, in the body fluids and connective tissues. When homogentisic acid oxidizes, it binds to collagen and turns the tissues gray to bluish black; and for unknown reasons, it causes degeneration of cartilages and other connective tissues. Among the multiple phenotypic effects of this disorder (fig. 4.20) are darkening of the skin; darkening and degeneration of the cartilages in places such as the ears, knees, and intervertebral discs; darkening of the urine when it stands long enough for the homogentisic acid to oxidize; discoloration of the teeth and the whites of the eyes; arthritis of the shoulders, hips, and knees; and damage to the heart valves, prostate gland, and other internal organs. Another well-known example of pleiotropy is sickle-cell disease, detailed in chapter 18.

Sex Linkage

Sex-linked traits are carried on the X or Y chromosome and therefore tend to be inherited by one sex more than the other. Men are more likely than women to have red-green color blindness or hemophilia, for example, because the allele for each is recessive and located on the X chromosome (*X-linked*). Women have two X chromosomes. If a woman inherits the recessive color-blindness allele (*c*)

FIGURE 4.19 Polygenic Inheritance of Eye Color. A polygenic trait such as eye color is determined by the contributions of genes at multiple loci.

FIGURE 4.20 Pleiotropy in Alkaptonuria. Multiple phenotypic effects can result from a single gene mutation. In alkaptonuria, a single mutation leads to darkening of the skin, dark patches in the sclera (“white”) of the eye, and darkening of the urine as it stands and oxidizes.

on one of her X chromosomes, there is still a good chance that her other X chromosome will carry a dominant allele (*C*) for normal color vision. Men, on the other hand, have only one X chromosome and normally express any allele found there (fig. 4.21). Ironically, even though color blindness is far more common among men than women, a man can inherit it only from his mother. Why? Because only his mother contributes an X chromosome to him. If he inherits *c* on his mother’s X chromosome, he will be color-blind. He has no “second chance” to inherit a normal allele on a second X chromosome. A woman, however, gets an X chromosome from both parents. Even

FIGURE 4.21 Sex-Linked Inheritance of Red-Green Color Blindness. Left: A female who inherits a recessive allele (*c*) for color blindness from one parent may not exhibit the trait, because she is likely to inherit the dominant allele (*C*) for normal vision from her other parent. Right: A male who inherits *c* from his mother will exhibit red-green color blindness, because the Y chromosome inherited from his father does not have a corresponding gene locus and therefore has no ability to mask the effect of *c*.

if one parent transmits the recessive allele to her, the chances are high that she will inherit a normal allele from her other parent. She would have to have the extraordinarily bad luck to inherit it from both parents in order for her to have a trait such as red-green color blindness.

The X chromosome is thought to carry about 260 genes, most of which have nothing to do with determining an individual's sex. There are so few functional genes on the Y chromosome—concerned mainly with development of the testes—that virtually all sex-linked traits are associated with the X chromosome.

Penetrance and Environmental Effects

A given genotype does not inevitably produce the expected phenotype. For example, a dominant allele causes *polydactyly*,¹⁷ the presence of extra fingers or toes. We might predict that since it is dominant, anyone who inherited the allele would exhibit this trait. Most do, but others known to have the allele have the normal number of digits. **Penetrance** is the percentage of a population with a given genotype that actually exhibits the predicted phenotype. If 80% of people with the polydactyly allele actually exhibit extra digits, the allele has 80% penetrance.

Another reason the connection between genotype and phenotype is not inevitable is that environmental factors play an important role in the expression of all genes. At the very least, all gene expression depends on nutrition. Brown eyes, for example, require not only genes for the enzymes that synthesize the pigment melanin, but also the dietary raw material, phenylalanine, from which the melanin is made (fig. 4.22).

FIGURE 4.22 The Roles of Environment and Heredity in Producing a Phenotype. Brown eye color requires phenylalanine from the diet (environment) and two genetically coded (hereditary) enzymes to convert phenylalanine to melanin, the eye pigment.

No gene can produce a phenotypic effect without nutritional and other environmental input, and no nutrients can produce a body or specific phenotype without genetic instructions that tell cells what to do with them. Just as you need both a recipe and ingredients to make a cake, it takes both heredity and environment to make a phenotype.

Dominant and Recessive Alleles at the Population Level

It is a common misconception that dominant alleles must be more common in the gene pool than recessive alleles. The truth is that dominance and recessiveness have little to do with how common an allele is. For example, type O is the most common ABO blood type in North America, but it is caused by the recessive allele *i*. Blood type AB, caused by the two dominant ABO alleles, is the rarest. Polydactyly, caused by a dominant allele, also is rare in the population.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. Why must the carrier of a genetic disease be heterozygous?
17. State at least three reasons why a person's phenotype can't always be determined from the genotype.
18. A man can inherit color blindness only from his mother, whereas a woman must inherit it from both her father and mother to show the trait. Explain this apparent paradox.

¹⁷poly = many + dactyl = fingers, toes

INSIGHT 4.3 Clinical Application

Cancer

Anyone awaiting the results of a tumor biopsy hopes for the good news: benign! This means the tumor is slow-growing and contained in a fibrous capsule, so it will not metastasize and in most cases it is relatively easy to treat. The dreaded news is that it's malignant, meaning that it tends to grow rapidly and to *metastasize*—to give off cells that seed the growth of multiple tumors elsewhere, such as colon cancer metastasizing to the lungs and brain.

Oncology is a medical specialty that deals with both benign and malignant tumors, but only malignancies are called *cancer*. The word literally means “crab.” Hippocrates was the first to use the word this way, upon seeing a breast tumor with a tangle of blood vessels that reminded him of a crab's outstretched legs. Energy-hungry tumors often stimulate such ingrowth of blood vessels—a phenomenon called *tumor angiogenesis*.

Cancers are named for the tissue of origin: *carcinomas* originate in epithelial tissue; *lymphomas* in the lymph nodes; *melanomas* in pigment cells (melanocytes) of the epidermis; *leukemias* in blood-forming tissues such as bone marrow; and *sarcomas* in bone, other connective tissue, or muscle. About 90% of malignancies are carcinomas, probably because epi-

thelial cells have a high rate of mitosis, making them especially subject to mutation, and because epithelia are more exposed than other tissues to *carcinogens* (environmental cancer-causing agents).

Only 5% to 10% of cancers are hereditary, but cancer is always a genetic disease. This is not as contradictory as it might seem. Most cases are due to mutations arising anew in the affected individual, not to genes received from a parent. Mutations can arise simply through errors in DNA replication, or from exposure to carcinogens—radiation such as ultraviolet rays and X-rays; chemicals such as cigarette tar; and viruses such as human papillomavirus (HPV), hepatitis C, and type 2 herpes simplex.

Oncologists are especially interested in two families of cancer genes called oncogenes and tumor-suppressor genes. An *oncogene* is analogous to a stuck accelerator on a car—it causes cell division to accelerate out of control, sometimes by inducing the excessive secretion of growth factors that stimulate mitosis, or the production of excessive growth-factor receptors. An oncogene called *ras* underlies about one-quarter of human cancers, and *erbB2* is a common factor in breast and ovarian cancer. A *tumor-suppressor (TS) gene* is like a broken brake pedal. Healthy TS genes inhibit cancer by opposing oncogene action, coding for DNA-repair enzymes, and other means. Consequently, mutations that destroy their protective “braking” function can lead to cancer. Mutation of a TS gene called *p53*, for example, is involved in about 50% of cases of leukemia and colon, lung, breast, liver, brain, and esophageal tumors.

Cancer seldom results from just one mutation, however. It usually requires 5 to 10 mutations at different gene loci. It takes time for so many mutations to accumulate, which is why cancer is more common in the elderly than in the young. In addition, as we age, we accrue more lifetime exposure to carcinogens, our DNA and tissue repair mechanisms become less efficient, and our immune system grows weaker and less able to detect and destroy malignant cells.

Cancer claims the lives of about one in five Americans, and is almost always fatal if not treated. Malignant tumors replace functional tissue in vital organs (fig. 4.23); they steal nutrients from the rest of the body, sometimes causing a severe wasting away called *cachexia*; they weaken one's immunity, opening the door to *opportunistic infections* that a healthier person could ward off; and they often invade blood vessels, lung tissue, or brain tissue, with such consequences as hemorrhage, pulmonary collapse, seizures, or coma. Mortality usually results not from the original (primary) tumor, but from metastasis.

Cancer is usually treated with surgery, chemotherapy, or radiation therapy. A lively area of cancer research today is the development of drugs to starve tumors by blocking tumor angiogenesis.

FIGURE 4.23 Wilms Tumor. This is a malignant tumor of the kidney occurring especially in children.

CHAPTER REVIEW

Review of Key Concepts

4.1 DNA and RNA—The Nucleic Acids
(p. 124)

1. DNA is a polymer of four kinds of nucleotides, each composed of a sugar, a phosphate group, and a nitrogenous base.
2. The nitrogenous bases of DNA are the two single-ring *pyrimidines*, cytosine (C) and thymine (T), and the two double-ring purines, adenine (A) and guanine (G).
3. The DNA molecule is a double helix, with each chain having a backbone of alternating phosphate groups and sugars (deoxyribose), and the nitrogenous bases facing the core of the helix. Each adenine on one helix is normally paired with a thymine on the other, and each guanine with a cytosine. This arrangement is called the *law of complementary base pairing*.
4. About 2% of one's DNA composes the 25,000 to 35,000 genes in the human genome. The other 98% is noncoding and plays various roles in gene regulation and chromosome structure.
5. The *chromatin* in a cell nucleus is composed of DNA and protein. It is elaborately coiled to pack the vast amount of DNA into a limited space and to prevent damage to it. Part of this compaction involves coiling of the DNA around clusters of *histones* to form *nucleosomes*. In most cells, the chromatin consists of 46 DNA-protein complexes, the *chromosomes*.
6. As a cell approaches and enters division, its nuclear DNA is replicated; checked for accuracy; and then consolidated into thicker, shorter chromosomes visible as a pair of identical *chromatids* joined at a *centromere*.
7. RNA is a family of shorter polymers, each composed of a single nucleotide chain and containing ribose and uracil in place of deoxyribose and thymine, respectively. Three types of RNA—*mRNA*, *rRNA*, and *tRNA*—are especially known for their direct roles in protein synthesis.

4.2 Genes and Their Action (p. 129)

1. A *gene* is a segment of DNA that codes for a molecule of RNA, which in most cases goes on to play a role in the synthesis of a protein or group of proteins. The amino acid sequence of any protein is determined by the nucleotide sequence of the DNA.
2. The human genome consists of all the DNA in one set of 23 chromosomes. Study of the genome is called *genomics* and its application to health is called *genomic medicine*.
3. Each sequence of three nitrogenous bases in DNA, called a *triplet*, is represented by a complementary three-base *codon* in mRNA. The codons include 61 that code for amino acids and 3 *stop codons* that code for the end of a gene. The *genetic code* is the correspondence between the mRNA codons and the 20 amino acids that they represent.
4. Protein synthesis begins with *transcription*, a process in which the enzyme *RNA polymerase* makes an mRNA mirror-image copy of the gene. Messenger RNA usually leaves the nucleus and binds to a ribosome in the cytoplasm.
5. Protein synthesis continues with *translation*, in which a ribosome binds mRNA, reads the coded message, and assembles the corresponding protein.
6. After translation, a protein may undergo structural changes called *posttranslational modification*, often carried out in the rough ER and Golgi complex, followed in many cases by secretion from the cell.
7. Genes are turned on or off by *regulatory proteins* in accordance with changing needs for the proteins they encode. Regulatory proteins may be activated by hormones and other chemical messengers.
8. DNA directly controls protein structure and indirectly controls the synthesis of other molecules by coding for the enzymes that make them.

4.3 DNA Replication and the Cell Cycle
(p. 138)

1. Since every cell division divides a cell's DNA between two daughter cells, the DNA must be replicated before the next division.
2. The enzyme *DNA helicase* prepares DNA for replication by opening up the double helix at several points and exposing the nitrogenous bases.
3. *DNA polymerase* molecules read the base sequence on each chain of DNA and synthesize the complementary chain. This occurs simultaneously at many points along each DNA molecule.
4. Each of the two helices of DNA thereby acquires a new, complementary helix to become a new, double-helical DNA molecule.
5. There are multiple mechanisms for proofreading the new DNA and correcting replication errors, but if an error goes undetected, it persists as a *mutation* in the genome. Many or most mutations are harmless, but others can cause cell death or diseases such as cancer.
6. Cells have a life cycle, from division to division, of four phases: G_1 , S, G_2 , and M. G_1 through G_2 are collectively called *interphase* (the period between cell divisions) and M is *mitosis*.
7. G_1 is a period of cell growth and performance of the cell's overall tasks for the body. S is a period of DNA replication. G_2 is a period for checking the accuracy of DNA replication and preparing for cell division. M is the process of division itself.
8. Mitosis is responsible for embryonic development; tissue growth; and replacement of old, injured, or dead cells. It occurs in four stages—*prophase*, *metaphase*, *anaphase*, and *telophase*—followed by *cytokinesis*, the division of the cytoplasm into two cells.
9. Normal tissue structure depends on a balance between cell division and cell death. Cell division is stimulated

by *growth factors* and suppressed by *contact inhibition*.

4.4 Chromosomes and Heredity (p. 142)

1. *Heredity* is the transmission of genetic characteristics from parent to offspring.
2. Most of the body's cells are called *somatic cells* and contain 46 paired chromosomes. These pairs are shown in the *karyotype*, a chart of metaphase chromosomes arranged in pairs and by size. The two chromosomes of each pair are called *homologous chromosomes*; one comes from each parent.
3. One pair of chromosomes, the *sex chromosomes* (X and Y), determine the sex of the individual; the other 22 pairs are called *autosomes*.
4. *Germ cells* (developing and mature eggs and sperm) have 23 unpaired chromosomes and are thus called *haploid cells*. *Somatic cells* (all of the body's nonreproductive cells) usually have 23 *pairs* of chromosomes and are thus called *diploid cells*.
5. Many genes occur in alternative forms called *dominant* and *recessive alleles*. Individuals with two identical alleles at a given locus are *homozygous*, and those with nonidentical alleles are *heterozygous*.
6. The *genotype* is an individual's combination of alleles for a particular trait; the *phenotype* is the visible trait that results from genetic and environmental influences.
7. Recessive traits can skip a generation if masked by a dominant allele. Heterozygous *carriers* lack the trait but transmit the hidden allele to the next generation.
8. The alleles possessed by all members of a population collectively are called the *gene pool*. For some genes, there are three or more alleles in the gene pool, as in the ABO blood type alleles.
9. Some alleles interact in such a way that both are fully expressed (*codominance*) or an intermediate trait is produced (*incomplete dominance*).
10. In *polygenic inheritance*, genes at several loci collaborate to produce a single trait such as skin or eye color. In *pleiotropy*, a single gene locus can produce multiple phenotypic effects, as in alkaptonuria and sickle-cell disease.
11. Some traits occur more often in one sex (usually males) than in the other because they are carried on one of the sex chromosomes. These are called *sex-linked traits*, and include color blindness and hemophilia.
12. *Penetrance* is the percentage of individuals with a given genotype that show the expected phenotype. Influences outside of the genotype may cause it not to be expressed, thus producing a penetrance of less than 100%.
13. All traits result from a combination of genetic and environmental influences, so the environment affects whether a given genotype is expressed.
14. Whether an allele is dominant or recessive has no relationship to whether it is more or less common in the population. Some recessive traits are very common (such as blood type O), and some dominant traits are very rare (such as polydactyly).

Testing Your Recall

1. Production of more than one phenotypic trait by a single gene is called
 - a. pleiotropy.
 - b. genetic determinism.
 - c. codominance.
 - d. penetrance.
 - e. genetic recombination.
2. When a ribosome reads a codon on mRNA, it must bind to the _____ of a corresponding tRNA.
 - a. start codon
 - b. stop codon
 - c. intron
 - d. exon
 - e. anticodon
3. The normal functions of a liver cell—synthesizing proteins, detoxifying wastes, storing glycogen, and so forth—are done during its
 - a. anaphase.
 - b. telophase.
 - c. G1 phase.
 - d. G2 phase.
 - e. synthesis phase.
4. Two genetically identical strands of a metaphase chromosome, joined at the centromere, are its
 - a. kinetochores.
 - b. centrioles.
 - c. sister chromatids.
 - d. homologous chromatids.
 - e. nucleosomes.
5. Which of the following is *not* found in DNA?
 - a. thymine
 - b. phosphate
 - c. cytosine
 - d. deoxyribose
 - e. uracil
6. Genetic transcription is performed by
 - a. ribosomes.
 - b. RNA polymerase.
 - c. DNA polymerase.
 - d. helicase.
 - e. chaperones.
7. A chaperone comes into play in
 - a. the folding of a new protein into its tertiary structure.
 - b. keeping DNA organized within the nucleus.
 - c. escorting sister chromatids to opposite daughter cells during mitosis.
 - d. repairing DNA that has been damaged by mutagens.
 - e. preventing malignant cells from metastasizing.
8. An allele that is not phenotypically expressed in the presence of an alternative allele of the same gene is said to be
 - a. codominant.
 - b. lacking penetrance.
 - c. heterozygous.
 - d. recessive.
 - e. subordinate.
9. Semiconservative replication occurs during
 - a. transcription.
 - b. translation.
 - c. posttranslational modification.
 - d. the S phase of the cell cycle.
 - e. mitosis.

150 PART ONE Organization of the Body

10. Mutagens sometimes cause no harm to cells for all of the following reasons *except*
- some mutagens are natural, harmless products of the cell itself.
 - most of the human DNA does not code for any proteins.
 - the body's DNA repair mechanisms detect and correct genetic damage.
 - change in a codon does not always change the amino acid encoded by it.
 - some mutations change protein structure in ways that are not critical to normal function.
11. The cytoplasmic division at the end of mitosis is called _____.
12. The alternative forms in which a single gene can occur are called _____.
13. The pattern of nitrogenous bases that represents the 20 amino acids of a protein is called the _____.
14. Several ribosomes attached to one mRNA, which they are all transcribing, form a cluster called a/an _____.
15. The enzyme that produces pre-mRNA from the instructions in DNA is _____.
16. All the DNA in a haploid set of chromosomes is called a person's _____.
17. At prophase, a cell has _____ chromosomes, _____ chromatids, and _____ molecules of DNA.
18. The cytoplasmic granule of RNA and protein that reads the message in mRNA is a _____.
19. Cells are stimulated to divide by chemical signals called _____.
20. All chromosomes except the sex chromosomes are called _____.

*Answers in appendix B***True or False**

Determine which five of the following statements are false, and briefly explain why.

- Proteins destined to be exported from a cell are made by ribosomes on the surface of the Golgi complex.
- Each of a cell's products—such as steroids, carbohydrates, and phospholipids—is encoded by a separate gene.
- A molecule of RNA would weigh about half as much as a segment of DNA of the same length.
- Each amino acid of a protein is represented by a three-base sequence in DNA.
- One gene can code for more than one protein.
- The law of complementary base pairing describes the way the bases in an mRNA codon pair up with the bases of a tRNA anticodon during translation.
- Most of the DNA in a human cell does not code for any proteins.
- Some mutations are harmless.
- Males have only one sex chromosome whereas females have two.
- A gene can be transcribed by only one RNA polymerase at a time.

*Answers in appendix B***Testing Your Comprehension**

- Why would the supercoiled, condensed form of chromosomes seen in metaphase not be suitable for the G₁ phase of the cell cycle? Why would the finely dispersed chromatin of the G₁ phase not be suitable for mitosis?
- Suppose a woman was heterozygous for blood type A and her husband had blood type AB. With the aid of a Punnett square, explain what blood type(s) their children could possibly have.
- Given the information in this chapter, present an argument that evolution is not merely possible but inevitable. (*Hint: Review the definition of evolution in chapter 1.*)
- What would be the minimum length (approximate number of bases) of an mRNA that coded for a protein 300 amino acids long?
- Until recently, textbooks taught the concept of “one gene, one protein”—that a gene is a segment of DNA that codes for just one protein, and every protein is represented by a separate gene. Discuss the evidence that shows that this can no longer be regarded as true.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Body cavities and membranes (pp. 34–37)
- Glycoproteins and proteoglycans (p. 71)
- Terminology of cell shapes (p. 88)
- Secretory vesicles and exocytosis (p. 108)

Each organ system in
Anatomy & Physiology | Revealed
contains a section with histology views.

With its 50 trillion cells and thousands of organs, the human body may seem to be a structure of forbidding complexity. Fortunately for our health, longevity, and self-understanding, the biologists of past generations were not discouraged by this complexity, but discovered patterns that made it more understandable. One of these patterns is the fact that these trillions of cells belong to only 200 different types or so, and these cells are organized into tissues that fall into just four broad categories: *epithelial*, *connective*, *nervous*, and *muscular tissue*.

An organ is a structure with discrete boundaries that is composed of two or more of these tissue types (frequently all four). Organs derive their function not from their cells alone but from how the cells are organized into tissues. Cells are specialized for certain tasks: muscle contraction, defense, enzyme secretion, and so forth. No one cell type has the mechanisms to carry out all of the body's vital functions. Cells work together at certain tasks and form tissues that carry out a particular function, such as nerve signaling or nutrient digestion.

The study of tissues and how they are arranged into organs is called **histology**,¹ or **microscopic anatomy**. That is the subject of this chapter. Here we study the four tissue classes; the variations within each class; how to recognize tissue types microscopically and relate their microscopic anatomy to their function; how tissues are arranged to form an organ; and how tissues change as they grow, shrink, or change from one tissue type to another over the life of the individual. Histology bridges the gap between the *cytology* of the preceding chapters and the *organ system* approach of the chapters that follow.

¹histo = tissue + logy = study of

5.1 The Study of Tissues

Objectives

When you have completed this section, you should be able to

- name the four primary classes into which all adult tissues are classified;
- name the three embryonic germ layers and some adult tissues derived from each; and
- visualize the three-dimensional shape of a structure from a two-dimensional tissue section.

The Primary Tissue Classes

A **tissue** is a group of similar cells and cell products that arise from the same region of the embryo and work together to perform a specific structural or physiological role in an organ. The four *primary tissues* are epithelial, connective, nervous, and muscular tissue (table 5.1). These differ from one another in the types and functions of their cells, the characteristics of the **matrix (extracellular material)** that surrounds the cells, and the relative amount of space occupied by cells versus matrix. In muscle and epithelium, the cells are so close together that the matrix is scarcely visible, while in connective tissues, the matrix usually occupies much more space than the cells do.

The matrix is composed of fibrous proteins and, usually, a clear gel variously known as **ground substance**, **tissue fluid**, **extracellular fluid (ECF)**, **interstitial² fluid**, or **tissue gel**. In cartilage and bone, it can be rubbery or stony in consistency. The ground substance contains water, gases, minerals, nutrients, wastes, and other chemicals.

In summary, a tissue is composed of cells and matrix, and the matrix is composed of fibers and ground substance.

²inter = between + stit = to stand

TABLE 5.1 The Four Primary Tissue Classes

Type	Definition	Representative Locations
Epithelial	Tissue composed of layers of closely spaced cells that cover organ surfaces, form glands, and serve for protection, secretion, and absorption	Epidermis Inner lining of digestive tract Liver and other glands
Connective	Tissue with more matrix than cell volume, often specialized to support, bind together, and protect organs	Tendons and ligaments Cartilage and bone Blood
Nervous	Tissue containing excitable cells specialized for rapid transmission of coded information to other cells	Brain Spinal cord Nerves
Muscular	Tissue composed of elongated, excitable cells specialized for contraction	Skeletal muscles Heart (cardiac muscle) Walls of viscera (smooth muscle)

Embryonic Tissues

Human development begins with a single cell, the fertilized egg, which soon divides to produce scores of identical, smaller cells. The first tissues appear when these cells start to organize themselves into layers—first two, and soon three strata called the **primary germ layers**, which give rise to all of the body's mature tissues. The three layers are called *ectoderm*, *mesoderm*, and *endoderm*. The **ectoderm**³ is an outer layer that gives rise to the epidermis and nervous system. The inner layer, the **endoderm**,⁴ gives rise to the mucous membranes of the digestive and respiratory tracts and to the digestive glands, among other things. Between these two is the **mesoderm**,⁵ a layer of more loosely organized cells. Mesoderm eventually turns to a gelatinous tissue called **mesenchyme**, composed of fine, wispy collagen (protein) fibers and branching cells called *fibroblasts* embedded in a gelatinous ground substance. Mesenchyme gives rise to muscle, bone, and blood, among other tissues. Most organs are composed of tissues derived from two or more primary germ layers. The rest of this chapter concerns the “mature” tissues that exist from infancy through adulthood.

³*ecto* = outer + *derm* = skin

⁴*endo* = inner + *derm* = skin

⁵*meso* = middle + *derm* = skin

Interpreting Tissue Sections

Histologists use a variety of techniques for preserving, sectioning (slicing), and staining tissues to show their structural details as clearly as possible. Tissue specimens are preserved in a **fixative**—a chemical such as formalin that prevents decay. After fixation, most tissues are cut into very thin slices called **histological sections**. These sections are typically only one or two cells thick, to allow the light of a microscope to pass through and to reduce the confusion of the image that would result from many layers of overlapping cells. They are mounted on slides and artificially colored with histological **stains** to bring out detail. If they were not stained, most tissue sections would appear very pale gray. With stains that bind to different components of a tissue, however, you may see pink cytoplasm, violet nuclei, and blue, green, or golden brown protein fibers, depending on the stain used.

Sectioning a tissue reduces a three-dimensional structure to a two-dimensional slice. You must keep this in mind and try to translate the microscopic image into a mental image of the whole structure. Like the boiled egg and elbow macaroni in figure 5.1, an object may look quite different when it is cut at various levels, or *planes of section*. A coiled tube, such as a gland of the uterus (fig. 5.1c), is often broken up into multiple portions since it meanders in and out of the plane of section. An experienced

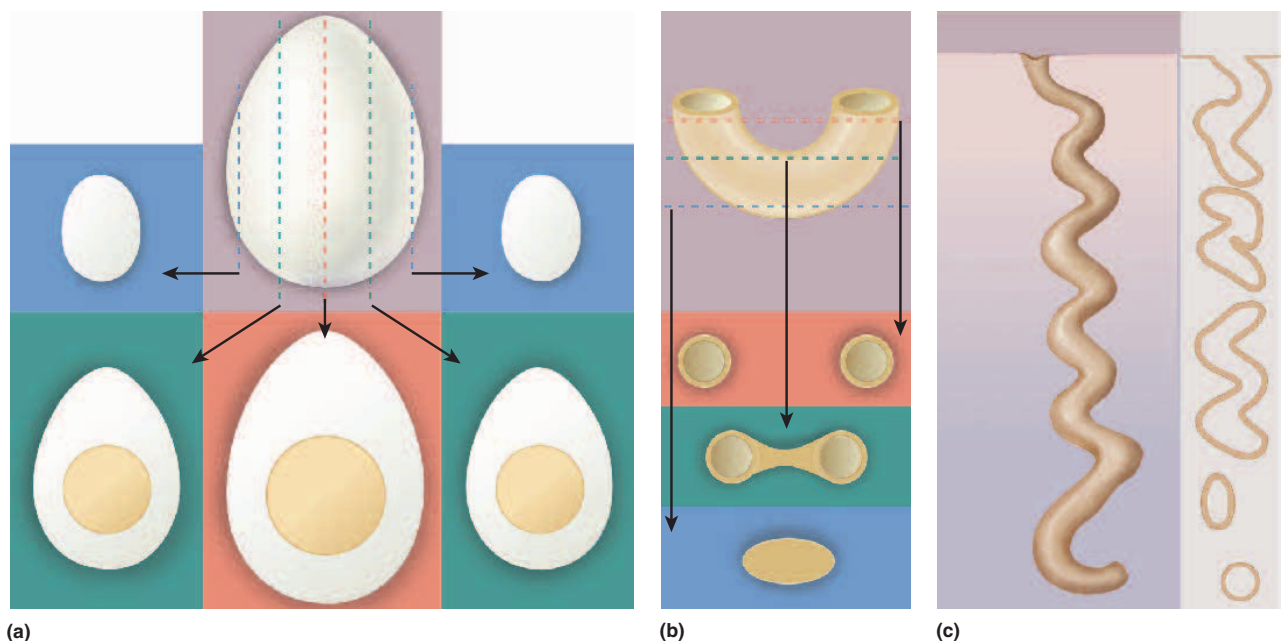

FIGURE 5.1 Three-Dimensional Interpretation of Two-Dimensional Images. (a) A boiled egg. Note that grazing sections (top left and right) would miss the yolk, just as a tissue section may miss a nucleus or other structure. (b) Elbow macaroni, which resembles many curved ducts and tubules. A section far from the bend would give the impression of two separate tubules; a section near the bend would show two interconnected lumina (cavities); and a section still farther down could miss the lumen completely. (c) A coiled gland in three dimensions and as it would look in a vertical tissue section.

viewer, however, would recognize that the separated pieces are parts of a single tube winding its way to the organ surface. Note that a grazing slice through a boiled egg might miss the yolk, just as a tissue section might miss the nucleus of a cell or an egg in the ovary, even though these structures were present.

Many anatomical structures are significantly longer in one direction than another—the humerus and esophagus, for example. A tissue cut in the long direction is called a **longitudinal section (l.s.)**, and one cut perpendicular to this is a **cross section (c.s. or x.s.)**, or **transverse section (t.s.)**. A section cut on a slant between a longitudinal and cross section is an **oblique section**. Figure 5.2 shows how certain organs look when sectioned on each of these planes.

Not all histological preparations are sections. Liquid tissues such as blood and soft tissues such as spinal cord may be prepared as **smears**, in which the tissue is rubbed or spread across the slide rather than sliced. Some membranes

and cobwebby tissues like the *areolar tissue* in figure 5.14 are sometimes mounted as **spreads**, in which the tissue is laid out on the slide, like placing a small square of tissue paper or a tuft of lint on a sheet of glass.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Classify each of the following into one of the four primary tissue classes: the skin surface, fat, the spinal cord, most heart tissue, bone, tendons, blood, and the inner lining of the stomach.
2. What are tissues composed of in addition to cells?
3. What embryonic germ layer gives rise to nervous tissue? To the liver? To muscle?
4. What is the term for a thin, stained slice of tissue mounted on a microscope slide?

5.2 Epithelial Tissue

Objectives

When you have completed this section, you should be able to

- describe the properties that distinguish epithelium from other tissue classes;
- list and classify eight types of epithelium, distinguish them from each other, and state where each type can be found in the body;
- explain how the structural differences between epithelia relate to their functional differences; and
- visually recognize each epithelial type from specimens or photographs.

Epithelial⁶ tissue consists of a flat sheet of closely adhering cells, one or more cells thick, with the upper surface usually exposed to the environment or to an internal space in the body. Epithelium covers the body surface, lines body cavities, forms the external and internal linings of many organs, and constitutes most gland tissue. The extracellular material is so thin it is not visible with the light microscope, and epithelia allow no room for

⁶epi = upon + theli = nipple, female

FIGURE 5.2 Longitudinal, Cross, and Oblique Sections.

Note the effect of the plane of section on the two-dimensional appearance of elongated structures such as bones and blood vessels.

• Would you classify the egg sections in the previous figure as longitudinal, cross, or oblique sections? How would the egg look if sectioned in the other two planes?

blood vessels. They do, however, almost always lie on a layer of loose connective tissue and depend on its blood vessels for nourishment and waste removal.

Between an epithelium and the underlying connective tissue is a layer called the **basement membrane**. It contains collagen, adhesive glycoproteins called *laminin* and *fibronectin*, and a large protein-carbohydrate complex called *heparan sulfate*. It gradually blends with collagenous and reticular fibers on the connective tissue side. The basement membrane serves to anchor an epithelium to the connective tissue below it. The surface of an epithelial cell that faces the basement membrane is its *basal surface*, and the one that faces away from the basement membrane is the *apical surface*.

Epithelia are classified into two broad categories—*simple* and *stratified*—with four types in each category. In a simple epithelium, every cell touches the basement membrane, whereas in a stratified epithelium, some cells rest on top of other cells and do not contact the basement membrane (fig. 5.3). *Pseudostratified columnar* epithelium is a special type of epithelium described in the next paragraph.

Simple Epithelia

Generally, a **simple epithelium** has only one layer of cells, although this is a somewhat debatable point in the pseudostratified type. Three types of simple epithelia are named for the shapes of their cells: **simple squamous**⁷ (thin scaly cells), **simple cuboidal** (square or round cells), and **simple columnar** (tall narrow cells). In

the fourth type, **pseudostratified columnar**, not all cells reach the free surface; the shorter cells are covered over by the taller ones. This epithelium looks stratified in most tissue sections, but careful examination, especially with the electron microscope, shows that every cell reaches the basement membrane—like trees in a forest all anchored in the soil, but with some growing taller than others. Simple columnar and pseudostratified columnar epithelia often produce protective mucous coatings over the mucous membranes. The mucus is secreted by wineglass-shaped **goblet cells**.

Table 5.2 illustrates and summarizes the structural and functional differences among the four simple epithelia. In this and the subsequent tables, each tissue is represented by a photograph and a corresponding line drawing with labels. The drawings help to clarify cell boundaries and other relevant features that may otherwise be difficult to see or identify in photographs or through the microscope. Each figure indicates the approximate magnification at which the original photograph was made. Each is enlarged much more than this when printed in the book, but selecting the closest magnification on a microscope should enable you to see a comparable level of detail (resolution).

Stratified Epithelia

Stratified epithelia range from 2 to 20 or more layers of cells, with some cells resting directly on others and only the deepest layer attached to the basement membrane. Three of the stratified epithelia are named for the shapes of their surface

⁷squam = scale

(text continued on p. 160)

FIGURE 5.3 Cell Shapes and Epithelial Types. Pseudostratified columnar epithelium is a special type of simple epithelium that gives a false appearance of multiple cell layers.

TABLE 5.2

Simple Epithelia

Simple Squamous Epithelium

(a)

Squamous epithelial cells Nuclei of smooth muscle

Basement membrane

(b)

FIGURE 5.4 Simple Squamous Epithelium on the External Surface (Serosa) of the Small Intestine. (x400)

Microscopic appearance: Single layer of thin cells, shaped like fried eggs with bulge where nucleus is located; nucleus flattened in the plane of the cell, like an egg yolk; cytoplasm may be so thin it is hard to see in tissue sections; in surface view, cells have angular contours and nuclei appear round

Representative locations: Air sacs (alveoli) of lungs; glomerular capsules of kidneys; some kidney tubules; inner lining (endothelium) of heart and blood vessels; serous membranes of stomach, intestines, and some other viscera; surface mesothelium of pleura, pericardium, peritoneum, and mesenteries

Functions: Allows rapid diffusion or transport of substances through membrane; secretes lubricating serous fluid

Simple Cuboidal Epithelium

(a)

Lumen of kidney tubule Cuboidal epithelial cells Basement membrane

(b)

FIGURE 5.5 Simple Cuboidal Epithelium in the Kidney Tubules. (x400)

Microscopic appearance: Single layer of square or round cells; in glands, cells often pyramidal and arranged like segments of an orange around a central space; spherical, centrally placed nuclei; with a brush border of microvilli in some kidney tubules; ciliated in bronchioles of lung

Representative locations: Liver, thyroid, mammary, salivary, and other glands; most kidney tubules; bronchioles

Functions: Absorption and secretion; production of protective mucous coat; movement of respiratory mucus

TABLE 5.2

Simple Epithelia (cont.)

Simple Columnar Epithelium

(a)

(b)

FIGURE 5.6 Simple Columnar Epithelium on the Internal Surface (Mucosa) of the Small Intestine. (x400)

Microscopic appearance: Single layer of tall, narrow cells; oval or sausage-shaped nuclei, vertically oriented, usually in basal half of cell; apical portion of cell often shows secretory vesicles visible with TEM; often shows a brush border of microvilli; ciliated in some organs; may possess goblet cells

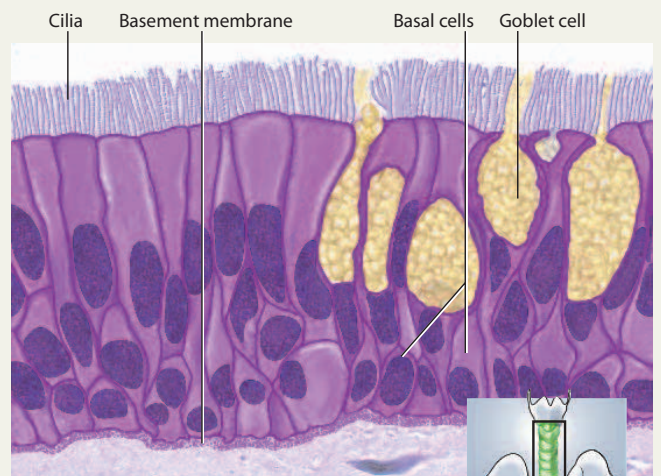

Representative locations: Inner lining of stomach, intestines, gall-bladder, uterus, and uterine tubes; some kidney tubules

Functions: Absorption; secretion of mucus and other products; movement of egg and embryo in uterine tube

Pseudostratified Columnar Epithelium

(a)

(b)

FIGURE 5.7 Ciliated Pseudostratified Columnar Epithelium in the Mucosa of the Trachea. (x400)

Microscopic appearance: Looks multilayered; some cells do not reach free surface, but all cells reach basement membrane; nuclei at several levels in deeper half of epithelium; often with goblet cells; often ciliated

Representative locations: Respiratory tract from nasal cavity to bronchi; portions of male urethra

Functions: Secretes and propels mucus

TABLE 5.3

Stratified Epithelia

Stratified Squamous Epithelium—Keratinized

(a)

(b)

FIGURE 5.8 Keratinized Stratified Squamous Epithelium on the Sole of the Foot. (x400)

Microscopic appearance: Multiple cell layers with cells becoming increasingly flat and scaly toward surface; surface covered with a layer of compact dead cells without nuclei; basal cells may be cuboidal to columnar

Representative locations: Epidermis; palms and soles are especially heavily keratinized

Functions: Resists abrasion; retards water loss through skin; resists penetration by pathogenic organisms

Stratified Squamous Epithelium—Nonkeratinized

(a)

(b)

FIGURE 5.9 Nonkeratinized Stratified Squamous Epithelium in the Mucosa of the Vagina. (x400)

Microscopic appearance: Same as keratinized epithelium but without the surface layer of dead cells

Representative locations: Tongue, oral mucosa, esophagus, anal canal, vagina

Functions: Resists abrasion and penetration by pathogenic organisms

TABLE 5.3 Stratified Epithelia (*cont.*)

Stratified Cuboidal Epithelium

(a)

(b)

FIGURE 5.10 Stratified Cuboidal Epithelium in the Duct of a Sweat Gland. (x400)

Microscopic appearance: Two or more layers of cells; surface cells square or round

Representative locations: Sweat gland ducts; egg-producing vesicles (follicles) of ovaries; sperm-producing ducts (seminiferous tubules) of testis

Functions: Contributes to sweat secretion; secretes ovarian hormones; produces sperm

Transitional Epithelium

(a)

(b)

FIGURE 5.11 Transitional Epithelium in the Kidney. (x400)

Microscopic appearance: Somewhat resembles stratified squamous epithelium, but surface cells are rounded, not flattened, and often bulge at surface; typically five or six cells thick when relaxed and two or three cells thick when stretched; cells may be flatter and thinner when epithelium is stretched (as in a distended bladder); some cells have two nuclei

Representative locations: Urinary tract—part of kidney, ureter, bladder, part of urethra; allantoic duct in umbilical cord

Functions: Stretches to allow filling of urinary tract

cells: **stratified squamous**, **stratified cuboidal**, and **stratified columnar epithelia**. The deeper cells, however, may be of a different shape than the surface cells. The fourth type, **transitional epithelium**, was named when it was thought to represent a transitional stage between stratified squamous and stratified columnar epithelium. This is now known to be untrue, but the name has persisted.

Stratified columnar epithelium is rare—seen only in places where two other epithelial types meet, as in limited regions of the pharynx, larynx, anal canal, and male urethra. We will not consider this type any further. The other three types are illustrated and summarized in table 5.3.

The most widespread epithelium in the body is stratified squamous epithelium, which deserves further discussion. Its deepest layer of cells are cuboidal to columnar stem cells, which undergo continual mitosis. Their daughter cells push toward the surface and become flatter (more *squamous*, or scalelike) as they migrate farther upward, until they finally die and flake off. Their separation from the surface is called **exfoliation**, or **desquamation** (fig. 5.12); the study of exfoliated cells is called *exfoliate cytology*. You can easily study exfoliated cells by scraping your gums with a toothpick, smearing this material on a slide, and staining it. A similar procedure is used in the *Pap smear*, an examination of exfoliated cells from the cervix for signs of uterine cancer (see fig. 28.5, p. 1082, for normal and cancerous Pap smears).

FIGURE 5.12 Exfoliation of Squamous Cells from the Mucosa of the Vagina. [Copyright by R. G. Kessel and R. H. Kardon, *Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy*, 1979, W. H. Freeman, All rights reserved.]

◀ Aside from the gums and vagina, name another epithelium in the body that would look like this to the scanning electron microscope.

Stratified squamous epithelia are of two kinds: keratinized and nonkeratinized. A **keratinized** epithelium, found on the skin surface (epidermis), is covered with a layer of compact, dead squamous cells. These cells are packed with the durable protein keratin and coated with a water repellent glycolipid. The skin surface is therefore relatively dry, it retards water loss from the body, and it resists penetration by disease organisms. (Keratin is also the protein of which animal horns are made, hence its name.⁸) The tongue, esophagus, vagina, and a few other internal membranes are covered with the **nonkeratinized** type, which lacks the surface layer of dead cells. This type provides a surface that is, again, abrasion-resistant, but also moist and slippery. These characteristics are well suited to resist stress produced by the chewing and swallowing of food and by sexual intercourse and childbirth.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

5. Distinguish between simple and stratified epithelia, and explain why pseudostratified columnar epithelium belongs in the former category.
6. Explain how to distinguish a stratified squamous epithelium from a transitional epithelium.
7. What function do keratinized and nonkeratinized stratified squamous epithelia have in common? What is the structural difference between these two? How is this structural difference related to a functional difference between them?
8. How do the epithelia of the esophagus and stomach differ? How does this relate to their respective functions?

5.3 Connective Tissue

Objectives

When you have completed this section, you should be able to

- describe the properties that most connective tissues have in common;
- discuss the types of cells found in connective tissue;
- explain what the matrix of a connective tissue is and describe its components;
- name 10 types of connective tissue, describe their cellular components and matrix, and explain what distinguishes them from each other; and
- visually recognize each connective tissue type from specimens or photographs.

⁸kerat = horn

Overview

Connective tissue is a type of tissue in which cells usually occupy less space than the extracellular material, and that serves in most cases to bind organs to each other (for example, the way a tendon connects muscle to bone) or to support and protect organs. Most cells of a connective tissue are not in direct contact with each other, but are well separated by extracellular material. Most kinds of connective tissue are highly vascular—richly supplied with blood vessels. Connective tissue is the most abundant, widely distributed, and histologically variable of the primary tissues. This category includes fibrous tissue, fat, cartilage, bone, and blood. The mesenchyme described earlier in this chapter is a form of embryonic connective tissue.

The functions of connective tissue include the following:

- **Binding of organs.** Tendons bind muscle to bone, ligaments bind one bone to another, fat holds the kidneys and eyes in place, and fibrous tissue binds the skin to underlying muscle.
- **Support.** Bones support the body, and cartilage supports the ears, nose, trachea, and bronchi.
- **Physical protection.** The cranium, ribs, and sternum protect delicate organs such as the brain, lungs, and heart; fatty cushions around the kidneys and eyes protect these organs.
- **Immune protection.** Connective tissue cells attack foreign invaders, and connective tissue fiber forms a “battlefield” under the skin and mucous membranes where immune cells can be quickly mobilized against disease agents.
- **Movement.** Bones provide the lever system for body movement, cartilages are involved in movement of the vocal cords, and cartilages on bone surfaces ease joint movements.
- **Storage.** Fat is the body’s major energy reserve; bone is a reservoir of calcium and phosphorus that can be drawn upon when needed.
- **Heat production.** Metabolism of brown fat generates heat in infants and children.
- **Transport.** Blood transports gases, nutrients, wastes, hormones, and blood cells.

Fibrous Connective Tissue

Fibrous connective tissue is the most diverse type of connective tissue. It is also called *fibroconnective tissue* or *connective tissue proper*. Nearly all connective tissues contain fibers, but the tissues considered here are classified together because the fibers are so conspicuous. Fibers are, of course, just one component of the tissue, which also includes cells and ground substance. Before examining specific types of fibrous connective tissue, let’s examine these components.

Components of Fibrous Connective Tissue

Cells The cells of fibrous connective tissue include the following types:

- **Fibroblasts.**⁹ These are large, fusiform cells that often show slender, wispy branches. They produce the fibers and ground substance that form the matrix of the tissue.
- **Macrophages.**¹⁰ These are large phagocytic cells that wander through the connective tissues, where they engulf and destroy bacteria, other foreign particles, and dead or dying cells of our own body. They also activate the immune system when they sense foreign matter called *antigens*. They arise from certain white blood cells called *monocytes* or from the same stem cells that produce monocytes.
- **Leukocytes,**¹¹ or **white blood cells (WBCs).** WBCs travel briefly in the bloodstream, then crawl out through the walls of small blood vessels and spend most of their time in the connective tissues. Most of them are *neutrophils*, which wander about attacking bacteria. The mucous membranes often exhibit dense patches of tiny WBCs called *lymphocytes*, which react against bacteria, toxins, and other foreign agents.
- **Plasma cells.** Certain lymphocytes turn into plasma cells when they detect foreign agents. The plasma cells then synthesize disease-fighting proteins called *antibodies*. Plasma cells are rarely seen except in the walls of the intestines and in inflamed tissue.
- **Mast cells.** These cells, found especially alongside blood vessels, secrete a chemical called *heparin* that inhibits blood clotting, and one called *histamine* that increases blood flow by dilating blood vessels.
- **Adipocytes (AD-ih-po-sites), or fat cells.** These appear in small clusters in some fibrous connective tissues. When they dominate an area, the tissue is called *adipose tissue*. Each cell is filled mainly by a globule of triglycerides (fat molecules), with the nucleus and cytoplasm pressed against the inside of the plasma membrane in a thin layer.

Fibers Three types of protein fibers are found in fibrous connective tissues:

- **Collagenous (col-LADJ-eh-nus) fibers.** These fibers, made of collagen, are tough and flexible and resist stretching. Collagen is the most abundant of the body’s proteins, constituting about 25% of the total. It is the base of such animal products as gelatin,

⁹*fibro* = fiber + *blast* = producing

¹⁰*macro* = big + *phage* = eater

¹¹*leuko* = white + *cyte* = cell

FIGURE 5.13 Tendons. The white glistening appearance results from the collagen of which tendons are composed. The braceletlike band across the wrist is also composed of collagen.

leather, and glue.¹² In fresh tissue, collagenous fibers have a glistening white appearance, as seen in tendons and some cuts of meat (fig. 5.13); thus, they are often called *white fibers*. In tissue sections, collagen forms coarse, wavy bundles, often dyed pink, blue, or green by the most common histological stains. Tendons, ligaments, and the deep layer of the skin (the dermis) are made mainly of collagen. Less visibly, collagen pervades the matrix of cartilage and bone.

- **Reticular¹³ fibers.** These are thin collagen fibers coated with glycoprotein. They form a spongelike framework for such organs as the spleen and lymph nodes.
- **Elastic fibers.** These are thinner than collagenous fibers, and they branch and rejoin each other along their course. They are made of a protein called **elastin**, whose coiled structure allows it to stretch

¹²*colia* = glue + *gen* = producing

¹³*ret* = network + *icul* = little

and recoil like a rubber band. Elastic fibers account for the ability of the skin, lungs, and arteries to spring back after they are stretched. (Elasticity is not the ability to stretch, but the tendency to recoil when tension is released.) Fresh elastic fibers are yellowish and therefore often called *yellow fibers*.

Ground Substance Amid the cells and fibers in some tissue sections, there appears to be a lot of empty space. In life, this space is occupied by the featureless **ground substance**. Ground substance usually has a gelatinous to rubbery consistency resulting from three classes of large molecules: glycosaminoglycans, proteoglycans, and adhesive glycoproteins. It absorbs compressive forces and, like the styrofoam packing in a shipping carton, protects the more delicate cells from mechanical injury.

A **glycosaminoglycan (GAG)** (gly-COSE-ah-MEE-no-GLY-can) is a long polysaccharide composed of unusual disaccharides called *amino sugars* and *uronic acid*. GAGs are negatively charged and thus tend to attract sodium and potassium ions, which in turn cause the GAGs to absorb and hold water. Thus, GAGs play an important role in regulating the water and electrolyte balance of tissues. The most abundant GAG is **chondroitin (con-DRO-ih-tin) sulfate**. It is abundant in blood vessels and bones and is responsible for the relative stiffness of cartilage. Some other GAGs that you will read of elsewhere in this book are *heparin* (an anticoagulant) and *hyaluronic (HY-uh-loo-RON-ic) acid*. The latter is a gigantic molecule up to 20 μm long, as large as most cells. It is a viscous, slippery substance that forms a very effective lubricant in the joints and constitutes much of the jellylike *vitreous body* of the eyeball.

A **proteoglycan** is another gigantic molecule. It is shaped somewhat like a test-tube brush, with a central core of protein and bristlelike outgrowths composed of GAGs. The entire proteoglycan may be attached to hyaluronic acid, thus forming an enormous molecular complex. Proteoglycans form thick colloids similar to those of gravy, pudding, gelatin, and glue. This gel slows the spread of pathogenic organisms through the tissues. Some proteoglycans are embedded in the plasma membranes of cells, attached to the cytoskeleton on the inside and to other extracellular molecules on the outside. Thus, they create a strong structural bond between cells and extracellular macromolecules and help to hold tissues together.

Adhesive glycoproteins are protein-carbohydrate complexes that bind plasma membrane proteins to collagen and proteoglycans outside the cell. They bind all the components of a tissue together and mark pathways that guide migrating embryonic cells to their destinations in a tissue.

Types of Fibrous Connective Tissue

Fibrous connective tissue is divided into two broad categories according to the relative abundance of fiber: *loose* and *dense connective tissue*. In **loose connective tissue**,

much of the space is occupied by ground substance, which is dissolved out of the tissue during histological fixation and leaves empty space in prepared tissue sections. The loose connective tissues we will discuss are *areolar* and *reticular tissue* (table 5.4). In **dense connective tissue**, fiber occupies more space than the cells and ground substance, and appears closely packed in tissue sections. The two dense connective tissues we will discuss are *dense regular* and *dense irregular connective tissue* (table 5.5).

Areolar¹⁴ (AIR-ee-OH-lur) **tissue** exhibits loosely organized fibers, abundant blood vessels, and a lot of seemingly empty space. It possesses all six of the aforementioned cell types. Its fibers run in random directions and are mostly collagenous, but elastic and reticular fibers are also present. Areolar tissue is highly variable in appearance. In many serous membranes, it looks like figure 5.14, but in the skin and mucous membranes, it is more compact (see fig. 5.8) and sometimes difficult to distinguish from dense irregular connective tissue. Some advice on how to tell them apart is given after the discussion of dense irregular connective tissue.

Areolar tissue is found in tissue sections from almost every part of the body. It surrounds blood vessels and nerves and penetrates with them even into the small spaces of muscle, tendon, and other tissues. Nearly every epithelium rests on a layer of areolar tissue, whose blood vessels provide the epithelium with nutrition, waste removal, and a ready supply of infection-fighting leukocytes in times of need. Because of the abundance of open, fluid-filled space, leukocytes can move about freely in areolar tissue and can easily find and destroy pathogens.

Reticular tissue is a mesh of reticular fibers and fibroblasts. It forms the structural framework (stroma) of such organs as the lymph nodes, spleen, thymus, and bone marrow. The space amid the fibers is filled with blood cells. If you imagine a kitchen sponge soaked with blood, the sponge fibers are analogous to the reticular tissue stroma.

Dense regular connective tissue is named for two properties: (1) the collagen fibers are closely packed and leave relatively little open space, and (2) the fibers are parallel to each other. It is found especially in tendons and ligaments. The parallel arrangement of fibers is an adaptation to the fact that tendons and ligaments are pulled in predictable directions. With some minor exceptions such as blood vessels and sensory nerve fibers, the only cells in this tissue are fibroblasts, visible by their slender, violet-staining nuclei squeezed between bundles of collagen. This type of tissue has few blood vessels, so injured tendons and ligaments are slow to heal.

The vocal cords, suspensory ligament of the penis, and some ligaments of the vertebral column are made of a type of dense regular connective tissue called **yellow elastic tissue**. In addition to the densely packed collagen

fibers, it exhibits branching elastic fibers and more fibroblasts. The fibroblasts have larger, more conspicuous nuclei than seen in most dense regular connective tissue.

Elastic tissue also takes the form of wavy sheets in the walls of the large and medium arteries. When the heart pumps blood into the arteries, these sheets enable them to expand and relieve some of the pressure on smaller vessels downstream. When the heart relaxes, the arterial wall springs back and keeps the blood pressure from dropping too low between heartbeats. The importance of this elastic tissue becomes especially clear when there is not enough of it—for example, in Marfan syndrome (see Insight 5.1)—or when it is stiffened by arteriosclerosis (see chapter 19).

Dense irregular connective tissue also has thick bundles of collagen and relatively little room for cells and ground substance, but the collagen bundles run in random directions. This arrangement enables the tissue to resist unpredictable stresses. This tissue constitutes most of the dermis, where it binds the skin to the underlying muscle and connective tissue. It forms a protective capsule around organs such as the kidneys, testes, and spleen and a tough fibrous sheath around the bones, nerves, and most cartilages.

It is sometimes difficult to judge whether a tissue is areolar or dense irregular. In the dermis, for example, these tissues occur side by side, and the transition from one to the other is not at all obvious (see fig. 5.8). A relatively

INSIGHT 5.1

Clinical Application

Marfan Syndrome—A Connective Tissue Disease

*Marfan*¹⁵ *syndrome* is a hereditary defect in elastin fibers, usually resulting from a mutation in the gene for *fibrillin*, a glycoprotein that forms the structural scaffold for elastin. Clinical signs of Marfan syndrome include hyperextensible joints, hernias of the groin, and vision problems resulting from abnormally elongated eyes and deformed lenses. People with Marfan syndrome typically show unusually tall stature, long limbs, spidery fingers, abnormal spinal curvature, and a protruding “pigeon breast.” More serious problems are weakened heart valves and arterial walls. The aorta, where blood pressure is highest, is sometimes enormously dilated close to the heart and may rupture. Marfan syndrome is present in about 1 out of 20,000 live births, and most victims die by their mid-30s. Some authorities speculate that Abraham Lincoln’s tall, gangly physique and spindly fingers were signs of Marfan syndrome, which may have ended his life prematurely had he not been assassinated. A number of star athletes have died at a young age of Marfan syndrome, including Olympic volleyball champion Flo Hyman, who died of a ruptured aorta during a game in Japan in 1986 at the age of 31.

¹⁴areola = little space

¹⁵Antoine Bernard-Jean Marfan (1858–1942), French physician

TABLE 5.4 Loose Connective Tissues**Areolar Tissue**

(a)

(b)

FIGURE 5.14 Areolar Tissue in a Spread of the Mesentery. (x400)

Microscopic appearance: Loose arrangement of collagenous and elastic fibers; scattered cells of various types; abundant ground substance; numerous blood vessels

Representative locations: Underlying nearly all epithelia; surrounding blood vessels, nerves, esophagus, and trachea; fascia between muscles; mesenteries; visceral layers of pericardium and pleura

Functions: Loosely binds epithelia to deeper tissues; allows passage of nerves and blood vessels through other tissues; provides an arena for immune defense; blood vessels provide nutrients and waste removal for overlying epithelia

Reticular Tissue

(a)

(b)

FIGURE 5.15 Reticular Tissue of the Spleen. (x400)

Microscopic appearance: Loose network of reticular fibers and cells, infiltrated with numerous leukocytes, especially lymphocytes

Representative locations: Lymph nodes, spleen, thymus, bone marrow

Functions: Supportive stroma (framework) for lymphatic organs

TABLE 5.5 Dense Connective Tissues

Dense Regular Connective Tissue

(a)

(b)

FIGURE 5.16 Dense Regular Connective Tissue of a Tendon. (x400)

Microscopic appearance: Densely packed, parallel, often wavy collagen fibers; slender fibroblast nuclei compressed between collagen bundles; scanty open space (ground substance); scarcity of blood vessels

Representative locations: Tendons and ligaments

Functions: Ligaments tightly bind bones together; resist stress; tendons attach muscle to bone and transfer muscular tension to bones

Dense Irregular Connective Tissue

(a)

(b)

FIGURE 5.17 Dense Irregular Connective Tissue in the Dermis of the Skin. (x400)

Microscopic appearance: Densely packed collagen fibers running in random directions; scanty open space (ground substance); few visible cells; scarcity of blood vessels

Representative locations: Deeper portion of dermis of skin; capsules around viscera such as liver, kidney, spleen; fibrous sheaths around cartilages and bones

Functions: Durable, hard to tear; withstands stresses applied in unpredictable directions

large amount of clear space suggests areolar tissue, and thicker bundles of collagen with relatively little clear space suggests dense irregular tissue.

Adipose Tissue

Adipose tissue, or **fat**, is tissue in which adipocytes are the dominant cell type (table 5.6). Adipocytes may also occur singly or in small clusters in areolar tissue. Adipocytes usually range from 70 to 120 μm in diameter, but they may be five times as large in obese people. The space between adipocytes is occupied by areolar tissue, reticular tissue, and blood capillaries.

Fat is the body's primary energy reservoir. The quantity of stored triglyceride and the number of adipocytes are quite stable in a person, but this doesn't mean stored fat is stagnant. New triglycerides are constantly synthesized and stored as others are hydrolyzed and released into circulation. Thus, there is a constant turnover of stored triglyceride, with an equilibrium between synthesis and hydrolysis, energy storage and energy use. Adipose tissue also provides thermal insulation, anchors and cushions such organs as the eyeballs and kidneys, and contributes to body contours such as the female breasts and hips. On average, women have more fat relative to body weight than men do. Female body fat helps to meet the caloric needs of pregnancy and nursing an infant, and having too little fat can reduce female fertility.

Most adipose tissue is a type called *white fat*, but fetuses, infants, and children also have a heat-generating tissue called *brown fat*, which accounts for up to 6% of an infant's weight. Brown fat gets its color from an unusual abundance of blood vessels and certain enzymes in its mitochondria. It stores lipid in the form of multiple droplets rather than one large one. Brown fat has numerous mitochondria, but their oxidation pathway is not linked to ATP synthesis. Therefore, when these cells oxidize fats, they release all of the energy as heat. Hibernating animals accumulate brown fat in preparation for winter.

Think About It

Why would infants and children have more need for brown fat than adults do? (Hint: Smaller bodies have a higher ratio of surface area to volume than larger bodies do.)

Cartilage

Cartilage (table 5.7) is a supportive connective tissue with a flexible rubbery matrix. It gives shape to the external ear, the tip of the nose, and the larynx (voicebox)—the most easily palpated cartilages in the body. Cells called **chondroblasts**¹⁶ (CON-dro-blasts) secrete the matrix and surround themselves with it until they become trapped in

TABLE 5.6

Adipose Tissue

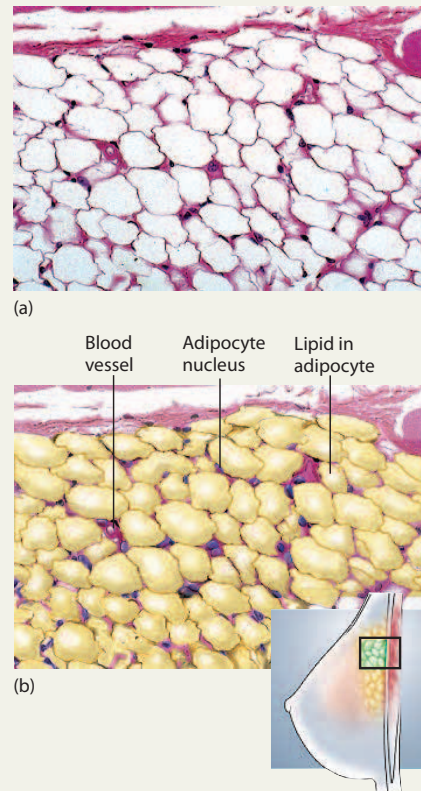

FIGURE 5.18 Adipose Tissue of the Breast. (x100)

Microscopic appearance: Dominated by adipocytes—large, empty-looking cells with thin margins; tissue sections often very pale because of scarcity of stained cytoplasm; adipocytes shrunken; nucleus pressed against plasma membrane; blood vessels often present

Representative locations: Subcutaneous fat beneath skin; breast; heart surface; mesenteries; surrounding organs such as kidneys and eyes

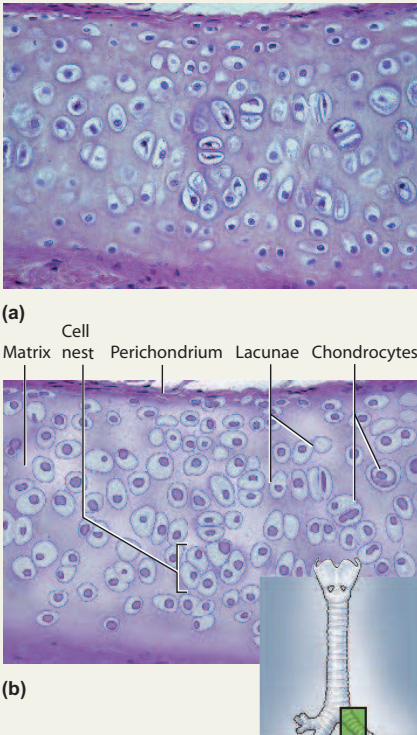

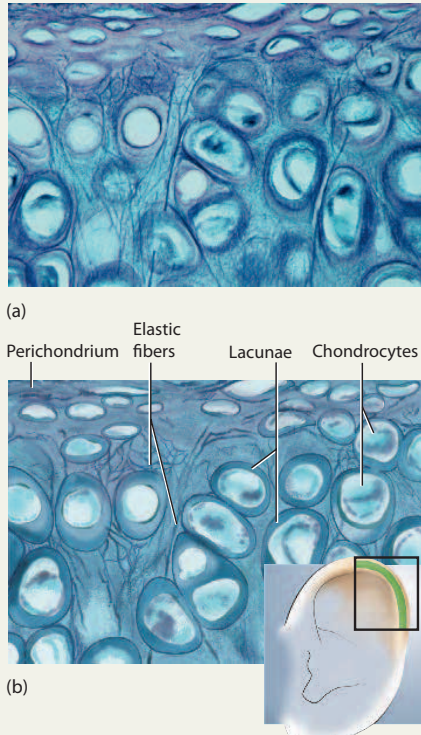

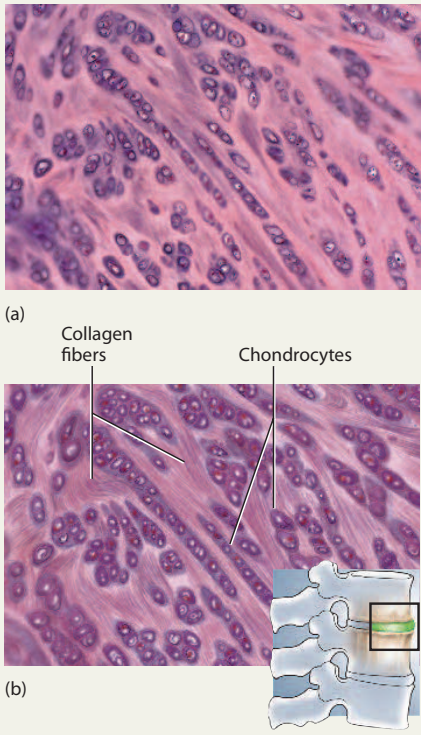

Functions: Energy storage; thermal insulation; heat production by brown fat; protective cushion for some organs; filling space, shaping body

little cavities called **lacunae**¹⁷ (la-CUE-nee). Once enclosed in lacunae, the cells are called **chondrocytes** (CON-dro-sites). Cartilage is usually free of blood vessels except when transforming into bone; thus, nutrition and waste removal depend on solute diffusion through the stiff matrix. Because this is a slow process, chondrocytes have low rates of metabolism and cell division, and injured cartilage heals slowly. The matrix is rich in chondroitin

¹⁶chondro = cartilage, gristle + blast = forming

<p>FIGURE 5.19 Hyaline Cartilage of a Bronchus. (x400)</p> <p>Microscopic appearance: Clear, glassy matrix, often stained light blue or pink in tissue sections; fine, dispersed collagen fibers, not usually visible; chondrocytes often in small clusters of three or four cells (<i>cell nests</i>), enclosed in lacunae; usually covered by perichondrium</p> <p>Representative locations: Forms a thin <i>articular cartilage</i>, lacking perichondrium, over the ends of bones at movable joints; a <i>costal cartilage</i> attaches the end of a rib to the breastbone; forms supportive rings and plates around trachea and bronchi; forms a boxlike enclosure around the larynx; forms much of the fetal skeleton</p> <p>Functions: Eases joint movements; holds airway open during respiration; moves vocal cords during speech; a precursor of bone in the fetal skeleton and the growth zones of long bones of children</p>	<p>FIGURE 5.20 Elastic Cartilage of the External Ear. (x1,000)</p> <p>Microscopic appearance: Elastic fibers form weblike mesh amid lacunae; always covered by perichondrium</p> <p>Representative locations: External ear; epiglottis</p> <p>Functions: Provides flexible, elastic support</p>	<p>FIGURE 5.21 Fibrocartilage of an Intervertebral Disc. (x400)</p> <p>Microscopic appearance: Parallel collagen fibers similar to those of tendon; rows of chondrocytes in lacunae between collagen fibers; never has a perichondrium</p> <p>Representative locations: Pubic symphysis (anterior joint between two halves of pelvic girdle); intervertebral discs, which separate bones of vertebral column; menisci, or pads of shock-absorbing cartilage, in knee joint; at points where tendons insert on bones near articular hyaline cartilage</p> <p>Functions: Resists compression and absorbs shock in some joints; often a transitional tissue between dense connective tissue and hyaline cartilage (for example, at some tendon-bone junctions)</p>

sulfate and contains collagen fibers that range in thickness from invisibly fine to conspicuously coarse. Differences in the fibers provide a basis for classifying cartilage into three types: *hyaline cartilage*, *elastic cartilage*, and *fibrocartilage*.

Hyaline¹⁸ (HY-uh-lin) **cartilage** is named for its clear, glassy microscopic appearance, which stems from the usually invisible fineness of its collagen fibers. **Elastic cartilage** is named for its conspicuous elastic fibers, and **fibrocartilage** for its coarse, readily visible bundles of collagen. Elastic cartilage and most hyaline cartilage are surrounded by a sheath of dense irregular connective tissue called the **perichondrium**.¹⁹ A reserve population of chondroblasts between the perichondrium and cartilage contributes to cartilage growth throughout life. There is no perichondrium around fibrocartilage.

You can feel the texture of hyaline cartilage by palpating the tip of your nose, your “Adam’s apple” at the front of the larynx (voicebox), and periodic rings of cartilage around the trachea (windpipe) just below the larynx. Hyaline cartilage is easily seen in many grocery items—it is the “gristle” at the ends of pork ribs, on chicken leg and breast bones, and at the joints of pigs’ feet, for example. Elastic cartilage gives shape to the external ear. You can get some idea of its springy resilience by folding your ear down and releasing it.

Bone

The term *bone* has two meanings: an organ of the body such as the femur and mandible, composed of multiple tissue types; and bone tissue, or **osseous tissue**, which makes up most of the mass of bones. There are two forms of osseous tissue: (1) **Spongy bone** fills the heads of the long bones and forms the middle layer of flat bones such as the sternum (breastbone). Although it is calcified and hard, its delicate slivers and plates give it a spongy appearance. (2) **Compact (dense) bone** is a denser calcified tissue with no spaces visible to the naked eye. It forms the external surfaces of all bones, so spongy bone, when present, is always covered by compact bone.

The differences between compact and spongy bone are described in chapter 7. Here, we examine only compact bone (table 5.8). Most specimens you study will probably be chips of dead, dried bone ground to microscopic thinness. In such preparations, the cells are absent but spaces reveal their former locations. Most compact bone is arranged in cylinders of tissue that surround **central (haversian**²⁰ or **osteonic) canals**, which run longitudinally through the shafts of long bones such as the femur. Blood vessels and nerves travel through the central canals in life. The bone matrix is deposited in **concentric lamellae**,

TABLE 5.8

Bone

(a)

(b)

FIGURE 5.22 Compact Bone. (x100)

Microscopic appearance (compact bone): Calcified matrix arranged in concentric lamellae around central canals; osteocytes in lacunae between adjacent lamellae; lacunae interconnected by delicate canaliculi

Representative locations: Skeleton

Functions: Physical support of body; leverage for muscle action; protective enclosure of viscera; reservoir of calcium and phosphorus

¹⁸hyal = glass

¹⁹peri = around + chondri = cartilage

²⁰Clopton Havers (1650–1702), English anatomist

onionlike layers around each central canal. A central canal and its surrounding lamellae are called an **osteon**. Tiny lacunae between the lamellae are occupied in life by mature bone cells, or **osteocytes**.²¹ Delicate canals called **canaliculi** radiate from each lacuna to its neighbors and allow the osteocytes to contact each other. The bone as a whole is covered with a tough fibrous **periosteum** (PERR-ee-OSS-tee-um) similar to the perichondrium of cartilage.

About a third of the dry weight of bone is composed of collagen fibers and chondroitin sulfate; two-thirds consists of minerals (mainly calcium salts) deposited around the collagen fibers.

Blood

Blood (table 5.9) is a fluid connective tissue that travels through tubular vessels. Its primary function is to transport cells and dissolved matter from place to place. Blood consists of a ground substance called **plasma** and of cells and cell fragments collectively called **formed elements**.

Erythrocytes²² (eh-RITH-ro-sites), or red blood cells, are the most abundant formed elements. In stained blood films, they look like pink discs with a thin, pale center. They have no nuclei. Erythrocytes transport oxygen and carbon dioxide. **Leukocytes**, or white blood cells, serve various roles in defense against infection and other diseases. They travel from one organ to another in the bloodstream and lymph but spend most of their lives in the connective tissues. Leukocytes are somewhat larger than erythrocytes and have conspicuous nuclei, which usually appear violet in stained preparations. There are five kinds, distinguished partly by variations in nuclear shape: *neutrophils*, *eosinophils*, *basophils*, *lymphocytes*, and *monocytes*. Their individual characteristics are considered in detail in chapter 18. **Platelets** are small cell fragments scattered amid the blood cells. They are involved in clotting and other mechanisms for minimizing blood loss, and in secreting growth factors that promote blood vessel growth and maintenance.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

9. What features do most or all connective tissues have in common to set this class apart from nervous, muscular, and epithelial tissue?
10. List the cell and fiber types found in fibrous connective tissues and state their functional differences.
11. What substances account for the gelatinous consistency of connective tissue ground substance?
12. What is areolar tissue? How can it be distinguished from any other kind of connective tissue?

²¹oste = bone + cyte = cell

²²erythro = red + cyte = cell

TABLE 5.9

Blood

(a)

(b)

FIGURE 5.23 Blood Smear. (x1,000)

Microscopic appearance: Erythrocytes appear as pale pink discs with light centers and no nuclei; leukocytes are slightly larger, are much fewer, and have variously shaped nuclei, usually stained violet; platelets are cell fragments with no nuclei, about one-quarter the diameter of erythrocytes

Representative locations: Contained in heart and blood vessels

Functions: Transports gases, nutrients, wastes, chemical signals, and heat throughout body; provides defensive leukocytes; contains clotting agents to minimize bleeding; platelets secrete growth factors that promote tissue maintenance and repair

13. Discuss the difference between dense regular and dense irregular connective tissue as an example of the relationship between form and function.
14. Describe some similarities, differences, and functional relationships between hyaline cartilage and bone.
15. What are the three basic kinds of formed elements in blood, and what are their respective functions?

5.4 Nervous and Muscular Tissues—Excitable Tissues

Objectives

When you have completed this section, you should be able to

- explain what distinguishes excitable tissues from other tissues;
- name the cell types that compose nervous tissue;
- identify the major parts of a nerve cell;
- visually recognize nervous tissue from specimens or photographs;
- name the three kinds of muscular tissue and describe the differences between them; and
- visually identify any type of muscular tissue from specimens or photographs.

Excitability is a characteristic of all living cells, but it is developed to its highest degree in nervous and muscular tissues, which are therefore described as **excitable tissues**. The basis for their excitation is an electrical charge difference (voltage) called the **membrane potential**, which occurs across the plasma membranes of all cells. Nervous and muscular tissues respond quickly to outside stimuli by means of changes in membrane potential. In nerve cells, these changes result in the rapid transmission of signals to other cells. In muscle cells, they result in contraction, or shortening of the cell.

Nervous Tissue

Nervous tissue (table 5.10) is specialized for communication by means of electrical and chemical signals. It consists of **neurons** (NOOR-ons), or nerve cells, and a much greater number of **neuroglia** (noo-ROG-lee-uh), or **glial cells** (GLEE-ul) **cells**, which protect and assist the neurons. Neurons detect stimuli, respond quickly, and transmit coded information rapidly to other cells. Each neuron has a prominent **neurosoma**, or cell body, that houses the nucleus and most other organelles. This is the cell's center of genetic control and protein synthesis. Neurosomas are usually round, ovoid, or stellate in shape. Extending from the neurosoma, there are usually multiple short,

TABLE 5.10 Nervous Tissue

(a)

Nuclei of glial cells Axon Neurosoma Dendrites

(b)

FIGURE 5.24 A Neuron and Glial Cells of a Spinal Cord Smear. (x400)

Microscopic appearance: Most sections show a few large neurons, usually with rounded or stellate cell bodies (neurosomas) and fibrous processes (axon and dendrites) extending from the neurosomas; neurons are surrounded by a greater number of much smaller glial cells, which lack dendrites and axons

Representative locations: Brain, spinal cord, nerves, ganglia

Function: Internal communication

branched processes called **dendrites**,²³ which receive signals from other cells and transmit messages to the neurosoma; and a single, much longer **axon**, or **nerve fiber**, which sends outgoing signals to other cells. Some axons are more than a meter long and extend from the brainstem to the foot.

Glial cells greatly outnumber neurons and constitute most of the volume of the nervous tissue. They are usually much smaller than neurons. There are six types of glial cells, described in chapter 13, which provide a variety of supportive, protective, and “housekeeping” functions for the nervous system. Although they communicate with neurons and each other, they do not transmit long-distance information.

Nervous tissue is found in the brain, spinal cord, nerves, and ganglia, which are knotlike swellings in nerves. Local variations in the structure of nervous tissue are described in chapters 12 to 16.

Muscular Tissue

Muscular tissue consists of elongated cells that are specialized to contract in response to stimulation; thus, its primary job is to exert physical force on other tissues and organs—for example, when a skeletal muscle pulls on a bone, the heart contracts and expels blood, or the bladder contracts and expels urine. Not only do movements of the body and its limbs depend on muscle, but so do such processes as digestion, waste elimination, breathing, speech, and blood circulation. The muscles are also an important source of body heat. The word *muscle* means “little mouse,” apparently referring to the appearance of rippling muscles under the skin.

There are three histological types of muscle—*skeletal*, *cardiac*, and *smooth*—which differ in appearance, physiology, and function (table 5.11). **Skeletal muscle** consists of long threadlike cells called **muscle fibers**. Most of it is attached to bones, but there are exceptions in the tongue, upper esophagus, some facial muscles, and some **sphincter**²⁴ (SFINK-tur) muscles (ringlike or cufflike muscles that open and close body passages). Each cell contains multiple nuclei adjacent to the plasma membrane. Skeletal muscle is described as *striated* and *voluntary*. The first term refers to alternating light and dark bands, or **striations** (stry-AY-shuns), created by the overlapping pattern of cytoplasmic protein filaments that cause muscle contraction. The second term, *voluntary*, refers to the fact that we usually have conscious control over skeletal muscle.

Cardiac muscle is limited to the heart. It too is striated, but it differs from skeletal muscle in its other features. Its cells are much shorter, so they are commonly called **myocytes**²⁵ or **cardiocytes** rather than fibers. The

myocytes are branched or notched at the ends. They contain only one nucleus, which is located near the center and often surrounded by a light-staining region of glycogen. Cardiac myocytes are joined end to end by junctions called **intercalated**²⁶ (in-TUR-kuh-LAY-ted) **discs**. Electrical connections at these junctions enable a wave of excitation to travel rapidly from cell to cell, and mechanical connections keep the myocytes from pulling apart when the heart contracts. The electrical junctions allow all the myocytes of a heart chamber to be stimulated, and contract, almost simultaneously. Intercalated discs appear as dark transverse lines separating each myocyte from the next. They may be only faintly visible, however, unless the tissue has been specially stained for them. Cardiac muscle is considered *involuntary* because it is not usually under conscious control; it contracts even if all nerve connections to it are severed.

Smooth muscle lacks striations and is involuntary. Smooth muscle cells are fusiform (thick in the middle and tapered at the ends) and relatively short. They have only one, centrally placed nucleus. Small amounts of smooth muscle are found in the iris of the eye and in the skin, but most of it, called **visceral muscle**, forms layers in the walls of the digestive, respiratory, and urinary tracts; blood vessels; the uterus; and other viscera. In locations such as the esophagus and small intestine, smooth muscle forms adjacent layers, with the cells of one layer encircling the organ and the cells of the other layer running longitudinally. When the circular smooth muscle contracts, it may propel contents such as food through the organ. When the longitudinal layer contracts, it makes the organ shorter and thicker. By regulating the diameter of blood vessels, smooth muscle is very important in controlling blood pressure and flow. Both smooth and skeletal muscle form sphincters that control the emptying of the bladder and rectum.

Think About It

How does the meaning of the word fiber differ in the following uses: muscle fiber, nerve fiber, and connective tissue fiber?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. What do nervous and muscular tissue have in common? What is the primary function of each?
17. What kinds of cells compose nervous tissue, and how can they be distinguished from each other?
18. Name the three kinds of muscular tissue, describe how to distinguish them from each other in microscopic appearance, and state a location and function for each.

²³dendr = tree + ite = little

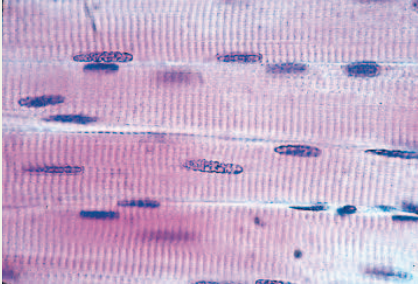

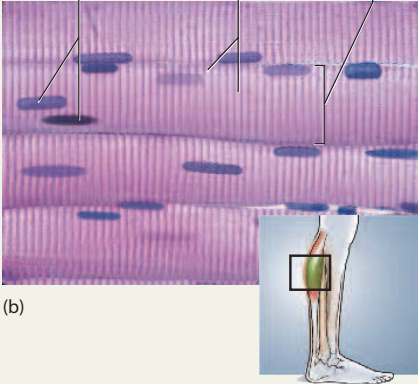

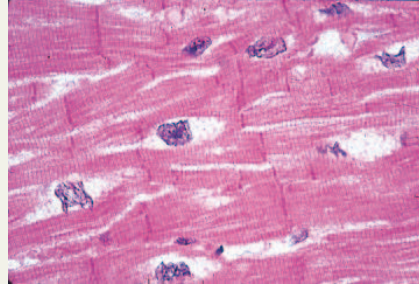

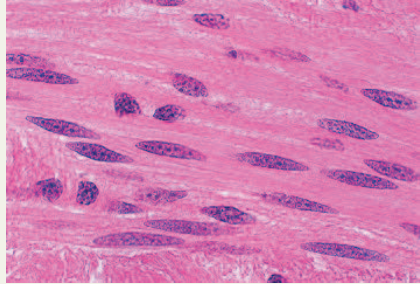

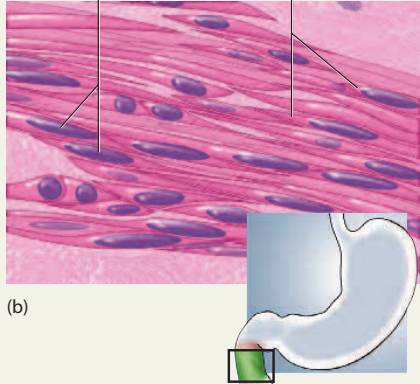

²⁴sphinc = squeeze, bind tightly

²⁵myo = muscle + cyte = cell

²⁶inter = between + calated = inserted

5.5 Intercellular Junctions, Glands, and Membranes

Objectives

When you have completed this section, you should be able to

- describe the junctions that hold cells and tissues together;
- describe or define different types of glands;
- describe the typical anatomy of a gland;
- name and compare different modes of glandular secretion;
- describe the way tissues are organized to form the body's membranes; and
- name and describe the major types of membranes in the body.

Intercellular Junctions

Most cells, with the exception of blood and metastatic cancer cells, must be anchored to each other and to the matrix if they are to grow and divide normally. The connections between one cell and another are called **intercellular junctions**. These attachments enable the cells to resist stress and communicate with each other. Without them, cardiac muscle cells would pull apart when they contracted, and every swallow of food would scrape away the lining of your esophagus. The principal types of intercellular junctions are shown in figure 5.28.

Tight Junctions

A **tight junction** is a region in which adjacent cells are bound together by fusion of the outer phospholipid layer of their plasma membranes. In epithelia, this forms a zone that completely encircles each cell near its apical pole, sealing off the intercellular space like a zipper and making it difficult or impossible for substances to pass between cells, somewhat like the plastic harness on a six-pack of soda cans.

In the stomach and intestines, tight junctions prevent digestive juices from seeping between epithelial cells and digesting the underlying connective tissue. They also help to prevent intestinal bacteria from invading the tissues, and they ensure that most digested nutrients pass *through* the epithelial cells and not *between* them.

Desmosomes

A **desmosome**²⁷ (DEZ-mo-some) is a patch that holds cells together more like a snap than a zipper. Desmosomes are not continuous and therefore cannot prevent substances

from passing between cells. They serve to keep cells from pulling apart and thus enable a tissue to resist mechanical stress. Desmosomes are common in the epidermis, the epithelium of the uterine cervix, other epithelia, and cardiac muscle. Hooklike J-shaped proteins arise from the cytoskeleton, approach the cell surface and penetrate into a thick protein plaque on the inner face of the plasma membrane; then the short arm of the J turns back into the cell—thus anchoring the cytoskeleton to the membrane plaque. Proteins of the plaque are linked to transmembrane proteins that, in turn, interdigitate with the transmembrane proteins of the next cell; this forms a zone of strong cell adhesion. Thus, each cell mirrors the other and contributes half of the desmosome. Such connections among neighboring cells create a strong structural network that binds cells together throughout the tissue. The basal cells of an epithelium are similarly linked to the underlying basement membrane by half desmosomes called *hemidesmosomes*, so an epithelium cannot easily peel away from the underlying tissue.

Think About It

Why would desmosomes not be suitable as the only intercellular junctions in the epithelium of the stomach?

Gap Junctions

A **gap (communicating) junction** is formed by a ringlike *connexon*, which consists of six transmembrane proteins arranged somewhat like the segments of an orange, surrounding a water-filled pore. Ions, glucose, amino acids,

INSIGHT 5.2

Clinical Application

Pemphigus Vulgaris—A Result of Defective Desmosomes

The immune system normally produces defensive *antibodies* that selectively attack foreign substances and leave the normal tissues of our bodies alone. But in a family of disorders called *autoimmune diseases*, antibodies fail to distinguish our own cells and tissues from foreign ones. Such misguided antibodies, called *autoantibodies*, thus launch destructive attacks on our own bodies. (Autoimmune diseases are discussed in more detail on p. 852.) One such disease is *pemphigus vulgaris*²⁸ (PEM-fih-gus vul-GAIR-iss), a disorder in which autoantibodies attack the proteins of the desmosomes in the skin and mucous membranes. This breaks down the attachments between epithelial cells and causes widespread blistering of the skin and oral mucosa, loss of tissue fluid, and sometimes death. The condition can be controlled with drugs that suppress the immune system, but such drugs reduce the patient's immune defenses against other diseases.

²⁷desmo = band, bond, ligament + som = body

²⁸pemphigus = blistering + vulgaris = common

FIGURE 5.28 Types of Intercellular Junctions.

Which of these junctions allows material to pass from one cell directly into the next?

and other small solutes can pass directly from the cytoplasm of one cell into the next through these pores. In the embryo, nutrients pass from cell to cell through gap junctions until the circulatory system forms and takes over the role of nutrient distribution. Gap junctions are found in the intercalated discs of cardiac muscle and between the cells of most smooth muscle. The flow of ions through these junctions allows electrical excitation to pass directly

from cell to cell so that the cells contract in near unison. Gap junctions are absent from skeletal muscle.

Glands

A **gland** is a cell or organ that secretes substances for use elsewhere in the body or releases them for elimination from the body. The gland product may be something

synthesized by the gland cells (such as digestive enzymes) or something removed from the tissues and modified by the gland (such as urine). Glands are composed predominantly of epithelial tissue, but usually have a supportive connective tissue framework and capsule.

Endocrine and Exocrine Glands

Glands are broadly classified as endocrine or exocrine. Both types originate as invaginations of a surface epithelium. In **exocrine**²⁹ (EC-so-crin) **glands**, they usually maintain their contact with the surface by way of a **duct**, an epithelial tube that conveys their secretion to the surface. The secretion may be released to the body surface, as in the case of sweat, mammary, and tear glands. More often, however, it is released into the cavity (lumen) of another organ such as the mouth or intestine; this is the case with salivary glands, the liver, and the pancreas. **Endocrine**³⁰ (EN-doe-crin) **glands** lose their contact with the surface and have no ducts. They do, however, have a high density of blood capillaries and secrete their products directly into the blood. The secretions of endocrine glands, called *hormones*, function as chemical messengers to stimulate cells elsewhere in the body. Endocrine glands include the pituitary, thyroid, and adrenal glands.

The exocrine–endocrine distinction is not always clear. The liver is an exocrine gland that secretes one of its products, bile, through a system of ducts, but secretes hormones, albumin, and other products directly into the bloodstream. Several glands, such as the pancreas, testis, ovary, and kidney, have both exocrine and endocrine components. Nearly all of the viscera have at least some cells that secrete hormones, even though most of these organs are not usually thought of as glands (for example, the brain and heart).

Unicellular glands are secretory cells found in an epithelium that is predominantly nonsecretory. They can be endocrine or exocrine. For example, the respiratory tract, which is lined mainly by ciliated cells, also has a liberal scattering of nonciliated, mucus-secreting goblet cells, which are exocrine (see figs. 5.6 and 5.7). The stomach and small intestine have scattered endocrine cells, which secrete hormones that regulate digestion.

Endocrine glands are the subject of chapter 17 and are not further considered here.

Exocrine Gland Structure

Figure 5.29 shows a generalized multicellular exocrine gland—a structural arrangement found in such organs as

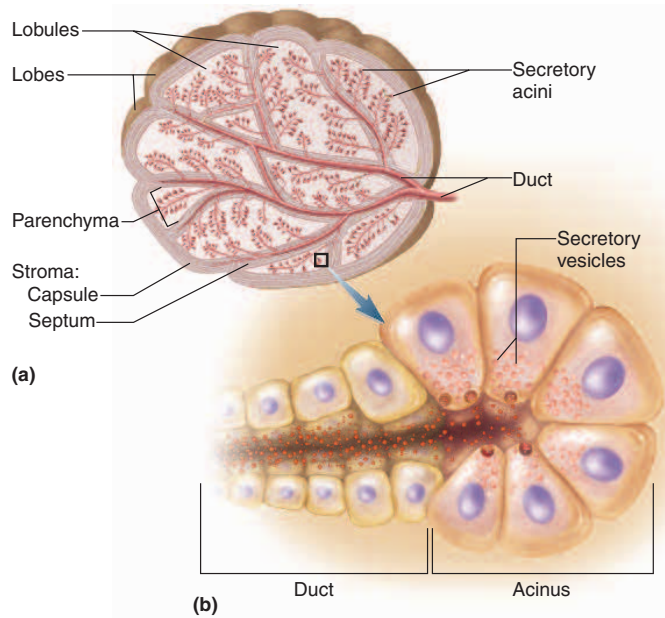

FIGURE 5.29 General Structure of an Exocrine Gland. (a) The gland duct branches repeatedly, following the connective tissue septa, until its finest divisions end on saccular acini of secretory cells. (b) Detail of an acinus and the beginning of a duct.

the mammary gland, pancreas, and salivary glands. Most glands are enclosed in a fibrous **capsule**. The capsule often gives off extensions called **septa**, or **trabeculae** (trah-BEC-you-lee), that divide the interior of the gland into compartments called **lobes**, which are visible to the naked eye. Finer connective tissue septa may further subdivide each lobe into microscopic **lobules** (LOB-yools). Blood vessels, nerves, and the gland's own ducts generally travel through these septa. The connective tissue framework of the gland, called its **stroma**, supports and organizes the glandular tissue. The cells that perform the tasks of synthesis and secretion are collectively called the **parenchyma** (pa-REN-kih-muh). This is typically simple cuboidal or simple columnar epithelium.

Exocrine glands are classified as **simple** if they have a single unbranched duct and **compound** if they have a branched duct. If the duct and secretory portion are of uniform diameter, the gland is called **tubular**. If the secretory cells form a dilated sac, the gland is called **acinar** and the sac is an **acinus**³¹ (ASS-ih-nus), or **alveolus**³² (AL-vee-OH-lus). A gland with secretory cells in both the tubular and acinar portions is called a **tubulo-acinar gland** (fig. 5.30).

²⁹*exo* = out + *crin* = to separate, secrete

³⁰*endo* = in, into + *crin* = to separate, secrete

³¹*acinus* = berry

³²*alveol* = cavity, pit

FIGURE 5.30 Some Types of Exocrine Glands. Glands are simple if their ducts do not branch and compound if they do; they are tubular if they have a uniform diameter, acinar if their secretory cells are limited to saccular acini, and tubuloacinar if they have secretory cells in both the acinar and tubular regions.

• Predict and sketch the appearance of a simple acinar gland.

Types of Secretions

Glands are classified not only by their structure but also by the nature of their secretions. **Serous** (SEER-us) **glands** produce relatively thin, watery fluids such as perspiration, milk, tears, and digestive juices. **Mucous glands**, found in the tongue and roof of the mouth among other places, secrete a glycoprotein called *mucin* (MEW-sin). After it is secreted, mucin absorbs water and forms the sticky product *mucus*. Goblet cells are unicellular mucous glands. (Note that *mucus*, the secretion, is spelled differently from *mucous*, the adjective form of the word.) **Mixed glands**, such as the two pairs of salivary glands in the chin, contain both serous and mucous cells and produce a mixture of the two types of secretions. **Cytogenic**³³ **glands** release whole cells. The only examples of these are the testes and ovaries, which produce sperm and egg cells.

Methods of Secretion

Glands are classified as merocrine or holocrine depending on how they produce their secretions. **Merocrine**³⁴ (MERR-oh-crin) **glands**, also called **eccrine**³⁵ (EC-rin) **glands**, have vesicles that release their secretion by exocytosis, as described in chapter 3 (fig. 5.31a). These include the tear glands, pancreas, gastric glands, and many others. In **holocrine**³⁶ **glands**, cells accumulate a product and then the entire cell disintegrates, so the secretion is a mixture

of cell fragments and the substance the cell had synthesized prior to its disintegration (fig. 5.31b). Only a few glands use this mode of secretion, such as the oil-producing glands of the scalp and certain glands of the eyelid. Holocrine secretions tend to be thicker than merocrine secretions.

Some glands, such as the axillary (armpit) sweat glands and mammary glands, are named **apocrine**³⁷ **glands** from a former belief that the secretion was composed of bits of apical cytoplasm that broke away from the cell surface. Closer study showed this to be untrue; these glands are primarily merocrine in their mode of secretion. These glands are nevertheless different from other merocrine glands in function and histological appearance, and they are still referred to as apocrine glands even though their mode of secretion is not unique.

Membranes

In atlas A, the major cavities of the body were described, as well as some of the membranes that line them and cover their viscera. We now consider some histological aspects of the major body membranes.

The largest membrane of the body is the **cutaneous** (cue-TAY-nee-us) **membrane**—or more simply, the skin (detailed in chapter 6). It consists of a stratified squamous epithelium (epidermis) resting on a layer of connective tissue (dermis). Unlike the other membranes to be considered, it is relatively dry. It resists dehydration of the body

³³*cyto* = cell + *genic* = producing

³⁴*mero* = part + *crin* = to separate, secrete

³⁵*ec* = *ex* = out + *crin* = to separate, secrete

³⁶*holo* = whole, entire + *crin* = to separate, secrete

³⁷*apo* = from, off, away + *crin* = to separate, secrete

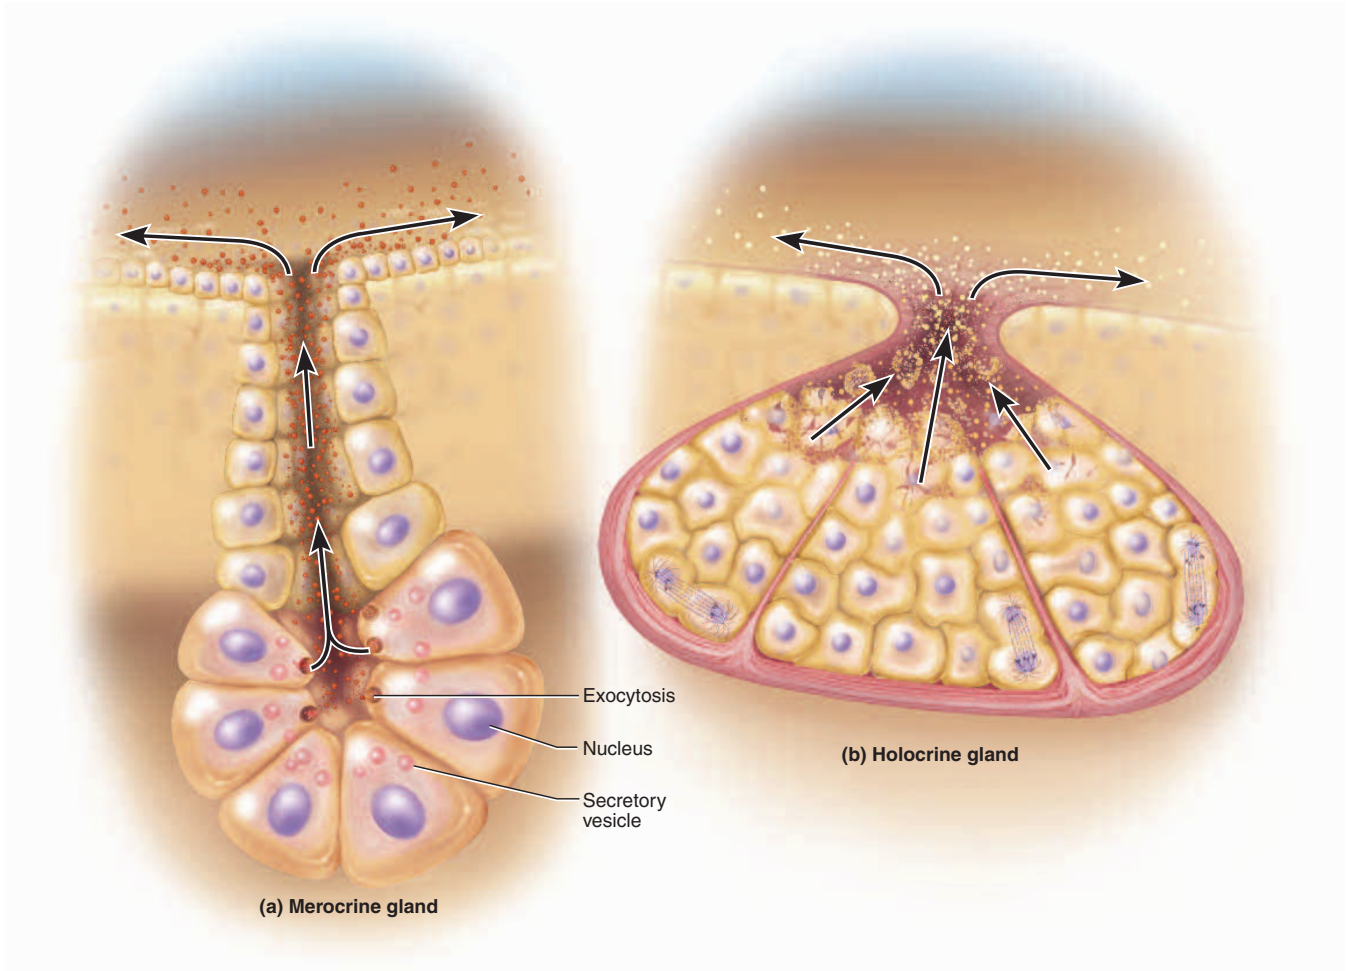

FIGURE 5.31 Modes of Exocrine Secretion. (a) A merocrine gland, which secretes its product by means of exocytosis at the apical surfaces of the secretory cells. (b) A holocrine gland, whose secretion is composed of disintegrated secretory cells.

Which of these glands would require a higher rate of mitosis in its parenchymal cells? Why?

and provides an inhospitable environment for the growth of infectious organisms.

The two principal kinds of internal membranes are mucous and serous membranes. A **mucous membrane (mucosa)** (fig. 5.32) lines passageways that open to the exterior environment: the digestive, respiratory, urinary, and reproductive tracts. A mucous membrane consists of two to three layers: (1) an epithelium; (2) an areolar connective tissue layer called the **lamina propria**³⁸ (LAM-ih-nuh PRO-pree-uh); and sometimes (3) a layer of smooth muscle called the **muscularis mucosae** (MUSK-you-LAIR-iss mew-CO-see). Mucous membranes have absorptive, secretory, and protective functions. They are often covered with mucus secreted by goblet cells, multicellular mucous glands, or both. The mucus traps bacteria and

foreign particles, which keeps them from invading the tissues and aids in their removal from the body. The epithelium of a mucous membrane may also include absorptive, ciliated, and other types of cells.

A **serous membrane (serosa)** is composed of a simple squamous epithelium resting on a thin layer of areolar connective tissue. Serous membranes produce watery **serous fluid**, which arises from the blood and derives its name from the fact that it is similar to blood serum in composition. Serous membranes line the insides of some body cavities and form a smooth outer surface on some of the viscera, such as the digestive tract. The pleura, pericardium, and peritoneum described in atlas A are serous membranes.

The circulatory system is lined with a simple squamous epithelium called **endothelium**, derived from mesoderm. The endothelium rests on a thin layer of areolar

³⁸lamina = layer + propria = of one's own

FIGURE 5.32 Histology of a Mucous Membrane.

tissue, which often rests in turn on an elastic sheet. Collectively, these tissues make up a membrane called the *tunica interna* of the blood vessels and *endocardium* of the heart. The simple squamous epithelium that lines the pleural, pericardial, and peritoneal cavities is called **mesothelium**.

Some joints of the skeletal system are lined by fibrous **synovial** (sih-NO-vee-ul) **membranes**, made only of connective tissue. These membranes span the gap from one bone to the next and secrete slippery *synovial fluid* into the joint.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

19. Compare the structure of tight junctions and gap junctions. Relate their structural differences to their functional differences.
20. Distinguish between a simple gland and a compound gland, and give an example of each. Distinguish between a tubular gland and an acinar gland, and give an example of each.
21. Contrast the merocrine and holocrine methods of secretion, and name a gland product produced by each method.
22. Describe the differences between a mucous and a serous membrane.
23. Name the layers of a mucous membrane, and state which of the four primary tissue classes composes each layer.

5.6 Tissue Growth, Development, Repair, and Death

Objectives

When you have completed this section, you should be able to

- name and describe the modes of tissue growth;
- define *adult* and *embryonic stem cells* and their varied degrees of developmental plasticity;
- name and describe the ways that a tissue can change from one type to another;
- name and describe the modes and causes of tissue shrinkage and death; and
- name and describe the ways the body repairs damaged tissues.

Tissue Growth

Tissues grow either because their cells increase in number or because the existing cells grow larger. Most embryonic and childhood growth occurs by **hyperplasia**³⁹ (HY-pur-PLAY-zhuh), tissue growth through cell multiplication. Exercised muscles grow, however, through **hypertrophy**⁴⁰ (hy-PUR-truh-fee), the enlargement of preexisting cells.

³⁹hyper = excessive + plas = growth

⁴⁰hyper = excessive + trophy = nourishment

Accumulation of body fat is also by hypertrophy. Even a very muscular or fat adult has essentially the same number of muscle fibers or adipocytes as he or she had in childhood, but the cells may be substantially larger. **Neoplasia**⁴¹ (NEE-oh-PLAY-zhuh) is the development of a tumor (neoplasm)—whether benign or malignant—composed of abnormal, nonfunctional tissue.

Changes in Tissue Type

You have studied the form and function of more than two dozen discrete types of human tissue in this chapter. You should not leave this subject, however, with the impression that once these tissue types are established in the adult, they never change. Tissues are, in fact, capable of changing from one type to another within certain limits. Most obviously, unspecialized tissues of the embryo develop into more diverse and specialized types of mature tissue—mesenchyme to muscle, for example. This development of a more specialized form and function is called **differentiation**.

Epithelia sometimes exhibit **metaplasia**,⁴² a change from one type of mature tissue to another. For example, the vagina of a young girl is lined with a simple cuboidal epithelium. At puberty, it changes to a stratified squamous epithelium, better adapted to the future demands of intercourse and childbirth. The nasal cavity is lined with ciliated pseudostratified columnar epithelium. However, if we block one nostril and breathe through the other one for several days, the epithelium in the unblocked passage changes to stratified squamous. In smokers, the pseudostratified columnar epithelium of the bronchi may transform into a stratified squamous epithelium.

Think About It

What functions of a pseudostratified columnar epithelium could not be served by a stratified squamous epithelium? In light of this, what might be some consequences of bronchial metaplasia in heavy smokers?

Stem Cells

The growth and differentiation of tissues depends upon a supply of reserve **stem cells**. These are undifferentiated cells that are not yet performing any specialized function, but that have the potential to differentiate into one or more types of mature functional cells, such as liver, brain, cartilage, or skin cells. Such cells have various degrees of **developmental plasticity**, or diversity of mature cell types to which they can give rise.

There are two types of stem cells: *embryonic* and *adult*. **Embryonic stem cells** compose the early human embryo—for example, the cells in the photograph on page 1. In the early stages of development, these are called **totipotent** stem cells,

because they have the potential to develop into any type of fully differentiated human cell—not only cells of the later embryonic, fetal, or adult body, but also cells of the temporary structures of pregnancy, such as the placenta and amniotic sac. Totipotency is unlimited developmental plasticity. About 4 days after fertilization, the developing embryo enters the *blastocyst* stage. The blastocyst is a hollow ball with an *outer cell mass* that helps form the placenta and other accessory organs of pregnancy, and an *inner cell mass* that becomes the embryo itself (see fig. 29.4). Cells of the inner cell mass are called **pluripotent** stem cells; they can still develop into any cell type of the embryo, but not into the accessory organs of pregnancy. Thus their developmental plasticity is already somewhat limited.

Adult stem cells occur in small numbers in mature organs and tissues throughout a person's life. Typically an adult stem cell divides mitotically; one of its daughter cells remains a stem cell and the other one differentiates into a mature specialized cell. The latter cell may replace another that has grown old and died, contribute to the development of growing organs (as in a child), or help to repair damaged tissue. Some adult stem cells are **multipotent**—able to develop into two or more different cell lines, but not just any type of body cell. Certain multipotent bone marrow stem cells, for example, can give rise to red blood cells, five kinds of white blood cells, and platelet-producing cells. **Unipotent** stem cells have the most limited plasticity, as they can produce only one mature cell type. Examples include the cells that give rise to sperm, eggs, and keratinocytes (the majority cell type of the epidermis).

Both embryonic and adult stem cells have enormous potential for therapy, but stem cell research has been embroiled in great political controversy in the past several years. Insight 5.4 addresses their clinical potential and the ethical and political issues surrounding stem cell research.

Tissue Repair

Damaged tissues can be repaired in two ways: *regeneration* or *fibrosis*. **Regeneration** is the replacement of dead or damaged cells by the same type of cells as before. Regeneration restores normal function to the organ. Most skin injuries (cuts, scrapes, and minor burns) heal by regeneration. The liver also regenerates remarkably well. **Fibrosis** is the replacement of damaged tissue with scar tissue, composed mainly of collagen produced by fibroblasts. Scar tissue helps to hold an organ together, but it does not restore normal function. Examples include the healing of severe cuts and burns, the healing of muscle injuries, and scarring of the lungs in tuberculosis.

Figure 5.33 illustrates the following stages in the healing of a cut in the skin, where both regeneration and fibrosis are involved:

- 1 Severed blood vessels bleed into the cut. Mast cells and cells damaged by the cut release histamine,

⁴¹neo = new + plas = form, growth

⁴²meta = change + plas = form, growth

FIGURE 5.33 Stages in the Healing of a Skin Wound.

which dilates blood vessels, increases blood flow to the area, and makes blood capillaries more permeable. Blood plasma seeps into the wound, carrying antibodies, clotting proteins, and blood cells.

- ② A blood clot forms in the tissue, loosely knitting the edges of the cut together and inhibiting the spread of pathogens from the site of injury into healthy tissues. The surface of the blood clot dries and hardens in the air, forming a scab that temporarily seals the wound and blocks infection. Beneath the scab, macrophages begin to phagocytize and digest tissue debris.
- ③ New blood capillaries sprout from nearby vessels and grow into the wound. The deeper portions of the clot become infiltrated by capillaries and fibroblasts and transform into a soft mass called **granulation tissue**. Macrophages remove the blood clot while fibroblasts deposit new collagen to replace it. This *fibroblastic (reconstructive) phase* of repair begins 3 to 4 days after the injury and lasts up to 2 weeks.
- ④ Surface epithelial cells around the wound multiply and migrate into the wounded area, beneath the scab. The scab loosens and eventually falls off, and the epithelium grows thicker. Thus, the epithelium *regenerates* while the underlying connective tissue undergoes *fibrosis*, or scarring. Capillaries withdraw from the area as fibrosis progresses. The scar tissue may or may not show through the epithelium, depending on the severity of the wound. The wound may exhibit a depressed area at first, but this is often filled in by continued fibrosis and remodeling from below, until the scar becomes unnoticeable. This *remodeling (maturation) phase* of tissue repair begins several weeks after injury and may last as long as 2 years.

Tissue Shrinkage and Death

Atrophy⁴³ (AT-ruh-fee) is the shrinkage of a tissue through a loss in cell size or number. It results from both normal aging (*senile atrophy*) and lack of use of an organ (*disuse atrophy*). Muscles that are not exercised exhibit disuse atrophy as their cells become smaller. This was a serious problem for the first astronauts who participated in prolonged microgravity space flights. Upon return to normal gravity, they were sometimes too weak from muscular atrophy to walk. Space stations and shuttles now include exercise equipment to maintain the crews' muscular condition. Disuse atrophy also occurs when a limb is immobilized in a cast or by paralysis.

Necrosis⁴⁴ (neh-CRO-sis) is the premature, pathological death of tissue due to trauma, toxins, infection, and so

forth. **Infarction** is the sudden death of tissue, such as cardiac muscle (*myocardial infarction*) or brain tissue (*cerebral infarction*), that occurs when its blood supply is cut off. **Gangrene** is any tissue necrosis resulting from an insufficient blood supply, usually involving infection. *Dry gangrene* often occurs in diabetics, especially in the feet. A lack of sensation due to diabetic nerve damage can make a person oblivious to injury and infection, and poor blood circulation due to diabetic arterial damage results in slow healing and rapid spread of infection. This often necessitates the amputation of toes, feet, or legs. A **decubitus ulcer** (bed sore) is a form of dry gangrene that occurs when immobilized persons, such as those confined to a hospital bed or wheelchair, are unable to move, and continual pressure on the skin cuts off blood flow to an area. *Gas gangrene* is necrosis of a wound resulting from infection with certain bacteria of the genus *Clostridium*, usually introduced when a wound is contaminated with soil. The disorder is named for bubbles of gas (mainly hydrogen) that accumulate in the tissues. This is a deadly condition that requires immediate intervention, often including amputation.

Cells dying by necrosis usually swell, exhibit *blebbing* (bubbling) of their plasma membranes, and then rupture. The cell contents released into the tissues trigger an inflammatory response in which macrophages phagocytize the cellular debris.

Apoptosis⁴⁵ (AP-op-TOE-sis), or **programmed cell death**, is the normal death of cells that have completed their function and best serve the body by dying and getting out of the way. Cells undergoing apoptosis shrink and are quickly phagocytized by macrophages and other cells. The cell contents never escape, so there is no inflammatory response. Although billions of cells die every hour by apoptosis, they are engulfed so quickly that they are almost never seen except within macrophages. For this reason, apoptosis was not discovered until recently.

Apparently every cell has a built-in "suicide program" that enables the body to dispose of it when necessary. In some cases, an extracellular suicide signal binds to a receptor protein in the plasma membrane called *Fas*. *Fas* then activates intracellular enzymes that destroy the cell, including an *endonuclease* that chops up its DNA and a *protease* that destroys cellular proteins. In other cases, cells seem to undergo apoptosis automatically if they stop receiving growth factors from other cells. For example, in embryonic development we produce about twice as many neurons as we need. Those that make connections with target cells survive, while the excess neurons die for lack of *nerve growth factor*. Apoptosis also dissolves the webbing between the fingers and toes during embryonic development; it frees the earlobe from the side of the head in people with the genotype for detached earlobes; and it causes shrinkage of the breasts after lactation ceases.

⁴³*a* = without + *trophy* = nourishment

⁴⁴*necr* = death + *osis* = process

⁴⁵*apo* = away + *ptosis* = falling

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

24. Distinguish between differentiation and metaplasia.
25. Tissues can grow through an increase in cell size or cell number. What are the respective terms for these two kinds of growth?
26. Distinguish between atrophy, necrosis, and apoptosis, and describe a circumstance under which each of these forms of tissue loss may occur.
27. Distinguish between regeneration and fibrosis. Which process restores normal cellular function? What good is the other process if it does not restore function?

INSIGHT 5.3 Clinical Application

Tissue Engineering

Tissue repair is not only a natural process but also a lively area of research in biotechnology. **Tissue engineering** is the artificial production of tissues and organs in the laboratory for implantation in the human body. The process commonly begins with building a scaffold (supportive framework) of collagen or biodegradable polyester, sometimes in the shape of a desired organ such as a blood vessel or an ear. The scaffold is seeded with human cells and put in a “bioreactor” to grow. The bioreactor supplies nutrients, oxygen, and growth factors. It may be an artificial chamber, or the body of a human patient or laboratory animal. When a lab-grown tissue reaches a certain point, it is implanted into the patient.

Tissue-engineered skin grafts are already on the market (see Insight 6.5). Scientists are not yet close to anything as complex as a lab-grown heart, but some are working on components such as valves, coronary arteries, patches of cardiac tissue, and whole heart chambers. Others have grown liver, bone, ureter, tendon, intestinal, and breast tissue in the laboratory. Scientists at the University of Massachusetts and the Massachusetts Institute of Technology have grown a “human” outer ear on the back of a mouse (fig. 5.34). They seeded a polymer scaffold with human cartilage cells and grew it in an immunodeficient mouse unable to reject the human tissue. They see potential in growing ears and noses for cosmetic treatment of children with birth defects or who have suffered disfiguring injuries from playground fights, accident, or animal bites. In 2006, scientists at Children’s Hospital in Boston reported

FIGURE 5.34 Tissue Engineering. Scientists have grown external ears from human tissue on the backs of immunodeficient mice. The ear can be removed without killing the mouse. In the future, such artificial organs might be used to improve the facial appearance of patients with missing parts.

that several patients had been successfully treated for defective urinary bladders by growing new bladders from the patients’ own cells and replacing all but the basal region where the ureters join the bladder.

INSIGHT 5.4 Clinical Application**The Stem-Cell Controversy**

Stem-cell research has been one of the most politically controversial areas of biological science at the dawn of this century. At least 18 countries have recently debated or enacted laws to regulate it. Politicians, scientists, bioethicists, philosophers, and theologians have joined in the debate; legions of lay citizens have voiced their opinions in newspaper editorial pages; and stem cells have been a contentious issue in United States presidential politics. In 2001, President George W. Bush signed into law an act that prohibited federal funding for research on any embryonic stem (ES) cell lines created after that date, on the grounds that he regarded the harvesting of the cells to be the taking of a human life. Although the administration claimed that this made 64 preexisting ES cell lines available to investigators, most experts in the field said that only 5 or 6 of them were suitable for research. Even the approved cell cultures are now old and do not grow very well. During the 2004 presidential campaign, actors Christopher Reeve and Michael J. Fox expressed hopes that stem-cell research could one day help people like them who suffered, respectively, from spinal cord injuries and Parkinson disease. Nancy and Ron Reagan, the widow and son of President Reagan, also expressed hope that federal support for embryonic stem-cell research would be permitted to move forward, since it might prove effective in treating Alzheimer disease—the neurodegenerative disorder that took President Reagan’s life. President Bush won reelection; the ban on federal funding for ES cell research remained in effect; and in 2006, he vetoed a congressional bill for expanded funding of stem-cell research. Even before the presidential election was decided, however, California voters approved a bill to provide state funds for ES cell research, amounting to \$300 million per year for 10 years.

Not surprisingly, biologists see stem cells as a possible treatment for diseases that result from the loss of functional cells. Skin and bone marrow stem cells have been used in therapy for many years. Scientists hope that with a little coaxing, stem cells might replace cardiac muscle damaged by heart attack; restore function to an injured spinal cord; cure parkinsonism by replacing lost brain cells; or cure diabetes mellitus by replacing lost insulin-secreting cells. But *adult stem (AS) cells* have limited

developmental potential and probably cannot make all the cell types needed to treat a broad range of degenerative diseases. In addition, they are present in very small numbers and are difficult to harvest and culture in the quantities needed for therapy.

ES cells, however, may hold greater potential. New laboratory methods have made them easier to culture than AS cells and have greatly accelerated stem cell research in recent years. In animal studies, ES cells have already proven effective for treating degenerative disease. In rats, for example, neurons have been produced from ES cells, implanted into the animal, and shown to reverse the signs of Parkinson disease.

The road to therapy with ES cells remains full of technical, ethical, and legal speed bumps. Will ES cells be rejected by the recipient’s immune system? Can the ES cells or the growth media in which they are cultured introduce viruses or other pathogens into the recipient? How can the ES cells be made to lodge and grow in the right place in the patient’s body? Could they grow into tumors instead of healthy tissue? Can ES cell therapy ever be economical enough to be affordable to any but the very rich? Scientists can scarcely begin to tackle these problems, however, unless and until a bioethical question is resolved: Can we balance the benefits of stem-cell therapy against the destruction of early human embryos from which the ES cells are harvested?

Where do these embryos come from? Most are donated by couples using *in vitro fertilization (IVF)* to conceive a child. IVF entails collecting numerous eggs from the prospective mother, fertilizing them in glassware with the father’s sperm, letting them develop into embryos (technically, preembryos) of about 8 to 16 cells, and then transplanting *some* of these into the mother’s uterus (see Insight 29.4). To overcome the low odds of success, excess embryos are always produced and some are always left over. The excess embryos are often destroyed, but many couples choose instead to donate them for research that may ultimately benefit other patients. It would seem sensible to use the embryos for beneficial purposes rather than to simply destroy and discard them. Opponents of stem-cell research argue, however, that potential medical benefits cannot justify the destruction of a human embryo, and even stem-cell researchers admit that IVF clinics alone could not meet the demand for ES cells if research and therapy do move ahead. Understandably, such issues have aroused an intense debate that is likely to restrain stem-cell research for some time to come.

CHAPTER REVIEW

Review of Key Concepts

5.1 The Study of Tissues (p. 152)

1. *Histology (microscopic anatomy)* is the study of tissues.
2. The body is composed of four primary tissues: epithelial, connective, nervous, and muscular tissue.
3. Tissues are composed of *cells* and *matrix (extracellular material)*. The matrix is composed of *fibers* and *ground substance*.
4. Mature tissues develop from three *primary germ layers* of the embryo: *ectoderm*, *mesoderm*, and *endoderm*.
5. Most tissues are studied as thin slices called *histological sections* colored with *stains* to show detail. Histological sections of elongated structures can be *longitudinal*, *cross*, or *oblique* sections. Some histological specimens are prepared as *smears* or *spreads*.

5.2 Epithelial Tissue (p. 154)

1. *Epithelia* are sheets of cells that cover organ surfaces and form glands.
2. Epithelia are composed of one or more layers of closely adhering cells, and lack blood vessels.
3. Epithelia are connected to the underlying connective tissue by a thin *basement membrane*.
4. In a *simple epithelium*, all cells contact the basement membrane. The four kinds of simple epithelium are *simple squamous* (with flat cells), *simple cuboidal* (with cubical to round cells), *simple columnar* (with tall narrow cells), and *pseudostratified columnar* (in which there are basal cells that do not reach the free surface, creating an appearance of stratification) (table 5.2).
5. In a *stratified epithelium*, the cells are multilayered and some rest on top of others, without touching the basement membrane. The four types of stratified epithelium are *stratified squamous*, *stratified cuboidal*, *stratified columnar*, and *transitional* (table 5.3).
6. Stratified squamous epithelium has two forms: *keratinized*, in which the surface cells are dead and packed with keratin, and *nonkeratinized*, in which the surface cells are living. The former constitutes the epidermis

and the latter is found in internal passages such as the esophagus.

5.3 Connective Tissue (p. 160)

1. *Connective tissue* consists mostly of fibers and ground substance, with widely separated cells.
2. Connective tissue binds, supports, and protects organs, and plays diverse roles in immunity, movement, transport, energy storage, and other processes.
3. The cells of *fibrous connective tissue* include *fibroblasts*, *macrophages*, *leukocytes*, *plasma cells*, *mast cells*, and *adipocytes*.
4. Fibrous connective tissue has especially conspicuous fibers, which are of three kinds: collagenous, reticular, and elastic fibers.
5. The ground substance of fibrous connective tissue usually has a gelatinous consistency due to *glycosaminoglycans*, *proteoglycans*, and *adhesive glycoproteins*.
6. Fibrous connective tissue includes *areolar*, *reticular*, *dense irregular*, and *dense regular* types (tables 5.4 and 5.5).
7. *Adipose tissue* (table 5.6) is a connective tissue dominated by adipocytes. Most of it is *white fat* but some, especially in infants and children, is heat-generating *brown fat*.
8. *Cartilage* is a connective tissue with a rubbery matrix. Its principal cells are *chondrocytes*, housed in cavities called *lacunae*. The three types of cartilage are *hyaline cartilage*, *elastic cartilage*, and *fibrocartilage* (table 5.7).
9. *Bone (osseous tissue)* has a stony calcified matrix. The two types of bone are *spongy* and *compact bone*.
10. The principal cells of bone are *osteocytes*, housed in lacunae. Much of the matrix of compact bone is deposited in cylindrical layers around a *central canal* occupied by blood vessels and nerves (table 5.8).
11. *Blood* is a fluid connective tissue composed of *erythrocytes*, *leukocytes*, and *platelets* in a liquid matrix, the *plasma* (table 5.9).

5.4 Nervous and Muscular Tissues—Excitable Tissues (p. 170)

1. Nervous and muscular tissues are called *excitable* tissues because they show quick electrical responses to stimuli.
2. *Nervous tissue* is composed of *neurons (nerve cells)* and supporting *glial cells* (table 5.10).
3. Neurons have a *cell body (neurosoma)* and usually one *axon* and multiple *dendrites*.
4. *Muscular tissue* is specialized to contract and move other tissues or materials.
5. There are three kinds of muscle: *skeletal*, *cardiac*, and *smooth* (table 5.11).

5.5 Intercellular Junctions, Glands, and Membranes (p. 173)

1. Intercellular junctions attach cells to each other.
2. Zipperlike *tight junctions* seal off the space between cells; snap- or weldlike *desmosomes* connect cells at patches rather than continuous zones of attachment; and *gap junctions* have pores that allow substances to pass directly from cell to cell.
3. *Glands* are organs that release secretions for use in the body or for waste elimination.
4. *Exocrine glands* usually release their secretions through a duct onto the surface of an organ. *Endocrine glands* lack ducts and release their secretions (*hormones*) into the bloodstream.
5. The connective tissue framework of a gland is called its *stroma*, and includes a capsule and internal septa. The secretory part is the *parenchyma* and is composed of epithelial secretory cells and ducts.
6. *Simple* glands have a single unbranched duct; *compound* glands have branched ducts. *Tubular* glands have ductile and secretory portions of uniform diameter; *acinar* glands have dilated sacs (*acini*) of secretory cells at the end of a duct.
7. *Serous* glands secrete thin runny fluids; *mucous* glands secrete viscous mucus; *mixed* glands secrete both;

and *cytogenic* glands produce cells (eggs and sperm) as their products.

8. *Merocrine* gland cells release their secretion by *exocytosis*; *holocrine* gland cells break down to become the secretion; *apocrine* glands are specialized glands with a merocrine mode of secretion but different histological appearance.
9. Membranes of the body include the relatively dry *cutaneous membrane* (skin), moist *serous membranes* covered with serous fluid; and *mucous membranes* that secrete mucus. Blood vessels are lined with a membrane called the *endothelium*; the thoracic and abdominopelvic cavities are lined with a membrane called *mesothelium*; and some joints are lined with *synovial membranes*.

5.6 Tissue Growth, Development, Repair, and Death (p. 178)

1. Organs grow through tissue *hyperplasia* (cell multiplication), *hypertrophy* (cell enlargement), or *neoplasia* (abnormal growth of tumors).
2. *Differentiation* is the development of a mature specialized tissue from an unspecialized one. *Metaplasia* is the normal conversion of one mature tissue type into another.
3. Stem cells are undifferentiated cells that have the *developmental plasticity* to develop into multiple mature cell types. They range from *unipotent* stem cells that can develop into only one lineage, to *totipotent* stem cells that can produce any mature cell type. *Embryonic stem cells*, which come from embryos up

to a week old, are *pluripotent*; *adult stem cells* are either *multipotent* or *unipotent*. Stem cell research is aimed at using stem cells to repair damaged tissues.

4. Two kinds of tissue repair are *regeneration* (which restores the preexisting tissue type and function) and *fibrosis* (which replaces the previous tissue with fibrous scar tissue).
5. Organs shrink through tissue *atrophy* (shrinkage due to aging or disuse).
6. Two kinds of tissue death are *necrosis* (pathological death of tissues from such causes as trauma, infection, toxins, and oxygen deprivation) and *apoptosis* (normal, programmed death of cells that have completed their function).

Testing Your Recall

1. Transitional epithelium is found in
 - a. the urinary system.
 - b. the respiratory system.
 - c. the digestive system.
 - d. the reproductive system.
 - e. all of the above.
2. The external surface of the stomach is covered by
 - a. a mucosa.
 - b. a serosa.
 - c. the parietal peritoneum.
 - d. a lamina propria.
 - e. a basement membrane.
3. Which of these is a primary germ layer?
 - a. epidermis
 - b. mucosa
 - c. ectoderm
 - d. endothelium
 - e. epithelium
4. A seminiferous tubule of the testis is lined with _____ epithelium.
 - a. simple cuboidal
 - b. pseudostratified columnar ciliated
 - c. stratified squamous
 - d. transitional
 - e. stratified cuboidal
5. _____ prevent fluids from seeping between epithelial cells.
 - a. Glycosaminoglycans
 - b. Hemidesmosomes
 - c. Tight junctions
 - d. Communicating junctions
 - e. Basement membranes
6. A fixative serves to
 - a. stop tissue decay.
 - b. improve contrast.
 - c. repair a damaged tissue.
 - d. bind epithelial cells together.
 - e. bind cardiac myocytes together.
7. The collagen of areolar tissue is produced by
 - a. macrophages.
 - b. fibroblasts.
 - c. mast cells.
 - d. leukocytes.
 - e. chondrocytes.
8. Tendons are composed of _____ connective tissue.
 - a. skeletal
 - b. areolar
 - c. dense irregular
 - d. yellow elastic
 - e. dense regular
9. The shape of the external ear is due to
 - a. skeletal muscle.
 - b. elastic cartilage.
 - c. fibrocartilage.
 - d. articular cartilage.
 - e. hyaline cartilage.
10. The most abundant formed element(s) of blood is/are
 - a. plasma.
 - b. erythrocytes.
 - c. platelets.
 - d. leukocytes.
 - e. proteins.
11. Any form of pathological tissue death is called _____.
12. The simple squamous epithelium that lines the peritoneal cavity is called _____.
13. Osteocytes and chondrocytes occupy little cavities called _____.
14. Muscle cells and axons are often called _____ because of their shape.
15. Tendons and ligaments are made mainly of the protein _____.
16. The only type of muscle that lacks gap junctions is _____.
17. An epithelium rests on a layer called the _____ between its deepest cells and the underlying connective tissue.
18. Fibers and ground substance make up the _____ of a connective tissue.
19. A _____ adult stem cell can differentiate into two or more mature cell types.
20. Any epithelium in which every cell touches the basement membrane is called a/an _____ epithelium.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- The esophagus is protected from abrasion by a keratinized stratified squamous epithelium.
- All cells of a pseudostratified columnar epithelium contact the basement membrane.
- Not all skeletal muscle is attached to bones.
- The stroma of a gland does not secrete anything.
- In all connective tissues, the matrix occupies more space than the cells do.
- Adipocytes are limited to adipose tissue.
- Tight junctions function primarily to prevent cells from pulling apart.
- Metaplasia is a normal, healthy tissue transformation but neoplasia is not.
- Nerve and muscle cells are not the body's only electrically excitable cells.
- Cartilage is always covered by a fibrous perichondrium.

Answers in appendix B

Testing Your Comprehension

- A woman in labor is often told to push. In doing so, is she consciously contracting her uterus to expel the baby? Justify your answer based on the muscular composition of the uterus.
- A major tenet of the cell theory is that all bodily structure and function are based on cells. The structural properties of bone, cartilage, and tendons, however, are due more to their extracellular material than to their cells. Is this an exception to the cell theory? Why or why not?
- When cartilage is compressed, water is squeezed out of it, and when pressure is taken off, water flows back into the matrix. This being the case, why do you think cartilage at weight-bearing joints such as the knees can degenerate from lack of exercise?
- The epithelium of the respiratory tract is mostly of the pseudostratified columnar ciliated type, but in the alveoli—the tiny air sacs where oxygen and carbon dioxide are exchanged between the blood and inhaled air—the epithelium is simple squamous. Explain the functional significance of this histological difference. That is, why don't the alveoli have the same kind of epithelium as the rest of the respiratory tract?
- Which do you think would heal faster, cartilage or bone? Stratified squamous or simple columnar epithelium? Why?

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Stratified squamous epithelium (p. 158)
- Collagenous fibers (p. 161)
- Areolar tissue (p. 164)
- Dense irregular connective tissue (p. 165)
- Desmosomes (p. 173)
- Merocrine and holocrine glands (p. 176)

The skin is also known as the **integument**,¹ whereas the **integumentary system** consists of the skin and its *accessory organs*—the hair, nails, and cutaneous glands. We pay more attention to this organ system than to any other. It is, after all, the most visible one, and its appearance strongly affects our social interactions. Few people venture out of the house without first looking in a mirror to see if their skin and hair are presentable. Social considerations aside, the integumentary system is important to one's self-image, and a positive self-image is important to the attitudes that promote overall good health. Care of the integumentary system is thus a particularly important part of the total plan of patient care.

Inspection of the skin, hair, and nails is a significant part of a physical examination. The integumentary system provides clues not only to its own health, but also to deeper disorders such as liver cancer, anemia, and heart failure. The skin also is the most vulnerable of our organs, exposed to radiation, trauma, infection, and injurious chemicals. Consequently, it needs and receives more medical attention than any other organ system. The scientific study and medical treatment of the integumentary system is called **dermatology**.²

6.1 The Skin and Subcutaneous Tissue

Objectives

When you have completed this section, you should be able to

- list the functions of the skin and relate them to its structure;
- describe the histological structure of the epidermis, dermis, and subcutaneous tissue;
- describe the normal and pathological colors that the skin can have, and explain their causes; and
- describe the common markings of the skin.

The **skin** is the body's largest and heaviest organ. In adults, it covers an area of 1.5 to 2.0 m² and accounts for about 15% of the body weight. It consists of two layers: a stratified squamous epithelium called the *epidermis* and a deeper connective tissue layer called the *dermis* (fig. 6.1). Below the dermis is another connective tissue layer, the

hypodermis, which is not part of the skin but is customarily studied in conjunction with it.

Most of the skin is 1 to 2 mm thick, but it ranges from less than 0.5 mm on the eyelids to 6 mm between the shoulder blades. The difference is due mainly to variation in the thickness of the dermis, although skin is classified as thick or thin based on the relative thickness of the epidermis alone. **Thick skin** covers the palms, soles, and corresponding surfaces of the fingers and toes. Its epidermis alone is about 0.5 mm thick, due to a very thick surface layer of dead cells called the *stratum corneum* (fig. 6.3). Thick skin has sweat glands but no hair follicles or sebaceous (oil) glands. The rest of the body is covered with **thin skin**, which has an epidermis about 0.1 mm thick, with a thin stratum corneum (see fig. 6.6). It possesses hair follicles, sebaceous glands, and sweat glands.

Functions of the Skin

The skin is much more than a container for the body. It has a variety of important functions that go well beyond appearance, as we shall see here.

1. **Resistance to trauma and infection.** The skin suffers the most physical injuries to the body, but it resists and recovers from trauma better than other organs do. The epidermal cells are packed with the tough protein **keratin** and linked by strong desmosomes that give this epithelium its durability. Few infectious organisms can penetrate the intact skin. Bacteria and fungi colonize the surface, but their numbers are kept in check by its relative dryness and slight acidity (pH 4–6). This protective, acidic film is called the *acid mantle*.
2. **Other barrier functions.** The skin is important as a barrier to water. It prevents the body from absorbing excess water when you are swimming or bathing, but even more importantly, it prevents the body from losing excess water. The epidermis is also a barrier to ultraviolet (UV) radiation, blocking much of this cancer-causing radiation from reaching deeper tissue layers; and it is a barrier to many potentially harmful chemicals. It is, however, permeable to several drugs and poisons (see Insight 6.1).
3. **Vitamin D synthesis.** The skin carries out the first step in the synthesis of vitamin D, which is needed for bone development and maintenance. The liver and kidneys complete the process.
4. **Sensation.** The skin is our most extensive sense organ. It is equipped with a variety of nerve endings that react to heat, cold, touch, texture, pressure, vibration, and tissue injury (see chapter 16). These sensory receptors are especially abundant on the face, palms, fingers, soles, nipples, and genitals. There are relatively few on the back and in skin overlying joints such as the knees and elbows.

¹integument = covering

²dermat = skin + logy = study of

FIGURE 6.1 Structure of the Skin and Subcutaneous Tissue.

5. **Thermoregulation.** In response to chilling, the skin helps to retain heat. The dermis has nerve endings called **thermoreceptors** that transmit signals to the brain, and the brain sends signals back to the dermal

INSIGHT 6.1 Clinical Application

Transdermal Absorption

The ability of the skin to absorb chemicals makes it possible to administer several medicines as ointments or lotions, or by means of adhesive patches that release the medicine steadily through a membrane. For example, inflammation can be treated with a hydrocortisone ointment, nitroglycerine patches are used to relieve heart pain, nicotine patches are used to help overcome tobacco addiction, and other medicated patches are used to control high blood pressure and motion sickness.

Unfortunately, the skin can also be a route for absorption of poisons. These include toxins from poison ivy and other plants; metals such as mercury, arsenic, and lead; and solvents such as carbon tetrachloride (a cleaning solvent), acetone (nail polish remover), paint thinner, and pesticides. Some of these can cause brain damage, liver failure, or kidney failure, which is good reason for using protective gloves when handling such substances.

blood vessels. Vasoconstriction, or narrowing of these blood vessels, reduces the flow of blood close to the skin surface and thus reduces heat loss. When one is overheated, vasodilation, or widening of the dermal blood vessels increases cutaneous blood flow and increases heat loss. If this is not enough to restore normal temperature, the brain also triggers sweating.

6. **Nonverbal communication.** The skin is an important means of nonverbal communication. Humans, like most other primates, have much more expressive faces than other mammals. Complex skeletal muscles insert on dermal collagen fibers and pull on the skin to create subtle and varied facial expressions (fig. 6.2). The general appearance of the skin, hair, and nails is also important to social acceptance and to a person's self-image and emotional state—whether the ravages of adolescent acne, the presence of a birthmark or scar, or just a “bad hair day.”

The Epidermis

The **epidermis**³ is a keratinized stratified squamous epithelium, as described in chapter 5. That is, its surface consists of dead cells packed with the tough protein

³epi = above, upon + derm = skin

FIGURE 6.2 Importance of the Skin in Nonverbal Expression. Primates differ from other mammals in having very expressive faces due to facial muscles that insert on the collagen fibers of the dermis and move the skin.

(a)

(b)

keratin. Like other epithelia, the epidermis lacks blood vessels and depends on the diffusion of nutrients from the underlying connective tissue. It has sparse nerve endings for touch and pain, but most sensations of the skin are due to nerve endings in the dermis.

Cells of the Epidermis

The epidermis is composed of five types of cells (fig. 6.3):

1. **Stem cells** are undifferentiated cells that divide and give rise to the keratinocytes described next. They

are found only in the deepest layer of the epidermis, called the *stratum basale* (described later).

2. **Keratinocytes** (keh-RAT-ih-no-sites) are the great majority of epidermal cells. They are named for their role in synthesizing keratin. In ordinary histological specimens, nearly all of the epidermal cells you see are keratinocytes.
3. **Melanocytes** also occur only in the stratum basale, amid the stem cells and deepest keratinocytes. They synthesize the brown to black pigment *melanin*. They have branching processes that spread among

FIGURE 6.3 Strata and Cell Types of the Epidermis.

the keratinocytes and continually shed melanin-containing fragments from their tips. The keratinocytes phagocytize these fragments and accumulate melanin granules on the “sunny side” of the nucleus. Like a parasol, the pigment shields the DNA from ultraviolet radiation.

4. **Tactile (Merkel⁴) cells**, relatively few in number, are receptors for the sense of touch. They, too, are found in the basal layer of the epidermis and are associated with an underlying dermal nerve fiber. The tactile cell and its nerve fiber are collectively called a *tactile (Merkel) disc*.
5. **Dendritic⁵ (Langerhans⁶) cells** are found in two layers of the epidermis called the *stratum spinosum* and *stratum granulosum* (described in the next section). They are macrophages that originate in the bone marrow but migrate to the epidermis and epithelia of the oral cavity, esophagus, and vagina. The epidermis has as many as 800 dendritic cells per square millimeter. They stand guard against toxins, microbes, and other pathogens that penetrate into the skin. When they detect such invaders, they alert the immune system so the body can defend itself.

Layers of the Epidermis

Cells of the epidermis are arranged in four to five zones, or strata (five in thick skin) (fig. 6.3). The following description progresses from deep to superficial, and from the youngest to the oldest keratinocytes.

1. The **stratum basale** (bah-SAY-lee) consists mainly of a single layer of cuboidal to low columnar stem cells and keratinocytes resting on the basement membrane. Scattered among these are the melanocytes and tactile cells. As stem cells of the stratum basale divide, they give rise to keratinocytes that migrate toward the skin surface and replace lost epidermal cells. The life history of these cells is described in the next section.
2. The **stratum spinosum** (spy-NO-sum) consists of several layers of keratinocytes. In most skin, this is the thickest stratum, but in thick skin it is usually exceeded by the stratum corneum. The deepest cells of the stratum spinosum remain capable of mitosis, but as they are pushed farther upward, they cease dividing. Instead, they produce more and more keratin filaments, which cause the cells to flatten. Therefore, the higher up you look in the stratum spinosum, the flatter the cells appear. Dendritic cells are also found throughout the stra-

tum spinosum, but are not usually visible in tissue sections.

The stratum spinosum is named for an artificial appearance (*artifact*) created by the histological fixation of tissue specimens. Keratinocytes are firmly attached to each other by numerous desmosomes, which partly account for the toughness of the epidermis. Histological fixatives shrink the keratinocytes so they pull away from each other, but they remain attached by the desmosomes—like two people holding hands while they step farther apart. The desmosomes thus create bridges from cell to cell, giving each cell a spiny appearance from which we derive the word *spinosum*.

Epidermal keratinocytes are also bound to each other by tight junctions, which make an essential contribution to water retention by the skin. This is further discussed in the next section.

3. The **stratum granulosum** consists of three to five layers of flat keratinocytes—more in thick skin than in thin skin. The keratinocytes of this layer contain coarse, dark-staining *keratohyalin granules* that give the layer its name. The functional significance of these granules will be explained shortly.
4. The **stratum lucidum⁷** (LOO-sih-dum) is a thin zone superficial to the stratum granulosum, seen only in thick skin. Here, the keratinocytes are densely packed with a clear protein named *eleidin* (ee-LEE-ih-din). The cells have no nuclei or other organelles. This zone has a pale, featureless appearance with indistinct cell boundaries.
5. The **stratum corneum** consists of up to 30 layers of dead, scaly, keratinized cells that form a durable surface layer. This layer is especially resistant to abrasion, penetration, and water loss.

The Life History of a Keratinocyte

Dead cells constantly flake off the skin surface. They float around as tiny white specks in the air, settling on household surfaces and forming much of the house dust that accumulates there (see Insight 6.2). Because we constantly lose these epidermal cells, they must be continually replaced.

Keratinocytes are produced deep in the epidermis by the mitosis of stem cells in the stratum basale. Some of the deepest keratinocytes in the stratum spinosum also multiply and increase their number. Mitosis requires an abundant supply of oxygen and nutrients, which these deep cells can acquire from the blood vessels in the nearby dermis. Once the epidermal cells

⁴Friedrich Sigmund Merkel (1845–1919), German anatomist

⁵*dendr* = tree, branch

⁶Paul Langerhans (1847–88), German anatomist

⁷*lucid* = light, clear

INSIGHT 6.2 Clinical Application**Dead Skin and Dust Mites**

In the beams of late afternoon sun that shine aslant through a window, you may see tiny white specks floating through the air. Most of these are flakes of dander; the dust on top of your bookshelves is largely a film of dead human skin. Composed of protein, this dust in turn supports molds and other microscopic organisms that feed on the skin cells and each other. One of these organisms is the house dust mite, *Dermatophagoides*⁸ (der-MAT-oh-fah-GOY-deez) (fig. 6.4). (What wonders may be found in humble places!)

Dermatophagoides thrives abundantly in pillows, mattresses, and upholstery—warm, humid places that are liberally sprinkled with edible flakes of keratin. No home is without these mites, and it is impossible to entirely exterminate them. What was once regarded as “house dust allergy” has been identified as an allergy to the inhaled feces of these mites.

FIGURE 6.4 The House Dust Mite, *Dermatophagoides*.

migrate more than two or three cells away from the dermis, their mitosis ceases. Mitosis is seldom seen in prepared slides of the skin, because it occurs mainly at night and most histological specimens are taken during the day.

As new keratinocytes are formed, they push the older ones toward the surface. In 30 to 40 days, a keratinocyte makes its way to the skin surface and then flakes off. This migration is slower in old age and faster in skin that has been injured or stressed. Injured epidermis regenerates more rapidly than any other tissue in the body. Mechanical stress from manual labor or tight shoes accelerates keratinocyte multiplication and results in *calluses* or *corns*, thick accumulations of dead keratinocytes on the hands or feet.

As keratinocytes are shoved upward by the dividing cells below, their cytoskeleton proliferates, the cells grow flatter, and they produce lipid-filled **membrane-coating vesicles (lamellar granules)**. In the stratum granulosum, three important developments occur. (1) The keratinocyte nuclei and other organelles degenerate and the cells die. (2) The keratohyalin granules release a protein called *filaggrin* that binds the cytoskeletal keratin filaments together into coarse, tough bundles. (3) The membrane-coating vesicles release a lipid mixture that spreads out over the cell surface and waterproofs it.

An **epidermal water barrier** forms between the stratum granulosum and stratum spinosum. It consists of the lipids secreted by the keratinocytes, tight junctions between the keratinocytes, and a thick layer of insoluble protein on the inner surfaces of the keratinocyte plasma membranes. The epidermal water barrier is crucial to retaining water in the body and preventing dehydration. Cells above the barrier quickly die because the barrier cuts them off from the supply of nutrients below. Thus, the stratum corneum consists of compact layers of dead keratinocytes and keratinocyte fragments. Dead keratinocytes soon **exfoliate** (fall away) from the epidermal surface as tiny specks called **dander**. *Dandruff* is composed of clumps of dander stuck together by sebum (oil).

A curious effect of the epidermal water barrier is the way our skin wrinkles when we linger in the bath or a lake. The keratin of the stratum corneum absorbs water and swells, whereas the deeper layers of the skin do not. The greater surface area of the stratum corneum forces it to wrinkle. This is especially conspicuous on the fingers and toes (“prune fingers”) because they have such a thick stratum corneum and they lack the sebaceous glands that produce water-resistant oil elsewhere on the body.

The Dermis

Beneath the epidermis is a connective tissue layer, the **dermis**. It ranges from 0.2 mm thick in the eyelids to about 4 mm thick in the palms and soles. It is composed mainly of collagen, but also contains elastic and reticular fibers, fibroblasts, and the other cells typical of fibrous connective tissue (described in chapter 5). It is well supplied with blood vessels, sweat glands, sebaceous glands, and nerve endings. The hair follicles and nail roots are embedded in the dermis. Smooth muscles (*piloerector muscles*) associated with hair follicles contract in response

⁸dermato = skin + phag = eat

to such stimuli as cold, fear, and touch. This makes the hair stand on end, causes “goose bumps,” and wrinkles the skin in areas such as the scrotum and areola. In the face, skeletal muscles attach to dermal collagen fibers and produce such expressions as a smile, a wrinkle of the forehead, and the lifting of an eyebrow.

The boundary between the epidermis and dermis is histologically conspicuous and usually wavy. The upward waves are fingerlike extensions of the dermis called **dermal papillae**⁹ (see fig. 6.3), and the downward waves are extensions of the epidermis called **epidermal ridges**. The dermal and epidermal boundaries thus interlock like corrugated cardboard, an arrangement that resists slippage of the epidermis across the dermis. If you look closely at your hand and wrist, you will see delicate furrows that divide the skin into tiny rectangular to rhomboidal areas. The dermal papillae produce the raised areas between the furrows. On the fingertips, this wavy boundary forms the *friction ridges* that leave fingerprints on the things we touch. In highly sensitive areas such as the lips and genitals, exceptionally tall dermal papillae allow nerve fibers to reach close to the surface.

⁹*pap* = nipple + *illa* = little

Think About It

Dermal papillae are relatively high and numerous in palmar and plantar skin but low and few in number in the skin of the face and abdomen. What do you think is the functional significance of this difference?

There are two zones of dermis called the papillary and reticular layers (fig. 6.5). The **papillary** (PAP-ih-lerr-ee) **layer** is a thin zone of areolar tissue in and near the dermal papillae. This loosely organized tissue allows for mobility of leukocytes and other defenses against organisms introduced through breaks in the epidermis. This layer is especially rich in small blood vessels.

The **reticular**¹⁰ **layer** of the dermis is deeper and much thicker. It consists of dense irregular connective tissue. The boundary between the papillary and reticular layers is often vague. In the reticular layer, the collagen forms thicker bundles with less room for ground substance, and there are often small clusters of adipocytes. Stretching of the skin in obesity and pregnancy can tear the collagen fibers and produce *striae* (STRY-ee), or

¹⁰*reti* = network + *cul* = little

(a)

(b) Papillary layer of dermis

(c) Reticular layer of dermis

FIGURE 6.5 The Dermis. (a) Light micrograph of axillary skin, with the collagen stained blue. (b) The papillary layer, made of loose (areolar) tissue, forms the dermal papillae. (c) The reticular layer, made of dense irregular connective tissue, forms the deeper four-fifths of the dermis. [Copyright by R. G. Kessel and R. H. Kardon, *Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy*, 1979, W. H. Freeman, All rights reserved.]

stretch marks. These occur especially in areas most stretched by weight gain: the thighs, buttocks, abdomen, and breasts.

The Hypodermis

Beneath the skin is a layer called the **hypodermis**¹¹ or **subcutaneous tissue** (see fig. 6.1). The boundary between the dermis and hypodermis is indistinct, but the hypodermis generally has more areolar and adipose tissue. It pads the body and binds the skin to the underlying tissues. Drugs are introduced into the hypodermis by injection because the subcutaneous tissue is highly vascular and absorbs them quickly.

Subcutaneous fat is hypodermis composed predominantly of adipose tissue. It serves as an energy reservoir and thermal insulation. It is not uniformly distributed; for example, it is virtually absent from the scalp but relatively abundant in the breasts, abdomen, hips, and thighs. The subcutaneous fat averages about 8% thicker in women than in men, and varies with age. Infants and elderly people have less subcutaneous fat than other people and are therefore more sensitive to cold.

Table 6.1 summarizes the layers of the skin and hypodermis.

Skin Color

The most significant factor in skin color is **melanin**. This is produced by the melanocytes but accumulates in the keratinocytes of the stratum basale and stratum spinosum

(fig. 6.6). There are two forms of melanin: a brownish black **eumelanin**¹² and a reddish yellow sulfur-containing pigment, **pheomelanin**.¹³ People of different skin colors have essentially the same number of melanocytes, but in dark-skinned people, the melanocytes produce greater quantities of melanin, the melanin granules in the keratinocytes are more spread out than tightly clumped, and the melanin breaks down more slowly. Thus, melanized cells may be seen throughout the epidermis, from stratum basale to stratum corneum. In light-skinned people, the melanin is clumped near the keratinocyte nucleus, so it imparts less color to the cells. It also breaks down more rapidly, so little of it is seen beyond the stratum basale, if even there.

The amount of melanin in the skin also varies with exposure to the ultraviolet (UV) rays of sunlight, which stimulate melanin synthesis and darken the skin. A suntan fades as melanin is degraded in older keratinocytes and as the keratinocytes migrate to the surface and exfoliate. The amount of melanin also varies substantially from place to place on the body. It is relatively concentrated in freckles and moles, on the dorsal surfaces of the hands and feet as compared with the palms and soles, on the nipple and surrounding area (areola) of the breast, around the anus, on the scrotum and penis, and on the lateral surfaces of the female genital folds (labia majora). The contrast between heavily melanized and lightly melanized regions of the skin is more pronounced in some people than others, but it exists to some extent in nearly everyone. Variations in ancestral exposure to UV

TABLE 6.1

Stratification of the Skin and Hypodermis

Layer	Description
Epidermis	Keratinized stratified squamous epithelium
Stratum corneum	Dead, keratinized cells of the skin surface
Stratum lucidum	Clear, featureless, narrow zone seen only in thick skin
Stratum granulosum	Two to five layers of cells with dark-staining keratohyalin granules; scanty in thin skin
Stratum spinosum	Many layers of keratinocytes, typically shrunken in fixed tissues but attached to each other by desmosomes, which give them a spiny look; progressively flattened the farther they are from the dermis. Dendritic cells are abundant here but are not visible in routinely stained preparations.
Stratum basale	Single layer of cuboidal to columnar cells resting on basement membrane; site of most mitosis; consists of stem cells, keratinocytes, melanocytes, and tactile cells, but these are difficult to distinguish with routine stains. Melanin is conspicuous in keratinocytes of this layer in black to brown skin.
Dermis	Fibrous connective tissue, richly endowed with blood vessels and nerve endings. Sweat glands and hair follicles originate here and in hypodermis.
Papillary layer	Superficial one-fifth of dermis; composed of areolar tissue; often extends upward as dermal papillae
Reticular layer	Deeper four-fifths of dermis; dense irregular connective tissue
Hypodermis	Areolar or adipose tissue between skin and muscle

FIGURE 6.6 Variations in Skin Pigmentation. (a) The stratum basale shows heavy deposits of melanin in dark skin. (b) Light skin shows little to no visible melanin.

Which of the five types of epidermal cells are the melanized cells in part (a)?

radiation are the primary reason for geographic and ethnic differences in skin color today (see Insight 6.3).

Other factors in skin color are hemoglobin and carotene. **Hemoglobin**, the red pigment of blood, imparts reddish to pinkish hues as blood vessels show through the skin. Its color is lightened by the white of the dermal collagen. The skin is redder in places such as the lips, where blood capillaries come closer to the surface and the hemoglobin shows through more vividly. **Carotene**¹⁴ is a yellow pigment acquired from egg yolks and yellow and orange vegetables. Depending on the diet, it can become concentrated to various degrees in the stratum corneum and subcutaneous fat. It is often most conspicuous in skin of the heel and in “corns” or calluses of the feet, because this is where the stratum corneum is thickest.

The skin may also exhibit abnormal colors of diagnostic value:

- **Cyanosis**¹⁵ is blueness of the skin resulting from a deficiency of oxygen in the circulating blood. Oxygen deficiency turns the hemoglobin a reddish violet color, which is lightened to blue-violet as it shows through the dermal collagen. Oxygen deficiency can result from conditions that prevent the blood from picking up a normal load of oxygen in the lungs, such as airway obstructions in drowning

and choking, lung diseases such as emphysema, and respiratory arrest. Cyanosis also occurs in situations such as cold weather and cardiac arrest, when blood flows so slowly through the skin that the tissues consume most of its oxygen faster than freshly oxygenated blood arrives.

- **Erythema**¹⁶ (ERR-ih-THEE-muh) is abnormal redness of the skin. It occurs in such situations as exercise, hot weather, sunburn, anger, and embarrassment. Erythema is caused by increased blood flow in dilated cutaneous blood vessels or by dermal pooling of red blood cells that have escaped from abnormally permeable capillaries, as in sunburn.
- **Pallor** is a pale or ashen color that occurs when there is so little blood flow through the skin that the white color of the dermal collagen shows through. It can result from emotional stress, low blood pressure, circulatory shock, cold temperatures, or severe anemia.
- **Albinism**¹⁷ is a genetic lack of melanin that usually results in milky white hair and skin, and blue-gray eyes. Melanin is synthesized from the amino acid tyrosine by the enzyme tyrosinase. People with albinism have inherited a recessive, nonfunctional tyrosinase allele from both parents.

¹⁴carot = carrot

¹⁵cyan = blue + osis = condition

¹⁶eryth = red + em = blood

¹⁷alb = white + ism = state, condition

INSIGHT 6.3 Evolutionary Medicine**The Evolution of Skin Color**

One of the most conspicuous signs of human variation is skin color, which can range from the color of espresso or milk chocolate to cafe au lait or light peach. Such variation results from a combination of evolutionary selection pressures, especially differences in exposure to ultraviolet radiation (UVR).

UVR can have two adverse effects: It causes skin cancer and it breaks down folic acid, a B vitamin needed for normal cell division, fertility, and fetal development. It also has a desirable effect: It stimulates keratinocytes to synthesize vitamin D, which is needed for the absorption of dietary calcium and thus for healthy bone development. Too much UVR and one is at risk of infertility and fetal deformities such as spina bifida; too little and one is at risk of bone deformities such as rickets. Consequently, populations native to the tropics and people descended from them tend to have well-melanized skin to screen out excessive UVR. Populations native to far northern and southern latitudes, where the sunlight is weak, tend to have light skin to allow for adequate UVR penetration. Ancestral skin color is thus partly a compromise between vitamin D and folic acid requirements. Worldwide, women have skin averaging about 4% lighter than men do, perhaps because of their greater need for vitamin D and calcium to support pregnancy and lactation.

But for multiple reasons, there are exceptions to this trend. UVR exposure is determined by more than latitude. It increases at higher elevations and in dry air, because the thinner, drier atmosphere filters out less UVR. This helps to explain the dark skin of people in such localities as the Andes and the high plateaus of Tibet and Ethiopia. UVR levels account for up to 77% of the variation in human skin color. Some other exceptions may be the result of human migrations from one latitude to another occurring too recently for their skin color to have adapted to the new level of UVR exposure. Variation may also result from cultural differences in clothing and shelter, intermarriage among people of different geographic ancestries, and darwinian sexual selection—a preference in mate choice for partners of light or dark complexion.

- **Jaundice**¹⁸ is a yellowing of the skin and whites of the eyes resulting from high levels of bilirubin in the blood. Bilirubin is a hemoglobin breakdown product. When erythrocytes get old, they disintegrate and release their hemoglobin. The liver and spleen convert hemoglobin to bilirubin, which the liver excretes in the bile. Bilirubin can accumulate enough to discolor the skin, however, in such situations as a rapid rate of erythrocyte destruction; when diseases such as cancer, hepatitis, and cirrhosis compromise liver function; and in

premature infants, where the liver is not well enough developed to dispose of bilirubin efficiently.

- A **hematoma**,¹⁹ or bruise, is a mass of clotted blood showing through the skin. It is usually due to accidental trauma (blows to the skin), but it may indicate hemophilia, other metabolic or nutritional disorders, or physical abuse.

Think About It

An infant brought to a clinic shows abnormally yellow skin. What sign could you look for to help decide whether this was due to jaundice or to a large amount of carotene from strained vegetables in the diet?

Skin Markings

The skin is marked by many lines, creases, ridges, and patches of accentuated pigmentation. **Friction ridges** are the markings on the fingertips that leave distinctive oily fingerprints on surfaces we touch. They are characteristic of most primates. They help prevent monkeys, for example, from slipping off a branch as they walk across it, and they enable us to manipulate small objects more easily. Friction ridges form during fetal development and remain essentially unchanged for life. Everyone has a unique pattern of friction ridges; not even identical twins have identical fingerprints.

Flexion lines (flexion creases) are the lines on the flexor surfaces of the digits, palms, wrists, elbows, and other places (see fig. B.8, p. 395). They mark sites where the skin folds during flexion of the joints. The skin is tightly bound to deeper connective tissues along these lines.

Freckles and moles are tan to black aggregations of melanocytes. **Freckles** are flat melanized patches that vary with heredity and exposure to the sun. A **mole (nevus)** is an elevated patch of melanized skin, often with hair. Moles are harmless and sometimes even regarded as “beauty marks,” but they should be watched for changes in color, diameter, or contour that may suggest malignancy (skin cancer) (see p. 205).

Birthmarks, or **hemangiomas**,²⁰ are patches of discolored skin caused by benign tumors of the blood capillaries. *Capillary hemangiomas* (strawberry birthmarks) usually develop about a month after birth. They become bright red to deep purple and develop small capillary-dense elevations that give them a strawberry-like appearance. About 90% of capillary hemangiomas disappear by the age of 5 or 6 years. *Cavernous hemangiomas* are flatter and duller in color. They are present at birth, enlarge up to 1 year of age, and then regress. About 90% disappear by the age of 9 years. A *port-wine stain* is flat and pinkish to dark purple in color. It can be quite large and remains for life.

¹⁸jaun = yellow¹⁹hemat = blood + oma = mass²⁰hem = blood + angi = vessels + oma = mass, tumor

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What is the major histological difference between thick and thin skin? Where on the body is each type of skin found?
2. How does the skin help control body temperature?
3. List the five cell types of the epidermis. Describe their locations and functions.
4. List the five layers of epidermis from deep to superficial. What are the distinctive features of each layer? Which layer is often absent?
5. What are the two layers of the dermis? What type of tissue composes each layer?
6. Name the pigments responsible for normal skin colors and explain how certain conditions can produce discolorations of the skin.

6.2 Hair and Nails

Objectives

When you have completed this section, you should be able to

- distinguish between three types of hair;
- describe the histology of a hair and its follicle;
- discuss some theories of the purposes served by various kinds of hair; and
- describe the structure and function of nails.

The hair, nails, and cutaneous glands are the **accessory organs (appendages)** of the skin. Hair and nails are composed mostly of dead, keratinized cells. The stratum corneum of the skin is made of pliable **soft keratin**, but the hair and nails are composed mostly of **hard keratin**. Hard keratin is more compact than soft keratin and is toughened by numerous cross-linkages between the keratin molecules.

Hair

A hair is also known as a **pilus** (PY-lus); in the plural, *pili* (PY-lye). It is a slender filament of keratinized cells that grows from an oblique tube in the skin called a **hair follicle** (fig. 6.7).

Distribution and Types

Hair is found almost everywhere on the body except the palms and soles; ventral and lateral surfaces of the fingers and toes; distal segment of the fingers; and the lips, nipples, and parts of the genitals. The limbs and trunk have

about 55 to 70 hairs per square centimeter, and the face has about 10 times as many. There are about 30,000 hairs in a man's beard and about 100,000 hairs on the average person's scalp. The number of hairs in a given area does not differ much from one person to another or even between the sexes; indeed, it is virtually the same in humans, chimpanzees, and gorillas. Differences in apparent hairiness are due mainly to differences in the texture and pigmentation of the hair.

Not all hair is alike, even on one person. Over the course of our lives, we grow three kinds of hair: lanugo, vellus, and terminal hair. **Lanugo**²¹ is fine, downy, unpigmented hair that appears on the fetus in the last 3 months of development. By the time of birth, most of it is replaced by **vellus**,²² similarly fine, pale hair. Vellus constitutes about two-thirds of the hair of women, one-tenth of the hair of men, and all of the hair of children except for the eyebrows, eyelashes, and hair of the scalp. **Terminal hair** is longer, coarser, and usually more heavily pigmented. It forms the eyebrows and eyelashes and covers the scalp; after puberty, it forms the axillary and pubic hair, the male facial hair, and some of the hair on the trunk and limbs.

Structure of the Hair and Follicle

A hair is divisible into three zones along its length: (1) the **bulb**, a swelling at the base where the hair originates in the dermis or hypodermis; (2) the **root**, which is the remainder of the hair within the follicle; and (3) the **shaft**, which is the portion above the skin surface. The only living cells of a hair are in and near the bulb. The bulb grows around a bud of vascular connective tissue called the **dermal papilla**, which provides the hair with its sole source of nutrition. Immediately above the papilla is a region of mitotically active cells, the **hair matrix**, which is the hair's growth center. All cells higher up are dead.

In cross section, a hair reveals up to three layers. From the inside out, these are the medulla, cortex, and cuticle. The **medulla** is a core of loosely arranged cells and air spaces. It is most prominent in thick hairs such as those of the eyebrows, but narrower in hairs of medium thickness and absent from the thinnest hairs of the scalp and elsewhere. The **cortex** constitutes most of the bulk of a hair. It consists of several layers of elongated keratinized cells that appear cuboidal to flattened in cross sections of a hair. The **cuticle** is composed of multiple layers of very thin, scaly cells that overlap each other like roof shingles with their free edges directed upward (fig. 6.7c). Cells lining the follicle are like shingles facing in the opposite direction. They interlock with the scales of the hair cuticle and resist pulling on the hair. When a hair is pulled out, this layer of follicle cells comes with it.

²¹lan = down, wool

²²vellus = fleece

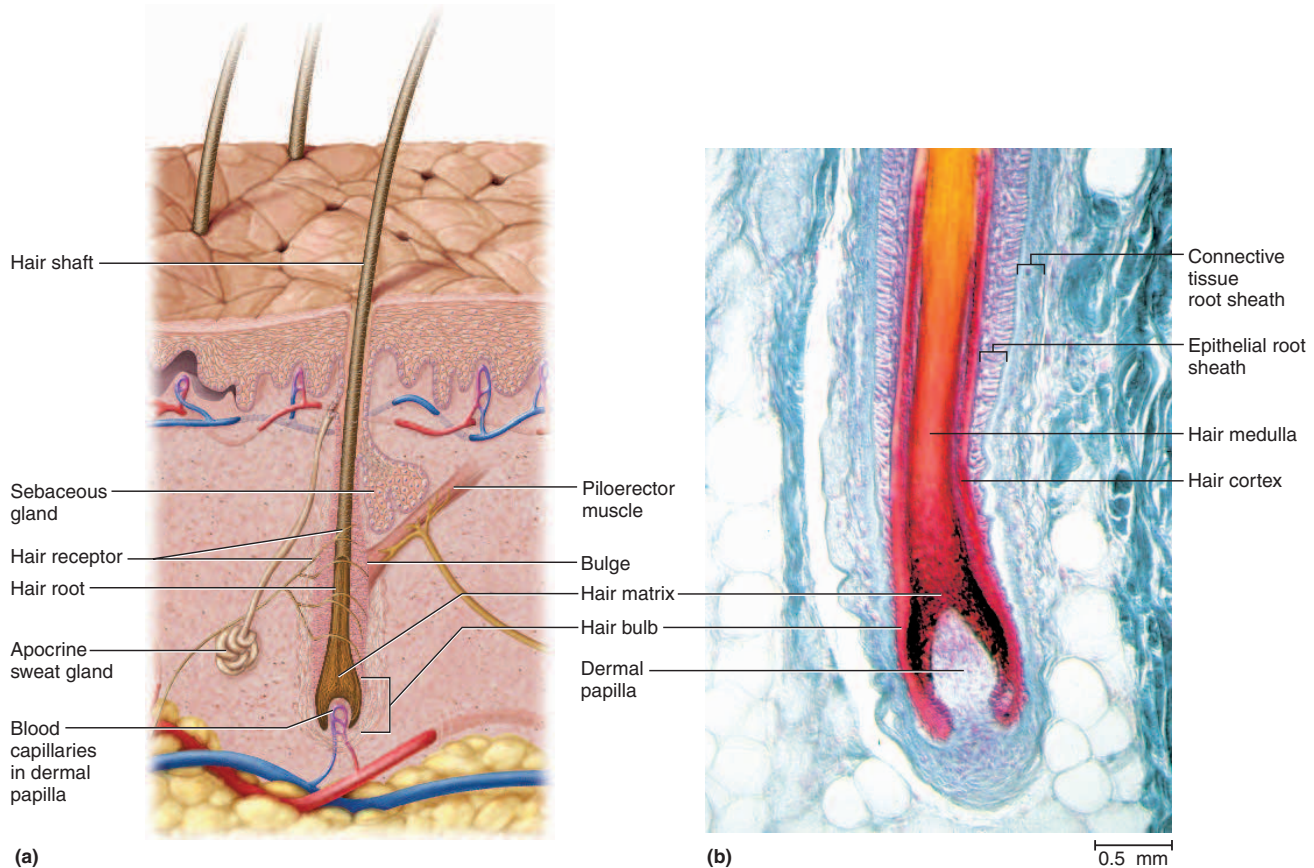

FIGURE 6.7 Structure of a Hair and Its Follicle. (a) Anatomy of the follicle and associated structures. (b) Light micrograph of the base of a hair follicle. (c) SEM of two hairs emerging from their follicles.

The follicle is a diagonal tube that dips deeply into the dermis and sometimes extends as far as the hypodermis. It has two principal layers: an **epithelial root sheath** and a **connective tissue root sheath**. The epithelial root sheath, which is an extension of the epidermis, lies immediately adjacent to the hair root. Toward the deep end of the follicle, it widens to form a **bulge**, a source of stem cells for follicle growth. The connective tissue root sheath, derived from the dermis, surrounds the epithelial sheath and is somewhat denser than the adjacent dermal connective tissue.

Associated with the follicle are nerve and muscle fibers. Nerve fibers called **hair receptors** entwine each follicle and respond to hair movements. You can feel their effect by carefully moving a single hair with a pin or by lightly running your finger over the hairs of your forearm without touching the skin. Also associated with each hair is a **piloerector muscle**—also known as a *pilomotor*

or *arrector pili*²³—a bundle of smooth muscle cells extending from dermal collagen fibers to the connective tissue root sheath of the follicle (see figs. 6.1 and 6.7a). In response to cold, fear, or other stimuli, the sympathetic nervous system stimulates these muscles to contract and thereby makes the hair stand on end. In other mammals, this traps an insulating layer of warm air next

²³arrect = erect + pili = of hair

FIGURE 6.8 The Basis of Hair Color and Texture. Straight hair (a and b) is round in cross section, whereas curly hair (c and d) is flatter. Blond hair (a) has scanty eumelanin and a moderate amount of pheomelanin. Eumelanin predominates in black and brown hair (b). Red hair (c) derives its color predominantly from pheomelanin. Gray and white hair (d) lack pigment and have air in the medulla.

Which of the hair layers illustrated here corresponds to the scales seen on the hair in the photo on page 187?

to the skin or makes the animal appear larger and less vulnerable to a potential enemy. In humans, it pulls the follicles into a vertical position and causes “goose bumps” but serves no useful purpose.

Hair Texture and Color

The texture of hair is related to differences in cross-sectional shape (fig. 6.8)—straight hair is round, wavy hair is oval, and tightly curly hair is relatively flat. Hair color is due to pigment granules in the cells of the cortex. Brown and black hair are rich in eumelanin. Red hair has a slight amount of eumelanin but a high concentration of pheomelanin. Blond hair has an intermediate amount of pheomelanin but very little eumelanin. Gray and white

hair result from a scarcity or absence of melanins in the cortex and the presence of air in the medulla.

Hair Growth and Loss

A given hair goes through a **hair cycle** consisting of three developmental stages: anagen, catagen, and telogen (fig. 6.9). At any given time, about 90% of the scalp follicles are in a period of growth called the **anagen**²⁴ phase. Stem cells from the bulge in the follicle multiply and travel downward, pushing the dermal papilla deeper into the skin and forming the epithelial root sheath. Root sheath cells directly above the dermal papilla form the

²⁴ana = up + gen = build, produce

FIGURE 6.9 The Hair Cycle.

hair matrix. Here, sheath cells transform into hair cells, which synthesize keratin and then die as they are pushed upward away from the papilla. The new hair grows up the follicle, often alongside an old *club hair* left from the previous cycle.

In the **catagen**²⁵ phase, mitosis in the hair matrix ceases and sheath cells below the bulge die. The follicle shrinks and the dermal papilla is drawn up toward the bulge. The base of the hair keratinizes into a hard club and the hair, now known as a **club hair**, loses its anchorage. Club hairs are easily pulled out by brushing the hair, and the hard club can be felt at the hair's end. When the papilla reaches the bulge, the hair goes into a resting period called the **telogen**²⁶ phase. Eventually, anagen begins anew and the cycle repeats itself. A club hair may fall out during catagen or telogen, or as it is pushed out by the new hair in the next anagen phase. We lose about 50 to 100 scalp hairs daily.

In a young adult, scalp follicles typically spend 6 to 8 years in anagen, 2 to 3 weeks in catagen, and 1 to 3 months in telogen. Scalp hairs grow at a rate of about 1 mm per 3 days (10–18 cm/yr) in the anagen phase.

Hair grows fastest from adolescence until the 40s. After that, an increasing percentage of follicles are in the catagen and telogen phases rather than the growing anagen phase. Follicles also shrink and begin producing wispy vellus hairs instead of thicker terminal hairs. Thinning of the hair, or baldness, is called **alopecia**²⁷

(AL-oh-PEE-she-uh). It occurs to some degree in both sexes and may be worsened by disease, poor nutrition, fever, emotional trauma, radiation, or chemotherapy. In the great majority of cases, however, it is simply a matter of aging.

Pattern baldness is the condition in which hair is lost from specific regions of the scalp rather than thinning uniformly across the entire scalp. It results from a combination of genetic and hormonal influences. The relevant gene has two alleles: one for uniform hair growth and a baldness allele for patchy hair growth. The baldness allele is dominant in males and is expressed only in the presence of the high level of testosterone characteristic of men. In men who are either heterozygous or homozygous for the baldness allele, testosterone causes the terminal hair of the scalp to be replaced by thinner vellus, beginning on top of the head and later the sides. In women, the baldness allele is recessive. Homozygous dominant and heterozygous women show normal hair distribution; only homozygous recessive women are at risk of pattern baldness. Even then, they exhibit the trait only if their testosterone levels are abnormally high for a woman (for example, because of a tumor of the adrenal gland, a woman's principal source of testosterone). Such characteristics in which an allele is dominant in one sex and recessive in the other are called *sex-influenced traits*.

Excessive or undesirable hairiness in areas that are not usually hairy, especially in women and children, is called **hirsutism**.²⁸ It tends to run in families and usually results from either masculinizing ovarian tumors or

²⁵cata = down

²⁶telo = end

²⁷alopecia = fox mange

²⁸hirsut = shaggy

hypersecretion of testosterone by the adrenal cortex. It is often associated with menopause.

Contrary to popular misconceptions, hair and nails do not continue to grow after a person dies, cutting hair does not make it grow faster or thicker, and emotional stress cannot make the hair turn white overnight.

Functions of Hair

Compared with other mammals, the relative hairlessness of humans is so unusual that it raises the question, Why do we have any hair at all? What purpose does it serve? There are different answers for the different types of hair; furthermore, some of the answers would make little sense if we limited our frame of reference to industrialized societies, where barbers and hairdressers are engaged to alter the natural state of the hair. It is more useful to take a comparative approach to this question and consider the purposes hair serves in other species of mammals.

Most hair of the human trunk and limbs is probably best interpreted as vestigial, with little present function. Body hair undoubtedly served to keep our ancestors warm, but in modern humans it is too scanty for this purpose. Stimulation of the hair receptors, however, alerts us to parasites crawling on the skin, such as lice and fleas.

The scalp is normally the only place where the hair is thick enough to retain heat. Heat loss from a bald scalp can be substantial and quite uncomfortable. The brain receives a rich supply of warm blood, and most of the scalp lacks an insulating fat layer. Heat is easily conducted through the bones of the skull and lost to the surrounding air. In addition, without hair there is nothing to break the wind and stop it from carrying away heat. Hair also protects the scalp from sunburn, since the scalp is otherwise most directly exposed to the sun's rays. These may be the reasons humans have retained thick hair on their heads while losing most of it from the rest of the body.

Tufts and patches of hair, sometimes with contrasting colors, are important among mammals for advertising species, age, sex, and individual identity. For the less groomed members of the human species, scalp hair may play a similar role. The indefinitely growing hair of a man's scalp and beard, for example, could provide a striking contrast to a face that is otherwise almost hairless. It creates a badge of recognition instantly visible at a distance.

The beard and pubic and axillary hair signify sexual maturity and aid in the transmission of sexual scents. We will further reflect on this in a later discussion of apocrine sweat glands, whose distribution and function add significant evidence to support this theory.

Stout protective **guard hairs**, or **vibrissae** (vy-BRISS-ee), guard the nostrils and ear canals and prevent foreign particles from entering easily. The eyelashes can shield the eye from windblown debris with a quick blink. In

windy or rainy conditions, we can squint so that the eyelashes protect the eyes without completely obstructing our vision.

The eyebrows are often presumed to keep sweat or debris out of the eyes, but this seems a negligible role. It is more plausible that they function mainly to enhance facial expression. Movements of the eyebrows are an important means of nonverbal communication in humans of all cultures, and we even have special *frontalis* muscles for this purpose. Eyebrow expressiveness is not unique to humans; many species of monkeys and apes use quick flashes of the eyebrows to greet each other, assert their dominance, and break up quarrels.

Nails

Fingernails and toenails are clear, hard derivatives of the stratum corneum. They are composed of very thin, dead, scaly cells, densely packed together and filled with parallel fibers of hard keratin. Most mammals have claws, whereas flat nails are one of the distinguishing characteristics of primates. Flat nails allow for more fleshy and sensitive fingertips, while they also serve as strong keratinized “tools” that can be used for digging, grooming, picking apart food, and other manipulations.

The hard part of the nail is the **nail plate**, which includes the **free edge** overhanging the tip of the finger or toe; the **nail body**, which is the visible attached part of the nail; and the **nail root**, which extends proximally under the overlying skin (fig. 6.10). The surrounding skin rises a bit above the nail as a **nail fold**, separated from the margin of the nail plate by a **nail groove**. The nail groove and space under the free edge accumulate dirt and bacteria and require special attention when scrubbing for duty in an operating room or nursery.

The skin underlying the nail plate is the **nail bed**. The epidermis of the nail bed is the **hyponychium**²⁹ (HIPE-o-NICK-ee-um). At the proximal end of the nail, its stratum basale thickens to constitute a growth zone called the **nail matrix**. Mitosis here in the matrix accounts for the growth of the nail—about 1 mm per week in the fingernails and slightly slower in the toenails. The thickness of this stratum basale obscures the underlying dermal blood vessels and is the reason why an opaque white crescent, the **lunule**³⁰ (LOON-yule), often appears at the proximal end of a nail. A narrow zone of dead skin, the **eponychium**³¹ (EP-o-NICK-ee-um) (**cuticle**), also commonly overhangs this end of the nail.

The appearance of the fingertips and nails can be valuable in medical diagnosis. The fingertips become swollen or *clubbed* in response to long-term hypoxemia—a deficiency of oxygen in the blood stemming from conditions

²⁹*hypo* = below + *onych* = nail

³⁰*lun* = moon + *ule* = little

³¹*ep* = above + *onych* = nail

FIGURE 6.10 Anatomy of a Fingernail.

such as congenital heart defects and emphysema. Dietary deficiencies may be reflected in the appearance of the nails. An iron deficiency, for example, may cause them to become flat or concave (spoonlike) rather than convex. Contrary to popular belief, adding gelatin to the diet has no effect on the growth or hardness of the nails.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. What is the difference between vellus and terminal hair?
8. State the functions of the hair papilla, hair receptors, and piloerector.
9. Describe what happens in the anagen, catagen, and telogen phases of the hair cycle.
10. State some reasonable theories for the different functions of hair of the eyebrows, eyelashes, scalp, nostrils, and axilla.
11. Define or describe the nail plate, nail fold, eponychium, hyponychium, and nail matrix.

6.3 Cutaneous Glands

Objectives

When you have completed this section, you should be able to

- name two types of sweat glands, and describe the structure and function of each;
- describe the location, structure, and function of sebaceous and ceruminous glands; and
- discuss the distinction between breasts and mammary glands, and explain their respective functions.

The skin has five types of glands: *merocrine sweat glands*, *apocrine sweat glands*, *sebaceous glands*, *ceruminous glands*, and *mammary glands*.

Sweat Glands

Sweat glands, or **sudoriferous**³² (soo-dor-IF-er-us) **glands**, are of two kinds, described in chapter 5: merocrine and apocrine. **Merocrine (eccrine) sweat glands**, the most numerous glands of the skin, produce watery perspiration that serves primarily to cool the body (fig. 6.11b). There are 3 to 4 million of these in the adult skin, with a total weight about equal to that of a kidney. They are especially abundant on the palms, soles, and forehead, but they are widely distributed over the rest of the body as well. Each is a simple tubular gland with a twisted coil in the dermis or hypodermis and an undulating or coiled duct leading to a sweat pore on the skin surface. This duct is lined by a stratified cuboidal epithelium in the dermis and by keratinocytes in the epidermis. Amid the secretory cells at the deep end of the gland, there are specialized **myoepithelial**³³ **cells** with properties similar to smooth muscle. They contract in response to stimulation by the sympathetic nervous system and squeeze perspiration up the duct.

Sweat begins as a protein-free filtrate of the blood plasma produced by the deep secretory portion of the gland. Most sodium chloride is reabsorbed from the filtrate as the secretion passes through the duct. Potassium ions, urea, lactic acid, ammonia, and some sodium chloride remain in the sweat. Some drugs are also excreted in the perspiration. On average, sweat is 99% water and has a pH ranging from 4 to 6, contributing the earlier-mentioned *acid mantle* that inhibits bacterial growth on the skin. Each day, the sweat glands secrete about 500 mL of **insensible perspiration**, which does not produce noticeable wetness of the skin. Sweating with wetness of

³²*sudor* = sweat + *fer* = carry, bear

³³*myo* = muscle

FIGURE 6.11 Cutaneous Glands. (a) Apocrine sweat glands have a large lumen and a duct that conveys their aromatic secretion into a hair follicle. (b) Merocrine sweat glands have a relatively narrow lumen and a duct that opens by way of a pore on the skin surface. (c) Sebaceous glands have cells that break down in entirety to form an oily secretion that is released into the hair follicle.

Which gland type do you think requires the fastest rate of stem cell mitosis? Explain.

the skin is called **diaphoresis**³⁴ (DY-uh-foe-REE-sis). Under conditions of exercise or heat, a person may lose as much as a liter of perspiration in an hour. In fact, so much fluid can be lost from the bloodstream by sweating as to cause circulatory shock.

Apocrine sweat glands occur in the groin, anal region, axilla, and areola, and in mature males, the beard area. They are absent from the axillary region of Koreans, however, and are sparse in the Japanese. Their ducts lead into nearby hair follicles rather than opening directly onto the skin surface (fig. 6.11a). They produce their secretion in the same way that merocrine glands do—by exocytosis. The secretory part of an apocrine gland, however, has a much larger lumen than that of a merocrine gland, so these glands have continued to be referred to as apocrine to distinguish them functionally and histologically from the

merocrine type. Apocrine sweat is thicker and more milky than merocrine sweat because it has more fatty acids in it.

Apocrine sweat glands are scent glands that respond especially to stress and sexual stimulation. They do not develop until puberty, and they apparently correspond to the scent glands that develop in other mammals on attainment of sexual maturity. In women, they enlarge and shrink in phase with the menstrual cycle. Apocrine sweat does not have a disagreeable odor; indeed, it is considered attractive or arousing in some cultures, where it is as much a part of courtship as artificial perfume is to other people. Clothing, however, traps stale sweat long enough for bacteria to degrade the secretion and release free fatty acids with a rancid odor. Disagreeable body odor is called *bromhidrosis*.³⁵ It occasionally indicates a metabolic disorder, but more often it simply reflects poor hygiene.

³⁴dia = through + phoresis = carrying

³⁵brom = stench + hidros = sweat

Many mammals have apocrine scent glands associated with specialized tufts of hair. In humans, apocrine glands are found mainly in the regions covered by the pubic hair, axillary hair, and beard. This suggests that like other mammalian scent glands, they serve to produce *pheromones*, chemicals that influence the physiology or behavior of other members of the species (see Insight 16.1, p. 599). The hair serves to retain the aromatic secretion and regulate its rate of evaporation from the skin. Thus, it seems no mere coincidence that women's faces lack both apocrine scent glands and a beard.

Sebaceous Glands

Sebaceous³⁶ (see-BAY-shus) **glands** produce an oily secretion called **sebum** (SEE-bum). They are flask-shaped, with short ducts that usually open into a hair follicle (fig. 6.11c), although some of them open directly onto the skin surface. These are holocrine glands with little visible lumen. Their secretion consists of broken-down cells that are replaced by mitosis at the base of the gland. Sebum keeps the skin and hair from becoming dry, brittle, and cracked. The sheen of well-brushed hair is due to sebum distributed by the hairbrush. Ironically, we go to great lengths to wash sebum from the skin, only to replace it with various skin creams and hand lotions made of little more than lanolin, which is sheep sebum.

Ceruminous Glands

Ceruminous (seh-ROO-mih-nus) **glands** are found only in the external ear canal, where their secretion combines with sebum and dead epidermal cells to form earwax, or **cerumen**.³⁷ They are simple, coiled, tubular glands with ducts leading to the skin surface. Cerumen keeps the eardrum pliable, waterproofs the canal, kills bacteria, and coats the guard hairs of the ear, making them sticky and more effective in blocking foreign particles from entering the auditory canal.

Mammary Glands

The **mammary glands** and breasts (*mammae*) are often mistakenly regarded as one and the same. Breasts, however, are present in both sexes, and even in females they rarely contain more than small traces of mammary gland. The mammary glands, by contrast, are the milk-producing glands that develop within the female breast only during pregnancy and lactation. They are modified apocrine sweat glands that produce a richer secretion and channel it through ducts to a nipple for more efficient conveyance to the offspring. The anatomy and physiology of the mammary gland are discussed in more detail in chapter 28.

³⁶ *seb* = fat, *tallow* + *aceous* = possessing

³⁷ *cer* = wax

TABLE 6.2

Cutaneous Glands

Gland Type	Definition
Sudoriferous glands	Sweat glands
Merocrine glands	Sweat glands that function in evaporative cooling; widely distributed over the body surface; open by ducts onto the skin surface
Apocrine glands	Sweat glands that function as scent glands; found in the regions covered by the pubic, axillary, and male facial hair; open by ducts into hair follicles
Sebaceous glands	Oil glands associated with hair follicles
Ceruminous glands	Glands of the ear canal that contribute to the cerumen (earwax)
Mammary glands	Milk-producing glands located in the breasts

In most mammals, two rows of mammary glands form along lines called the *mammary ridges*, or *milk lines*. Primates have dispensed with all but two of these glands. A few people of both sexes, however, develop additional nipples or mammae along the milk line inferior to the primary mammae. In the Middle Ages and colonial America, this condition, called *polythelia*,³⁸ was used to incriminate women as supposed witches.

The glands of the skin are summarized in table 6.2.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- How do merocrine and apocrine sweat glands differ in structure and function?
- What other type of gland is associated with hair follicles? How does its mode of secretion differ from that of sweat glands?
- What is the difference between the breast and mammary gland?

6.4 Skin Disorders

Objectives

When you have completed this section, you should be able to

- describe the three most common forms of skin cancer; and
- describe the three classes of burns and the priorities in burn treatment.

³⁸ *poly* = many + *theli* = nipples

Because it is the most exposed of all our organs, skin is not only the most vulnerable to injury and disease, but is also the one place where we are most likely to notice anything out of the ordinary. Skin diseases become increasingly common in old age, and most people over age 70 have complaints about their integumentary system. Aging of the skin is discussed more fully on page 1140. The healing of cuts and other injuries to the skin occurs by the process described at the end of chapter 5. We focus here on two particularly common and serious disorders: skin cancer and burns. Other skin diseases are briefly summarized in table 6.3.

Skin Cancer

Skin cancer is induced by the ultraviolet rays of the sun. It occurs most often on the head and neck, where exposure to the sun is greatest. It is most common in fair-skinned people and the elderly, who have had the longest lifetime UV exposure (see Insight 6.4). The ill-advised popularity of suntanning, however, has caused an alarming increase in skin cancer among younger people. Skin cancer is one of the most common cancers, but it is also one of the easiest to treat and has one of the highest survival rates when it is detected and treated early.

Think About It

Skin cancer is relatively rare in people with dark skin. Other than possible differences in behavior, such as lack of intentional suntanning, why do you think this is so?

There are three types of skin cancer named for the epidermal cells in which they originate: basal cell *carcinoma*, *squamous cell carcinoma*, and *malignant melanoma*. The three types are also distinguished from each other by the appearance of their **lesions**³⁹ (zones of tissue injury).

Basal cell carcinoma⁴⁰ is the most common type, but it is also the least dangerous because it seldom metastasizes. It arises from cells of the stratum basale and eventually invades the dermis. On the surface, the lesion first appears as a small, shiny bump. As the bump enlarges, it often develops a central depression and a beaded “pearly” edge (fig. 6.12a).

Squamous cell carcinoma arises from keratinocytes of the stratum spinosum. Lesions usually appear on the scalp, ears, lower lip, or back of the hand. They have a raised, reddened, scaly appearance, later forming a concave ulcer with raised edges (fig. 6.12b). The chance of recovery is good with early detection and surgical removal, but if it goes unnoticed or is neglected, this cancer tends to metastasize to the lymph nodes and can be lethal.

Malignant melanoma is a skin cancer that arises from the melanocytes, often in a preexisting mole. It accounts for no more than 5% of skin cancers, but it is the most deadly form. It can be treated surgically if it is caught early, but if it metastasizes—which it does quickly—it is unresponsive to chemotherapy and is usually fatal. The average person with metastatic melanoma lives only 6 months from diagnosis, and only 5% to 14% of patients survive with it

³⁹lesio = injure

⁴⁰carcin = cancer + oma = tumor

TABLE 6.3

Some Disorders of the Integumentary System

Acne	Inflammation of the sebaceous glands, especially beginning at puberty; follicle becomes blocked with keratinocytes and sebum and develops into a whitehead (<i>comedo</i>) composed of these and bacteria; continued inflammation of follicle results in pus production and appearance of pimples, and oxidation of sebum turns a whitehead into a blackhead.
Dermatitis	Any inflammation of the skin, typically marked by itching and redness; often <i>contact dermatitis</i> , caused by exposure to toxic foliage such as poison ivy.
Eczema (ECK-zeh-mah)	Itchy, red, “weeping” skin lesions caused by an allergy, usually beginning before age 5; may progress to thickened, leathery, darkly pigmented patches of skin.
Psoriasis (so-RY-ah-sis)	Recurring, reddened plaques covered with silvery scale; sometimes disfiguring; possibly caused by an autoimmune response; runs in families.
Rosacea (ro-ZAY-she-ah)	A red rashlike area, often in the area of the nose and cheeks, marked by fine networks of dilated blood vessels; worsened by hot drinks, alcohol, and spicy food.
Seborrheic (seb-oh-REE-ik) dermatitis	Recurring patches of scaly white or yellowish inflammation often on the head, face, chest, and back; called <i>cradle cap</i> (a yellow, crusty scalp lesion) in infants. Cause unknown, but correlated with genetic and climatic factors.
Tinea	Any fungal infection of the skin; common in moist areas such as the axilla, groin, and foot (<i>athlete’s foot</i>). Misnamed <i>ringworm</i> because of the circular, wormlike growth pattern sometimes exhibited.

INSIGHT 6.4 Clinical Application**UVA, UVB, and Sunscreens**

Photobiologists divide ultraviolet radiation into two wavelength ranges: UVA with wavelengths from 320 to 400 nm and UVB with wavelengths from 290 to 320 nm. (Visible light extends from about 400 nm, the deepest violet we can see, to about 700 nm, the deepest red.) UVA and UVB are sometimes called “tanning rays” and “burning rays,” respectively. Tanning salons often advertise that the UVA rays they use are safe, but public health authorities are more skeptical. UVA can burn as well as tan, and it inhibits the immune system, while both UVA and UVB are now thought to initiate skin cancer. As dermatologists say, there is no such thing as a healthy tan.

It was once assumed that sunscreens furnish protection against skin cancer, but more careful studies have cast doubt on this and made the issue increasingly puzzling and controversial. Sunburn and skin cancer are caused by different mechanisms, and sunscreen can protect against the former while providing no protection against the latter. Ironically, as the sale of sunscreen has risen in recent decades, so has the incidence of skin cancer—perhaps because people falsely assume that when they use sunscreen, they can safely stay in the sun longer. Sunscreen does provide some protection against squamous cell carcinoma, but apparently not against basal cell carcinoma or malignant melanoma. Indeed, people who use sunscreen have a higher incidence of basal cell carcinoma than people who do not. Some of the chemicals used in sunscreens damage DNA and generate harmful free radicals when exposed to UV—chemicals such as zinc oxide and titanium dioxide—but much is still unknown about how sunscreen reacts on and with the skin. Epidemiological data also are yet inconclusive; skin cancer is most prevalent in older people, and not enough data are available on older people who have used sunscreen their entire lives.

Given the uncertainty, it is best not to assume that merely because sunscreens protect you from sunburn, they also protect against skin cancer. Above all, one should not assume that using sunscreen makes it safe (with respect to cancer) to spend longer hours on the beach or tanning by the pool.

for 5 years. The greatest risk factor for malignant melanoma is a family history of the disease. It has a relatively high incidence in men, in redheads, and in people who experienced severe sunburns in childhood.

About two-thirds of cases of malignant melanoma in men result from an oncogene called *BRAF*. In women, *BRAF* does not appear to trigger malignant melanoma, but it has been linked to some breast and ovarian cancers. *BRAF* mutations are commonly found in moles. *BRAF* was recently discovered in the course of the new Cancer Genome Project, a multinational effort to identify cancer genes.

It is important to distinguish a mole from malignant melanoma. A mole usually has a uniform color and even contour, and it is no larger in diameter than the end of a pencil eraser (about 6 mm). If it becomes malignant, however, it forms a large, flat, spreading lesion with a scalloped

(a) Basal cell carcinoma

(b) Squamous cell carcinoma

(c) Malignant melanoma

FIGURE 6.12 Skin Cancer.

Which of the ABCD rules can you identify in part (c)?

border (fig. 6.12c). The American Cancer Society suggests an “ABCD rule” for recognizing malignant melanoma: *A* for asymmetry (one side of the lesion looks different from the other); *B* for border irregularity (the contour is not uniform but wavy or scalloped); *C* for color (often a mixture of

brown, black, tan, and sometimes red and blue); and *D* for diameter (greater than 6 mm).

Skin cancer is treated by surgical excision, radiation therapy, or destruction of the lesion by heat (electrodesiccation) or cold (cryosurgery).

Burns

Burns are the leading cause of accidental death. They are usually caused by fires, kitchen spills, or excessively hot bath water, but they also can be caused by sunlight, ionizing radiation, strong acids and bases, or electrical shock. Burn deaths result primarily from fluid loss, infection, and the toxic effects of **eschar** (ESS-car)—the burned, dead tissue.

Burns are classified according to the depth of tissue involvement (fig. 6.13). **First-degree burns** involve only the epidermis and are marked by redness, slight edema, and pain. They heal in a few days and seldom leave scars. Most sunburns are first-degree burns.

Second-degree burns involve the epidermis and part of the dermis but leave at least some of the dermis intact. First- and second-degree burns are therefore also known as **partial-thickness burns**. A second-degree burn may be red, tan, or white and is blistered and very painful. It may take from 2 weeks to several months to heal and may leave scars. The epidermis regenerates by division of epithelial cells in the hair follicles and sweat glands and around the edges of the lesion. Some sunburns and many scalds are second-degree burns.

Third-degree burns are also called **full-thickness burns** because the epidermis, all of the dermis, and often some deeper tissues (muscle and bone) are destroyed. Since no dermis remains, the skin can regenerate only from the edges of the wound. Third-degree burns often require skin grafts (see Insight 6.5). If a third-degree burn is left to itself to heal, contracture (abnormal connective tissue fibrosis) and severe disfigurement may result.

FIGURE 6.13 Burns. (a) First-degree burn, involving only the epidermis. (b) Second-degree burn, involving the epidermis and part of the dermis. (c) Third-degree burn, extending through the entire dermis and often involving even deeper tissue.

Think About It

A third-degree burn may be surrounded by painful areas of first- and second-degree burns, but the region of the third-degree burn is painless. Explain the reason for this lack of pain.

The two most urgent considerations in treating a burn patient are fluid replacement and infection control. A patient can lose several liters of water, electrolytes, and protein each day from the burned area. As fluid is lost from the tissues, more is transferred from the bloodstream to replace it, and the volume of circulating blood declines. A patient may lose up to 75% of the blood plasma within a few hours, potentially leading to circulatory shock and cardiac arrest—the principal cause of death in burn patients. Intravenous fluid must be given to make up for this loss. A severely burned patient may also require thousands of extra calories daily to compensate for protein loss and the demands of tissue repair. Supplemental nutrients are given intravenously or via gastric tube.

INSIGHT 6.5 Clinical Application**Skin Grafts and Artificial Skin**

Third-degree burns leave no dermal tissue to regenerate what was lost, and therefore they generally require skin grafts. The ideal graft is an *autograft*⁴¹—tissue taken from another location on the same person's body—because it is not rejected by the immune system. An autograft is performed by taking epidermis and part of the dermis from an undamaged area such as the thigh or buttock and grafting it to a burned area. This method is called a *split-skin* graft because part of the dermis is left behind to proliferate and replace the epidermis that was removed—the same way a second-degree burn heals.

An autograft may not be possible, however, if the burns are too extensive. The best treatment option in this case is an *isograft*,⁴² which uses skin from an identical twin. Because the donor and recipient are genetically identical, the recipient's immune system is unlikely to reject the graft. Since identical twins are rare, however, the best one can hope for in most cases is donor skin from another close relative.

An *allograft*,⁴³ or *homograft*,⁴⁴ is a graft from any other person. Skin banks provide skin from deceased persons for this purpose. The immune system attempts to reject allografts, but they suffice as temporary coverings for the burned area. They can be replaced by autografts when the patient is well enough for healthy skin to be removed from an undamaged area of the body.

Pig skin is sometimes used on burn patients but presents the same problem of immune rejection. A graft of tissue from a different species is called a *heterograft*,⁴⁵ or *xenograft*.⁴⁶ This is a special case of a *heterotransplant*, which also includes transplantation of

infection is controlled by keeping the patient in an aseptic (germ-free) environment and administering antibiotics. The eschar is sterile for the first 24 hours, but then it quickly becomes infected and may have toxic effects on the digestive, respiratory, and other systems. Its removal, called **debridement**⁴⁷ (deh-BREED-ment), is essential to infection control.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

15. What types of cells are involved in each type of skin cancer?
16. Which type of skin cancer is most dangerous? What are its early warning signs?
17. What are the differences between first-, second-, and third-degree burns?
18. What are the two most urgent priorities in treating a burn victim? How are these needs addressed?

organs such as baboon hearts or livers into humans. Heterografts and heterotransplants are short-term methods of maintaining a patient until a better, long-term solution is possible. The immune reaction can be suppressed by drugs called *immunosuppressants*. This procedure is risky, however, because it lowers a person's resistance to infection, which is already compromised in a burn patient.

Some alternatives to skin grafts are also being used. Burns are sometimes temporarily covered with amnion (the membrane that surrounds a developing fetus) obtained from afterbirths. In addition, tiny keratinocyte patches cultured with growth stimulants have produced sheets of epidermal tissue as large as the entire body surface. These can replace large areas of burned tissue. Dermal fibroblasts also have been successfully cultured and used for autografts. A drawback to these approaches is that the culture process requires 3 or 4 weeks, which is too long a wait for some patients with severe burns.

Various kinds of artificial skin have also been developed as a temporary burn covering. One concept is a sheet with an upper layer of silicone and a lower layer of collagen and chondroitin sulfate. It stimulates growth of connective tissue and blood vessels from the patient's underlying tissue. The artificial skin can be removed after about 3 weeks and replaced with a thin layer of cultured or grafted epidermis. At least two bioengineering companies produce artificial skins for patient use. The manufacture of one such product begins by culturing fibroblasts on a collagen gel to produce a dermis, then culturing keratinocytes on this dermal substrate to produce an epidermis. Such products are used to treat burn patients as well as leg and foot ulcers that result from diabetes mellitus. This is one aspect of the larger field of *tissue engineering*, which biotechnology companies hope will lead, within a few decades, even to engineering replacement livers and other organs (see Insight 5.3, p. 182).

⁴¹ *auto* = self

Vitamin D promotes intestinal absorption of calcium →

Provides nutrients; nutritional disorders often cause pathological changes in integumentary system →

REPRODUCTIVE SYSTEM

Cutaneous receptors respond to erotic stimuli; mammary glands produce milk to nourish infants; apocrine glands produce pheromones with subtle sexual functions →

Gonadal sex hormones promote growth, maturation, and maintenance of skin →

CHAPTER REVIEW

Review of Key Concepts

6.1 The Skin and Subcutaneous Tissue (p. 188)

- Dermatology* is the study of the *integumentary system*, a system that includes the skin (*integument*), hair, nails, and cutaneous glands.
- The skin is composed of a superficial *epidermis* of keratinized stratified squamous epithelium, and a deeper *dermis* of fibrous connective tissue. Beneath the skin is a connective tissue *hypodermis*.
- Skin ranges from less than 0.5 mm to as much as 6 mm thick. *Thick skin* is named for a thick, heavily keratinized epidermis, not necessarily for total thickness; it is found on the palms, soles, and corresponding surfaces of the digits, and it is hairless. The rest of the body is covered with *thin skin*, in which the epidermis is more lightly keratinized.
- Functions of the skin include resistance to trauma and infection, water retention, vitamin D synthesis, sensation, thermoregulation, and nonverbal communication.
- The epidermis has five types of cells: *stem cells*, *keratinocytes*, *melanocytes*, *tactile cells*, and *dendritic cells*.
- Layers of the epidermis from deep to superficial are the *stratum basale*, *stratum spinosum*, *stratum granulosum*, *stratum lucidum* (in thick skin only), and *stratum corneum*.
- Keratinocytes are the majority of epidermal cells. They originate by mitosis of stem cells in the stratum basale and push the older keratinocytes upward. Keratinocytes flatten and produce *membrane-coating vesicles* and keratin filaments as they migrate upward. In the stratum granulosum, the keratin filaments are bound into coarser bundles by the protein *filaggrin*; the membrane-coating vesicles release lipids that help to render the cells water-resistant; and the cells die. Above the stratum granulosum, dead keratinocytes become compacted into the stratum corneum. Thirty to 40 days after its mitotic

birth, the average keratinocyte flakes off the epidermal surface. This loss of the dead cells is called *exfoliation*.

- The dermis is 0.2 to 4 mm thick. It is composed mainly of collagen but also includes elastic and reticular fibers, fibroblasts, and other cell types. It contains blood vessels, sweat glands, sebaceous glands, nerve endings, hair follicles, nail roots, smooth muscle, and in the face, skeletal muscle.
- In most places, upward projections of the dermis called *dermal papillae* interdigitate with downward *epidermal ridges* to form a wavy boundary. The papillae form the friction ridges of the fingertips and irregular ridges, separated by furrows, elsewhere.
- The dermis is composed of a superficial *papillary layer*, which is composed of areolar tissue and forms the dermal papillae; and a thicker, deeper *reticular layer* composed of dense irregular connective tissue. The reticular layer provides toughness to the dermis, and the papillary layer forms an arena for the mobilization of defenses against pathogens that breach the epidermis.
- The *hypodermis* (subcutaneous tissue) is composed of more areolar and adipose tissue than the reticular layer of dermis. It pads the body and binds the skin to underlying muscle or other tissues. In areas composed mainly of adipocytes, it is called *subcutaneous fat*.
- Normal skin colors result from various proportions of *eumelanin*, *pheomelanin*, the hemoglobin of the blood, and the white collagen of the dermis, and dietary *carotene*. Pathological conditions with abnormal skin coloration include *cyanosis*, *erythema*, *pallor*, *albinism*, *jaundice*, and *hematomas*.
- Skin markings include *friction ridges* of the fingertips (the source of oily fingerprints); *flexion lines* of the palm, wrist, and other places; *freckles* and *moles*; and *hemangiomas* (birthmarks).

6.2 Hair and Nails (p. 197)

- Hair and nails are composed of compact, highly cross-linked *hard keratin*.
- A hair (*pilus*) is a slender filament of keratinized cells growing from an oblique *hair follicle*.
- The three types of hair are *lanugo*, present only prenatally; *vellus*, a fine pale body hair; and the coarser, pigmented *terminal hair* of the eyebrows, scalp, beard, and other areas.
- Deep in the follicle, a hair begins with a dilated *bulb*, continues as a narrower *root* below the skin surface, and extends above the skin as the *shaft*. The bulb contains a *dermal papilla* of vascular connective tissue. The *hair matrix* just above the papilla is the site of hair growth by mitosis. In cross section, a hair exhibits a thin outer *cuticle*, a thicker layer of keratinized cells forming the hair *cortex*, and sometimes a core called the *medulla*.
- A hair follicle consists of an inner *epithelial root sheath* (an extension of the epidermis) and an outer *connective tissue root sheath*. It is supplied by nerve endings called *hair receptors* that detect hair movements, and a bundle of smooth muscle called the *piloerector muscle*, which erects the hair.
- Differences in hair texture are attributable to differences in cross-sectional shape—straight hair is round, wavy hair is oval, and tightly curly hair is relatively flat.
- Variations in hair color arise from the relative amounts of eumelanin and pheomelanin.
- A hair has a life cycle consisting of a growing *anagen* stage, a shrinking *catagen* stage, and a resting *telogen* stage. Hairs usually fall out during the catagen or telogen stage. A scalp hair typically lives 6 to 8 years and grows about 10 to 18 cm/yr.
- Thinning of hair is called *alopecia*. Loss of hair from specific regions of the scalp is called *pattern baldness*, and is a hereditary sex-influenced condition. Excessive hairiness is called *hirsutism*.

- The functions of hair include thermal insulation, protection from the sun and foreign objects, sensation, facial expression, signaling sexual maturity, and regulating the dispersal of pheromones.
- Fingernails and toenails are hard plates of densely packed, dead, keratinized cells. They arise from a growth zone called the *nail matrix*.

6.3 Cutaneous Glands (p. 202)

- The most abundant and widespread sweat glands are *merocrine sweat glands*, which produce a watery secretion that cools the body. Merocrine glands release their product by exocytosis.
- Apocrine sweat glands* are associated with hair follicles in the pubic and anal regions, axilla, areola, and beard. They develop at puberty along with

- the appearance of hair in these regions, and apparently function to secrete sex pheromones. Apocrine sweat glands also release their secretion by exocytosis.
- Sebaceous glands*, also usually associated with hair follicles, produce an oily secretion called *sebum*, which keeps the skin and hair pliable. These are holocrine glands; their cells break down in entirety to form the secretion.
 - Ceruminous glands* are found in the auditory canal. *Cerumen*, or earwax, is a mixture of ceruminous gland secretion, sebum, and dead epidermal cells. It keeps the eardrum pliable, waterproofs the auditory canal, and kills bacteria.
 - Mammary glands* are modified apocrine sweat glands that develop in

the breasts during pregnancy and lactation, and produce milk.

6.4 Skin Disorders (p. 204)

- The three forms of skin cancer are defined by the types of cells in which they originate: *basal cell carcinoma* (the most common but least dangerous form), *squamous cell carcinoma*, and *malignant melanoma* (the least common but most dangerous form).
- Burns can be *first-degree* (epidermal damage only, as in a mild sunburn); *second-degree* (some dermal damage, as in a scald); or *third-degree* (complete penetration of the dermis, as in burns from fire).
- People with serious burns must be treated first to restore fluid balance and second to control infection.

Testing Your Recall

- Cells of the _____ are keratinized and dead.
 - papillary layer
 - stratum spinosum
 - stratum basale
 - stratum corneum
 - stratum granulosum
- The epidermal water barrier is formed at the point where epidermal cells
 - pass from stratum basale to stratum spinosum.
 - enter the telogen phase.
 - pass from stratum spinosum to stratum granulosum.
 - form the epidermal ridges.
 - exfoliate.
- Which of the following skin conditions or appearances would most likely result from liver failure?
 - pallor
 - erythema
 - seborrheic dermatitis
 - jaundice
 - melanization
- All of the following interfere with microbial invasion of the body *except*
 - the acid mantle.
 - melanization.
 - dendritic cells.
 - keratinization.
 - sebum.
- The hair on a 6-year-old's arms is
 - vellus.
 - lanugo.
 - alopecia.
 - terminal hair.
 - rosacea.
- Which of the following terms is *least* related to the rest?
 - lunule
 - nail plate
 - hyponychium
 - free edge
 - cortex
- Which of the following is a scent gland?
 - eccrine gland
 - sebaceous gland
 - apocrine gland
 - ceruminous gland
 - merocrine gland
- _____ are skin cells with a sensory role.
 - Tactile cells
 - Dendritic cells
 - Stem cells
 - Melanocytes
 - Keratinocytes
- Which of the following glands produce the acid mantle?
 - merocrine sweat glands
 - apocrine sweat glands
 - mammary glands
 - ceruminous glands
 - sebaceous glands
- Which of the following skin cells alert the immune system to pathogens?
 - fibroblasts
 - melanocytes
 - keratinocytes
 - dendritic cells
 - tactile cells
- _____ is sweating without noticeable wetness of the skin.
- A muscle that causes a hair to stand on end is called a/an _____.
- The process of removing burned skin from a patient is called _____.
- Blueness of the skin due to low oxygen concentration in the blood is called _____.
- Projections of the dermis toward the epidermis are called _____.
- Cerumen is more commonly known as _____.
- The holocrine glands that secrete into a hair follicle are called _____.
- Hairs grow only during the _____ phase of the hair cycle.
- A hair is nourished by blood vessels in a connective tissue projection called the _____.
- A _____ burn destroys the entire dermis.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Dander consists of dead keratinocytes.
- The term *integument* means only the skin, but *integumentary system* includes the skin, hair, nails, and cutaneous glands.
- The dermis is composed mainly of keratin.
- Vitamin D synthesis begins in certain cutaneous glands.
- Cells of the stratum granulosum cannot undergo mitosis.
- Dermal papillae are better developed in skin subjected to a lot of mechanical stress than in skin subjected to less stress.
- The three layers of the skin are the epidermis, dermis, and hypodermis.
- People of African descent have a much higher density of epidermal melanocytes than do people of northern European descent.
- Pallor indicates a genetic lack of melanin.
- Apocrine sweat glands develop at the same time in life as the pubic and axillary hair.

Answers in appendix B

Testing Your Comprehension

- Many organs of the body contain numerous smaller organs, perhaps even thousands. Describe an example of this in the integumentary system.
- Certain aspects of human form and function are easier to understand when viewed from the perspective of comparative anatomy and evolution. Discuss examples of this in the integumentary system.
- Explain how the complementarity of form and function is reflected in the fact that the dermis has two histological layers and not just one.
- Cold weather does not normally interfere with oxygen uptake by the blood, but it can cause cyanosis anyway. Why?
- Why is it important for the epidermis to be effective, but not *too* effective, in screening out UV radiation?

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Histology of hyaline cartilage (p. 167)
- Introduction to bone histology (p. 168)
- Stem cells (p. 179)

In art and history, nothing has so often symbolized death as a skull or skeleton.¹ Bones and teeth are the most durable remains of a once-living body and the most vivid reminder of the impermanence of life.

The dry bones presented for laboratory study may wrongly suggest that the skeleton is a nonliving scaffold for the body, like the steel girders of a building. Seeing it in such a sanitized form makes it easy to forget that the living skeleton is made of dynamic tissues, full of cells—that it continually remodels itself and interacts physiologically with all of the other organ systems of the body. The skeleton is permeated with nerves and blood vessels, which attests to its sensitivity and metabolic activity.

Osteology,² the study of bone, is the subject of these next three chapters. In this chapter, we study bone as a tissue—its composition, its functions, how it develops and grows, how its metabolism is regulated, and some of its disorders. This will provide a basis for understanding the skeleton, joints, and muscles in the chapters that follow.

7.1 Tissues and Organs of the Skeletal System

Objectives

When you have completed this section, you should be able to

- name the tissues and organs that compose the skeletal system;
- state several functions of the skeletal system;
- distinguish between bone as a tissue and as an organ;
- describe four types of bones classified by shape; and
- describe the general features of a long bone and a flat bone.

The **skeletal system** is composed of bones, cartilages, and ligaments joined tightly to form a strong, flexible framework for the body. Cartilage, the forerunner of most bones in embryonic and childhood development, covers many joint surfaces in the mature skeleton. Ligaments hold bones together at the joints and are discussed in chapter 9. Tendons are structurally similar to ligaments but attach muscle to bone; they are discussed with the muscular system in chapter 10.

Functions of the Skeleton

The skeleton plays at least six roles:

1. **Support.** Bones of the lower limbs, pelvis, and vertebral column hold up the body; nearly all bones provide support for the muscles; the mandible and maxilla support the teeth.
2. **Protection.** Bones enclose and protect the brain, spinal cord, heart, lungs, pelvic viscera, and bone marrow.
3. **Movement.** Limb movements, breathing, and other movements are produced by the action of muscles on the bones.
4. **Electrolyte balance.** The skeleton stores calcium and phosphate ions and releases them into the tissue fluid and blood according to the body's physiological needs.
5. **Acid–base balance.** Bone tissue buffers the blood against excessive pH changes by absorbing or releasing alkaline salts such as calcium phosphate.
6. **Blood formation.** Red bone marrow is the major producer of blood cells, including cells of the immune system.

Bones and Osseous Tissue

Bone, or **osseous**³ **tissue**, is a connective tissue in which the matrix is hardened by the deposition of calcium phosphate and other minerals. The hardening process is called **mineralization** or **calcification**. (Bone is not the hardest substance in the body; that distinction goes to tooth enamel.) Osseous tissue is only one of the tissues that make up a bone. Also present are blood, bone marrow, cartilage, adipose tissue, nervous tissue, and fibrous connective tissue. The word *bone* can denote an organ composed of all these tissues, or it can denote just the osseous tissue.

The Shapes of Bones

Bones are classified into four groups according to their shapes and corresponding functions (fig. 7.1):

1. **Long bones** are conspicuously longer than wide. Like crowbars, they serve as rigid levers that are acted upon by the skeletal muscles to produce body movements. Long bones include the humerus of the arm, the radius and ulna of the forearm, the metacarpals and phalanges of the hand, the femur of the thigh, the tibia and fibula of the leg, and the metatarsals and phalanges of the feet.
2. **Short bones** are nearly equal in length and width. They include the carpal (wrist) and tarsal (ankle) bones. They have limited motion and merely glide across one another, enabling the ankles and wrists to bend in multiple directions.

¹*skelet* = dried up

²*osteo* = bone + *logy* = study of

³*os, osse, oste* = bone

FIGURE 7.1 Classification of Bones by Shape. The light blue areas are articular cartilages.

3. **Flat bones** enclose and protect soft organs and provide broad surfaces for muscle attachment. They include most cranial bones and the ribs, sternum (breastbone), scapula (shoulder blade), and hip bones. Most of them are not truly flat, but conspicuously

FIGURE 7.2 Anatomy of a Long Bone. (a) The femur, with its soft tissues including bone marrow, articular cartilage, blood vessels, and periosteum. (b) A dried femur in longitudinal section.

What is the functional significance of a long bone being wider at the epiphyses than at the diaphysis?

curved. However, they all have a relatively broad, thin, sandwichlike structure, as described later.

4. **Irregular bones** have elaborate shapes that do not fit into any of the preceding categories. They include the vertebrae and some skull bones, such as the sphenoid and ethmoid.

General Features of Bones

Figure 7.2 shows a typical long bone. Much of it is composed of an outer shell of dense white osseous tissue called **compact (dense) bone**. The cylinder encloses a

space called the **medullary** (MED-you-lerr-ee) **cavity**, or **marrow cavity**, which contains bone marrow. At the ends of the bone, the central space is occupied by a more loosely organized form of osseous tissue called **spongy (cancellous) bone**. The skeleton is about three-quarters compact bone and one-quarter spongy bone by weight. Spongy bone is found at the ends of the long bones and in the middle of nearly all others. It is always enclosed by more durable compact bone.

The principal features of a long bone are its shaft, called the **diaphysis**⁴ (dy-AF-ih-sis), and an expanded head at each end called the **epiphysis**⁵ (eh-PIF-ih-sis). The diaphysis provides leverage, and the epiphysis is enlarged to strengthen the joint and provide added surface area for the attachment of tendons and ligaments. The joint surface where one bone meets another is covered with a layer of hyaline cartilage called the **articular cartilage**. Together with a lubricating fluid secreted between the bones, this cartilage enables a joint to move far more easily than it would if one bone rubbed directly against the other. Blood vessels penetrate into the bone through minute holes called **nutrient foramina** (for-AM-ih-nuh); we will trace where they go when we consider the histology of bone.

Externally, a bone is covered with a sheath called the **periosteum**.⁶ This has a tough, outer *fibrous layer* of collagen and an inner *osteogenic layer* of bone-forming cells described later in the chapter. Some collagen fibers of the outer layer are continuous with the tendons that bind muscle to bone, and some penetrate into the bone matrix as **perforating (Sharpey)⁷ fibers**. The periosteum thus provides strong attachment and continuity from muscle to tendon to bone. The osteogenic layer is important to the growth of bone and healing of fractures. There is no periosteum over the articular cartilage.

The internal surface of a bone is lined with **endosteum**,⁸ a thin layer of reticular connective tissue with cells that dissolve osseous tissue and others that deposit it.

In children and adolescents, an **epiphyseal** (EP-ih-FIZZ-ee-ul) **plate** of hyaline cartilage separates the marrow spaces of the epiphysis and diaphysis (fig. 7.2a). On X-rays, it appears as a transparent line at the end of a long bone (see fig. 7.12). The epiphyseal plate is a zone where the bones grow in length. In adults, the epiphyseal plate is depleted and the bones can grow no longer, but an *epiphyseal line* marks where the plate used to be.

FIGURE 7.3 Anatomy of a Flat Bone.

Figure 7.3 shows a flat bone of the cranium. It has a sandwichlike construction with two layers of compact bone enclosing a middle layer of spongy bone. The spongy layer in the cranium is called **diploe**⁹ (DIP-lo-ee). A moderate blow to the skull can fracture the outer layer of compact bone, but the diploe may absorb the impact and leave the inner layer of compact bone unharmed. Both surfaces of a flat bone are covered with periosteum, and the marrow spaces amid the spongy bone are lined with endosteum.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Name at least five tissues found in a bone.
2. List three or more functions of the skeletal system other than supporting the body and protecting some of the internal organs.
3. Name the four bone shapes and give an example of each.
4. Explain the difference between compact and spongy bone, and describe their spatial relationship to each other.
5. State the anatomical terms for the shaft, head, growth zone, and fibrous covering of a long bone.

⁴*dia* = across + *physis* = growth; originally named for a ridge on the shaft of the tibia

⁵*epi* = upon, above + *physis* = growth

⁶*peri* = around + *oste* = bone

⁷William Sharpey (1802–80), Scottish histologist

⁸*endo* = within + *oste* = bone

⁹*diplo* = double

7.2 Histology of Osseous Tissue

Objectives

When you have completed this section, you should be able to

- list and describe the cells, fibers, and ground substance of bone tissue;
- state the importance of each constituent of bone tissue;
- compare the histology of the two types of bone tissue; and
- distinguish between the two types of bone marrow.

Bone Cells

Like any other connective tissue, bone consists of cells, fibers, and ground substance. There are four principal types of bone cells (fig. 7.4):

1. **Osteogenic¹⁰ (osteoprogenitor) cells** are stem cells that develop from embryonic mesenchymal cells

(see p. 153) and then give rise to most other bone cell types. They are found in the endosteum, the inner layer of the periosteum, and in the central canals. They multiply continually, and some go on to become the *osteoblasts* described next.

2. **Osteoblasts¹¹** are bone-forming cells. They are roughly cuboidal or angular, and line up in a single layer on the bone surface under the endosteum and periosteum and resemble a cuboidal epithelium (see fig. 7.9). Osteoblasts are nonmitotic, so the mitosis and differentiation of osteogenic cells is the only way new osteoblasts can be generated. They synthesize the soft organic matter of the bone matrix, which then hardens by mineral deposition. Stress and fractures stimulate osteogenic cells to multiply more rapidly and quickly generate increased numbers of osteoblasts, which reinforce or rebuild the bone. In 2007, it was discovered that osteoblasts also have a hormonal function. They secrete *osteocalcin*, previously thought to be only a structural protein of bone. Osteocalcin has now been shown to stimulate insulin secretion by the pancreas, increase insulin sensitivity in adipocytes, and limit the growth of adipose tissue.

¹⁰oste = bone + genic = producing

¹¹oste = bone + blast = form, produce

FIGURE 7.4 Bone Cells and Their Development. (a) Osteogenic cells give rise to osteoblasts, which deposit matrix around themselves and transform into osteocytes. (b) Bone marrow stem cells fuse to form osteoclasts.

3. **Osteocytes** are former osteoblasts that have become trapped in the matrix they deposited. They reside in tiny cavities called **lacunae**,¹² which are interconnected by slender channels called **canaliculi**¹³ (CAN-uh-LIC-you-lye). Each osteocyte has delicate fingerlike cytoplasmic processes that reach into the canaliculi to contact the processes from neighboring osteocytes. Some of them also contact osteoblasts on the bone surface. Neighboring osteocytes are connected by gap junctions where their processes meet, so they can pass nutrients and chemical signals to one another and pass their metabolic wastes to the nearest blood vessel for disposal.
- Osteocytes have multiple functions. Some resorb bone matrix and others deposit it, so they contribute to the homeostatic maintenance of both bone density and blood concentrations of calcium and phosphate ions. Perhaps even more importantly, they are strain sensors. When a load is applied to a bone, it produces a flow in the extracellular fluid of the lacunae and canaliculi. This stimulates the osteocytes to secrete biochemical signals that may regulate bone remodeling—adjustments in bone shape and density to adapt to stress.
4. **Osteoclasts**¹⁴ are bone-dissolving cells found on the bone surface. They develop from the same bone marrow stem cells that give rise to the blood cells. Thus, osteogenic cells, osteoblasts, and osteocytes all belong to one cell lineage (fig. 7.4a), but osteoclasts have an independent origin (fig. 7.4b). Each osteoclast is formed by the fusion of several stem cells, so osteoclasts are unusually large cells (up to 150 μm in diameter, visible to the naked eye). They typically have 3 or 4 nuclei, but sometimes up to 50, each contributed by one stem cell. The side of the osteoclast facing the bone surface has a *ruffled border* with many deep infoldings of the plasma membrane. These increase the cell surface area and thus enhance the efficiency of bone resorption. Osteoclasts often reside in pits called *resorption bays* (*Howship*¹⁵ *lacunae*) that they have etched into the bone surface. Bone remodeling results from the combined action of these bone-dissolving osteoclasts and bone-depositing osteoblasts.

The Matrix

The matrix of osseous tissue is, by dry weight, about one-third organic and two-thirds inorganic matter. The organic

matter, synthesized by the osteoblasts, includes collagen and various protein-carbohydrate complexes such as glycosaminoglycans, proteoglycans, and glycoproteins. The inorganic matter is about 85% **hydroxyapatite**, a crystallized calcium phosphate salt $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$, 10% calcium carbonate (CaCO_3), and lesser amounts of magnesium, sodium, potassium, fluoride, sulfate, carbonate, and hydroxide ions. Several foreign elements behave chemically like bone minerals and become incorporated into osseous tissue as contaminants, sometimes with deadly results (see Insight 7.1).

Bone is in a class of materials that engineers call a **composite**—a combination of two basic structural materials, in this case a ceramic and a polymer. A composite can combine the optimal mechanical properties of each component. Consider a fiberglass fishing rod, for example, made of a ceramic (glass fibers) embedded in a polymer (resin). The resin alone would be too brittle and the fibers alone too flexible and limp to serve the purpose of a fishing rod, but together they produce a material of great strength and flexibility.

In bone, the polymer is the collagen and the ceramic is the hydroxyapatite and other minerals. The ceramic component enables a bone to support the weight of the

INSIGHT 7.1 Medical History

Bone Contamination

When Marie and Pierre Curie and Henri Becquerel received their 1903 Nobel Prize for the discovery of radioactivity (see Insight 2.1, p. 55), radiation captured the public imagination. Not for several decades did anyone realize its dangers. For example, factories employed women to paint luminous numbers on watch and clock dials with radium paint. The women moistened their paint brushes with their tongues to keep them finely pointed and ingested radium in the process. The radium accumulated in their bones and caused many of them to develop a form of bone cancer called osteosarcoma.

Even more horrific, in the wisdom of hindsight, was a deadly health fad in which people drank “tonics” made of radium-enriched water. One famous enthusiast was the millionaire playboy and championship golfer Eben Byers (1880–1932), who drank several bottles of radium tonic each day and praised its virtues as a wonder drug and aphrodisiac. Like the factory women, Byers contracted osteosarcoma. By the time of his death, holes had formed in his skull and doctors had removed his entire upper jaw and most of his mandible in an effort to halt the spreading cancer. Byers’ bones and teeth were so radioactive they could expose photographic film in the dark. Brain damage left him unable to speak, but he remained mentally alert to the bitter end. His tragic decline and death shocked the world and put an end to the radium tonic fad.

¹²lac = lake, hollow + una = little

¹³canal = canal, channel + icul = little

¹⁴osteo = bone + clast = destroy, break down

¹⁵J. Howship (1781–1841), English surgeon

body without sagging. When the bones are deficient in calcium salts, they are soft and bend easily. One way to demonstrate this is to soak a clean dried bone, such as a chicken bone, in vinegar for a few days. As the mild acid of the vinegar dissolves the minerals away, the bone becomes flexible and rubbery. Such mineral deficiency and flexibility are the central problems in the childhood disease, *rickets*, in which the soft bones of the lower limbs bend under the body's weight and become permanently deformed.

The protein component gives bone a degree of flexibility. Without protein, a bone is excessively brittle, as in *osteogenesis imperfecta*, or *brittle bone disease* (see table 7.3). Without collagen, a jogger's bones would shatter under the impact of running. But normally, when a bone bends slightly toward one side, the tensile strength of the collagen fibers on the opposite side holds the bone together and prevents it from snapping like a stick of chalk.

Unlike fiberglass, bone varies from place to place in its ratio of minerals to collagen. Osseous tissue is thus adapted to different amounts of tension and compression exerted on different parts of the skeleton.

Compact Bone

The histological study of compact bone usually uses slices that have been dried, cut with a saw, and ground to translucent thinness. This procedure destroys the cells but reveals fine details of the matrix (fig. 7.5). Such sections show onionlike **concentric lamellae**—layers of matrix concentrically arranged around a **central (haversian¹⁶ or osteonic) canal** and connected with each other by canaliculi. A central canal and its lamellae constitute an **osteon (haversian system)**—the basic structural unit of compact bone. In longitudinal views and three-dimensional reconstructions, we can see that an osteon is actually a cylinder of tissue surrounding a central canal. Along their length, central canals are joined by transverse or diagonal passages called **perforating (Volkmann¹⁷) canals**.

Collagen fibers “corkscrew” down the matrix of a given lamella in a helical arrangement like the threads of a screw. The helices coil in one direction in one lamella and in the opposite direction in the next lamella (fig. 7.5b). This enhances the strength of bone on the same principle as plywood, made of thin layers of wood with the grain running in different directions from one layer to the next. In areas where the bone must resist tension (bending), the helix is loosely coiled like the threads on a wood screw and the fibers are more stretched out on the longitudinal axis of the bone. In weight-bearing areas, where the bone

must resist compression, the helix is more tightly coiled like the closely spaced threads on a bolt, and the fibers are more nearly transverse.

The skeleton receives about half a liter of blood per minute. Blood vessels, along with nerves, enter the bone tissue through nutrient foramina on the surface. These foramina open into the perforating canals that cross the matrix and feed into the central canals. The innermost osteocytes around each central canal receive nutrients from these blood vessels and pass them along through their gap junctions to neighboring osteocytes. They also receive wastes from their neighbors and convey them to the central canal for removal by the bloodstream. Thus, the cytoplasmic processes of the osteocytes maintain a two-way flow of nutrients and wastes between the central canal and the outermost cells of the osteon.

Not all of the matrix is organized into osteons. The inner and outer boundaries of dense bone are arranged in *circumferential lamellae* that run parallel to the bone surface. Between osteons, we can find irregular regions called *interstitial lamellae*, the remains of old osteons that broke down as the bone grew and remodeled itself.

Spongy Bone

Spongy bone (fig. 7.5a) consists of a lattice of delicate slivers of bone called **spicules¹⁸** (rods or spines, as in the photo on p. 213) and **trabeculae¹⁹** (thin plates). Although calcified and hard, it is named for its spongelike appearance. It is permeated by spaces filled with bone marrow. The matrix is arranged in lamellae like those of compact bone, but there are few osteons. Central canals are not needed here because no osteocyte is very far from the marrow. Spongy bone is well designed to impart strength to a bone while adding a minimum of weight. Its trabeculae are not randomly arranged as they might seem at a glance, but develop along the bone's lines of stress (fig. 7.6).

Bone Marrow

Bone marrow is a general term for soft tissue that occupies the marrow cavity of a long bone, the spaces amid the trabeculae of spongy bone, and the larger central canals. There are two kinds of marrow—red and yellow. We can best appreciate their differences by considering how marrow changes over a person's lifetime.

In a child, the marrow cavity of nearly every bone is filled with **red bone marrow (myeloid tissue)**. This is often described as *hemopoietic²⁰* (HE-mo-poy-ET-ic) *tissue*—tissue that produces blood cells—but it is actually

Lamellae of one osteon are telescoped to show their alternating arrangement of collagen fibers. (c) Microscopic appearance of decalcified spongy bone. (d) Microscopic appearance of a cross section of an osteon of dried compact bone.

Which type of bone, spongy or compact, has more surface area exposed to osteoclast action?

FIGURE 7.6 Spongy Bone Structure in Relation to Mechanical Stress. In this frontal section of the femur (thighbone), the trabeculae of spongy bone can be seen oriented along lines of mechanical stress applied by the weight of the body.

composed of multiple tissues in a delicate but intricate arrangement, and is properly considered an organ unto itself. Its structure is described in more detail in chapter 21 (see fig. 21.9, p. 823).

In adults, most of the red marrow turns to fatty **yellow bone marrow**, like the fat at the center of a ham bone. Yellow bone marrow no longer produces blood, although in the event of severe or chronic anemia, it can transform back into red marrow. In adults, red marrow is limited to the skull, vertebrae, ribs, sternum, part of the pelvic (hip) girdle, and the proximal heads of the humerus and femur (fig. 7.7).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Suppose you had unlabeled electron micrographs of the four kinds of bone cells and their neighboring tissues. Name the four cells and explain how you could visually distinguish each one from the other three.
- Name three organic components of the bone matrix.
- What are the mineral crystals of bone called, and what are they made of?
- Sketch a cross section of an osteon and label its major parts.
- What are the two kinds of bone marrow? What does hemopoietic tissue mean? Which type of bone marrow fits this description?

FIGURE 7.7 Distribution of Red and Yellow Bone Marrow. In an adult, red bone marrow occupies the marrow cavities of the axial skeleton and proximal heads of the humerus and femur. Yellow bone marrow occurs in the long bones of the limbs.

• What would be the most accessible places to draw red bone marrow from an adult?

7.3 Bone Development

Objectives

When you have completed this section, you should be able to

- describe two mechanisms of bone formation; and
- explain how mature bone continues to grow and remodel itself.

The formation of bone is called **ossification** (OSS-ih-fih-CAY-shun) or **osteogenesis**. In the human fetus and infant, bone develops by two methods called *intramembranous* and *endochondral* ossification, examined in the following sections.

FIGURE 7.8 Stages of Intramembranous Ossification. Developing cranial bones of the human fetus. Note the layers of osteoid tissue, osteoblasts, and fibrous periosteum on both sides of the bone.

With the aid of chapter 8, name at least two specific bones other than the clavicle that would form by this process.

Intramembranous Ossification

Intramembranous²¹ (IN-tra-MEM-bra-nus) **ossification** produces the flat bones of the skull and most of the clavicle (collarbone). Such bones develop within a fibrous sheet similar to the dermis of the skin, so they are sometimes called *dermal bones*. Figure 7.8 shows the stages of the process.

- Some of the embryonic connective tissue (mesenchyme) condenses into a layer of soft tissue with a dense supply of blood capillaries. The mesenchymal cells enlarge and differentiate into osteogenic cells, and regions of mesenchyme become a network of soft sheets called trabeculae.
- Osteogenic cells gather on these trabeculae and differentiate into osteoblasts. These cells deposit an organic matrix called **osteoid**²² **tissue**—soft collagenous tissue similar to bone except for a lack of minerals (fig. 7.9). As the trabeculae grow thicker, calcium phosphate is deposited in the matrix. Some osteoblasts become trapped in the matrix and are now osteocytes. Mesenchyme close to the surface of

a trabecula remains uncalcified, but becomes denser and more fibrous, forming a periosteum.

- Osteoblasts continue to deposit minerals, producing a honeycomb of bony trabeculae. Some trabeculae persist as permanent spongy bone, while osteoclasts resorb and remodel others to form a marrow cavity in the middle of the bone.
- Trabeculae at the surface continue to calcify until the spaces between them are filled in, converting the spongy bone to compact bone. This process gives rise to the sandwichlike arrangement typical of mature flat bones.

Endochondral Ossification

Endochondral²³ (EN-doe-CON-drul) **ossification** is a process in which a bone develops from a preexisting model composed of hyaline cartilage. It begins around the sixth week of fetal development and continues into a person's 20s. Most bones of the body, including the vertebrae, ribs, sternum, scapula, pelvis, and bones of the limbs, develop in this way. Figure 7.10 shows the following steps in

²¹intra = within + membran = membrane

²²oste = bone + oid = like, resembling

²³endo = within + chondr = cartilage

FIGURE 7.9 Intramembranous Ossification of a Cranial Bone of the Human Fetus. Note the layers of osteoid tissue, osteoblasts, and fibrous periosteum on both sides of the bone.

endochondral ossification, using the example of a *metacarpal bone* in the palmar region of the hand.

- 1 Mesenchyme develops into a body of hyaline cartilage, covered with a fibrous perichondrium, in the location of a future bone. For a time, the perichondrium produces chondrocytes and the cartilage model grows in thickness.

- 2 Eventually, the perichondrium stops producing chondrocytes and begins producing osteoblasts. These deposit a thin collar of bone around the middle of the cartilage model, encircling it like a napkin ring and providing physical reinforcement. The former perichondrium is now considered to be a periosteum. Meanwhile, chondrocytes in the middle of the model enlarge and the matrix between their lacunae is reduced to thin walls. This region of chondrocyte enlargement is called the **primary ossification center**. The walls of matrix between the lacunae calcify and block nutrients from reaching the chondrocytes. The cells die and their lacunae merge into a single cavity in the middle of the model.
- 3 Blood vessels penetrate the bony collar and invade the primary ossification center. As the center of the model is hollowed out and filled with blood and stem cells, it becomes the **primary marrow cavity**. Various stem cells introduced with the blood give rise to osteoblasts and osteoclasts. Osteoblasts line the cavity, begin depositing osteoid tissue, and calcify it to form a temporary network of bony trabeculae. As the bony collar under the periosteum thickens and elongates, a wave of cartilage death progresses toward the ends of the bone. Osteoclasts

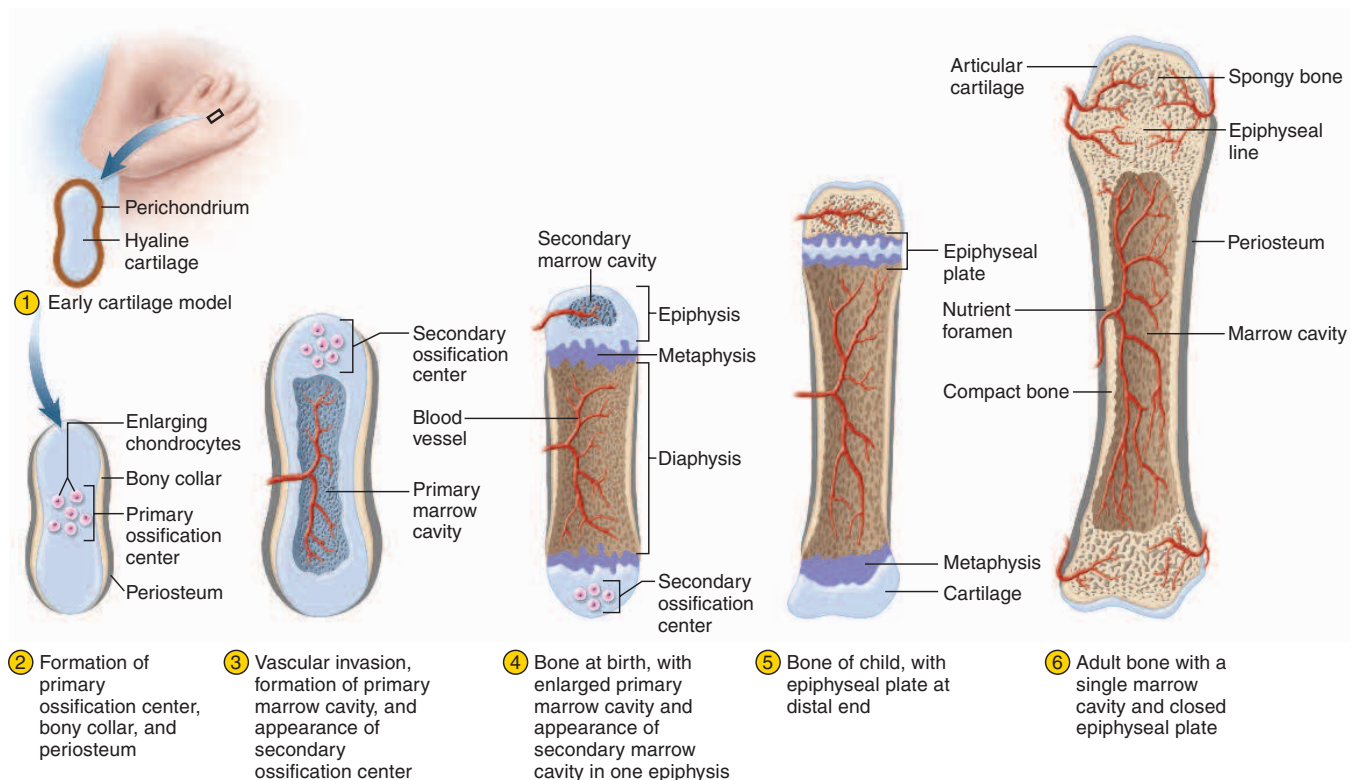

FIGURE 7.10 Stages of Endochondral Ossification. A metacarpal bone of the hand.

With the aid of chapter 8, name at least two specific bones that would have two epiphyseal plates (proximal and distal) at stage 5.

in the marrow cavity follow this wave, dissolving calcified cartilage remnants and enlarging the marrow cavity of the diaphysis. The region of transition from cartilage to bone at each end of the primary marrow cavity is called a **metaphysis**.

Soon, chondrocyte enlargement and death occur in the epiphysis of the model as well, creating a **secondary ossification center**. In the metacarpal bones, as illustrated in figure 7.10, this occurs in only one epiphysis. In longer bones of the arms, forearms, legs, and thighs, it occurs at both ends.

- ④ The secondary ossification center becomes hollowed out by the same process as the diaphysis, generating a **secondary marrow cavity** in the epiphysis. This cavity expands outward from the center, in all directions. At the time of birth, the bone typically looks like step 4 in figure 7.10. In bones with two secondary ossification centers, one center lags behind the other in development, so at birth there is a secondary marrow cavity at one end while chondrocyte growth has just begun at the other. The joints of the limbs are still cartilaginous at birth (fig. 7.11).
- ⑤ During infancy and childhood, the epiphyses fill with spongy bone. Cartilage is then limited to the articular cartilage covering each joint surface, and to an **epiphyseal (EP-ih-FIZ-ee-ul) plate**, a thin wall of

cartilage separating the primary and secondary marrow cavities at one or both ends of the bone. The epiphyseal plate persists through childhood and adolescence and serves as a growth zone for bone elongation. This growth process is described in the next section.

- ⑥ By the late teens to early twenties, all remaining cartilage in the epiphyseal plate is generally consumed and the gap between the epiphysis and diaphysis closes. The primary and secondary marrow cavities then unite into a single cavity, and the bone can no longer grow in length.

Bone Growth and Remodeling

Ossification does not end at birth, but continues throughout life with the growth and remodeling of bones. Bones grow in two directions: length and width.

Bone Elongation

To understand growth in length, we must return to the epiphyseal plates mentioned earlier (see fig. 7.10, step 5). From infancy through adolescence, an epiphyseal plate is present at one or both ends of a long bone, at the junction between the diaphysis and epiphysis. On X-rays, it appears as a translucent line across the end of a bone, since it is not yet ossified (fig. 7.12; compare the X-ray of an adult hand in fig. 8.34, p. 272). The epiphyseal plate is

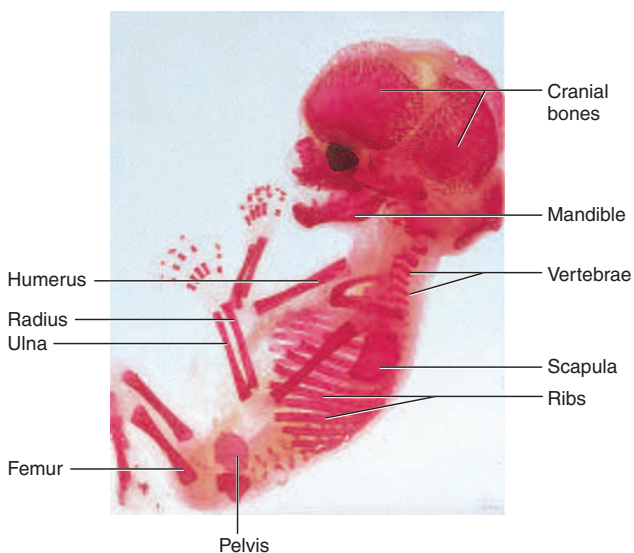

FIGURE 7.11 The Fetal Skeleton at 12 Weeks. The red-stained regions are calcified at this age, whereas the elbow, wrist, knee, and ankle joints appear translucent because they are still cartilaginous.

● Why are the joints of an infant weaker than those of an older child?

FIGURE 7.12 X-Ray of a Child's Hand. The cartilaginous epiphyseal plates are evident at the ends of the long bones. By adulthood, these will disappear and the epiphyses will fuse with the diaphyses. Long bones of the hand and fingers develop only one epiphyseal plate.

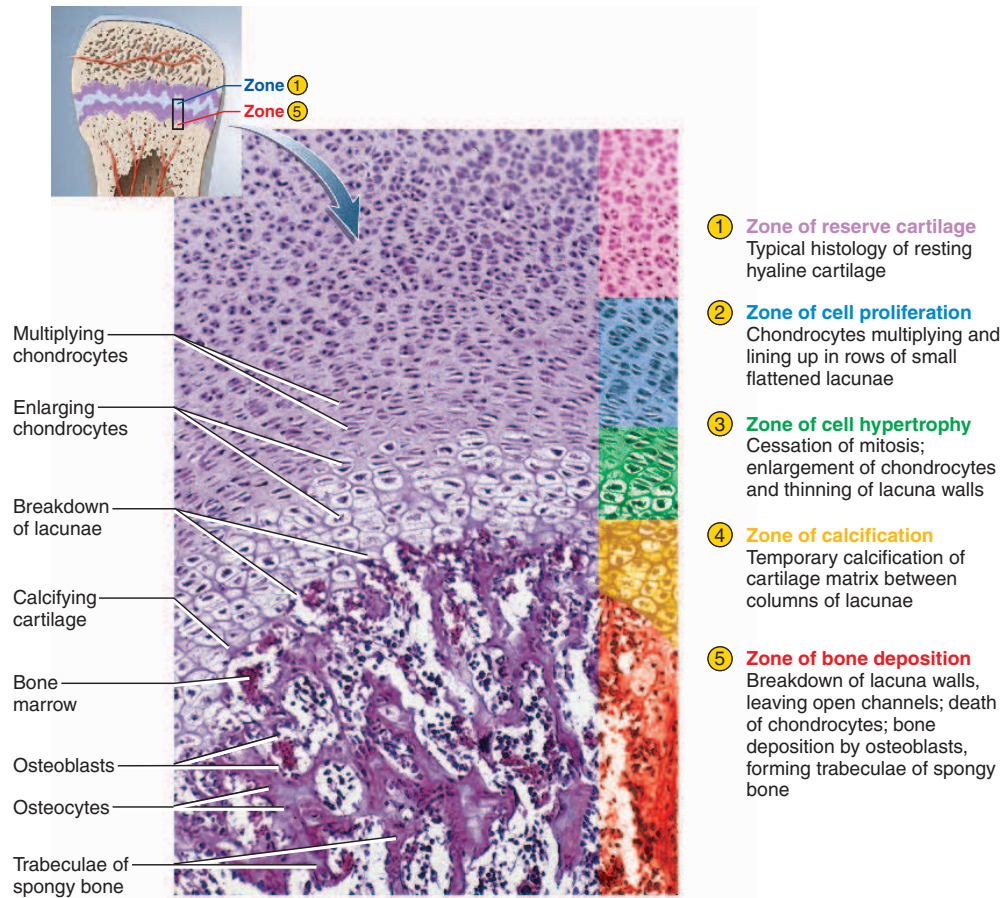

FIGURE 7.13 Zones of the Metaphysis. This micrograph shows the transition from cartilage to bone in the growth zone of a long bone. Which two zones in this figure account for a child's growth in height?

a region of transition from cartilage to bone, and functions as a growth zone where the bones elongate. Growth here is responsible for a person's increase in height.

The epiphyseal plate consists of typical hyaline cartilage in the middle, with a transitional zone on each side where cartilage is being replaced by bone. The transitional zone, facing the marrow cavity, is called the **metaphysis** (meh-TAF-ih-sis). In figure 7.10, step 4, the cartilage is the blue region and each metaphysis is violet. Figure 7.13 shows the histological structure of the metaphysis and the following steps in the conversion of cartilage to bone.

- ① **Zone of reserve cartilage.** This region, farthest from the marrow cavity, consists of typical hyaline cartilage that as yet shows no sign of transforming into bone.
- ② **Zone of cell proliferation.** A little closer to the marrow cavity, chondrocytes multiply and arrange themselves into longitudinal columns of flattened lacunae.

- ③ **Zone of cell hypertrophy.** Next, the chondrocytes cease to divide and begin to hypertrophy (enlarge), much like they do in the primary ossification center of the fetus. The walls of matrix between lacunae become very thin.
- ④ **Zone of calcification.** Minerals are deposited in the matrix between the columns of lacunae and calcify the cartilage. These are not the permanent mineral deposits of bone, but only a temporary support for the cartilage that would otherwise soon be weakened by the breakdown of the enlarged lacunae.
- ⑤ **Zone of bone deposition.** Within each column, the walls between the lacunae break down and the chondrocytes die. This converts each column into a longitudinal channel (white spaces in the figure), which is immediately invaded by blood vessels and marrow from the marrow cavity. Osteoblasts line up along the walls of these channels and begin depositing concentric lamellae of matrix, while osteoclasts dissolve the temporarily calcified cartilage.

The process of bone deposition in zone 5 creates a region of spongy bone at the end of the marrow cavity facing the metaphysis. This spongy bone remains for life, although with extensive lifelong remodeling. But around the perimeter of the marrow cavity, continuing ossification converts this spongy bone to compact bone. Osteoblasts lining the aforementioned channels deposit layer after layer of bone matrix, so the channel grows narrower and narrower. These layers become the concentric lamellae of an osteon. Finally only a slender channel persists, the central canal of a new osteon. As usual, osteoblasts trapped in the matrix become osteocytes.

Think About It

In a given osteon, which lamellae are the oldest—those immediately adjacent to the central canal or those around the perimeter of the osteon? Explain your answer.

How does a child or adolescent grow in height? Chondrocyte multiplication in zone 2 and hypertrophy in zone 3 continually push the zone of reserve cartilage (1) toward the ends of the bone, so the bone elongates. In the lower limbs, this process causes a person to grow in height, while bones of the upper limbs grow proportionately.

Thus, bone elongation is really a result of cartilage growth. Cartilage growth from within, by the multiplication of chondrocytes and deposition of new matrix in the interior, is called **interstitial growth**.²⁴ The most common form of dwarfism results from a failure of cartilage growth in the long bones (see Insight 7.2).

In the late teens to early twenties, all the cartilage of the epiphyseal plate is depleted. The primary and secondary marrow cavities now unite into one cavity (fig. 7.10, step 6). The junctional region where they meet is filled with spongy bone, and the site of the original epiphyseal plate is marked with a line of slightly denser spongy bone called the **epiphyseal line** (see figs. 7.2, 7.6, and 7.10 step 6). Often a delicate ridge on the bone surface marks the location of this line. When the epiphyseal plate is depleted, we say that the epiphyses have “closed” because no gap between the epiphysis and diaphysis is visible on an X-ray. Once the epiphyses have all closed in the lower limbs, a person can grow no taller. The epiphyseal plates close at different ages in different bones and in different regions of the same bone. The state of closure in various bones is often used in forensic science to estimate the age at death of a subadult skeleton.

Bone Widening and Thickening

Bones also continually grow throughout life in diameter and thickness. This involves a process called **appositional growth**,²⁵ the deposition of new tissue at the surface.

INSIGHT 7.2 Clinical Application

Achondroplastic Dwarfism

*Achondroplastic*²⁶ (a-con-dro-PLAS-tic) *dwarfism* is a condition in which the long bones of the limbs stop growing in childhood, while the growth of other bones is unaffected. As a result, a person has a short stature but a normal-size head and trunk (fig. 7.14). As its name implies, achondroplastic dwarfism results from a failure of cartilage growth—specifically, failure of the chondrocytes in zones 2 and 3 of the metaphysis to multiply and enlarge. This is different from *pituitary dwarfism*, in which a deficiency of growth hormone stunts the growth of all of the bones, and a person has short stature but normal proportions throughout the skeletal system.

Achondroplastic dwarfism results from a spontaneous mutation that can arise any time DNA is replicated. Two people of normal height with no family history of dwarfism can therefore have a child with achondroplastic dwarfism. The mutant allele is dominant, so the children of a heterozygous achondroplastic dwarf have at least a 50% chance of exhibiting dwarfism, depending on the genotype of the other parent.

FIGURE 7.14 Achondroplastic Dwarfism. The student on the right, pictured with her roommate of normal height, is an achondroplastic dwarf with a height of about 122 cm (48 in.). Her parents were of normal height. Note the normal proportion of head to trunk but shortening of the limbs.

²⁴*inter* = between + *stit* = to place, stand

²⁵*ap* = *ad* = to, near + *posit* = to place

²⁶*a* = without + *chondr* = cartilage + *plast* = growth

Cartilages can enlarge by both interstitial and appositional growth. In bone, however, the osteocytes are embedded in calcified matrix and have little room to spare for the deposition of more matrix internally. Bone is therefore limited to appositional growth.

Appositional growth is similar to intramembranous ossification. Osteoblasts in the inner layer of periosteum deposit osteoid tissue on the bone surface, calcify it, and become trapped in it as osteocytes—much like the process in figure 7.9. They lay down matrix in layers parallel to the surface, not in cylindrical osteons like those deeper in the bone. This process produces the surface layers of bone called *circumferential lamellae*, described earlier. As a bone increases in diameter, its marrow cavity also widens. This is achieved by osteoclasts of the endosteum dissolving tissue on the inner bone surface.

Bone Remodeling

In addition to their growth, bones are continually remodeled throughout life by the absorption of old bone and deposition of new. This process replaces about 10% of the skeletal tissue per year. It repairs microfractures, releases minerals into the blood, and reshapes bones in response to use and disuse.

Wolff's²⁷ law of bone states that the architecture of a bone is determined by the mechanical stresses placed upon it, and the bone thereby adapts to withstand those stresses. Wolff's law is a fine example of the complementarity of form and function, showing that the form of a bone is shaped by its functional experience. It is admirably demonstrated by figure 7.6, in which we see that the trabeculae of spongy bone have developed along the lines of stress placed on the femur. Wolff observed that these stress lines were very similar to the ones that engineers saw in mechanical cranes. The effect of stress on bone development is quite evident in tennis players, in whom the bones of the racket arm are more robust than those of the other arm.

Bone remodeling comes about through the collaborative action of osteoblasts and osteoclasts. If a bone is little used, osteoclasts remove matrix and get rid of unnecessary mass. If a bone is heavily used, or a stress is consistently applied to a particular region of a bone, osteoblasts deposit new osseous tissue and thicken the bone. Consequently, the comparatively smooth bones of an infant or toddler develop a variety of surface bumps, ridges, and spines (described in chapter 8) as the child begins to walk. The greater trochanter of the femur, for example (see figs. 7.6 and 8.38, p. 277), is a massive outgrowth of bone stimulated by the pull of tendons from several powerful hip muscles employed in walking.

On average, bones have a greater density and mass in athletes and people engaged in heavy manual labor than they do in sedentary people. Anthropologists who study

ancient skeletal remains use evidence of this sort to help distinguish between members of different social classes, such as distinguishing royalty from laborers. Even in studying modern skeletal remains, as in investigating a suspicious death, Wolff's law comes into play as the bones give evidence of a person's sex, race, height, weight, work or exercise habits, nutritional status, and medical history.

The orderly remodeling of bone depends on a precise balance between deposition and resorption, between osteoblasts and osteoclasts. If one process outpaces the other, or both processes occur too rapidly, various bone deformities, developmental abnormalities, and other disorders occur, such as *osteitis deformans* (Paget disease), *osteogenesis imperfecta* (brittle bone disease), and *osteoporosis* (see table 7.3 and Insight 7.4).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

11. Describe the stages of intramembranous ossification. Name a bone that is formed in this way.
12. Describe how a cartilage model is transformed into a long bone in endochondral ossification.
13. Describe the five zones of a metaphysis and the major distinctions between them.
14. How does Wolff's law explain some of the structural differences between the bones of a young child and the bones of a young adult?

7.4 Physiology of Osseous Tissue

Objectives

When you have completed this section, you should be able to

- describe the processes by which minerals are added to and removed from bone tissue;
- discuss the role of the bones in regulating blood calcium and phosphate levels; and
- name several hormones that regulate bone physiology and describe their effects.

Even after a bone is fully formed, it remains a metabolically active organ with many roles to play. Not only is it involved in its own maintenance, growth, and remodeling, it also exerts a profound influence on the rest of the body by exchanging minerals with the tissue fluid. Disturbances of calcium homeostasis in the skeleton can disrupt the functioning of other organ systems, especially the nervous and muscular systems. For reasons explained later, such disturbances can even cause death by suffocation. At this point, we turn our attention to the physiology of mature osseous tissue.

²⁷Julius Wolff (1836–1902), German anatomist and surgeon

Mineral Deposition and Resorption

Mineral deposition (mineralization) is a crystallization process in which calcium, phosphate, and other ions are taken from the blood plasma and deposited in bone tissue, mainly as crystals of hydroxyapatite. Deposition begins in fetal ossification and continues throughout life.

Osteoblasts begin the process by laying down collagen fibers in a helical pattern along the length of the osteon. These fibers then become encrusted with minerals that harden the matrix. Hydroxyapatite crystals form only when the product of calcium and phosphate concentration in the tissue fluids, represented $[Ca^{2+}] \cdot [PO_4^{3-}]$, reaches a critical value called the **solubility product**. Most tissues have inhibitors to prevent this so they do not become calcified. Osteoblasts, however, apparently neutralize these inhibitors and thus allow the salts to precipitate in the bone matrix. The first few crystals to form act as “seed crystals” that attract more calcium and phosphate from solution. The more hydroxyapatite that forms, the more it attracts additional minerals from the tissue fluid, until the matrix is thoroughly calcified.

Osseous tissue sometimes forms in the lungs, brain, eyes, muscles, tendons, arteries, and other organs. Such abnormal calcification of tissues is called **ectopic²⁸ ossification**. One example of this is arteriosclerosis, or “hardening of the arteries,” which results from calcification of the arterial walls. A calcified mass in an otherwise soft organ such as the lungs is called a **calculus**.²⁹

Think About It

What positive feedback process can you recognize in bone deposition?

Mineral resorption is the process of dissolving bone. It releases minerals into the blood and makes them available for other uses. Resorption is carried out by osteoclasts. Hydrogen pumps in the ruffled border of the osteoclast secrete hydrogen ions into the extracellular fluid, and chloride ions follow by electrical attraction. The space between the osteoclast and the bone thus becomes filled with concentrated hydrochloric acid with a pH of about 4. The acid dissolves the bone minerals. The osteoclast also secretes an enzyme called **acid phosphatase** that digests the collagen of the bone matrix. This enzyme is named for its ability to function in a highly acidic environment.

When orthodontic appliances (braces) are used to reposition teeth, a tooth moves because osteoclasts dissolve bone ahead of the tooth (where the appliance creates greater pressure of the tooth against the bone) and osteoblasts deposit bone in the low-pressure zone behind it.

Calcium Homeostasis

Calcium and phosphate are used for much more than bone structure. Phosphate groups are a component of DNA, RNA, ATP, phospholipids, and many other compounds. Phosphate ions also help to correct acid–base imbalances in the body fluids (see Insight 7.3). Calcium plays roles in communication among neurons, and in muscle contraction, blood clotting, and exocytosis. It is also a second messenger in many cell-signaling processes and a cofactor for some enzymes. The skeleton is a reservoir for these minerals. Minerals are deposited in the skeleton when the supply is ample and withdrawn when they are needed for other purposes.

The adult body contains about 1,100 g of calcium, with 99% of it in the bones. Bone has two calcium reserves: (1) a stable pool of calcium which is incorporated into hydroxyapatite and is not easily exchanged with the blood; and (2) exchangeable calcium, which is 1% or less of the total but is easily released to the tissue fluid. The adult skeleton exchanges about 18% of its calcium with the blood each year.

The calcium concentration in the blood plasma is normally 9.2 to 10.4 mg/dL. This is a rather narrow margin of safety, as we shall soon see. About 45% of it is in the ionized form (Ca^{2+}), which can diffuse through capillary walls and affect neighboring cells. The rest of it is bound to plasma proteins and other solutes. It is not physiologically active, but it serves as a reserve from which free Ca^{2+} can be obtained as needed.

Even slight changes in blood calcium concentration can have serious consequences. A calcium deficiency is called **hypocalcemia**³⁰ (HY-po-cal-SEE-me-uh). It causes excessive excitability of the nervous system and leads to muscle tremors, spasms, or **tetany**—the inability of the

INSIGHT 7.3 Clinical Application

Osseous Tissue and pH Balance

The urinary, respiratory, and skeletal systems cooperate to maintain the body's acid–base balance. If the pH of the blood drops below 7.35, a state of acidosis exists, triggering corrective mechanisms in these three organ systems. The role of the skeleton is to release calcium phosphate. As a base, calcium phosphate helps to prevent the blood pH from dropping lower. Patients with chronic kidney disease may have impaired hydrogen ion excretion in the urine. Their pH stabilizes at a level below normal but is kept from dropping indefinitely by the buffering action of the skeleton. This can have adverse effects on the skeleton, however, and lead to rickets or osteomalacia. Treatment of the acidosis with intravenous bicarbonate restores the pH to normal and prevents damage to the bones.

²⁸ec = out of + top = place

³⁰hypo = below normal + calc = calcium + emia = blood condition

FIGURE 7.15 **Carpopedal Spasm.** Such muscle tetany occurring in the hands and feet can be a sign of hypocalcemia.

muscle to relax. Tetany begins to occur as the plasma Ca^{2+} concentration falls to 6 mg/dL. One sign of hypocalcemia is a tetany of the hands and feet called *carpopedal spasm* (fig. 7.15). At 4 mg/dL, muscles of the larynx contract tightly, a condition called *laryngospasm*, which can shut off air flow and cause suffocation.

The reason for this hypocalcemic excitability is this: Calcium ions normally bind and neutralize negatively charged groups on the cell surface, contributing to the difference between the positively charged outer surface of the membrane and the negatively charged inner surface. In hypocalcemia, fewer calcium ions are present, so there is less charge difference between the two sides of the membrane. Sodium channels in the plasma membrane are sensitive to this charge difference, and when the difference is diminished, they open more easily and stay open longer. This allows sodium ions to enter the cell too freely. As you will see in chapters 11 and 12, an inflow of sodium is the normal process that excites nerve and muscle cells. In hypocalcemia, this excitation is excessive and results in the aforementioned tetany.

A blood calcium excess is called **hypercalcemia**.³¹ In this condition, excessive amounts of calcium bind to the cell surface, increasing the charge difference across the membrane and making sodium channels less responsive. Thus, nerve and muscle cells are less excitable than normal. At 12 mg/dL and higher, hypercalcemia causes depression of the nervous system, emotional disturbances, muscle weakness, sluggish reflexes, and sometimes cardiac arrest.

You can see how critical blood calcium level is, but what causes it to deviate from the norm, and how does the body correct such imbalances? Hypercalcemia is rare, but hypocalcemia can result from a wide variety of causes including vitamin D deficiency, diarrhea, thyroid tumors, or underactive parathyroid glands. Pregnancy and lactation put women at risk of hypocalcemia because of the

calcium demanded by ossification of the fetal skeleton and synthesis of milk. The leading cause of hypocalcemic tetany is accidental removal of the parathyroid glands during thyroid surgery. Without hormone replacement therapy, the lack of parathyroid glands can lead to fatal tetany within 4 days.

Calcium homeostasis depends on a balance between dietary intake, urinary and fecal losses, and exchanges with the osseous tissue. It is regulated by three hormones: *calcitriol*, *calcitonin*, and *parathyroid hormone*.

Calcitriol

Calcitriol (CAL-sih-TRY-ol) is a form of vitamin D produced by the sequential action of the skin, liver, and kidneys (fig. 7.16):

1. Epidermal keratinocytes use ultraviolet radiation from sunlight to convert a steroid, 7-dehydrocholesterol, to previtamin D_3 . Over another 3 days, the warmth of sunlight on the skin further converts this to vitamin D_3 , and a transport protein carries this to the bloodstream.
2. The liver adds a hydroxyl group to the molecule, converting it to *calcidiol*.
3. The kidney then adds another hydroxyl group, converting calcidiol to calcitriol, the most active form of vitamin D.

Calcitriol behaves as a hormone—a blood-borne chemical messenger from one organ to another. It is called a vitamin only because it is added to the diet, mainly in fortified milk, as a safeguard for people who do not get enough sunlight to initiate its synthesis in the skin.

The principal function of calcitriol is to raise the blood calcium concentration. It does this in three ways (fig. 7.17):

1. It increases calcium absorption by the small intestine.
2. It increases calcium resorption from the skeleton. Calcitriol binds to osteoblasts, which release another chemical messenger called RANKL. This is the ligand (L) for a receptor named RANK³² on the surfaces of osteoclast-producing stem cells. This messenger stimulates the stem cells to differentiate into osteoclasts. The new osteoclasts then liberate calcium and phosphate ions from bone.
3. It weakly promotes the reabsorption of calcium ions by the kidneys, so less calcium is lost in the urine.

Although calcitriol promotes bone resorption, it is also necessary for bone deposition. Without it, calcium and phosphate levels in the blood are too low for normal deposition. The result is a softness of the bones called **rickets** in children and **osteomalacia**³³ in adults.

³¹hyper = above normal + calc = calcium + emia = blood condition

³²RANK = receptor activator of nuclear factor kappa B

³³osteo = bone + malacia = softening

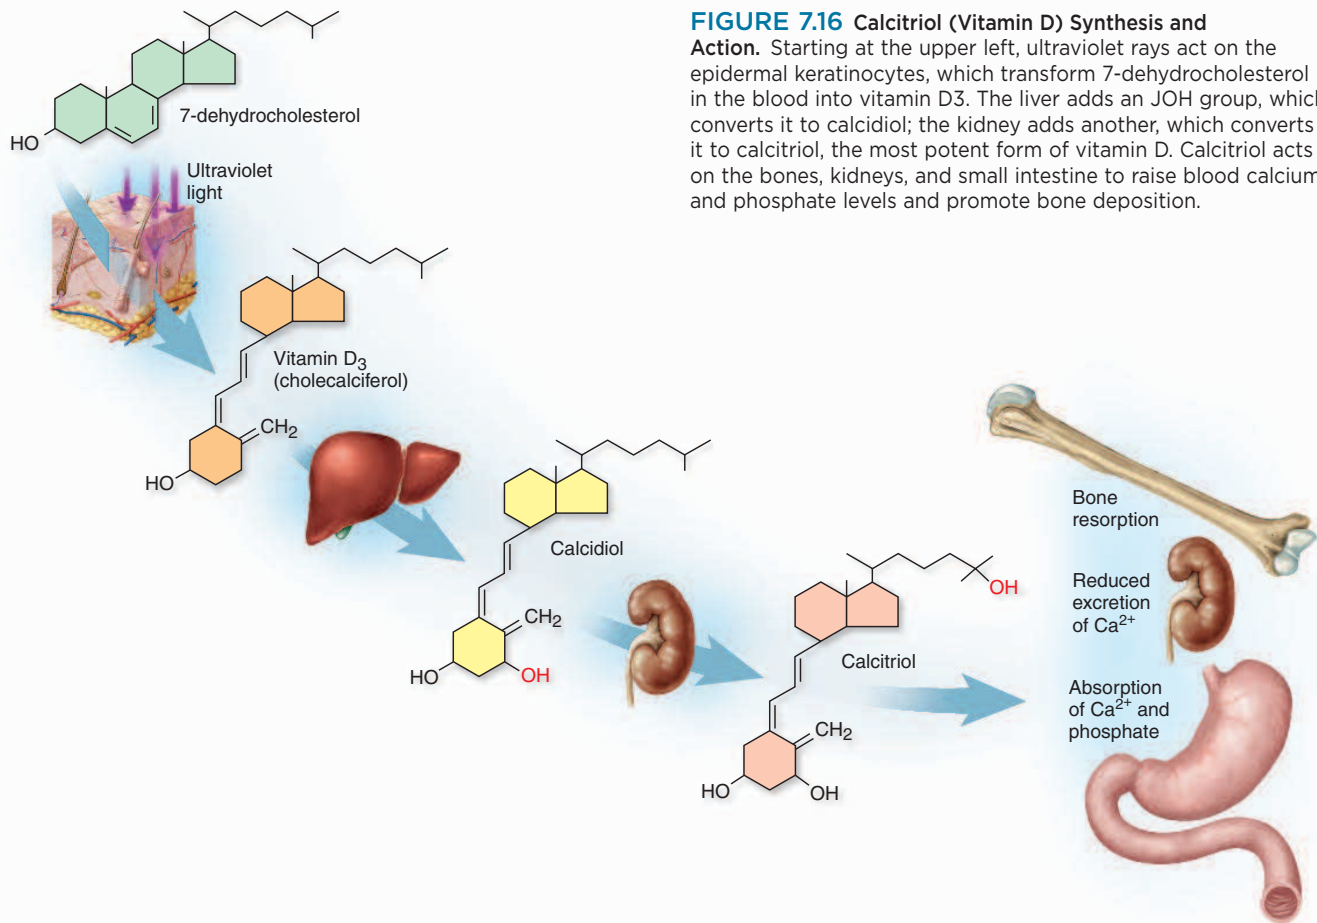

FIGURE 7.17 Hormonal Control of Calcium Balance. The central panel represents the blood reservoir of calcium and shows its normal (safe) range. Calcitriol and PTH regulate calcium exchanges between the blood and the small intestine and kidneys (left). Calcitonin, calcitriol, and PTH regulate calcium exchanges between blood and bone (right).

Calcitonin

Calcitonin is secreted by *C cells* (*clear cells*) of the thyroid gland, a large endocrine gland in the neck (see fig. 17.9, p. 651). It is secreted when the blood calcium concentration rises too high, and it lowers the concentration by two principal mechanisms (figs. 7.17 and 7.18a):

1. **Osteoclast inhibition.** Within 15 minutes after it is secreted, calcitonin reduces osteoclast activity by as much as 70%, so osteoclasts liberate less calcium from the skeleton.
2. **Osteoblast stimulation.** Within an hour, calcitonin increases the number and activity of osteoblasts, which deposit calcium into the skeleton.

Calcitonin plays an important role in children but has a weak effect, at most, in most adults. The osteoclasts of children are highly active in skeletal remodeling and release 5 g or more of calcium into the blood each day. By inhibiting this activity, calcitonin can significantly lower the blood calcium level in children. In adults, however, the osteoclasts release only about 0.8 g of calcium per day. Calcitonin cannot change adult blood calcium very much by suppressing this lesser contribution. Calcitonin deficiency is not known to cause any adult disease. Calcitonin may, however, prevent bone loss in pregnant and lactating women.

Parathyroid Hormone

Parathyroid hormone (PTH) is secreted by the parathyroid glands, which adhere to the posterior surface of the thyroid gland (see fig. 17.10, p. 652). These glands release PTH when blood calcium is low. A mere 1% drop in the blood calcium level doubles the secretion of PTH. PTH raises the blood calcium level by four mechanisms (figs. 7.17 and 7.18b):

1. PTH binds to receptors on the osteoblasts, stimulating them to secrete RANKL, which in turn raises the osteoclast population and promotes bone resorption.
2. PTH promotes calcium reabsorption by the kidneys, so less calcium is lost in the urine.
3. PTH promotes the final step of calcitriol synthesis in the kidneys, thus enhancing the calcium-raising effect of calcitriol.
4. PTH inhibits collagen synthesis by osteoblasts, thus inhibiting bone deposition.

Notwithstanding these normal effects of PTH, the intermittent secretion (or injection) of PTH at low levels can stimulate bone deposition. PTH can therefore increase or decrease bone mass, depending on other factors such as exercise, stress on the bones, calcium and phosphate availability, and the action of vitamin D and other hormones.

(a) Correction for hypercalcemia

(b) Correction for hypocalcemia

FIGURE 7.18 Negative Feedback Loops in Calcium Homeostasis. (a) The correction of hypercalcemia by calcitonin. (b) The correction of hypocalcemia by parathyroid hormone.

Phosphate Homeostasis

The average adult has 500 to 800 g of phosphorus, of which 85% to 90% is in the bones. The phosphorus concentration in the plasma ranges between 3.5 and 4.0 mg/dL. It occurs in two principal forms, HPO_4^{2-} and H_2PO_4^- (monohydrogen and dihydrogen phosphate ions, respectively).

TABLE 7.1 Agents Affecting Calcium and Bone Metabolism

Name	Effect
Hormones	
Calcitonin	Little effect in adults; promotes mineralization and lowers blood Ca^{2+} concentration in children; may prevent bone loss in pregnant and lactating women
Calcitriol (vitamin D)	Promotes intestinal absorption of Ca^{2+} and phosphate; reduces urinary excretion of both; promotes both resorption and mineralization; stimulates osteoclast activity
Cortisol	Inhibits osteoclast activity, but if secreted in excess (Cushing disease), can cause osteoporosis by reducing bone deposition (inhibiting cell division and protein synthesis)
Estrogen	Stimulates osteoblasts and adolescent growth; prevents osteoporosis
Growth hormone	Stimulates bone elongation and cartilage proliferation at epiphyseal plate; increases urinary excretion of Ca^{2+} but also increases intestinal Ca^{2+} absorption, which compensates for the loss
Insulin	Stimulates bone formation; significant bone loss occurs in untreated diabetes mellitus
Parathyroid hormone	Indirectly activates osteoclasts, which resorb bone and raise blood Ca^{2+} concentration; inhibits urinary Ca^{2+} excretion; promotes calcitriol synthesis
Testosterone	Stimulates osteoblasts and promotes protein synthesis, thus promoting adolescent growth and epiphyseal closure
Thyroid hormone	Essential to bone growth; enhances effects of growth hormone, but excesses can cause hypercalcemia, increased Ca^{2+} excretion in urine, and osteoporosis
Growth factors	At least 12 hormonelike substances produced in bone itself that stimulate neighboring bone cells, promote collagen synthesis, stimulate epiphyseal growth, and produce many other effects
Vitamins	
Vitamin A	Promotes glycosaminoglycan (chondroitin sulfate) synthesis
Vitamin C (ascorbic acid)	Promotes collagen cross-linking, bone growth, and fracture repair
Vitamin D	Normally functions as a hormone (see calcitriol)

Phosphate levels are not regulated nearly as tightly as calcium levels. Nor, apparently, do they need to be; changes in plasma phosphate level are not associated with any immediate functional disorder. Calcitriol raises the phosphate level by promoting its absorption from the diet by the small intestine. This makes sense, because the principal role of calcitriol is to promote bone deposition, and that requires both calcium and phosphate. Parathyroid hormone, on the other hand, lowers the blood phosphate level by promoting its urinary excretion.

Think About It

While raising the blood calcium level, PTH lowers the phosphate level. Explain why this is important for achieving the purpose of PTH.

Other Factors Affecting Bone

At least 20 more hormones, growth factors, and vitamins affect osseous tissue in complex ways that are still not well understood (table 7.1). Bone growth is especially rapid in puberty and adolescence, when surges of growth hormone, estrogen, and testosterone promote ossification. These hormones stimulate rapid multiplication of osteogenic cells, matrix deposition by osteoblasts, and multi-

plication and hypertrophy of the chondrocytes in the metaphyses. Adolescent girls grow faster than boys and attain their full height earlier, not only because they begin puberty earlier but also because estrogen has a stronger effect than testosterone. Since males grow for a longer time, however, they usually grow taller. A deficiency or excess of these steroids can therefore cause abnormalities ranging from stunted growth to very tall stature. The use of anabolic steroids by adolescent athletes can cause premature closure of the epiphyseal plates and results in abnormally short adult stature (see p. 83).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe the role of collagen and seed crystals in bone mineralization.
- Why is it important to regulate blood calcium concentration within such a narrow range?
- What effect does calcitonin have on blood calcium concentration, and how does it produce this effect? Answer the same questions for parathyroid hormone.
- How is vitamin D synthesized, and what effect does it have on blood calcium concentration?

7.5 Bone Disorders

Objectives

When you have completed this section, you should be able to

- name and describe several bone diseases;
- name and describe the types of fractures;
- explain how a fracture is repaired; and
- discuss some clinical treatments for fractures and other skeletal disorders.

Most people probably give little thought to their skeletal systems unless they break a bone. This section describes bone fractures, their healing, and their treatment, followed by a summary of other bone diseases and a clinical insight on osteoporosis.

Fractures and Their Repair

There are multiple ways of classifying bone fractures. A **stress fracture** is a break caused by abnormal trauma to a bone, such as fractures incurred in falls, athletics, and

military combat. A **pathologic fracture** is a break in a bone weakened by some other disease, such as bone cancer or osteoporosis, usually caused by a stress that would not normally fracture a bone. Fractures are also classified according to the direction of the fracture line, whether the skin is broken, and whether a bone is merely cracked or broken into separate pieces (table 7.2; fig. 7.19).

The Healing of Fractures

An uncomplicated fracture heals in about 8 to 12 weeks, but complex fractures take longer and all fractures heal more slowly in older people. The healing process occurs in the following stages (fig. 7.20):

- 1 **Formation of hematoma and granulation tissue.** A bone fracture severs blood vessels of the bone and periosteum, causing bleeding and the formation of a blood clot (*fracture hematoma*). Blood capillaries soon grow into the clot, while fibroblasts, macrophages, osteoclasts, and osteogenic cells invade the tissue from both the periosteal and medullary sides of the fracture. Osteogenic cells become very abundant within 48 hours of the injury. All of this capillary and cellular invasion converts the blood clot to a soft fibrous mass called **granulation tissue**.

TABLE 7.2

Classification of Fractures

Type	Description
Closed	Skin is not broken (formerly called a <i>simple</i> fracture)
Open	Skin is broken; bone protrudes through skin, or wound extends to fractured bone (formerly called a <i>compound</i> fracture)
Complete	Bone is broken into two or more pieces
Incomplete	Partial fracture that extends only partway across bone; pieces remain joined
Nondisplaced	The portions of bone are still in correct anatomical alignment (fig. 7.19a)
Displaced	The portions of a fractured bone are out of anatomical alignment (fig. 7.19b)
Comminuted	Bone is broken into three or more pieces (fig 7.19c)
Greenstick	Bone is bent on one side and has incomplete fracture on opposite side (fig 7.19d)
Hairline	Fine crack in which sections of bone remain aligned; common in skull
Impacted	One bone fragment is driven into the marrow cavity or spongy bone of the other
Depressed	Broken portion of bone forms a concavity, as in skull fractures
Linear	Fracture parallel to long axis of bone
Transverse	Fracture perpendicular to long axis of bone
Oblique	Diagonal fracture, between linear and transverse
Spiral (torsion)	Fracture spirals around axis of long bone, like a spiral staircase, as the result of a twisting stress such as might occur in a skiing accident
Epiphyseal	Epiphysis is separated from the diaphysis along the epiphyseal plate; seen in juveniles
Colles ³⁴	Fracture of the distal end of the radius and ulna; common in osteoporosis
Pott ³⁵	Fracture at the distal end of the tibia, fibula, or both; a common sports injury

³⁴Abraham Colles (1773–1843), Irish surgeon

³⁵Sir Percivall Pott (1714–88), British surgeon

FIGURE 7.19 X-rays of Representative Fracture Types. (a) Nondisplaced fracture of the distal humerus in a 3-year-old. (b) Displaced fracture of the tibia and fibula. (c) Comminuted fracture of the tibia and fibula. (d) Greenstick fracture of the ulna.

② **Formation of a soft callus.**³⁶ Fibroblasts deposit collagen in the granulation tissue, while some osteogenic cells become chondroblasts and produce patches of fibrocartilage called the **soft callus**.

③ **Conversion to hard callus.** Other osteogenic cells differentiate into osteoblasts, which produce a bony collar called the **hard callus** around the fracture. The hard callus is cemented to dead bone around the injury site and acts as a temporary splint to join the broken ends or bone fragments together. It takes about 4 to 6 weeks for a hard callus to form. During this period, it is important that a broken bone be immobilized by traction or a cast to prevent reinjury.

④ **Remodeling.** The hard callus persists for 3 to 4 months. Meanwhile, osteoclasts dissolve small fragments of broken bone, and osteoblasts deposit spongy bone to bridge the gap between the broken ends. This spongy bone gradually fills in to become compact bone, in a manner similar to intramembranous ossification. Usually the fracture leaves a slight thickening of the bone visible by X-ray, but in some cases, healing is so complete that no trace of the fracture can be found.

The Treatment of Fractures

Most fractures are set by **closed reduction**, a procedure in which the bone fragments are manipulated into their normal positions without surgery. **Open reduction** involves the surgical exposure of the bone and the use of plates, screws, or pins to realign the fragments (fig. 7.21). To stabilize the bone during healing, fractures are often set in

³⁶call = hard, tough

① **Hematoma formation**
The hematoma is converted to granulation tissue by invasion of cells and blood capillaries.

② **Soft callus formation**
Deposition of collagen and fibrocartilage converts granulation tissue to a soft callus.

③ **Hard callus formation**
Osteoblasts deposit a temporary bony collar around the fracture to unite the broken pieces while ossification occurs.

④ **Bone remodeling**
Small bone fragments are removed by osteoclasts, while osteoblasts deposit spongy bone and then convert it to compact bone.

FIGURE 7.20 The Healing of a Bone Fracture.

FIGURE 7.21 Open Reduction of an Ankle Fractures. This fracture has been set by surgically exposing the bone and realigning the fragments with plates and screws.

casts. Traction is used to treat fractures of the femur in children. It aids in the alignment of the bone fragments by overriding the force of the strong thigh muscles. Traction is rarely used for elderly patients, however, because the risks from long-term confinement to bed outweigh the benefits. Hip fractures are usually pinned and early ambulation (walking) is encouraged because it promotes blood circulation and healing. Fractures that take longer

than 2 months to heal may be treated with electrical stimulation, which accelerates repair by suppressing the effects of parathyroid hormone.

Orthopedics³⁷ is the branch of medicine that deals with the prevention and correction of injuries and disorders of the bones, joints, and muscles. As the word suggests, this field originated as the treatment of skeletal deformities in children, but it is now much more extensive. It includes the design of artificial joints and limbs and the treatment of athletic injuries.

Other Bone Disorders

Several additional bone disorders are summarized in table 7.3. The most common bone disease, **osteoporosis**,³⁸ receives special consideration in Insight 7.4. The effects of aging on the skeletal system are described on page 1141.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

19. Name and describe any five types of bone fractures.
20. Why would osteomyelitis be more likely to occur in an open fracture than in a closed fracture?
21. What is a callus? How does it contribute to fracture repair?

³⁷ortho = straight + ped = child, foot

³⁸osteo = bone + por = porous + osis = condition

TABLE 7.3 Bone Diseases	
Osteitis deformans (Paget ³⁹ disease)	Excessive proliferation of osteoclasts and resorption of excess bone, with osteoblasts attempting to compensate by depositing extra bone. This results in rapid, disorderly bone remodeling and weak, deformed bones. Osteitis deformans usually passes unnoticed, but in some cases it causes pain, disfiguration, and fractures. It is most common in males over the age of 50.
Osteomyelitis ⁴⁰	Inflammation of osseous tissue and bone marrow as a result of bacterial infection. This disease was often fatal before the discovery of antibiotics and is still very difficult to treat.
Osteogenesis imperfecta (brittle bone disease)	A defect in collagen deposition that renders bones exceptionally brittle, resulting in fractures present at birth or occurring with extraordinary frequency during childhood; also causing tooth deformity, and hearing loss due to deformity of middle-ear bones.
Osteosarcoma ⁴¹ (osteogenic sarcoma)	The most common and deadly form of bone cancer. It occurs most often in the tibia, femur, and humerus of males between the ages of 10 and 25. In 10% of cases, it metastasizes to the lungs or other organs; if untreated, death occurs within 1 year.
Disorders described elsewhere	
Achondroplastic dwarfism p. 226	Fractured clavicle p. 268
Cleft palate p. 255	Fractured skull p. 254
Ectopic ossification p. 228	Fractures p. 233
Fallen arches p. 280	Herniated disc p. 261
	Joint diseases p. 314
	Kyphosis p. 260
	Lordosis p. 260
	Mastoiditis p. 252
	Osteomalacia p. 229
	Osteoporosis p. 236
	Rickets p. 229
	Scoliosis p. 260

³⁹Sir James Paget (1814–99), English surgeon

⁴⁰osteo = bone + myel = marrow + itis = inflammation

⁴¹osteo = bone + sarc = flesh + oma = tumor

INSIGHT 7.4 Clinical Application

Osteoporosis

The most common bone disease is osteoporosis (literally, “porous bones”), a severe loss of bone density. It affects especially spongy bone, since this is more metabolically active than dense bone and has more surface area exposed to bone-dissolving osteoclasts (fig. 7.22a). As a result, the bones become brittle and highly subject to pathologic fractures from stresses as slight as sitting down too quickly. Fractures occur especially in the hip, wrist, and vertebral column. As the vertebrae lose bone, they become compressed and the spine is often deformed into a condition called *kyphosis* (“widow’s hump”) (fig. 7.22b, c). Hip fractures are especially serious. Each year, about 275,000 elderly Americans experience hip fracture, and about 1 in 5 of these die within a year from complications of the resulting loss of mobility, such as pneumonia and thrombosis.

Osteoporosis occurs in both sexes and at all ages from adolescence to old age. Postmenopausal white women, however, are at the greatest risk. In contrast to men and black women, they have less bone density; white women begin losing it earlier (as young as age 35); and they lose it more rapidly. By age 70, the average white woman loses 30% of her bone tissue. Until menopause, estrogen maintains bone density by inhibiting osteoclasts. At menopause, the ovaries cease to secrete estrogen and osteoclast activity begins to outpace bone deposition by osteoblasts. Black women also lose bone density after menopause, but having denser bones to begin with, they usually do not lose enough to suffer osteoporosis. About 20% of osteoporosis patients are men. For most, the testes and adrenal glands secrete enough estrogen even in old age to maintain adequate bone density. Other than age, race, and sex, some

other risk factors for osteoporosis include smoking, diabetes mellitus, poor diet, and inadequate weight-bearing exercise. Osteoporosis is surprisingly common among young female runners, dancers, and gymnasts. Their percentage of body fat is often so low that they stop ovulating and ovarian estrogen secretion is low. In early long-term space flights, astronauts developed osteoporosis because in a microgravity environment, their bones were subjected to too little of the stress that normally would stimulate bone deposition. This and the prevention of muscle atrophy are reasons that exercise equipment is now standard on space shuttles and stations.

Osteoporosis is now diagnosed with *dual-energy X-ray absorptiometry (DEXA)*, which uses low-dose X-rays to measure bone density. DEXA allows for early diagnosis and more effective drug treatment. Treatments for osteoporosis are aimed at slowing the rate of bone resorption. Estrogen-replacement therapy is out of favor because it increases the risk of breast cancer, stroke, and coronary artery disease. The *bisphosphonates* (Fosamax, Actonel), among the current preferred treatments, act by destroying osteoclasts. They have been shown to increase bone mass by 5% to 10% over 3 years, and to reduce the incidence of fractures by 50%. Parathyroid hormone and derivatives such as *teriparatide* (Forteo) also are highly effective, but present a risk of bone cancer if used too long. The quest for safer drugs continues.

But as is so often true, an ounce of prevention is worth a pound of cure. Drug treatments for osteoporosis cost a patient thousands of dollars annually; exercise and a good bone-building diet are far less costly. The optimal means of preventing osteoporosis is with good diet and exercise habits between the ages of 25 and 40, when bone density is on the rise. The greater bone density a person has going into middle age, the less he or she will be affected by osteoporosis later.

CONNECTIVE ISSUES

Interactions Between the SKELETAL SYSTEM and Other Organ Systems

■ indicates ways in which this system affects other systems

■ indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

Bones lying close to body surfaces shape the skin

Initiates synthesis of vitamin D needed for bone deposition

MUSCULAR SYSTEM

Bones provide leverage and sites of attachment for muscles; provide calcium needed for muscle contraction

Muscles move bones; stress produced by muscles affects patterns of ossification and remodeling, as well as shape of mature bones

NERVOUS SYSTEM

Cranium and vertebral column protect brain and spinal cord; bones provide calcium needed for neural function

Sensory receptors provide sensations of body position and pain from bones and joints

ENDOCRINE SYSTEM

Bones protect endocrine organs in head, chest, and pelvis; bones secrete the hormone osteocalcin, which promotes insulin action

Hormones regulate mineral deposition and resorption, bone growth, and skeletal mass and density

CIRCULATORY SYSTEM

Bone marrow forms blood cells; bone matrix stores calcium needed for cardiac contraction

Delivers O₂, nutrients, and hormones to bone tissue and carries away wastes; delivers blood cells to marrow

LYMPHATIC/IMMUNE SYSTEM

Most types of blood cells produced in myeloid tissue function as part of immune system

Maintains balance of interstitial fluid in bones; lymphocytes assist in defense and repair of bones

RESPIRATORY SYSTEM

Bones form respiratory passageway through nasal cavity; protect lungs and aid in ventilation

Provides O₂ and removes CO₂

URINARY SYSTEM

Skeleton physically supports and protects organs of urinary system

Kidneys activate vitamin D and regulate calcium and phosphate excretion

DIGESTIVE SYSTEM

Skeleton provides bony protection for digestive organs

Provides nutrients needed for bone growth and maintenance

REPRODUCTIVE SYSTEM

Skeleton protects some reproductive organs

Gonads produce hormones that affect bone growth and closure of epiphyseal plates

CHAPTER REVIEW

Review of Key Concepts

7.1 Tissues and Organs of the Skeletal System (p. 214)

1. *Osteology* is the study of bone. The *skeletal system* consists of bones, cartilages, and ligaments.
2. The functions of the skeletal system include bodily support, protection of internal organs, movement, electrolyte and acid–base balance, and blood formation.
3. *Bone (osseous tissue)* is a connective tissue with a mineralized matrix.
4. Bones are classified by shape as long, short, flat, and irregular bones.
5. A long bone is a shell of *compact bone* enclosing more porous *spongy bone* and a central *marrow cavity*.
6. The shaft of a long bone is the *diaphysis* and each expanded end is an *epiphysis*. The epiphysis is covered with *articular cartilage* where it meets an adjacent bone. An *epiphyseal plate* separates the marrow cavities of the diaphysis and epiphysis in children and adolescents.
7. A bone is externally covered with a fibrous *periosteum* and internally lined with a thin *endosteum*.
8. A flat bone consists of a layer of spongy bone sandwiched between two layers of compact bone.

7.2 Histology of Osseous Tissue (p. 217)

1. Osseous tissue has four types of cells: stem cells called *osteogenic cells*, matrix-depositing cells called *osteoblasts*, strain detectors called *osteocytes* enclosed in lacunae of the matrix, and matrix-dissolving cells called *osteoclasts*.
2. The bone matrix is a composite of collagen fibers and protein–carbohydrate complexes embedded in a ground substance of *hydroxyapatite*, calcium carbonate, and other minerals. The minerals enable bones to resist compression and support weight, and the proteins enable bones to bend slightly without breaking.
3. *Compact bone* consists mostly of *osteons*. An osteon is a cylindrical group of concentric *lamellae* of matrix surrounding a *central canal*

occupied by a nerve and blood vessels. *Interstitial lamellae*, the remains of old osteons, occupy some of the spaces between osteons, and *circumferential lamellae* parallel to the bone surface form the inner and outer boundaries of compact bone. Blood vessels reach the central canals by way of *perforating canals* that open on the bone surface.

4. *Spongy bone* is a porous lattice of bony *trabeculae* with lamellae but few osteons. The trabeculae are oriented along lines of stress, giving spongy bone strength without excessive weight.
5. The marrow cavity and the spaces between spongy bone trabeculae are occupied by bone marrow. *Red bone marrow* is *hemopoietic* (blood-forming) tissue, and *yellow bone marrow* is adipose tissue.

7.3 Bone Development (p. 221)

1. *Intramembranous ossification* is a process in which flat bones develop from sheets of embryonic mesenchyme. Osteoblasts deposit an organic matrix that transforms the mesenchyme into a soft collagenous *osteoid tissue*.
2. Osteoblasts then deposit calcium salts that harden the osteoid tissue and transform it to spongy bone. The surface zones of this spongy bone are gradually filled in with calcified matrix to become compact bone.
3. *Endochondral ossification* is a process in which bones develop from hyaline cartilage. Most of the fetal skeleton forms in this manner.
4. Endochondral ossification begins with enlargement of the lacunae and death of chondrocytes in the *primary ossification center*, which is soon hollowed out to form a *primary marrow space*. Osteoblasts populate this space and create a temporary scaffold of spongy bone.
5. Between the epiphysis and the primary marrow space is a *metaphysis*, which exhibits five zones of histological transformation from cartilage to bone.

6. *Secondary ossification centers* appear later in one or both epiphyses of a long bone. The cartilaginous epiphyseal plate persists through adolescence as a growth zone for the long bone.
7. Mature bones continue to be remodeled throughout life, employing *appositional growth* to grow in diameter and thickness and to reshape bone surfaces in response to stress.

7.4 Physiology of Osseous Tissue (p. 227)

1. The addition of inorganic salts to osseous tissue is called *mineral deposition*. Osteoblasts produce collagen fibers on which hydroxyapatite and other minerals crystallize. Mineralization requires a critical ratio of calcium to inorganic phosphate called the *solubility product*.
2. The removal of salts from osseous tissue is called *mineral resorption*. Osteoclasts resorb bone by secreting hydrochloric acid, which dissolves the inorganic salts of the matrix, and acid phosphatase, an enzyme that digests the organic matrix.
3. The skeleton is the body's major reservoir of calcium, which is also needed for many other physiological processes. The Ca^{2+} concentration of the blood plasma is maintained within narrow limits by resorbing Ca^{2+} from the skeleton or depositing excess Ca^{2+} into it.
4. *Hypocalcemia*, a Ca^{2+} deficiency, can cause potentially fatal muscle tetany, whereas *hypercalcemia*, a Ca^{2+} excess, can depress neuromuscular function. These imbalances are normally prevented by the actions of calcitriol, calcitonin, and parathyroid hormone.
5. *Calcitriol* is a form of vitamin D synthesized by the sequential action of the skin, liver, and kidneys. It raises blood Ca^{2+} concentration by promoting absorption of Ca^{2+} by the small intestine, conservation of Ca^{2+} by the kidneys, and resorption of Ca^{2+} from bone by osteoclasts.

6. *Calcitonin* is secreted by the thyroid gland in response to hypercalcemia. It lowers blood Ca^{2+} concentration by inhibiting osteoclasts and stimulating the depositional activity of osteoblasts.
7. *Parathyroid hormone* is secreted by the parathyroid glands in response to hypocalcemia. It raises blood Ca^{2+} levels by indirectly stimulating osteoclasts, inhibiting osteoblasts, promoting calcitriol synthesis, and promoting Ca^{2+} conservation by the kidneys.
8. Phosphate homeostasis is less critical. Calcitriol raises blood phosphate level by promoting phosphorus absorption by the small intestine;

parathyroid hormone lowers it by promoting its urinary excretion.

9. Many other hormones, growth factors, and vitamins influence bone physiology, such as growth hormone, testosterone, thyroid hormone, estrogen, insulin, and vitamins A and C.

7.5 Bone Disorders (p. 233)

1. The repair of a fractured bone begins when fibroblasts, osteogenic cells, and other cells invade the blood clot (*fracture hematoma*) and transform it into *granulation tissue*. Collagen and cartilage deposition convert this to a *soft callus*. This is followed by the formation of a calcified *hard callus* that encircles the fracture and

reunites the broken bone pieces. The hard callus is remodeled by osteoclasts and osteoblasts over several months.

2. *Closed reduction* is the realignment of the parts of a broken bone without surgery. *Open reduction* involves surgery and fragment realignment with the aid of plates and screws.
3. The most common bone disease is *osteoporosis*, a loss of bone mass resulting in brittleness and abnormal vulnerability to fractures. It is most common in postmenopausal white women. The risk of osteoporosis can be minimized with diet (adequate calcium intake) and exercise.

Testing Your Recall

1. Which cells have a ruffled border and secrete hydrochloric acid?
 - a. C cells
 - b. osteocytes
 - c. osteogenic cells
 - d. osteoblasts
 - e. osteoclasts
2. The marrow cavity of an adult bone may contain
 - a. myeloid tissue.
 - b. hyaline cartilage.
 - c. periosteum.
 - d. osteocytes.
 - e. articular cartilages.
3. The spurt of growth in puberty results from cell proliferation and hypertrophy in
 - a. the epiphysis.
 - b. the epiphyseal line.
 - c. compact bone.
 - d. the epiphyseal plate.
 - e. spongy bone.
4. Osteoclasts are most closely related, by common descent, to
 - a. osteoprogenitor cells.
 - b. osteogenic cells.
 - c. blood cells.
 - d. fibroblasts.
 - e. osteoblasts.
5. The walls between cartilage lacunae break down in the zone of
 - a. cell proliferation.
 - b. calcification.
 - c. reserve cartilage.
 - d. bone deposition.
 - e. cell hypertrophy.
6. Which of these is *not* an effect of PTH?
 - a. rise in blood phosphate level
 - b. reduction of calcium excretion
 - c. increased intestinal calcium absorption
 - d. increased number of osteoclasts
 - e. increased calcitriol synthesis
7. A child jumps to the ground from the top of a playground “jungle gym.” His leg bones do not shatter mainly because they contain
 - a. an abundance of glycosaminoglycans.
 - b. young, resilient osteocytes.
 - c. an abundance of calcium phosphate.
 - d. collagen fibers.
 - e. hydroxyapatite crystals.
8. One long bone meets another at its
 - a. diaphysis.
 - b. epiphyseal plate.
 - c. periosteum.
 - d. metaphysis.
 - e. epiphysis.
9. Calcitriol is made from
 - a. calcitonin.
 - b. 7-dehydrocholesterol.
 - c. hydroxyapatite.
 - d. estrogen.
 - e. PTH.
10. One sign of osteoporosis is
 - a. osteosarcoma.
 - b. osteomalacia.
 - c. osteomyelitis.
 - d. a Colles fracture.
 - e. hypocalcemia.
11. Calcium phosphate crystallizes in bone as a mineral called ____.
12. Osteocytes contact each other through channels called ____ in the bone matrix.
13. A bone increases in diameter only by ____ growth, the addition of new surface lamellae.
14. Seed crystals of hydroxyapatite form only when the levels of calcium and phosphate in the tissue fluid exceed the ____.
15. A calcium deficiency called ____ can cause death by suffocation.
16. ____ are cells that secrete collagen and stimulate calcium phosphate deposition.
17. The most active form of vitamin D, produced mainly by the kidneys, is ____.
18. The most common bone disease is ____.
19. The transitional region between epiphyseal cartilage and the primary marrow cavity of a young bone is called the ____.
20. A pregnant, poorly nourished woman may suffer a softening of the bones called ____.

True or False

Determine which five of the following statements are false, and briefly explain why.

- Spongy bone is always covered by compact bone.
- Most bones develop from hyaline cartilage.
- Fractures are the most common bone disorder.
- The growth zone of the long bones of adolescents is the articular cartilage.
- Osteoclasts develop from osteoblasts.
- Osteocytes develop from osteoblasts.
- The protein of the bone matrix is called hydroxyapatite.
- Blood vessels travel through the central canals of compact bone.
- Vitamin D promotes bone deposition, not resorption.
- Parathyroid hormone promotes bone resorption and raises blood calcium concentration.

Answers in appendix B

Testing Your Comprehension

- Most osteocytes of an osteon are far removed from blood vessels, but still receive blood-borne nutrients. Explain how this is possible.
- A 50-year-old business executive decides he has not been getting enough exercise for the last several years. He takes up hiking and finds that he really loves it. Within 2 years, he is spending many of his weekends hiking with a heavy backpack and camping in the mountains. Explain what changes in his anatomy could be predicted from Wolff's law of bone.
- How does the regulation of blood calcium concentration exemplify negative feedback and homeostasis?
- Describe how the arrangement of trabeculae in spongy bone demonstrates the unity of form and function.
- Identify two bone diseases you would expect to see if the epidermis were a completely effective barrier to UV radiation and a person took no dietary supplements to compensate for this. Explain your answer.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Directional terminology (p. 30)
- Body regions and cavities (pp. 31-36)

Knowledge of skeletal anatomy will be useful as you study later chapters. It provides a point of reference for studying the gross anatomy of other organ systems because many organs are named for their relationships to nearby bones. The subclavian artery and vein, for example, are located beneath the clavicles; the temporalis muscle is attached to the temporal bone; the ulnar nerve and radial artery travel beside the ulna and radius, respectively, of the forearm; and the frontal, parietal, temporal, and occipital lobes of the brain are named for bones of the cranium. An understanding of how the muscles produce body movements also depends on knowledge of skeletal anatomy. Additionally, the positions, shapes, and processes of bones can serve as landmarks for a clinician in determining where to give an injection or record a pulse, what to look for in an X-ray, or how to perform physical therapy and other medical procedures.

8.1 Overview of the Skeleton

Objectives

When you have completed this section, you should be able to

- state the approximate number of bones in the adult body;
- explain why this number varies with age and from one person to another; and
- define several terms that denote surface features of bones.

Students typically begin by examining an *articulated*¹ skeleton (dried bones held together by wires and rods to show their spatial relationships to one another) or a *disarticulated* one (one that is taken apart so that the anatomy of individual bones can be studied in more detail). The skeleton is shown in figure 8.1. Note that it is divided into two regions: the axial skeleton and the appendicular skeleton. The **axial skeleton**, which forms the central supporting axis of the body, includes the skull, auditory ossicles, hyoid bone, vertebral column, and thoracic cage (ribs and sternum). The **appendicular skeleton** includes the bones of the upper limb and pectoral girdle and the bones of the lower limb and pelvic girdle.

Bones of the Skeletal System

It is often stated that there are 206 bones in the skeleton, but this is only a typical adult count. At birth there are

about 270, and even more bones form during childhood. With age, however, the number decreases as separate bones gradually fuse. For example, each half of the adult pelvis is a single *hip bone*, which results from the fusion of three childhood bones: the ilium, ischium, and pubis. The fusion of several bones, completed by late adolescence to the mid-20s, brings about the average adult number of 206. These bones are listed in table 8.1.

This number varies even among adults. One reason is the development of **sesamoid**² bones—bones that form within some tendons in response to stress. The patella

²*sesam* = sesame seed + *oid* = resembling

TABLE 8.1

Bones of the Adult Skeletal System

Axial Skeleton	
Skull (22 bones)	Auditory ossicles (6 bones)
Cranial bones	Malleus (2)
Frontal bone (1)	Incus (2)
Parietal bone (2)	Stapes (2)
Occipital bone (1)	
Temporal bone (2)	Hyoid bone (1 bone)
Sphenoid bone (1)	
Ethmoid bone (1)	Vertebral column (26 bones)
Facial bones	Cervical vertebrae (7)
Maxilla (2)	Thoracic vertebrae (12)
Palatine bone (2)	Lumbar vertebrae (5)
Zygomatic bone (2)	Sacrum (1)
Lacrimal bone (2)	Coccyx (1)
Nasal bone (2)	
Vomer (1)	Thoracic cage (25 bones plus thoracic vertebrae)
Inferior nasal concha (2)	Ribs (24)
Mandible (1)	Sternum (1)
Appendicular Skeleton	
Pectoral girdle (4 bones)	Hip bones (2)
Scapula (2)	
Clavicle (2)	
Upper limb (60 bones)	Lower limb (60 bones)
Humerus (2)	Femur (2)
Radius (2)	Patella (2)
Ulna (2)	Tibia (2)
Carpals (16)	Fibula (2)
Metacarpals (10)	Tarsals (14)
Phalanges (28)	Metatarsals (10)
	Phalanges (28)
Grand Total: 206 Bones	

¹*artic* joint

FIGURE 8.1 The Adult Skeleton. The appendicular skeleton is colored green, and the rest is axial skeleton.

(kneecap) is the largest of these; most of the others are small, rounded bones in such locations as the knuckles. Another reason for adult variation is that some people have extra bones in the skull called **sutural** (SOO-chure-ul), or **wormian**,³ **bones** (see fig. 8.6).

Anatomical Features of Bones

A bone may exhibit a variety of ridges, spines, bumps, depressions, canals, pores, slits, cavities, and articular surfaces. It is important to know the names of these *bone markings* because later descriptions of joints, muscle attachments, and the routes traveled by nerves and blood vessels are based on this terminology. The terms for the most common of these features are listed in table 8.2, and several of them are illustrated in figure 8.2.

The rest of this chapter is divided into four sections: (1) the skull, (2) the vertebral column and thoracic cage, (3) the pectoral girdle and upper limb, and (4) the pelvic girdle and lower limb. As you study this chapter, use yourself as a model. You can easily palpate (feel) many of the bones and some of their details through the skin. Rotate your forearm, cross your legs, palpate your skull and wrist, and think about what is happening beneath the surface or what you can feel through the skin. You will gain the most from this chapter (and indeed, the entire book) if you are conscious of your own body in relation to what you are studying.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Name the major components of the axial skeleton. Name those of the appendicular skeleton.
2. Explain why an adult does not have as many bones as a child does. Explain why one adult may have more bones than another adult of the same age has.
3. Briefly describe each of the following bone features: a condyle, epicondyle, process, tubercle, fossa, sulcus, and foramen.

8.2 The Skull

Objectives

When you have completed this section, you should be able to

- name the bones of the skull and their anatomical features; and
- describe the development of the skull from infancy through childhood.

TABLE 8.2

Anatomical Features (Markings) of Bones

Term	Description and Example
Articulations	
Condyle	A rounded knob that articulates with another bone (occipital condyles of the skull)
Facet	A smooth, flat, slightly concave or convex articular surface (articular facets of the vertebrae)
Head	The prominent expanded end of a bone, sometimes rounded (head of the femur)
Extensions and projections	
Crest	A narrow ridge (iliac crest of the pelvis)
Epicondyle	A projection superior to a condyle (medial epicondyle of the femur)
Line	A slightly raised, elongated ridge (nuchal lines of the skull)
Process	Any bony prominence (mastoid process of the skull)
Protuberance	A bony outgrowth or protruding part (mental protuberance of the chin)
Spine	A sharp, slender, or narrow process (spine of the scapula)
Trochanter	Two massive processes unique to the femur
Tubercle	A small, rounded process (greater tubercle of the humerus)
Tuberosity	A rough elevated surface (tibial tuberosity)
Depressions	
Alveolus	A pit or socket (tooth socket)
Fossa	A shallow, broad, or elongated basin (mandibular fossa)
Fovea	A small pit (fovea capitis of the femur)
Sulcus	A groove for a tendon, nerve, or blood vessel (intertubercular sulcus of the humerus)
Passages and cavities	
Canal	A tubular passage or tunnel in a bone (condylar canal of the skull)
Fissure	A slit through a bone (orbital fissures behind the eye)
Foramen	A hole through a bone, usually round (foramen magnum of the skull)
Meatus	An opening into a canal (acoustic meatus of the ear)
Sinus	An air-filled space in a bone (frontal sinus of the forehead)

The skull is the most complex part of the skeleton. Figures 8.3 to 8.6 present an overview of its general anatomy. Although it may seem to consist only of the mandible (lower jaw) and “the rest,” it is composed of 22 bones and sometimes more. Most of these are connected by immovable joints called **sutures** (SOO-chures), which are visible as seams on the surface (fig. 8.4). These are important landmarks in the descriptions that follow.

³Ole Worm (1588–1654), Danish physician

FIGURE 8.2 Anatomical Features of Bones. Most of these features also occur on many other bones of the body.

FIGURE 8.3 The Skull, Anterior View.

(b) Superior view of cranial floor

FIGURE 8.5 The Base of the Skull.

FIGURE 8.6 The Calvaria (Skullcap), Superior View.

FIGURE 8.7 Major Cavities of the Skull (Frontal Section).

The skull contains several prominent cavities (fig. 8.7). The largest, with an adult volume of about 1,350 mL, is the **cranial cavity**, which encloses the brain. Other cavities include the **orbits** (eye sockets), **nasal cavity**, **oral (buccal) cavity** (mouth), **middle- and inner-ear cavities**, and **paranasal sinuses**. The paranasal sinuses are named for the bones in which they occur (fig. 8.8)—the **frontal**,

sphenoid, **ethmoid**, and **maxillary sinuses**. These cavities are connected with the nasal cavity, lined by mucous membranes, and filled with air. They lighten the anterior portion of the skull and act as chambers that add resonance to the voice. The latter effect can be sensed in the way your voice changes when you have a cold and mucus obstructs the travel of sound into the sinuses and back.

FIGURE 8.8 The Paranasal Sinuses.

Bones of the skull have especially conspicuous **foramina**—singular, *foramen* (fo-RAY-men)—holes that allow passage for nerves and blood vessels. The major foramina are summarized in table 8.3. The details of this table will mean more to you when you study cranial nerves and blood vessels in later chapters.

Cranial Bones

The cranial cavity is enclosed by the **cranium**⁴ (braincase), which protects the brain and associated sense organs. The cranium is a rigid structure with an opening, the *foramen magnum* (literally “large hole”), where the spinal cord enters. An important consideration in head injuries is swelling of the brain. Since the cranium cannot enlarge, swelling puts pressure on the brain and results in even more tissue damage. Severe swelling may force the brainstem out through the foramen magnum, usually with fatal consequences.

The delicate brain tissue does not directly contact the cranial bones but is separated from them by three membranes called the *meninges* (meh-NIN-jeez) (see chapter 14). The thickest and toughest of these, the *dura mater*⁵ (DUE-rah MAH-tur), lies loosely against the inside of the cranium in most places but is firmly attached to it at a few points.

The cranium consists of two major parts: the calvaria and the base. The **calvaria**⁶ (skullcap) forms the roof and

walls (see fig. 8.6). In study skulls it is often sawed so that part of it can be lifted off for examination of the interior. This reveals the **base** (floor) of the cranial cavity (see fig. 8.5b), which is divided into three basins corresponding to the contour of the inferior surface of the brain (fig. 8.9). The relatively shallow **anterior cranial fossa** is crescent-shaped and accommodates the frontal lobes of the brain. The **middle cranial fossa**, which drops abruptly deeper, is shaped like a pair of outstretched bird’s wings and accommodates the temporal lobes. The **posterior cranial fossa** is deepest and houses a large posterior division of the brain called the cerebellum.

The cranium is composed of eight **cranial bones**:

- | | |
|------------------|------------------|
| 1 frontal bone | 1 occipital bone |
| 2 parietal bones | 1 sphenoid bone |
| 2 temporal bones | 1 ethmoid bone |

We will now examine their individual distinguishing features.

Frontal Bone

The **frontal bone** extends from the forehead back to a prominent *coronal suture*, which crosses the crown of the head from right to left and joins the frontal bone to the parietal bones (see figs. 8.3 and 8.4). The frontal bone forms the anterior wall and about one-third of the roof of the cranial cavity, and it turns inward to form nearly all of the anterior cranial fossa and the roof of the orbit. Deep to the eyebrows it has a ridge called the **supraorbital margin**. The center of each margin is perforated by a single **supraorbital foramen** (see figs. 8.3 and 8.14),

⁴*crani* = helmet

⁵*dura* = tough, strong + *mater* = mother

⁶*calvar* = bald, skull

FIGURE 8.9 Cranial Fossae. The three fossae conform to the contours of the base of the brain.

TABLE 8.3 Foramina of the Skull and the Nerves and Blood Vessels Transmitted Through Them

Bones and Their Foramina	Structures Transmitted
Frontal bone	
Supraorbital foramen or notch	Supraorbital nerve, artery, and vein; ophthalmic nerve
Parietal bone	
Parietal foramen	Emissary vein of superior longitudinal sinus
Temporal bone	
Carotid canal	Internal carotid artery
External acoustic meatus	Sound waves to eardrum
Internal acoustic meatus	Vestibulocochlear nerve; internal auditory vessels
Stylomastoid foramen	Facial nerve
Mastoid foramen	Meningeal artery; vein from sigmoid sinus
Temporal-occipital region	
Jugular foramen	Internal jugular vein; glossopharyngeal, vagus, and accessory nerves
Temporal-occipital-sphenoid region	
Foramen lacerum	Closed by cartilage; not completely penetrated by any major nerves or vessels
Occipital bone	
Foramen magnum	Spinal cord; accessory nerve; vertebral arteries
Hypoglossal canal	Hypoglossal nerve to muscles of tongue
Condylar canal	Vein from transverse sinus
Sphenoid bone	
Foramen ovale	Mandibular division of trigeminal nerve; accessory meningeal artery
Foramen rotundum	Maxillary division of trigeminal nerve
Foramen spinosum	Middle meningeal artery; spinous nerve; part of trigeminal nerve
Optic foramen	Optic nerve; ophthalmic artery
Superior orbital fissure	Oculomotor, trochlear, and abducens nerves; ophthalmic division of trigeminal nerve; ophthalmic veins
Ethmoid bone	
Cribriform foramina	Olfactory nerves
Maxilla	
Infraorbital foramen	Infraorbital nerve and vessels
Incisive foramen	Nasopalatine nerves
Maxilla-sphenoid region	
Inferior orbital fissure	Infraorbital nerve; zygomatic nerve; infraorbital vessels
Lacrimal bone	
Lacrimal foramen	Tear duct leading to nasal cavity
Palatine bone	
Greater palatine foramen	Palatine nerves
Zygomatic bone	
Zygomaticofacial foramen	Zygomaticofacial nerve
Zygomaticotemporal foramen	Zygomaticotemporal nerve
Mandible	
Mental foramen	Mental nerve and vessels
Mandibular foramen	Inferior alveolar nerves and vessels to the lower teeth

*When two or more bones are listed together (for example, temporal-occipital), it indicates that the foramen passes between them.

which provides passage for a nerve, artery, and veins. In some people, the edge of this foramen breaks through the margin of the orbit and forms a *supraorbital notch*. A person may have a foramen on one supraorbital margin and a notch on the other. The smooth area of the frontal bone just above the root of the nose is called the **glabella**.⁷ The frontal bone also contains the frontal sinus. You may not see this on all study skulls. It is absent from some people, and on some skulls the calvaria is cut too high to show it. Along the cut edge of the calvaria, you can see the diploe—the layer of spongy bone in the middle of the cranial bones (see fig. 8.5b).

Parietal Bones

The right and left **parietal** (pa-RY-eh-tul) **bones** form most of the cranial roof and part of its walls (see figs. 8.4 and 8.6). Each is bordered by four sutures that join it to the neighboring bones: (1) a **sagittal suture** between the parietal bones; (2) the **coronal**⁸ **suture** at the anterior margin; the **lambdoid**⁹ (LAM-doyd) **suture** at the posterior margin; and (4) the **squamous suture** laterally. Small sutural (wormian) bones are often seen along the sagittal and lambdoid sutures, like little islands of bone with the suture lines passing around them. Internally, the parietal and frontal bones have markings that look a bit like aerial photographs of river tributaries (see fig. 8.4b). These represent places where the bone has been molded around blood vessels of the meninges.

Externally, the parietal bones have few features. A **parietal foramen** sometimes occurs near the corner of the lambdoid and sagittal sutures (see fig. 8.6). A pair of slight thickenings, the superior and inferior **temporal lines**, form an arc across the parietal and frontal bones (see fig. 8.4a). They mark the attachment of the large, fan-shaped *temporalis* muscle, a chewing muscle that inserts on the mandible.

Temporal Bones

If you palpate your skull just above and anterior to the ear—that is, the temporal region—you can feel the **temporal bone**, which forms the lower wall and part of the floor of the cranial cavity (fig. 8.10). The temporal bone derives its name from the fact that people often develop their first gray hairs on the temples with the passage of time.¹⁰ The relatively complex shape of the

FIGURE 8.10 The Right Temporal Bone. The lateral surface faces the scalp and external ear; the medial surface faces the brain.

◀ List five bones that articulate with the temporal bone.

temporal bone is best understood by dividing it into four parts:

1. The **squamous**¹¹ **part** (which you just palpated) is relatively flat and vertical. It is encircled by the squamous suture. It bears two prominent features: (1) the **zygomatic process**, which extends anteriorly to form part of the zygomatic arch (cheekbone), and (2) the **mandibular fossa**, a depression where the mandible articulates with the cranium.
2. The **tympanic**¹² **part** is a small ring of bone that borders the **external acoustic meatus** (me-AY-tus), the opening into the ear canal. It has a pointed spine on its inferior surface, the **styloid process**, named for its resemblance to the stylus used by ancient Greeks and Romans to write on wax tablets. The styloid process provides attachment for muscles of the tongue, pharynx, and hyoid bone.
3. The **mastoid**¹³ **part** lies posterior to the tympanic part. It bears a heavy **mastoid process**, which you

⁷glab = smooth

⁸corona = crown

⁹Shaped like the Greek letter lambda (λ)

¹⁰tempor = time

¹¹squam = flat + os = characterized by

¹²tympan = drum (eardrum) + ic = pertaining to

¹³mast = breast + oid = resembling

can palpate as a prominent lump behind the earlobe. It is filled with small air sinuses that communicate with the middle-ear cavity. These sinuses are subject to infection and inflammation (*mastoiditis*), which can erode the bone and spread to the brain. A groove called the **mastoid notch** lies medial to the mastoid process (see fig. 8.5a). It is the origin of the *digastric muscle*, which opens the mouth. The notch is perforated by the **stylomastoid foramen** at its anterior end and the **mastoid foramen** at its posterior end.

- The **petrous**¹⁴ **part** can be seen in the cranial floor, where it resembles a little mountain range separating the middle cranial fossa from the posterior fossa (fig. 8.10b). It houses the middle- and inner-ear cavities. The **internal acoustic meatus**, an opening on its posteromedial surface, allows passage of the vestibulocochlear (vess-TIB-you-lo-COC-lee-ur) nerve, which carries sensations of hearing and balance from the inner ear to the brain. On the inferior surface of the petrous part are two prominent foramina named for the major blood vessels that pass through them (see fig. 8.5a): (1) The **carotid canal** is a passage for the internal carotid artery, a major blood supply to the brain. This artery is so close to the inner ear that you can sometimes hear the pulsing of its blood when your ear is resting on a pillow or your heart is beating hard. (2) The **jugular foramen** is a large, irregular opening just medial to the styloid process, between the temporal and occipital bones. Blood from the brain drains through this foramen into the internal jugular vein of the neck. Three cranial nerves also pass through this foramen (see table 8.3).

Occipital Bone

The **occipital** (oc-SIP-ih-tul) **bone** forms the rear of the skull (*occiput*) and much of its base (see fig. 8.5). Its most conspicuous feature, the **foramen magnum**, admits the spinal cord to the cranial cavity and provides a point of attachment for the dura mater. The occipital bone continues anterior to the foramen magnum as a thick medial plate, the **basilar part**. On either side of the foramen magnum is a smooth knob called the **occipital condyle** (CON-dile), where the skull rests on the vertebral column. At the anterolateral edge of each condyle is a **hypoglossal**¹⁵ **canal**, named for the hypoglossal nerve that passes through it to supply the muscles of the tongue. In some people, a **condylar** (CON-dih-lur) **canal** is found posterior to each occipital condyle.

Internally, the occipital bone displays impressions left by large venous sinuses that drain blood from the brain (see fig. 8.5b). One of these grooves travels along the mid-sagittal line. Just before reaching the foramen magnum, it branches into right and left grooves that wrap around the

occipital bone like outstretched arms before terminating at the jugular foramina. The venous sinuses that occupy these grooves are described in chapter 20.

Other features of the occipital bone can be palpated on the back of your head. One is a prominent medial bump called the **external occipital protuberance**—the attachment for the **nuchal**¹⁶ (NEW-kul) **ligament**, which binds the skull to the vertebral column. A ridge, the **superior nuchal line**, can be traced horizontally from the external occipital protuberance toward the mastoid process (see fig. 8.5a). It defines the superior limit of the neck and provides attachment to the skull for several neck and back muscles. It forms the boundary where, in palpating the upper neck, you feel the transition from muscle to bone. By pulling down on the occipital bone, some of these muscles help to keep the head erect. The **inferior nuchal line** provides attachment for some of the deep neck muscles. This inconspicuous ridge cannot be palpated on the living body but is visible on an isolated skull.

Sphenoid Bone

The **sphenoid**¹⁷ (SFEE-noyd) **bone** has a complex shape with a thick median **body** and outstretched **greater** and **lesser wings**, which give the bone as a whole a somewhat ragged mothlike shape. Most of it is best seen from the superior perspective (fig. 8.11a). In this view, the lesser wings form the posterior margin of the anterior cranial fossa and end at a sharp bony crest, where the sphenoid drops abruptly to the greater wings. The greater wings form about half of the middle cranial fossa (the temporal bone forming the rest) and are perforated by several foramina to be discussed shortly.

The greater wing also forms part of the lateral surface of the cranium just anterior to the temporal bone (see fig. 8.4a). The lesser wing forms the posterior wall of the orbit and contains the **optic foramen**, which permits passage of the optic nerve and ophthalmic artery (see fig. 8.14). Superiorly, a pair of bony spines of the lesser wing called the **anterior clinoid processes** appear to guard the optic foramina. A gash in the posterior wall of the orbit, the **superior orbital fissure**, angles upward lateral to the optic foramen. It serves as a passage for nerves that supply the muscles that move the eyes.

The body of the sphenoid has a saddlelike prominence named the **sella turcica**¹⁸ (SEL-la TUR-sih-ca). The sella consists of a deep pit called the *hypophyseal fossa*, which houses the pituitary gland (hypophysis); a raised anterior margin called the *tuberculum sellae* (too-BUR-cu-lum SEL-lee); and a posterior margin called the *dorsum sellae*. In life, a fibrous membrane is stretched over the sella turcica and attaches to the anterior clinoid processes. A stalk penetrates the membrane to connect the pituitary gland to the base of the brain.

Lateral to the sella turcica, the sphenoid is perforated by several foramina (see fig. 8.5a). The **foramen**

¹⁸*sella* = saddle + *turcica* = Turkish

FIGURE 8.11 The Sphenoid Bone.

rotundum and **foramen ovale** (oh-VAY-lee) are passages for two branches of the trigeminal nerve. The **foramen spinosum**, about the diameter of a pencil lead, provides passage for an artery of the meninges. An irregular gash called the **foramen lacerum**¹⁹ (LASS-eh-rum) occurs at the junction of the sphenoid, temporal, and occipital bones. It is filled with cartilage in life and transmits no major vessels or nerves.

In an inferior view, the sphenoid can be seen just anterior to the basilar part of the occipital bone. The internal openings of the nasal cavity seen here are called the **posterior nasal apertures**, or **choanae**²⁰ (co-AH-nee). Lateral to each aperture, the sphenoid bone exhibits a pair of parallel plates: the **medial** and **lateral pterygoid**²¹ (TERR-ih-goyd) **plates** (see fig. 8.5a). Each plate has a narrower inferior extension called the **pterygoid process**. These plates and processes provide attachment for some of the jaw muscles. The sphenoid sinus occurs within the body of the sphenoid bone.

Ethmoid Bone

The **ethmoid**²² (ETH-moyd) **bone** is an anterior cranial bone located between the eyes (figs. 8.7 and 8.12). It contributes to the medial wall of the orbit, the roof and walls

FIGURE 8.12 The Ethmoid Bone (Anterior View).

• List five bones that articulate with the ethmoid bone.

¹⁹lacerum = torn, lacerated

²⁰choana = funnel

²¹pteryg = wing + oid = resembling

of the nasal cavity, and the nasal septum. It is a very porous and delicate bone, with three major portions:

1. The vertical **perpendicular plate**, a thin median plate of bone that forms the superior two-thirds of the nasal septum (see fig. 8.4b). (The lower part is formed by the *vomer*, discussed later.) The septum divides the nasal cavity into right and left air spaces called the **nasal fossae** (FOSS-ee). The septum is often curved, or deviated, toward one nasal fossa or the other.
2. A horizontal **cribriform**²³ (CRIB-rih-form) **plate**, which forms the roof of the nasal cavity. This plate has a median crest called the **crista galli**²⁴ (GAL-eye), an attachment point for the meninges that enclose the brain. On each side of the crista is an elongated depressed area perforated with numerous holes, the **cribriform (olfactory) foramina**. A pair of *olfactory bulbs* of the brain, concerned with the sense of smell, rests in these depressions, and the foramina allow passage for olfactory nerves from the nasal cavity to the bulbs (see Insight 8.1).
3. The **labyrinth**, a large mass on each side of the perpendicular plate. The labyrinth is named for the fact that internally, it has a maze of air spaces called the **ethmoidal cells**. Collectively, these constitute the *ethmoid sinus* discussed earlier. The lateral surface of the labyrinth is a smooth, slightly concave **orbital plate** seen on the medial wall of the orbit (see fig. 8.14). The medial surface of the labyrinth gives rise to two curled, scroll-like plates of bone called

INSIGHT 8.1 Clinical Application

Injury to the Ethmoid Bone

The ethmoid bone is very delicate and is easily injured by a sharp upward blow to the nose, such as a person might suffer by striking an automobile dashboard in a collision. The force of a blow can drive bone fragments through the cribriform plate into the meninges or brain tissue. Such injuries are often evidenced by leakage of cerebrospinal fluid into the nasal cavity, and may be followed by the spread of infection from the nasal cavity to the brain. Blows to the head can also shear off the olfactory nerves that pass through the ethmoid bone and cause *anosmia*, an irreversible loss of the sense of smell and a great reduction in the sense of taste (most of which depends on smell). This not only deprives life of some of its pleasures, but can also be dangerous, as when a person fails to smell smoke, gas, or spoiled food.

the **superior and middle nasal conchae**²⁵ (CON-kee). These project into the nasal fossa from its lateral wall toward the septum (see figs. 8.7 and 8.13). There is also a separate bone, the *inferior nasal concha*, discussed later. The three of them together occupy most of the space in the nasal cavity. By filling space and creating turbulence in the flow of inhaled air, they ensure that the air contacts the mucous membranes that cover these bones, which cleanse, humidify, and warm the inhaled air before it reaches the lungs. The superior concha and adjacent part of the nasal septum also bear the sensory cells of smell.

²³ *cribri* = sieve + *form* = in the shape of

FIGURE 8.13 The Left Nasal Cavity (Sagittal Section).

FIGURE 8.14 The Left Orbit (Anterior View).

In studying an intact skull, all that can be seen of the ethmoid is the perpendicular plate, by looking into the nasal cavity (see fig. 8.3); the orbital plate, by looking at the medial wall of the orbit (fig. 8.14); and the crista galli and cribriform plate, viewed from within the cranial cavity (see fig. 8.5b).

Facial Bones

The **facial bones** are those that have no direct contact with the brain or meninges. They support the teeth, give shape and individuality to the face, form part of the orbital and nasal cavities, and provide attachment for the muscles of facial expression and mastication. There are 14 facial bones:

2 maxillae	2 nasal bones
2 palatine bones	2 inferior nasal conchae
2 zygomatic bones	1 vomer
2 lacrimal bones	1 mandible

Maxillae

The **maxillae** (mac-SILL-ee) are the largest facial bones. They form the upper jaw and meet each other at a median *intermaxillary suture* (see figs. 8.3, 8.4a, and 8.5a). Small points of maxillary bone called **alveolar processes** grow into the spaces between the bases of the teeth. The root of each tooth is inserted into a deep socket, or **alveolus**. If a tooth is lost or extracted so that chewing no longer puts stress on the maxilla, the alveolar processes are resorbed and the alveolus fills in with new bone, leaving a smooth area on the maxilla. Even though they are preserved with the skull, the teeth are not bones. They are discussed in detail in chapter 25.

Think About It

Suppose you were studying a skull with some teeth missing. How could you tell whether the teeth had been lost after the person's death or years before it?

Each maxilla extends from the teeth to the inferomedial wall of the orbit. Just below the orbit, it exhibits an **infraorbital foramen**, which provides passage for a blood vessel to the face and a nerve that receives sensations from the nasal region and cheek. This nerve emerges through the foramen rotundum into the cranial cavity. The maxilla forms part of the floor of the orbit, where it exhibits a gash called the **inferior orbital fissure** that angles downward and medially (fig. 8.14). The inferior and superior orbital fissures form a sideways V whose apex lies near the optic foramen. The inferior orbital fissure is a passage for blood vessels and sensory nerves from the face.

The **palate** forms the roof of the mouth and floor of the nasal cavity. It consists of a bony **hard palate** anteriorly and a fleshy **soft palate** posteriorly. Most of the hard palate is formed by horizontal extensions of the maxilla called **palatine (PAL-uh-tine) processes** (see fig. 8.5a). Near the anterior margin of each palatine process, just behind the incisors, is an **incisive foramen**. The palatine processes normally meet at the intermaxillary suture at about 12 weeks of gestation. Failure to join results in a *cleft palate*, often accompanied by a *cleft lip* lateral to the midline. Cleft palate and lip can be surgically corrected with good cosmetic results, but a cleft palate makes it difficult for an infant to generate the suction needed for nursing.

INSIGHT 8.2 Evolutionary Medicine**Evolutionary Significance of the Palate**

In most vertebrates, the nasal passages open into the oral cavity. Mammals, by contrast, have a palate that separates the nasal cavity from the oral cavity. In order to maintain our high metabolic rate, we must digest our food rapidly; in order to do this, we chew it thoroughly to break it up into small, easily digested particles before swallowing it. The palate allows us to continue breathing during this prolonged chewing.

Palatine Bones

The **palatine bones** form the rest of the hard palate, part of the wall of the nasal cavity, and part of the floor of the orbit (see figs. 8.5a and 8.13). At the posterolateral corners of the hard palate are two large **greater palatine foramina**.

Zygomatic Bones

The **zygomatic**²⁶ **bones** form the angles of the cheeks at the inferolateral margins of the orbits and part of the lateral wall of each orbit; they extend about halfway to the ear (see figs. 8.4a and 8.5a). Each zygomatic bone has an inverted T shape and usually a small **zygomaticofacial** (ZY-go-MAT-ih-co-FAY-shul) **foramen** near the intersection of the stem and crossbar of the T. The prominent zygomatic arch that flares from each side of the skull is formed mainly by the union of the zygomatic process of the temporal bone and the *temporal process* of the zygomatic bone (see fig. 8.4a).

Lacrimal Bones

The **lacrimal**²⁷ (LACK-rih-mul) **bones** form part of the medial wall of each orbit (fig. 8.14). They are the smallest bones of the skull, about the size of the little fingernail. A depression called the **lacrimal fossa** houses a membranous *lacrimal sac* in life. Tears from the eye collect in this sac and drain into the nasal cavity.

Nasal Bones

Two small rectangular **nasal bones** form the bridge of the nose (see fig. 8.3) and support cartilages that shape its lower portion. If you palpate the bridge, you can easily feel where the nasal bones end and the cartilages begin. The nasal bones are often fractured by blows to the nose.

Inferior Nasal Conchae

There are three conchae in the nasal cavity. The superior and middle conchae, as discussed earlier, are parts of

the ethmoid bone. The **inferior nasal concha**—the largest of the three—is a separate bone (see fig. 8.13).

Vomer

The **vomer** forms the inferior half of the nasal septum (see figs. 8.3 and 8.4b). Its name literally means “plow-share,” which refers to its resemblance to the blade of a plow. The superior half of the nasal septum is formed by the perpendicular plate of the ethmoid bone, as mentioned earlier. The vomer and perpendicular plate support a wall of *septal cartilage* that forms most of the anterior part of the nasal septum.

Mandible

The **mandible** (fig. 8.15) is the strongest bone of the skull and the only one that can move noticeably. It supports the lower teeth and provides attachment for muscles of mastication and facial expression. It develops as separate right and left bones in the fetus, joined by a median cartilaginous joint called the **mental symphysis** (SIM-fih-sis) at the point of the chin. This joint ossifies in early childhood, uniting the two halves into a single bone. The point of the chin itself is called the **mental protuberance**.

The mandible has two major parts on each side—the horizontal **body** that supports the teeth, and a vertical or oblique posterior portion, the **ramus** (RAY-mus), that articulates with the cranium. The body and ramus meet at a corner called the **angle**.

The body of the mandible, like the maxilla, exhibits pointed alveolar processes between the teeth. Slightly lateral to the mental symphysis, it has a prominent **mental foramen** that permits the passage of nerves and blood vessels of the chin. The inner surface of the body is marked by shallow depressions and ridges that accommodate muscles and salivary glands. In the region of the mental protuberance, the inner surface has a pair of small points,

**FIGURE 8.15** The Mandible.²⁶zygo = to join, unite²⁷lacrim = tear, to cry

the **mental spines**, which serve for attachment of certain chin muscles (see fig. 8.4b). The angle of the mandible has a rough lateral surface for insertion of the *masseter*, a muscle of mastication.

The ramus is somewhat Y-shaped. Its posterior branch, called the **condylar (CON-dih-lur) process**, bears the **mandibular condyle**—an oval knob that articulates with the mandibular fossa of the temporal bone. The meeting of this condyle with the temporal bone forms a hinge, the **temporomandibular joint (TMJ)**. The anterior branch of the ramus, called the **coronoid process**, is the point of insertion for the temporalis muscle, which pulls the mandible upward when you bite. The U-shaped arch between the two processes is called the **mandibular notch**. Just below the notch, on the medial surface of the ramus, is the **mandibular foramen**. The nerve and blood vessels that supply the lower teeth enter this foramen and then travel through the bone of the mandibular body, giving off branches to each tooth along the way. Dentists inject anesthetic near here to deaden sensation from the lower teeth.

Bones Associated with the Skull

Seven bones are closely associated with the skull but not considered part of it. These are the three auditory ossicles in each middle-ear cavity and the hyoid bone beneath the chin. The **auditory ossicles**²⁸—named the **malleus** (hammer), **incus** (anvil), and **stapes** (STAY-pee-z) (stirrup)—are discussed in connection with hearing in chapter 16. The **hyoid**²⁹ bone is a slender U-shaped bone between the chin and larynx (fig. 8.16). It is one of the few bones that does not articulate with any other. It is suspended from the styloid processes of the skull, somewhat like a hammock, by the small *stylohyoid muscles* and *stylohyoid ligaments*. The median **body** of the hyoid is flanked on either side by hornlike projections called the **greater** and **lesser horns (cornua)**. The hyoid bone serves for attachment of several muscles that control the mandible, tongue, and larynx. Forensic pathologists look for a fractured hyoid as evidence of strangulation.

The Skull in Infancy and Childhood

The head of an infant could not fit through the mother's pelvic outlet at birth were it not for the fact that the bones of its skull are not yet fused. The shifting of the skull bones during birth may cause the infant to appear deformed, but the head soon assumes a more normal shape. Spaces between the unfused cranial bones are called **fontanels**,³⁰ after the fact that pulsation of the infant's blood can be felt there. The bones are joined at these points only by fibrous membranes, in which

FIGURE 8.16 The Hyoid Bone.

INSIGHT 8.3

Clinical Application

Cranial Assessment of the Newborn

Obstetric nurses routinely assess the fontanels of newborns by palpation. In a difficult delivery, one cranial bone may override another along a suture line, which calls for close monitoring of the infant. Abnormally wide sutures may indicate hydrocephalus, the accumulation of excessive amounts of cerebrospinal fluid, which causes the cranium to swell. Bulging fontanels suggest abnormally high intracranial pressure, while depressed fontanels indicate dehydration.

intramembranous ossification is completed later. Four of these sites are especially prominent and regular in location: the **anterior**, **posterior**, **sphenoid (anterolateral)**, and **mastoid (posterolateral) fontanels** (fig. 8.17). Most fontanels ossify by the time the infant is a year old, but the largest one—the anterior fontanel—can still be palpated 18 to 24 months after birth.

The frontal bone and mandible are separate right and left bones at birth, but fuse medially in early childhood. The frontal bones usually fuse by age 5 or 6, but in some children a *metopic*³¹ suture persists between them. Traces of this suture are evident in some adult skulls.

The face of a newborn is flat and the cranium relatively large. To accommodate the growing brain, the skull grows more rapidly than the rest of the skeleton during childhood. It reaches about half its adult size by 9 months of age, three-quarters by age 2, and nearly final size by 8 or 9 years. The heads of babies and children are therefore

²⁸os = bone + icle = little

²⁹hy = the letter U + oid = resembling

³⁰fontan = fountain + el = little

³¹met = beyond + op = the eyes

FIGURE 8.17 The Fetal Skull Near the Time of Birth.

much larger in proportion to the trunk than the heads of adults—an attribute thoroughly exploited by cartoonists and advertisers who draw big-headed characters to give them a more endearing or immature appearance. In humans and other animals, the large rounded heads of the young are thought to promote survival by stimulating parental caregiving instincts.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

4. Name the paranasal sinuses and state their locations. Name any four other cavities in the skull.
5. Explain the difference between a cranial bone and a facial bone. Give four examples of each.
6. Draw an oval representing a superior view of the calvaria. Draw lines representing the coronal, lambdoid, and sagittal sutures. Label the four bones separated by these sutures.

7. State which bone has each of these features: a squamous part, hypoglossal foramen, greater horn, greater wing, condylar process, and cribriform plate.
8. Determine which of the following structures cannot normally be palpated on a living person: the mastoid process, crista galli, superior orbital fissure, palatine processes, zygomatic bone, mental protuberance, and stapes. You may find it useful to palpate some of these on your own skull as you try to answer.

8.3 The Vertebral Column and Thoracic Cage

Objectives

When you have completed this section, you should be able to

- describe the general features of the vertebral column and those of a typical vertebra;
- describe the special features of vertebrae in different regions of the vertebral column, and discuss the functional significance of the regional differences; and
- describe the anatomy of the sternum and ribs and how the ribs articulate with the thoracic vertebrae.

General Features of the Vertebral Column

The **vertebral** (VUR-teh-brul) **column** (**spine**) physically supports the skull and trunk, allows for their movement, protects the spinal cord, and absorbs stresses produced by walking, running, and lifting. It also provides attachment for the limbs, thoracic cage, and postural muscles. Although commonly called the backbone, it does not consist of a single bone but a chain of 33 **vertebrae** with **intervertebral discs** of fibrocartilage between most of them. The adult vertebral column averages about 71 cm (28 in.) long, with the intervertebral discs accounting for about one-quarter of the length.

Most people are about 1% shorter when they go to bed at night than when first rising in the morning. This is because during the day, the weight of the body compresses the intervertebral discs and squeezes water out of them. When one is sleeping, with the weight off the spine, the discs reabsorb water and swell.

As shown in figure 8.18, the vertebrae are divided into five groups, usually numbering 7 *cervical* (SUR-vih-cul) *vertebrae* in the neck, 12 *thoracic vertebrae* in the chest, 5 *lumbar vertebrae* in the lower back, 5 *sacral vertebrae* at the base of the spine, and 4 tiny *coccygeal* (coc-SIDJ-ee-ul) *vertebrae*. To help remember the numbers of cervical, thoracic, and lumbar vertebrae—7, 12, and 5—you might think of a typical work day: go to work at 7, have lunch at 12, and go home at 5.

Variations in this arrangement occur in about 1 person in 20. For example, the last lumbar vertebra is sometimes incorporated into the sacrum, producing four lumbar and six sacral vertebrae. In other cases, the first sacral vertebra fails to fuse with the second, producing six lumbar and four sacral vertebrae. The coccyx usually has four but sometimes five vertebrae. The cervical and thoracic vertebrae are more constant in number.

Beyond the age of 3 years, the vertebral column is slightly S-shaped, with four bends called the **cervical, thoracic, lumbar, and pelvic curvatures** (fig. 8.19). These are not present in the newborn, whose spine exhibits one continuous C-shaped curve (fig. 8.20) as it does in monkeys, apes, and most other four-legged animals. As an infant begins to crawl and lift its head, the cervical region becomes curved toward the posterior side, enabling an infant on its belly to look forward. As a toddler begins walking, another curve develops in

the same direction in the lumbar region. The resulting S shape makes sustained bipedal walking possible (see Insight 8.5, p. 281). The thoracic and pelvic curvatures are called *primary curvatures* because they were there from birth. The cervical and lumbar curvatures are called *secondary curvatures* because they develop later, in the child's first few years of crawling and walking.

General Structure of a Vertebra

A representative vertebra and intervertebral disc are shown in figure 8.22. The most obvious feature of a vertebra is the **body (centrum)**—a mass of spongy bone and red bone marrow covered with a thin shell of compact bone. This is the weight-bearing portion of the vertebra. Its rough superior and inferior surfaces provide firm attachment to the intervertebral discs.

FIGURE 8.18 The Vertebral Column.

FIGURE 8.19 Curvatures of the Adult Vertebral Column.

FIGURE 8.20 Spinal Curvature of the Newborn Infant. At this age, the spine forms a single C-shaped curve.

Think About It

The vertebral bodies and intervertebral discs get progressively larger as we look lower and lower on the vertebral column. What is the functional significance of this trend?

Posterior to the body of each vertebra is a triangular canal called the **vertebral foramen**. The vertebral foramina collectively form the **vertebral canal**, a passage for the spinal cord. Each foramen is bordered by a bony **vertebral arch** composed of two parts on each side: a pillarlike **pedicle**³² and platelike **lamina**.³³ Extending from the apex of the arch, a projection called the **spinous process** is directed posteriorly and downward. You can see and feel the spinous processes as a row of bumps along the spine. A **transverse process** extends laterally from the point where the pedicle and lamina meet. The spinous and transverse processes provide points of attachment for ligaments and spinal muscles.

A pair of **superior articular processes** projects upward from one vertebra and meets a similar pair of inferior articular processes that projects downward from the vertebra just above (fig. 8.23a). Each process has a flat articu-

³²ped = foot + icle = little

³³lamina = plate

INSIGHT 8.4 Clinical Application

Abnormal Spinal Curvatures

Abnormal spinal curvatures (fig. 8.21) can result from disease; weakness or paralysis of the trunk muscles; poor posture; pregnancy; or congenital defects in vertebral anatomy. The most common deformity is an abnormal lateral curvature called *scoliosis*. It occurs most often in the thoracic region, particularly among adolescent girls. It sometimes results from a developmental abnormality in which the body and arch fail to develop on one side of a vertebra. If the person's skeletal growth is not yet complete, scoliosis can be corrected with a back brace.

An exaggerated thoracic curvature is called *kyphosis* (hunchback, in lay language). It is usually a result of osteoporosis, but it also occurs in people with osteomalacia or spinal tuberculosis and in adolescent boys who engage heavily in such spine-loading sports as wrestling and weightlifting. An exaggerated lumbar curvature is called *lordosis* (swayback, in lay language). It may have the same causes as kyphosis, or it may result from added abdominal weight in pregnancy or obesity.

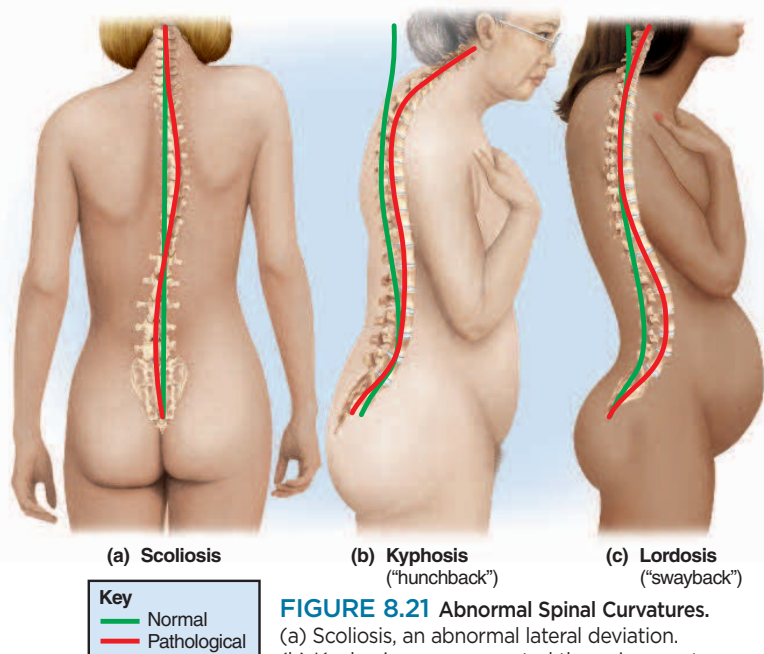

FIGURE 8.21 Abnormal Spinal Curvatures.

(a) Scoliosis, an abnormal lateral deviation. (b) Kyphosis, an exaggerated thoracic curvature common in old age. (c) Lordosis, an exaggerated lumbar curvature common in pregnancy and obesity.

(b) Intervertebral disc

(c) Herniated disc

FIGURE 8.22 A Representative Vertebra and Intervertebral Disc, Superior Views. (a) A typical vertebra. (b) An intervertebral disc, oriented the same way as the vertebral body in part (a) for comparison. (c) A herniated disc, showing compression of the spinal nerve roots by the nucleus pulposus oozing from the disc.

lar surface (facet) facing that of the adjacent vertebra. These processes restrict twisting of the vertebral column, which could otherwise severely damage the spinal cord.

When two vertebrae are joined, they exhibit an opening between their pedicles called the **intervertebral foramen**. This allows passage for spinal nerves that connect with the spinal cord at regular intervals. Each foramen is formed by an **inferior vertebral notch** in the pedicle of the upper vertebra and a **superior vertebral notch** in the pedicle of the lower one (fig. 8.23b).

Intervertebral Discs

An **intervertebral disc** is a pad consisting of an inner gelatinous **nucleus pulposus** surrounded by a ring of fibrocartilage, the **anulus fibrosus** (fig. 8.22b). There are 23 discs—the first one between cervical vertebrae 2 and 3 and the last one between the last lumbar vertebra and the sacrum. They help to bind adjacent vertebrae together, support the weight of the body, and absorb shock. Under stress—for example, when you lift a heavy weight—the discs bulge laterally. Excessive stress can crack the anulus and cause the nucleus to ooze out. This is called a **herniated disc** (“ruptured” or “slipped” disc in lay terms) and may put painful pressure on the spinal cord or a spinal nerve (fig. 8.22c).

Regional Characteristics of Vertebrae

We are now prepared to consider how vertebrae differ from one region of the vertebral column to another and from the generalized anatomy just described. Knowing these variations will enable you to identify the region of the spine from which an isolated vertebra was taken. More importantly, these modifications in form reflect functional differences among the vertebrae.

Cervical Vertebrae

The cervical vertebrae (C1–C7) are the smallest and lightest ones other than the coccygeals. The first two (C1 and C2) have unique structures that allow for head movements (fig. 8.24). Vertebra C1 is called the **atlas** because it supports the head in a manner reminiscent of the Titan of Greek mythology who was condemned by Zeus to carry the world on his shoulders. It scarcely resembles the typical vertebra; it has no body, and is little more than a delicate ring surrounding a large vertebral foramen. On each side is a **lateral mass** with a deeply concave **superior articular facet** that articulates with the occipital condyle of the skull. A nodding motion of the skull, as in gesturing “yes,” causes the occipital condyles to rock back and forth on these facets. The **inferior articular facets**, which are comparatively flat or only slightly concave, articulate with C2. The lateral masses are connected by an **anterior arch** and a **posterior arch**, which bear slight protuberances called the **anterior** and **posterior tubercle**, respectively.

Vertebra C2, the **axis**, allows rotation of the head as in gesturing “no.” Its most distinctive feature is a prominent knob called the **dens** (pronounced “denz”), or **odontoid**³⁴ **process**, on its anterosuperior side. No other vertebra has a dens. It begins to form as an independent ossification center during the first year of life and fuses with the axis by the age of 3 to 6 years. It projects into the vertebral foramen of the atlas, where it is nestled in a facet and held in place by a **transverse ligament** (fig. 8.24c). A heavy blow to the top of the head can cause a

³⁴*dens* = *odont* = tooth + *oid* = resembling

FIGURE 8.23 Articulated Vertebrae.

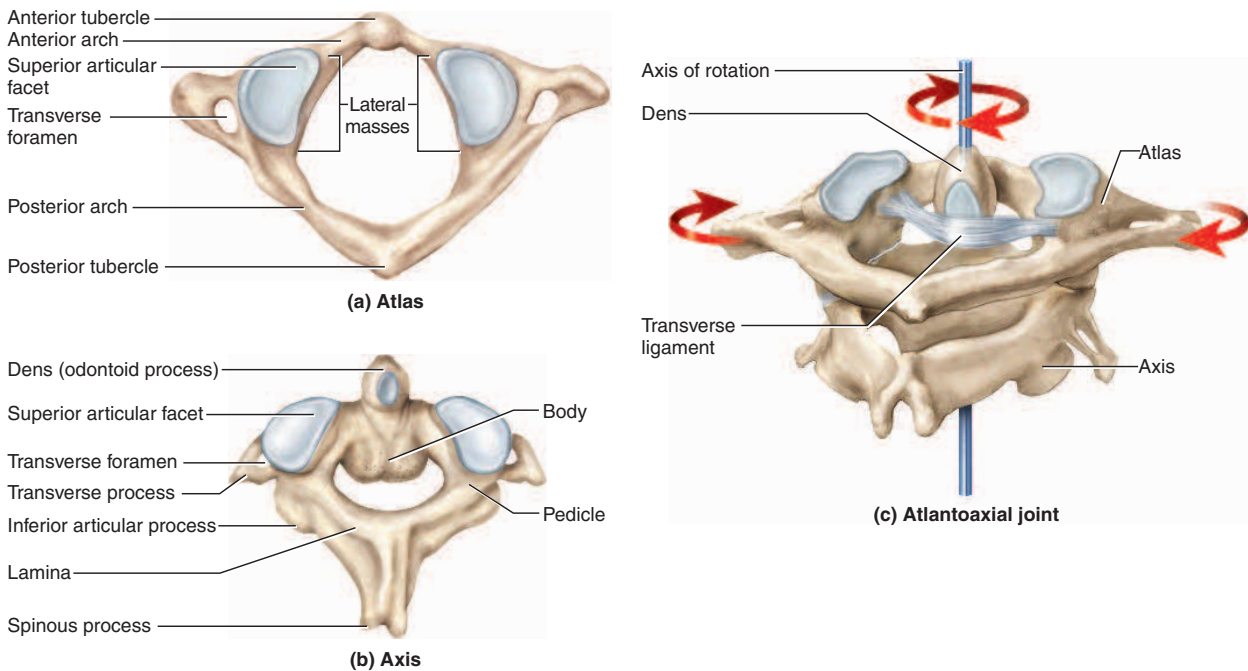

FIGURE 8.24 The Atlas and Axis, Cervical Vertebrae C1 and C2. (a) The atlas, superior view. (b) The axis, posterosuperior view. (c) Articulation of the atlas and axis and rotation of the atlas. This movement turns the head from side to side, as in gesturing “no.” Note the transverse ligament holding the dens of the axis in place.

• What serious consequence could result from a rupture of the transverse ligament?

fatal injury in which the dens is driven through the foramen magnum into the brainstem. The articulation between the atlas and the cranium is called the **atlanto-occipital joint**; the one between the atlas and axis is called the **atlantoaxial joint**.

The axis is the first vertebra that exhibits a spinous process. In vertebrae C2 to C6, the process is forked, or

bifid,³⁵ at its tip (fig. 8.25a). This fork provides attachment for the *nuchal ligament* of the back of the neck. All seven cervical vertebrae have a prominent round **transverse foramen** in each transverse process. These foramina provide passage and protection for the *vertebral arteries*,

³⁵*bifid* = cleft into two parts

FIGURE 8.25 Typical Cervical, Thoracic, and Lumbar Vertebrae. The left-hand figures are superior views and the right-hand figures are left lateral views.

which supply blood to the brain, and *vertebral veins*, which drain blood from various neck structures. Transverse foramina occur in no other vertebrae and thus provide an easy means of recognizing a cervical vertebra.

Think About It

How would head movements be affected if vertebrae C1 and C2 had the same structure as C3? What is the functional advantage of the lack of a spinous process in C1?

Cervical vertebrae C3 to C6 are similar to the typical vertebra described earlier, with the addition of the transverse foramina and bifid spinous processes. Vertebra C7 is a little different—its spinous process is not bifid, but it is especially long and forms a prominent bump on the lower back of the neck. This feature

is a convenient landmark for counting vertebrae. Because it is so conspicuous, C7 is sometimes called the *vertebra prominens*.

Thoracic Vertebrae

There are 12 **thoracic vertebrae** (T1–T12), corresponding to the 12 pairs of ribs attached to them. They lack the transverse foramina and bifid processes that distinguish the cervicals, but possess the following distinctive features of their own (fig. 8.25b):

- The spinous processes are relatively pointed and angle sharply downward.
- The body is somewhat heart-shaped, more massive than in the cervical vertebrae but less than in the lumbar vertebrae.

- The body has small, smooth, slightly concave spots called *costal facets* (to be described shortly) for attachment of the ribs.
- Vertebrae T1 to T10 have a shallow, cuplike **transverse costal³⁶ facet** at the end of each transverse process. These provide a second point of articulation for ribs 1 to 10. There are no transverse costal facets on T11 and T12 because ribs 11 and 12 attach only to the bodies of the vertebrae.

No other vertebrae have ribs articulating with them. Thoracic vertebrae vary among themselves mainly in the mode of articulation with the ribs. In most cases, a rib inserts between two vertebrae, so each vertebra contributes one-half of the articular surface. A rib articulates with the **inferior costal facet** (FASS-et) of the upper vertebra and the **superior costal facet** of the vertebra below that. This terminology may be a little confusing, but note that the superior and inferior facets are named for their position on the vertebral body, not for which part of the rib's articulation they provide. Vertebrae T1 and T10 to T12, however, have complete costal facets on the bodies for ribs 1 and 10 to 12, which articulate on the vertebral body instead of between vertebrae. Vertebrae T11 and T12, as noted, have no transverse costal facets. These variations will be more functionally understandable after you have studied the anatomy of the ribs, so we will return then to the details of these articular surfaces.

Each thoracic vertebra has a pair of superior articular facets that face posteriorly and a pair of inferior articular facets that face anteriorly (except in vertebra T12). Thus, the superior facets of one vertebra articulate with the inferior facets of the next one below it. In vertebra T12, however, the inferior articular facets face somewhat laterally instead of anteriorly. This positions them to articulate with the medially facing superior articular facets of the first lumbar vertebra. T12 thus shows an anatomical transition between the thoracic and lumbar pattern, described next.

Lumbar Vertebrae

There are five **lumbar vertebrae** (L1–L5). Their most distinctive features are a thick, stout body and a blunt, squarish spinous process (fig. 8.25c). In addition, their articular processes are oriented differently than on other vertebrae. The superior processes face medially (like the palms of your hands about to clap), and the inferior processes face laterally, toward the superior processes of the next vertebra. This arrangement makes the lumbar region of the spine especially resistant to twisting. These differences are best observed on an articulated skeleton.

Sacrum

The **sacrum** (SACK-rum, SAY-krum) is a bony plate that forms the posterior wall of the pelvic cavity (fig. 8.26). It is named for the fact that it was once considered the seat of the soul.³⁷ In children, there are five separate **sacral vertebrae** (S1–S5). They begin to fuse around age 16 and are fully fused by age 26.

The anterior surface of the sacrum is relatively smooth and concave and has four transverse lines that indicate where the five vertebrae have fused. This surface exhibits four pairs of large **anterior sacral (pelvic) foramina**, which allow for passage of nerves and arteries to the pelvic organs. The posterior surface is very rough. The spinous processes of the vertebrae fuse into a ridge called the **median sacral crest**. The transverse processes fuse into a less prominent **lateral sacral crest** on each side of the median crest. Again on the posterior side of the sacrum, there are four pairs of openings for spinal nerves, the **posterior sacral foramina**. The nerves that emerge here supply the gluteal region and lower limb.

A **sacral canal** runs through the sacrum and ends in an inferior opening called the **sacral hiatus** (hy-AY-tus). This canal contains spinal nerve roots. On each side of the sacrum is an ear-shaped region called the **auricular³⁸ surface**. This articulates with a similarly shaped surface on the hip bone (see fig. 8.36b) and forms the strong, nearly immovable **sacroiliac** (SAY-cro-ILL-ee-ac) (**SI**) **joint**. The body of vertebra S1 juts anteriorly to form a **sacral promontory**, which supports the body of vertebra L5. Lateral to the median sacral crest, S1 also has a pair of **superior articular processes** that articulate with vertebra L5. Lateral to these are a pair of large, rough, winglike extensions called the **alae³⁹** (AIL-ee).

Coccyx

The **coccyx⁴⁰** (fig. 8.26) usually consists of four (sometimes five) small vertebrae, Co1 to Co4, which fuse by the age of 20 to 30 into a single triangular bone. Vertebra Co1 has a pair of **horns (cornua)** that serve as attachment points for ligaments that bind the coccyx to the sacrum. The coccyx can be fractured by a difficult childbirth or a hard fall to the buttocks. Although it is the vestige of a tail, it is not entirely useless; it provides attachment for muscles of the pelvic floor.

The Thoracic Cage

The **thoracic cage** (fig. 8.27) consists of the thoracic vertebrae, sternum, and ribs. It forms a more or less conical enclosure for the lungs and heart and provides attachment for the pectoral girdle and upper limb. It has a broad base

³⁷sacr = sacred

³⁸auri = ear + cul = little + ar = pertaining to

³⁹alae = wings

⁴⁰coccyx = cuckoo (named for resemblance to a cuckoo's beak)

³⁶costa = rib + al = pertaining to

FIGURE 8.26 The Sacrum and Coccyx. (a) The anterior surface, which faces the viscera of the pelvic cavity. (b) The posterior surface. The processes of this surface can be palpated in the sacral region.

FIGURE 8.27 The Thoracic Cage and Pectoral Girdle (Anterior View).

and a somewhat narrower superior apex; it is rhythmically expanded by the respiratory muscles to create a vacuum that draws air into the lungs. The inferior border of the thoracic cage is formed by a downward arc of the ribs called the **costal margin**. The ribs protect not only the thoracic organs but also the spleen, most of the liver, and to some extent the kidneys.

Sternum

The **sternum** (breastbone) is a bony plate anterior to the heart. It is subdivided into three regions: the manubrium, body, and xiphoid process. The **manubrium**⁴¹ (ma-NOO-bree-um) is the broad superior portion. It has a median **suprasternal (jugular) notch**, which you can easily palpate between your clavicles (collarbones), and right and left **clavicular notches** where it articulates with the clavicles. The **body**, or **gladiolus**,⁴² is the longest part of the sternum. It joins the manubrium at the **sternal angle**, which can be palpated as a transverse ridge at the point where the sternum projects farthest forward. In some people, however, the angle is rounded or concave. The second rib attaches here, making the sternal angle a useful landmark for counting ribs in a physical examination. The manubrium and body have scalloped lateral margins where cartilages of the ribs are attached. At the inferior end of the sternum is a small, pointed **xiphoid**⁴³ (ZIF-oyd) **process** that provides attachment for some of the abdominal muscles. In cardiopulmonary resuscitation, improperly performed chest compressions can drive the xiphoid process into the liver and cause a fatal hemorrhage.

Ribs

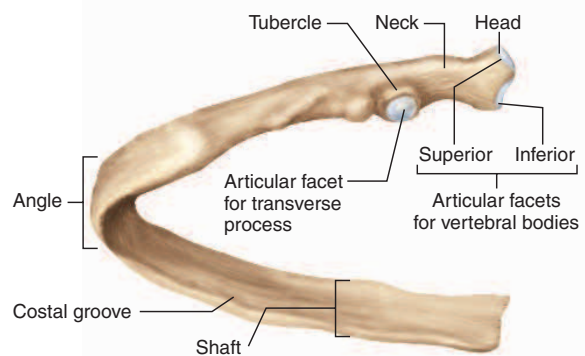

There are 12 pairs of **ribs**, with no difference between the sexes. Each is attached at its posterior (proximal) end to the vertebral column, and most of them are also attached at the anterior (distal) end to the sternum. The anterior attachment is by way of a long strip of hyaline cartilage called the **costal cartilage**.

As a general rule, the ribs increase in length from 1 through 7 and become progressively smaller again through rib 12. They are increasingly oblique (slanted) in orientation from 1 through 9, then less so from 10 through 12. They also differ in their individual structure and attachments at different levels of the thoracic cage, so we will examine them in order as we descend the torso, taking note of their universal characteristics as well as their individual variations.

Rib 1 is peculiar. On an articulated skeleton, you must look for its vertebral attachment just below the base of the neck; much of this rib lies above the level of the clavicle (fig. 8.27). It is a short, flat, C-shaped plate of bone (fig. 8.28a). At the vertebral end, it exhibits a knobby

(a) Rib 1

(b) Ribs 2–10

(c) Ribs 11–12

FIGURE 8.28 Anatomy of the Ribs. (a) Rib 1 is an atypical flat plate. (b) Typical features of ribs 2 to 10. (c) Appearance of the floating ribs, 11 and 12.

head that articulates with the body of vertebra T1. On an isolated vertebra, you can find a smooth costal facet for this attachment on the middle of the body. Immediately distal to the head, the rib narrows to a **neck** and then widens again to form a rough area called the **tubercle**. This is its point of attachment to the transverse costal facet of the same vertebra. Beyond the tubercle, the rib flattens and widens into a gently sloping blade-like **shaft**. The shaft ends distally in a squared-off, rough area. In the living individual, the costal cartilage begins here and spans the rest of the distance to the upper sternum.

Ribs 2 through 7 present a more typical appearance (fig. 8.28b). At the proximal end, each exhibits a head, neck, and tubercle. The head is wedge-shaped and inserts between two vertebrae. Each margin of the wedge has a smooth surface called an **articular facet**. The **superior articular facet** joins the inferior costal facet of the vertebra above; the **inferior articular facet** joins the superior costal facet of vertebra below. The tubercle of the rib articulates with the transverse costal facet of each same-numbered

⁴¹manubrium = handle

⁴²gladiolus = sword

⁴³xiphoid = sword + oid = resembling

vertebra. Figure 8.29 details the three rib–vertebra attachments typical of this region of the rib cage.

Beyond the tubercle, each rib makes a sharp curve around the side of the torso and then progresses anteriorly to approach the sternum (see fig. 8.27). The curve is called the **angle** of the rib and the rest of the bony blade distal to it is called the shaft. The inferior margin of the shaft has a **costal groove** that marks the path of the intercostal blood vessels and nerve. Each of these ribs, like rib 1, ends in a blunt, rough area where the costal cartilage begins. Each has its own costal cartilage connecting it to the sternum; because of this feature, ribs 1 through 7 are called **true ribs**.

Ribs 8 through 12 are called **false ribs** because they lack independent cartilaginous connections to the sternum. In 8 through 10, the costal cartilages sweep upward and end on the costal cartilage of rib 7 (see fig. 8.27). Rib 10 also differs from 2 through 9 in that it attaches to the body of a single vertebra (T10) rather than between vertebrae. Thus, vertebra T10 has a complete costal facet on its body for rib 10.

Ribs 11 and 12 are again quite unusual (fig. 8.28c). Posteriorly, they articulate with the bodies of vertebrae T11 and T12, but they do not have tubercles and do not

attach to the transverse processes of the vertebrae. Those two vertebrae therefore have no transverse costal facets. At the distal end, these two relatively small, delicate ribs taper to a point and are capped by a small cartilaginous tip, but there is no cartilaginous connection to the sternum or to any of the higher costal cartilages. The ribs are merely embedded in lumbar muscle at this end. Consequently, 11 and 12 are also called **floating ribs**. Among the Japanese and some other people, rib 10 is also usually floating. Table 8.4 summarizes these variations in rib anatomy and their vertebral and sternal attachments.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Construct a three-column table headed C4, T4, and L4. In each column, list all anatomical features that would distinguish that vertebra from the other two.
- Describe how rib 5 articulates with the spine. How do ribs 1 and 12 differ from this and from each other in their modes of articulation?
- Distinguish between true, false, and floating ribs. State which ribs fall into each category.
- Name the three divisions of the sternum and list the sternal features that can be palpated on a living person.

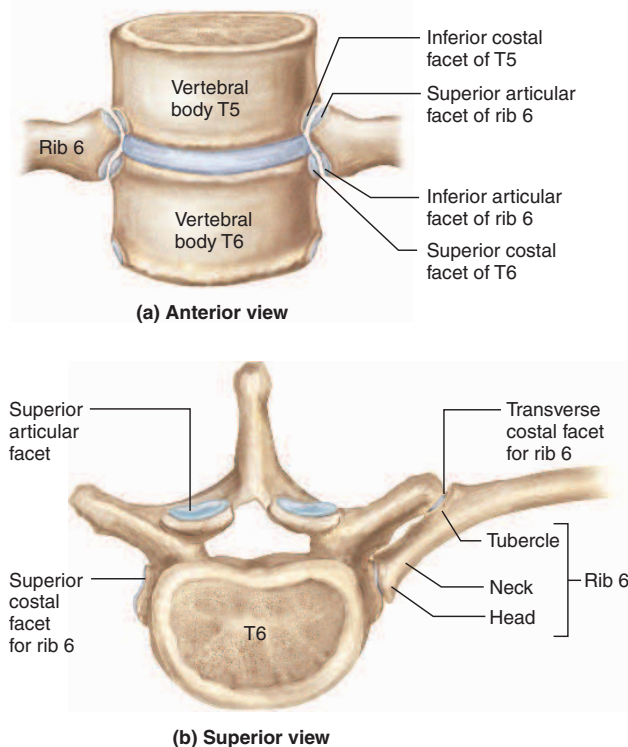

FIGURE 8.29 Articular surfaces of rib 6 with vertebrae T5 and T6. (a) Anterior view. Note the relationship of the articular facets of the rib with the costal facets of the two vertebrae. (b) Superior view. Note that the rib articulates with a vertebra at two points: the costal facet on the vertebral body and the transverse costal facet on the transverse process.

8.4 The Pectoral Girdle and Upper Limb

Objective

When you have completed this section, you should be able to

- identify and describe the features of the clavicle, scapula, humerus, radius, ulna, and bones of the wrist and hand.

Pectoral Girdle

The **pectoral girdle** (shoulder girdle) supports the arm. It consists of two bones on each side of the body: the *clavicle* (collarbone) and the *scapula* (shoulder blade). The medial end of the clavicle articulates with the sternum at the **sternoclavicular joint**, and its lateral end articulates with the scapula at the **acromioclavicular joint** (see fig. 8.27). The scapula also articulates with the humerus at the **glenohumeral joint**. These are loose attachments that result in a shoulder far more flexible than that of most other mammals, but they also make the shoulder joint easy to dislocate.

Think About It

How is the unusual flexibility of the human shoulder joint related to the habitat of our primate ancestors?

TABLE 8.4 Articularions of the Ribs

Rib	Type	Costal Cartilage	Articulating Vertebral Bodies	Articulating with a Transverse Costal Facet?	Rib Tubercle
1	True	Individual	T1	Yes	Present
2	True	Individual	T1 and T2	Yes	Present
3	True	Individual	T2 and T3	Yes	Present
4	True	Individual	T3 and T4	Yes	Present
5	True	Individual	T4 and T5	Yes	Present
6	True	Individual	T5 and T6	Yes	Present
7	True	Individual	T6 and T7	Yes	Present
8	False	Shared with rib 7	T7 and T8	Yes	Present
9	False	Shared with rib 7	T8 and T9	Yes	Present
10	False	Shared with rib 7	T10	Yes	Present
11	False, floating	None	T11	No	Absent
12	False, floating	None	T12	No	Absent

Clavicle

The **clavicle**⁴⁴ (fig. 8.30) is a slightly S-shaped, somewhat flattened bone, easily seen and palpated on the upper thorax (see fig. B.1b, p. 389). The superior surface is relatively smooth, whereas the inferior surface is marked by grooves and ridges for muscle attachment. The medial **sternal end** has a rounded, hammerlike head, and the lateral **acromial end** is markedly flattened. Near the acromial end is a rough tuberosity called the **conoid tubercle**—a ligament attachment that faces toward the rear and slightly downward.

The clavicle braces the shoulder, keeping the upper limb away from the midline of the body. It is thickened in people who do heavy manual labor, and because most

people are right-handed, the right clavicle is usually stronger and shorter than the left. Without the clavicles, the pectoralis major muscles would pull the shoulders forward and medially—which indeed happens when a clavicle is fractured. Indeed, the clavicle is the most commonly fractured bone in the body because it is so close to the surface and because people often reach out with their arms to break a fall.

Scapula

The **scapula**⁴⁵ (fig. 8.31), named for its resemblance to a spade or shovel, is a triangular plate that posteriorly overlies ribs 2 to 7. The three sides of the triangle are called the **superior**, **medial (vertebral)**, and **lateral (axillary) borders**, and its three angles are the **superior**, **inferior**, and **lateral angles**. A conspicuous **suprascapular notch** in the superior border provides passage for a nerve. The broad anterior surface of the scapula, called the **subscapular fossa**, is slightly concave and relatively featureless. The posterior surface has a transverse ridge called the **spine**, a deep indentation superior to the spine called the **supraspinous fossa**, and a broad surface inferior to it called the **infraspinous fossa**.⁴⁶

The most complex region of the scapula is its lateral angle, which has three main features:

1. The **acromion**⁴⁷ (ah-CRO-me-on) is a platelike extension of the scapular spine that forms the apex of the shoulder. It articulates with the clavicle—the sole point of attachment of the scapula and upper limb to the rest of the skeleton.

⁴⁴*clav* = hammer, club, key + *icle* = little

FIGURE 8.30 The Right Clavicle.

⁴⁵*scap* = spade, shovel + *ula* = little

⁴⁶*supra* = above; *infra* = below

⁴⁷*acr* = extremity, point + *omi* = shoulder

FIGURE 8.31 The Right Scapula.

- The **coracoid**⁴⁸ (COR-uh-coyd) **process** is shaped like a bent finger but named for a vague resemblance to a crow's beak; it provides attachment for tendons of the biceps brachii and other muscles of the arm.
- The **glenoid**⁴⁹ (GLEN-oyd) **cavity** is a shallow socket that articulates with the head of the humerus, forming the glenohumeral joint.

Upper Limb

The upper limb is divided into four regions containing a total of 30 bones per limb:

- The **brachium**⁵⁰ (BRAY-kee-um), or arm proper, extends from shoulder to elbow. It contains only one bone, the *humerus*.
- The **antebrachium**,⁵¹ or forearm, extends from elbow to wrist and contains two bones: the *radius* and *ulna*. In anatomical position, these bones are parallel and the radius is lateral to the ulna.
- The **carpus**,⁵² or wrist, contains eight small bones arranged in two rows.
- The **manus**,⁵³ or hand, contains 19 bones in two groups: 5 *metacarpals* in the palm and 14 *phalanges* in the fingers.

⁴⁸corac = crow + oid = resembling

⁴⁹glen = pit, socket + oid = resembling

⁵⁰brachi = arm

⁵¹ante = before

⁵²carp = wrist

⁵³man = hand

Humerus

The **humerus** has a hemispherical **head** that articulates with the glenoid cavity of the scapula (fig. 8.32). The smooth surface of the head (covered with articular cartilage in life) is bordered by a groove called the **anatomical neck**. Other prominent features of the proximal end are muscle attachments called the **greater** and **lesser tubercles** and an **intertubercular sulcus** between them that accommodates a tendon of the biceps muscle. The **surgical neck**, a common fracture site, is a narrowing of the bone just distal to the tubercles, at the transition from the head to the shaft. The shaft has a rough area called the **deltoid tuberosity** on its lateral surface. This is an insertion for the deltoid muscle of the shoulder.

The distal end of the humerus has two smooth condyles. The lateral one, called the **capitulum**⁵⁴ (ca-PIT-you-lum), is shaped somewhat like a wide tire and articulates with the radius. The medial one, called the **trochlea**⁵⁵ (TROCK-lee-uh), is pulleylike and articulates with the ulna. Immediately proximal to these condyles, the humerus flares out to form two bony processes, the **lateral** and **medial epicondyles**. The medial epicondyle protects the ulnar nerve, which passes close to the surface across the back of the elbow. This epicondyle is popularly known as the “funny bone” because striking the elbow on the edge of a table stimulates the ulnar nerve and produces a sharp tingling sensation. Just above these epicondyles, the

⁵⁴capit = head + ulum = little

⁵⁵troch = wheel, pulley

270 PART TWO Support and Movement

FIGURE 8.32 The Right Humerus.

margins of the humerus are called the **lateral** and **medial supracondylar ridges**. These are attachments for certain forearm muscles.

The distal end of the humerus also shows three deep pits: two anterior and one posterior. The posterior pit, called the **olecranon** (oh-LEC-ruh-non) **fossa**, accommodates the olecranon of the ulna when the forearm is extended. On the anterior surface, a medial pit called the **coronoid fossa** accommodates the coronoid process of the ulna when the forearm is flexed. The lateral pit is the **radial fossa**, named for the nearby head of the radius.

Radius

The **radius** has a distinctive disc-shaped **head** at its proximal end (fig. 8.33). When the forearm is rotated so the palm turns forward and back, the circular superior surface of this disc spins on the capitulum of the humerus, and the edge of the disc spins on the radial notch of the

FIGURE 8.33 The Right Radius and Ulna.

ulna. Immediately distal to the head, the radius has a narrower **neck** and then widens to a rough prominence, the **radial tuberosity**, on its medial surface. The distal tendon of the biceps muscle terminates on this tuberosity.

The distal end of the radius has the following features, from lateral to medial:

1. a bony point, the **styloid process**, which can be palpated proximal to the thumb;
2. two shallow depressions (articular facets) that articulate with the scaphoid and lunate bones of the wrist; and
3. the **ulnar notch**, which articulates with the end of the ulna.

Ulna

At the proximal end of the **ulna** (fig. 8.33) is a deep, C-shaped **trochlear notch** that wraps around the

trochlea of the humerus. The posterior side of this notch is formed by a prominent **olecranon**—the bony point where you rest your elbow on a table. The anterior side is formed by a less prominent **coronoid process**. Laterally, the head of the ulna has a less conspicuous **radial notch**, which accommodates the head of the radius. At the distal end of the ulna is a medial **styloid process**. The bony lumps you can palpate on each side of your wrist are the styloid processes of the radius and ulna.

The radius and ulna are attached along their shafts by a ligament called the **interosseous membrane (IM)**, which is attached to an angular ridge called the **interosseous margin** on each bone. Most fibers of the IM are oriented obliquely, slanting upward from the ulna to the radius. If you lean forward on a table supporting your weight on your hands, about 80% of the force is borne by the radius. This tenses the IM, which pulls the ulna upward and transfers some of this force through the ulna to the humerus. The IM thereby enables two elbow joints (humeroradial and humeroulnar) to share the load and reduces the wear and tear that one joint would otherwise have to bear alone. The IM also serves as an attachment for several forearm muscles.

Carpal Bones

The **carpal bones**, which form the wrist, are arranged in two rows of four bones each (fig. 8.34). These short bones allow movements of the wrist from side to side and anterior to posterior. The carpal bones of the proximal row, starting at the lateral (thumb) side, are the **scaphoid**, **lunate**, **triquetrum** (tri-QUEE-trum), and **pisiform** (PY-sih-form)—Latin for boat-, moon-, triangle-, and pea-shaped, respectively. Unlike the other carpal bones, the pisiform is a sesamoid bone; it is not present at birth but develops around the age of 9 to 12 years within the tendon of the *flexor carpi ulnaris muscle*.

The bones of the distal row, again starting on the lateral side, are the **trapezium**,⁵⁶ **trapezoid**, **capitate**,⁵⁷ and **hamate**.⁵⁸ The hamate can be recognized by a prominent hook called the **hamulus** on the palmar side (fig. 8.34b).

⁵⁶*trapez* = table, grinding surface

⁵⁷*capit* = head + *ate* = possessing

⁵⁸*ham* = hook + *ate* = possessing

Metacarpal Bones

Bones of the palm are called **metacarpals**.⁵⁹ Metacarpal I is located proximal to the base of the thumb and metacarpal V proximal to the base of the little finger. On a skeleton, the metacarpals look like extensions of the fingers, making the fingers seem much longer than they really are. The proximal end of a metacarpal bone is called the **base**, the shaft is called the **body**, and the distal end is called the **head**. The heads of the metacarpals form knuckles when you clench your fist.

Phalanges

The bones of the fingers are called **phalanges** (fah-LAN-jeez); in the singular, *phalanx* (FAY-lanks). There are two phalanges in the **pollex** (thumb) and three in each of the other digits. Phalanges are identified by roman numerals preceded by *proximal*, *middle*, and *distal*. For example, proximal phalanx I is in the basal segment of the thumb (the first segment beyond the web between the thumb and palm); the left proximal phalanx IV is where people usually wear wedding rings; and distal phalanx V forms the tip of the little finger. The three parts of a phalanx are the same as in a metacarpal: base, body, and head. The anterior (palmar) surface of a phalanx is slightly concave from end to end and flattened from side to side; the posterior surface is rounder and slightly convex.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe how to distinguish the medial and lateral ends of the clavicle from each other, and how to distinguish its superior and inferior surfaces.
- Name the three fossae of the scapula and describe the location of each.
- What three bones meet at the elbow? Identify the fossae, articular surfaces, and processes of this joint and state to which bone each of these features belongs.
- Name the four bones of the proximal row of the carpus from lateral to medial, and then the four bones of the distal row in the same order.
- Name the four bones from the tip of the little finger to the base of the hand on that side.

⁵⁹*meta* = beyond + *carp* = wrist

FIGURE 8.34 The Right Wrist and Hand, Anterior (Palmar)

View. (a) Carpal bones are color-coded to distinguish the proximal (yellow) and distal (green) rows. Some people remember the names of the carpal bones with the mnemonic, "Sally left the party to take Charlie home." The first letters of these words correspond to the first letters of the carpal bones, from lateral to medial, proximal row first. (b) The right hamate bone, viewed from the proximal side of the wrist to show its distinctive hook. This unique bone is a useful landmark for locating the others when studying the skeleton. (c) Color-enhanced X-ray of an adult hand. Identify the unlabeled bones in the X-ray by comparing it with the drawing in part (a).

● How does part (c) differ from the X-ray of a child's hand, figure 7.12?

8.5 The Pelvic Girdle and Lower Limb

Objectives

When you have completed this section, you should be able to

- identify and describe the features of the pelvic girdle, femur, patella, tibia, fibula, and bones of the foot; and
- compare the anatomy of the male and female pelvis and explain the functional significance of the differences.

Pelvic Girdle

The terms *pelvis* and *pelvic girdle* are used in contradictory ways by various anatomical authorities. Here we will follow the practice of *Gray's Anatomy* and the *Terminologia Anatomica* in considering the **pelvic girdle** to consist of a complete ring composed of three bones (fig. 8.35)—two **hip (coxal) bones** and the sacrum (which of course is also part of the vertebral column). Some authorities also call the hip bones the *ossa coxae*⁶⁰ (OS-sa COC-see) or *innominate*⁶¹ (ih-NOM-ih-nate) *bones*; the latter is arguably the

⁶⁰os = bone + coxae = of the hip

⁶¹in = without + nomin = name + ate = having

FIGURE 8.35 The Pelvic Girdle. (a) Anterosuperior view, tilted slightly toward the viewer to show the base of the sacrum and the pelvic inlet. (b) Median section, to show the greater and lesser pelvis and the pelvic inlet and outlet.

(b) Median section

most self-contradictory term in human anatomy (the “bones with no name”). The **pelvis**⁶² is a bowl-shaped structure composed of these bones as well as their ligaments and the muscles that line the pelvic cavity and form its floor. The pelvic girdle supports the trunk on the lower limbs and encloses and protects the viscera of the pelvic cavity—mainly the lower colon, urinary bladder, and internal reproductive organs.

Each hip bone is joined to the vertebral column at one point, the sacroiliac joint, where its **auricular surface** matches the auricular surface of the sacrum. The two hip bones articulate with each other on the anterior side of the pelvis, where they are joined by a pad of fibrocartilage called the **interpubic disc**. The interpubic disc and the adjacent region of pubic bone on each side constitute the **pubic symphysis**,⁶³ which can be palpated as a hard prominence immediately above the genitalia.

The pelvis has a bowl-like shape with the broad **greater (false) pelvis** between the flare of the hips, and the narrower **lesser (true) pelvis** below. The two are separated by a somewhat round margin called the **pelvic brim**. The opening circumscribed by the brim is called the **pelvic inlet**—an entry into the lesser pelvis through which an infant’s head passes during birth. The lower margin of the lesser pelvis is called the **pelvic outlet**.

The hip bones have three distinctive features that will serve as landmarks for further description. These are the **iliac**⁶⁴ **crest** (superior crest of the hip); **acetabulum**⁶⁵ (ASS-eh-TAB-you-lum) (the hip socket—named for its resemblance to vinegar cups used on ancient Roman dining tables); and **obturator**⁶⁶ **foramen** (a large round-to-triangular hole below the acetabulum, closed by a ligament called the *obturator membrane* in life).

FIGURE 8.36 The Right Hip Bone. The three childhood bones that fuse to form the adult hip bone are identified by color.

⁶² *pelv* = basin, bowl

⁶³ *sym* = together + *physis* = growth

⁶⁴ *ili* = flank, loin + *ac* = pertaining to

⁶⁵ *acetabulum* = vinegar cup

⁶⁶ *obtur* = to close, stop up + *ator* = that which

Each adult hip bone forms by the fusion of three childhood bones called the *ilium* (ILL-ee-um), *ischium* (ISS-kee-um), and *pubis* (PEW-biss), identified by color in figure 8.36. The largest of these is the **ilium**, which extends from the iliac crest to the center of the acetabulum. The iliac crest extends from an anterior point or angle called the **anterior superior spine** to a sharp posterior angle called the **posterior superior spine**. In a lean person, the anterior superior spines form visible anterior protrusions, and the posterior superior spines are sometimes marked by dimples above the buttocks where connective tissue attached to the spines pulls inward on the skin (see fig. B.4, p. 392).

Below the superior spines are the **anterior** and **posterior inferior spines**. Below the latter is a deep **greater sciatic** (sy-AT-ic) **notch**, named for the sciatic nerve that passes through it and continues down the posterior side of the thigh.

The posterolateral surface of the ilium is relatively rough-textured because it serves for attachment of several muscles of the buttocks and thighs. The anteromedial surface, by contrast, is the smooth, slightly concave **iliac fossa**, covered in life by the broad *iliacus* muscle. Medially, the ilium exhibits an auricular surface that matches the one on the sacrum, so that the two bones form the sacroiliac joint.

The **ischium** is the inferoposterior portion of the hip bone. Its heavy **body** is marked with a prominent **spine**. Inferior to the spine is a slight indentation, the **lesser sciatic notch**, and then the thick, rough-surfaced **ischial tuberosity**, which supports your body when you are sitting. The tuberosity can be palpated by sitting on your fingers. The **ramus** of the ischium joins the inferior ramus of the pubis anteriorly.

The **pubis (pubic bone)** is the most anterior portion of the hip bone. It has a **superior** and **inferior ramus**

and a triangular **body**. The body of one pubis meets the body of the other at the pubic symphysis. The pubis and ischium encircle the obturator foramen. The pubis is often fractured when the pelvis is subjected to violent anteroposterior compression, as in seat-belt injuries.

The pelvis is the most *sexually dimorphic* part of the skeleton—that is, the one whose anatomy most differs between the sexes. In identifying the sex of skeletal remains, forensic scientists focus especially on the pelvis. The average male pelvis is more robust (heavier and thicker) than the female’s owing to the forces exerted on the bone by stronger muscles. The female pelvis is adapted to the needs of pregnancy and childbirth. It is wider and shallower and has a larger pelvic inlet and outlet for passage of the infant’s head. Table 8.5 and figure 8.37 summarize the most useful features of the pelvis in sex identification.

Lower Limb

The number and arrangement of bones in the lower limb are similar to those of the upper limb. In the lower limb, however, they are adapted for weight-bearing and locomotion and are therefore shaped and articulated differently. The lower limb is divided into four regions containing a total of 30 bones per limb:

1. The **femoral region**, or thigh, extends from hip to knee and contains the *femur*. The *patella* (kneecap) is a sesamoid bone at the junction of the femoral and crural regions.
2. The **crural (CROO-rul) region**, or leg proper, extends from knee to ankle and contains two bones, the medial *tibia* and lateral *fibula*.

Feature	Male	Female
General appearance	More massive; rougher; heavier processes	Less massive; smoother; more delicate processes
Tilt	Upper end of pelvis relatively vertical	Upper end of pelvis tilted forward
Ilium, greater pelvis	Deeper; projects farther above sacroiliac joint	Shallower; does not project as far above sacroiliac joint
Lesser pelvis	Narrower and deeper	Wider and shallower
Sacrum	Narrower and longer	Wider and shorter
Coccyx	Less movable; more vertical	More movable; tilted posteriorly
Width of greater pelvis	Anterior superior spines closer together; hips less flared	Anterior superior spines farther apart; hips more flared
Pelvic inlet	Heart-shaped	Round or oval
Pelvic outlet	Smaller	Larger
Greater sciatic notch	Narrower	Wider
Obturator foramen	Round	Triangular to oval
Acetabulum	Faces more laterally, larger	Faces slightly anteriorly, smaller
Pubic arch	Usually 90° or less	Usually greater than 100°

FIGURE 8.37 Comparison of the Male and Female Pelvic Girdles. The pelvic brim is the margin highlighted in blue. Compare with table 8.5.

3. The **tarsal region (tarsus)**, or ankle, is the union of the crural region with the foot. The tarsal bones are treated as part of the foot.
4. The **pedal region (pes)**, or foot, is composed of 7 *tarsal bones*, 5 *metatarsals*, and 14 *phalanges* in the toes.

Femur

The **femur** (FEE-mur) is the longest and strongest bone of the body (fig. 8.38). It has a hemispherical head that articulates with the acetabulum of the pelvis, forming a quintessential *ball-and-socket joint*. A ligament extends from the acetabulum to a pit, the **fovea capitis**⁶⁷ (FOE-vee-uh CAP-ih-tiss), in the head of the femur. Distal to the head is a constricted **neck** and then two massive, rough processes called the **greater** and **lesser trochanters**⁶⁸ (tro-CAN-turs), which are insertions for the powerful muscles of the hip. The trochanters are connected on the posterior side by a thick oblique ridge of bone, the **intertrochanteric crest**, and on the anterior side by a more delicate **intertrochanteric line**.

The primary feature of the shaft is a posterior ridge called the **linea aspera**⁶⁹ (LIN-ee-uh ASS-peh-ruh) at its midpoint. At its upper end, the linea aspera forks into a medial **spiral (pectineal) line** and a lateral **gluteal tuberosity**. The gluteal tuberosity is a rough ridge (sometimes a depression) that serves for attachment of the powerful *gluteus maximus* muscle of the buttock. At its lower end, the linea aspera forks into **medial** and **lateral supracondylar lines**, which continue down to the respective epicondyles.

The **medial** and **lateral epicondyles** are the widest points of the femur at the knee. These and the supracondylar lines are attachments for certain thigh and leg

muscles and knee ligaments. At the distal end of the femur are two smooth round surfaces of the knee joint, the **medial** and **lateral condyles**, separated by a groove called the **intercondylar (IN-tur-CON-dih-lur) fossa**. On the anterior side of the femur, a smooth medial depression called the **patellar surface** articulates with the patella. On the posterior side is a flat or slightly depressed area called the **popliteal surface**.

Patella

The **patella**,⁷⁰ or kneecap (fig. 8.38), is a roughly triangular sesamoid bone embedded in the tendon of the knee. It is cartilaginous at birth and ossifies at 3 to 6 years of age. It has a broad superior **base**, a pointed inferior **apex**, and a pair of shallow **articular facets** on its posterior surface where it articulates with the femur. The lateral facet is usually larger than the medial. The *quadriceps femoris tendon* extends from the anterior muscle of the thigh (the *quadriceps femoris*) to the patella, and it continues as the *patellar ligament* from the patella to the tibia. This is a change in terminology more than a change in structure or function, as a tendon connects muscle to bone and a ligament connects bone to bone.

Tibia

The leg has two bones: a thick strong tibia (TIB-ee-uh) on the medial side and a slender fibula (FIB-you-luh) on the lateral side (fig. 8.39). The **tibia** is the only weight-bearing bone of the crural region. Its broad superior head has two fairly flat articular surfaces, the **medial** and **lateral condyles**, separated by a ridge called the **intercondylar eminence**. The condyles of the tibia articulate with those of the femur. The rough anterior surface of the tibia, the **tibial tuberosity**, can be palpated just below the patella. This is an attachment for the powerful thigh muscles that extend (straighten) the knee. Distal to this, the shaft has a

⁶⁷fovea = pit + capitis = of the head

⁶⁸trochanter = to run

⁶⁹linea = line + asper = rough

⁷⁰pat = pan + ella = little

FIGURE 8.38 The Right Femur and Patella.

sharply angular **anterior crest**, which can be palpated in the shin. At the ankle, just above the rim of a standard dress shoe, you can palpate a prominent bony knob on each side. These are the **medial and lateral malleoli**⁷¹ (MAL-ee-OH-lie). The medial malleolus is part of the tibia, and the lateral malleolus is the part of the fibula.

Fibula

The **fibula** (fig. 8.39) is a slender lateral strut that helps to stabilize the ankle. It does not bear any of the body's weight; indeed, orthopedic surgeons sometimes remove part of the fibula and use it to replace damaged or missing bone elsewhere in the body. The fibula is somewhat thicker and broader at its proximal end, the **head**, than at

the distal end. The point of the head is called the **apex**. The distal expansion is the lateral malleolus.

Like the radius and ulna, the tibia and fibula are joined by an interosseous membrane along their shafts.

Ankle and Foot

The **tarsal bones** of the ankle are arranged in proximal and distal groups somewhat like the carpal bones of the wrist (fig. 8.40). Because of the load-bearing role of the ankle, however, their shapes and arrangement are conspicuously different from those of the carpal bones, and they are thoroughly integrated into the structure of the foot. The largest tarsal bone is the **calcaneus**⁷² (cal-CAY-nee-us), which forms the heel. Its posterior end is the

⁷¹malle = hammer + olus = little

⁷²calc = stone, chalk

FIGURE 8.39 The Right Tibia and Fibula.

FIGURE 8.40 The Right Foot.

Contrast the tarsal bones with the carpal bones. Which ones are similar in location? Which ones are different?

point of attachment for the **calcaneal (Achilles) tendon** from the calf muscles. The second-largest tarsal bone, and the most superior, is the **talus**. It has three articular surfaces: an inferoposterior one that articulates with the calcaneus, a superior **trochlear surface** that articulates with the tibia, and an anterior surface that articulates with a short, wide tarsal bone called the **navicular**.⁷³ The talus, calcaneus, and navicular are considered the proximal row of tarsal bones.

The distal group forms a row of four bones. Proceeding from the medial to lateral, these are the **medial, intermediate, and lateral cuneiforms**⁷⁴ (cue-NEE-ih-forms) and the **cuboid**.⁷⁵ The cuboid is the largest.

The remaining bones of the foot are similar in arrangement and name to those of the hand. The proximal **metatarsals**⁷⁶ are similar to the metacarpals. They are **metatarsals I to V** from medial to lateral, metatarsal I being proximal to the great toe. Metatarsals I to III articulate with the first through third cuneiforms; metatarsals IV and V both articulate with the cuboid.

Bones of the toes, like those of the fingers, are called phalanges. The great toe is the **hallux** and contains only two bones, the proximal and distal phalanx I. The other toes each contain a proximal, middle, and distal phalanx,

and are numbered II through V from medial to lateral. Thus middle phalanx V, for example, would be the middle bone of the smallest toe. The metatarsal and phalangeal bones each have a base, body, and head, like the bones of the hand. All of them, especially the phalanges, are slightly concave on the inferior (plantar) side.

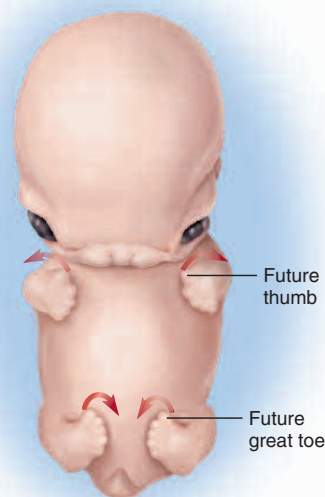

Note that roman numeral I represents the *medial* group of bones in the foot but the *lateral* group in the hand. In both cases, however, roman numeral I refers to the largest digit of the limb. The reason for the difference between the hand and foot lies in a rotation of the limbs that occurs in the seventh week of embryonic development. Early in the seventh week, the limbs extend anteriorly from the body, the foot is a paddlelike *foot plate*, and the hand is also more or less paddlelike with the finger buds showing early separation (fig. 8.41a). The future thumb and great toe are both directed superiorly, and the future palms and soles face each other medially. But then each limb rotates about 90° in opposite directions. The upper limb rotates laterally. To visualize this, hold your hands straight out in front of you with the palms facing each other as if you were about to clap. Then rotate your forearms so the thumbs face away from each other (laterally) and the palms face upward. The lower limbs rotate in the opposite direction, medially, so that the soles face downward and the great toes become medial. So even though the thumb and great toe (digit I of the hand and foot) start out facing in the same direction, these opposite

⁷³navi = boat + cul = little + ar = like

⁷⁵cub = cube + oid = resembling

⁷⁶meta = beyond + tars = ankle

(a) Seven weeks

(b) Eight weeks

FIGURE 8.41 Embryonic Limb Rotation. In the seventh week of development, the forelimbs and hindlimbs of the embryo rotate about 90° in opposite directions. This explains why the largest digits (digit I) are on opposite sides of the hand and foot, and why the elbow and knee flex in opposite directions.

rotations result in their being on opposite sides of the hand and foot (fig. 8.41b). This rotation also explains why the elbow flexes posteriorly and the knee flexes anteriorly, and why (as you will see in chapter 10) the muscles that flex the elbow are on the anterior side of the arm, whereas those that flex the knee are on the posterior side of the thigh.

The sole of the foot normally does not rest flat on the ground; rather, it has three springy arches that absorb the stress of walking (fig. 8.42). The **medial longitudinal arch**, which essentially extends from heel to hallux, is formed from the calcaneus, talus, navicular, cuneiforms, and metatarsals I to III. The **lateral longitudinal arch** extends from heel to little toe and includes the calcaneus, cuboid, and metatarsals IV and V. The **transverse arch** includes the cuboid, cuneiforms, and proximal heads of the metatarsals. These arches are held together by short, strong ligaments. Excessive weight, repetitious stress, or congenital weakness of these ligaments can stretch them, resulting in *pes planus* (commonly called flat feet or fallen

arches). This condition makes a person less tolerant of prolonged standing and walking. A comparison of the flat-footed apes with humans underscores the significance of the human foot arches (see Insight 8.5).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

18. Name the bones of the adult pelvic girdle. What three bones of a child fuse to form the hip bone of an adult?
19. Name any four structures of the pelvis that you can palpate and describe where to palpate them.
20. What parts of the femur are involved in the hip joint? What parts are involved in the knee joint?
21. Name the prominent knobs on each side of your ankle. What bones contribute to these structures?
22. Name all the bones that articulate with the talus and describe the location of each.

FIGURE 8.42 Arches of the Foot.

INSIGHT 8.5 Evolutionary Medicine

Skeletal Adaptations for Bipedalism

Some mammals can stand, hop, or walk briefly on their hind legs, but humans are the only mammals that are habitually bipedal. Footprints preserved in a layer of volcanic ash in Tanzania indicate that hominids walked upright as early as 3.6 million years ago. This bipedal locomotion is possible only because of several adaptations of the human feet, legs, spine, and skull (fig. 8.43). These features are so distinctive that paleoanthropologists (those who study human fossil remains) can tell with considerable certainty whether a fossil species was able to walk upright.

As important as the hand has been to human evolution, the foot may be an even more significant adaptation. Unlike other mammals, humans support their entire body weight on two feet. While apes are flat-footed, humans have strong, springy foot arches that absorb shock as the body jostles up and down during walking and running. The tarsal bones are tightly articulated with

one another, and the calcaneus is strongly developed. The hallux (great toe) is not opposable as it is in most Old World monkeys and apes, but it is highly developed so that it provides the “toe-off” that pushes the body forward in the last phase of the stride (fig. 8.43a). For this reason, loss of the hallux has a more crippling effect than the loss of any other toe.

While the femurs of apes are nearly vertical, in humans they angle medially from the hip to the knee (fig. 8.43b). This places our knees closer together, beneath the body’s center of gravity. We lock our knees when standing, allowing us to maintain an erect posture with little muscular effort. Apes cannot do this, and they cannot stand on two legs for very long without tiring—much as you would if you tried to maintain an erect posture with your knees slightly bent.

In apes and other quadrupedal (four-legged) mammals, the abdominal viscera are supported by the muscular abdominal wall. In humans, the viscera bear down on the floor of the pelvic cavity, and a bowl-shaped pelvis is necessary to support their weight. This has resulted in a narrower pelvic outlet—a condition that creates pain and difficulty in giving birth to

FIGURE 8.43 Skeletal Adaptations for Bipedalism. Human adaptations for bipedalism are best understood by comparison to our close living relative, the chimpanzee, which is not adapted for a comfortable or sustained erect stance. See the text for the relevance of each comparison.

such large-brained infants. The pain of childbirth seems unique to humans and, one might say, is a price we must pay for having both a large brain and a bipedal stance.

The largest muscle of the buttock, the *gluteus maximus*, serves in apes primarily as an abductor of the thigh—that is, it moves the leg laterally. In humans, however, the ilium has expanded posteriorly, so the *gluteus maximus* originates behind the hip joint. This changes the function of the muscle—instead of abducting the thigh, it pulls the thigh back in the second half of a stride (pulling back on your right thigh, for example, when your left foot is off the ground and swinging forward). Two other buttock muscles, the *gluteus medius* and *gluteus minimus*, extend laterally in humans from the surface of the ilium to the greater trochanter of the femur (fig. 8.43c). In walking, when one foot is lifted from the ground, these muscles shift the body weight over the other foot so we do not fall over. The actions of all three gluteal muscles, and the corresponding evolutionary remodeling of the pelvis, account for the smooth, efficient stride of a human as compared with the awkward, shuffling gait of a chimpanzee or gorilla when it is walking upright. The posterior growth of the ilium (fig. 8.43d) is the reason the greater sciatic notch is so deeply concave.

The lumbar curvature of the human spine allows for efficient bipedalism by shifting the body's center of gravity to the rear, above and slightly behind the hip joint (fig. 8.43e). Because of their C-shaped spines, chimpanzees cannot stand

as easily. Their center of gravity is anterior to the hip joint when they stand; they must exert a continual muscular effort to keep from falling forward, and fatigue sets in relatively quickly. Humans, by contrast, require little muscular effort to keep their balance. Our australopithecine ancestors probably could travel all day with relatively little fatigue.

The human head is balanced on the vertebral column with the gaze directed forward. The cervical curvature of the spine and remodeling of the skull have made this possible. The foramen magnum has moved to a more inferior and anterior location, and the face is much flatter than an ape's face (fig. 8.43f), so there is less weight anterior to the occipital condyles. Being balanced on the spine, the head does not require strong muscular attachments to hold it erect. Apes have prominent supraorbital ridges to brace the skull against the strong muscular contractions of mastication. In humans these ridges are much lighter.

The forelimbs of apes are longer than the hindlimbs; indeed, some species such as the orangutan and gibbons hold their long forelimbs over their heads when they walk on their hind legs. By contrast, our forelimbs are shorter than our hindlimbs and far less muscular than the forelimbs of apes. No longer needed for locomotion, our forelimbs have become better adapted for carrying objects, holding things closer to the eyes, and manipulating them more precisely.

CHAPTER REVIEW

Review of Key Concepts

8.1 Overview of the Skeleton (p. 242)

1. The skeletal system is divisible into the central *axial skeleton* (skull, vertebral column, and thoracic cage) and *appendicular skeleton* (bones of the upper and lower limbs and their supporting girdles).
2. There are typically 206 named bones in the adult (table 8.1), but the number varies from person to person, it is higher in newborns, and it increases in childhood before bone fusion leads to the adult number of bones.
3. Before studying individual bones, one must be familiar with the terminology of bone surface features (table 8.2).

8.2 The Skull (p. 244)

1. The skull consists of eight *cranial bones*, which contact the meninges around the brain, and 14 *facial bones*, which do not.
2. The skull encloses several spaces: the *cranial*, *nasal*, *buccal*, *middle-ear*, and *inner-ear cavities*; the *orbits*; and the *paranasal sinuses* (*frontal*, *sphenoid*, *ethmoid*, and *maxillary*).
3. Bones of the skull are perforated by numerous *foramina*, which allow passage for cranial nerves and blood vessels.
4. Some prominent features of the skull in general are the *foramen magnum* where the spinal cord joins the brainstem; the *calvaria*, which forms a roof over the cranial cavity; and the three *cranial fossae*, which form the floor of the cranial cavity.
5. The cranial bones are the *frontal*, *parietal*, *temporal*, *occipital*, *sphenoid*, and *ethmoid bones*. The parietal and temporal bones are paired, and the others single.
6. The facial bones are the *maxillae*; the *palatine*, *zygomatic*, *lacrimal*, and *nasal bones*; the *inferior nasal conchae*; and the *vomer* and *mandible*. All but the last two are paired. The mandible is the only significantly movable bone of the skull.

7. Associated with the skull are the *hyoid bone* in the neck and the three *auditory ossicles* (*malleus*, *incus*, and *stapes*) in each middle ear.
8. The skull of the fetus and infant is marked by six gaps, or *fontanels*, where the cranial bones have not fully fused: one *anterior*, one *posterior*, two *sphenoid*, and two *mastoid fontanels*. A child's skull attains nearly adult size by the age of 8 or 9 years.

8.3 The Vertebral Column and Thoracic Cage (p. 258)

1. The *vertebral column* normally consists of 33 *vertebrae* and 23 cartilaginous *intervertebral discs*. It is slightly S-shaped, with four curvatures: *cervical*, *thoracic*, *lumbar*, and *pelvic*.
2. A typical vertebra exhibits a *body*; a *vertebral foramen*; paired pedicles and laminae enclosing a vertebral arch; a *spinous process*; and two *transverse processes*. The shapes and proportions of these features, and some additional features, distinguish vertebrae from different regions of the vertebral column.
3. There are five classes of vertebrae, numbering 7 *cervical*, 12 *thoracic*, 5 *lumbar*, 5 *sacral*, and 4 *coccygeal vertebrae* in most people. In adults, the sacral vertebrae are fused into a single *sacrum* and the coccygeal vertebrae into a single *coccyx*.
4. An intervertebral disc is composed of a gelatinous *nucleus pulposus* enclosed in a fibrous ring, the *anulus fibrosus*.
5. The *thoracic cage* consists of the thoracic vertebrae, the sternum, and the ribs.
6. The *sternum* has three parts: *manubrium*, *body*, and *xiphoid process*.
7. There are 12 pairs of ribs. Ribs 1 through 7 are called *true ribs* because each has its own *costal cartilage* connecting it to the sternum; 8 through 12 are called *false ribs*, and 11 and 12, the only ones with no costal cartilages, are also called *floating ribs*.

8.4 The Pectoral Girdle and Upper Limb (p. 267)

1. The *pectoral girdle* attaches the upper limb to the axial skeleton. It consists of a *scapula* (shoulder blade) and *clavicle* (collar bone) on each side. The clavicle articulates with the sternum and the scapula articulates with the humerus.
2. The upper limb bones are the *humerus* in the brachium; the lateral *radius* and medial *ulna* in the antebrachium (forearm); eight *carpal bones* in the wrist; five *metacarpal bones* in the hand; two *phalanges* in the thumb; and three phalanges in each of the other four digits.

8.5 The Pelvic Girdle and Lower Limb (p. 273)

1. The *pelvic girdle* attaches the lower limb to the axial skeleton. It consists of the two *hip bones* and the sacrum. Each adult hip bone results from the fusion of three bones of the child: the *ilium*, *ischium*, and *pubis*. The pelvic girdle and its associated ligaments and muscles are collectively called the pelvis.
2. The pelvis forms two basinlike structures: a superior, wide *greater pelvis* and an inferior, narrower *lesser pelvis*. The passage from the greater to the lesser pelvis is called the *pelvic inlet* and its margin is the *pelvic brim*; the exit from the lesser pelvis is called the *pelvic outlet*.
3. Two other major features of the hip bone are the *iliac crest*, which forms the flare of the hip, and the *acetabulum*, the cuplike socket for the femur.
4. The lower limb bones are the *femur* in the thigh; the lateral *fibula* and larger, medial *tibia* in the leg proper; seven *tarsal* (ankle) *bones* forming the posterior half of the foot; five *metatarsal bones* in its anterior half; two phalanges in the great toe; and three phalanges in each of the other digits.

Testing Your Recall

- Which of these is *not* a paranasal sinus?
 - frontal
 - temporal
 - sphenoid
 - ethmoid
 - maxillary
- Which of these is a facial bone?
 - frontal
 - ethmoid
 - occipital
 - temporal
 - lacrimonal
- Which of these *cannot* be palpated on a living person?
 - the crista galli
 - the mastoid process
 - the zygomatic arch
 - the superior nuchal line
 - the hyoid bone
- All of the following are groups of vertebrae *except* for _____, which is a spinal curvature.
 - thoracic
 - cervical
 - lumbar
 - pelvic
 - sacral
- Thoracic vertebrae do *not* have
 - transverse foramina.
 - costal facets.
 - spinous processes.
 - transverse processes.
 - pedicles.
- The tubercle of a rib articulates with
 - the sternal notch.
 - the margin of the gladiolus.
 - the costal facets of two vertebrae.
 - the body of a vertebra.
 - the transverse process of a vertebra.
- The disc-shaped head of the radius articulates with the _____ of the humerus.
 - radial tuberosity
 - trochlea
 - capitulum
 - olecranon
 - glenoid cavity
- All of the following are carpal bones, *except* the _____, which is a tarsal bone.
 - trapezium
 - cuboid
 - trapezoid
 - triquetrum
 - pisiform
- The bone that supports your body weight when you are sitting down is
 - the acetabulum.
 - the pubis.
 - the ilium.
 - the coccyx.
 - the ischium.
- Which of these is the bone of the heel?
 - cuboid
 - calcaneus
 - navicular
 - trochlear
 - talus
- Gaps between the cranial bones of an infant are called _____.
 - fontanelles
 - foramina
 - sinuses
 - canals
 - fenestrations
- The external auditory canal is a passage in the _____ bone.
 - temporal
 - ethmoid
 - sphenoid
 - maxilla
 - mandible
- Bones of the skull are joined along lines called _____.
 - foramina
 - sinuses
 - fontanelles
 - sutures
 - canals
- The _____ bone has greater and lesser wings and protects the pituitary gland.
 - ethmoid
 - sphenoid
 - temporal
 - maxilla
 - mandible
- A herniated disc occurs when a ring called the _____ cracks.
 - vertebra
 - annulus fibrosus
 - intervertebral disc
 - vertebral body
 - vertebral foramen
- The transverse ligament of the atlas holds the _____ of the axis in place.
 - dens
 - odontoid process
 - odontoid foramen
 - odontoid fossa
 - odontoid notch
- The sacroiliac joint is formed where the _____ surface of the sacrum articulates with that of the ilium.
 - anterior
 - posterior
 - lateral
 - medial
 - inferior
- The _____ processes of the radius and ulna form bony protuberances on each side of the wrist.
 - styloid
 - radial
 - ulnar
 - distal
 - proximal
- The thumb is also known as the _____ and the great toe is also known as the _____.
 - pollex; hallux
 - hallux; pollex
 - pollex; hallux
 - hallux; pollex
 - pollex; hallux
- The _____ arch of the foot extends from the heel to the great toe.
 - transverse
 - longitudinal
 - metatarsal
 - metatarsal
 - metatarsal

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Not everyone has a frontal sinus.
- The hands have more phalanges than the feet.
- As an adaptation to pregnancy, the female's pelvis is deeper than the male's.
- There are more carpal bones than tarsal bones.
- On a living person, it would be possible to palpate the muscles in the infrapinnous fossa but not those of the subscapular fossa.
- If you rest your chin on your hands and your elbows on a table, the olecranon of the ulna rests on the table.
- The lumbar vertebrae do not articulate with any ribs and therefore do not have transverse processes.
- The most frequently broken bone is the humerus.
- In strict anatomical terminology, the words *arm* and *leg* both refer to regions with only one bone.
- The pisiform bone and patella are both sesamoid bones.

Answers in appendix B

Testing Your Comprehension

- A child was involved in an automobile collision. She was not wearing a safety restraint, and her chin struck the dashboard hard. When the physician looked into her ear, he could see into her throat. What do you infer from this about the nature of her injury?
- By palpating the hind leg of a cat or dog or by examining a laboratory skeleton, you can see that cats and dogs stand on the heads of their metatarsal bones; the calcaneus does not touch the ground. How is this similar to the stance of a woman wearing high-heeled shoes? How is it different?
- Between any two of the unfused vertebrae (cervical through lumbar), there is an intervertebral disc—except between C1 and C2. Give some reasons for the unique absence of an intervertebral disc at that location.
- In adolescents, trauma sometimes separates the head of the femur from the neck. Why do you think this is more common in adolescents than in adults?
- Andy, a 55-year-old, 75 kg (165 lb) roofer, is shingling the steeply pitched roof of a new house when he loses his footing and slides down the roof and over the edge, feet first. He braces himself for the fall, and when he hits the ground he cries out and doubles up in excruciating pain. Emergency medical technicians called to the scene tell him he has broken his hips. Describe, more specifically, where his fractures most likely occurred. On the way to the hospital, Andy says, "You know it's funny, when I was a kid, I used to jump off roofs that high, and I never got hurt." Why do you think Andy was more at risk of a fracture as an adult than he was as a boy?

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Anatomical planes (p. 30)
- Names of all major bones (table 8.1, p. 242; fig. 8.1, p. 243)
- Surface features of bones, especially of their articular surfaces (table 8.2, p. 244)

Joints, or articulations, link the bones of the skeletal system into a functional whole—a system that supports the body, permits effective movement, and protects the softer organs. Joints such as the shoulder, elbow, and knee are remarkable specimens of biological design—self-lubricating, almost frictionless, and able to bear heavy loads and withstand compression while executing smooth and precise movements (fig. 9.1). Yet it is equally important that other joints be less movable or even immobile. Such joints are better able to support the body and protect delicate organs. The vertebral column, for example, is only moderately movable, for it must allow for flexibility of the torso and yet protect the delicate spinal cord and support much of the body's weight. Bones of the cranium must protect the brain and sense organs, but need not allow for movement (except during birth); thus, they are locked together by immobile joints, the sutures studied in chapter 8.

In everyday life, we take the greatest notice of the most freely movable joints of the limbs, and it is here that people feel most severely compromised by such disabling diseases as arthritis. Much of the work of physical therapists focuses on limb mobility. In this chapter, we will survey all types of joints, from the utterly immobile to the most movable, but with an emphasis on the latter. This survey of joint anatomy and movements will provide a foundation for the study of muscle actions in chapter 10.

9.1 Joints and Their Classification

Objectives

When you have completed this section, you should be able to

- explain what joints are, how they are named, and what functions they serve;
- name and describe the four major classes of joints;
- describe the three types of fibrous joints and give an example of each;
- distinguish between the three types of sutures;
- describe the two types of cartilaginous joints and give an example of each; and
- name some joints that become synostoses as they age.

Any point where two bones meet is called a **joint (articulation)**, whether or not the bones are movable at that interface. The science of joint structure, function, and

FIGURE 9.1 Joint Flexibility. This gymnast demonstrates the flexibility, precision, and weight-bearing capacity of the body's joints.

dysfunction is called **arthrology**.¹ The study of musculo-skeletal movement is **kinesiology**² (kih-NEE-see-OL-oh-jee). This is a branch of **biomechanics**, which deals with a broad variety of movements and mechanical processes in the body, including the physics of blood circulation, respiration, and hearing.

The name of a joint is typically derived from the names of the bones involved. For example, the *atlanto-occipital joint* is where the occipital condyles meet the atlas; the *glenohumeral joint* is where the humerus meets the glenoid cavity of the scapula; and the *radioulnar joint* is where the radius meets the ulna.

Joints are classified according to the manner in which the adjacent bones are bound to each other, with

¹arthro = joint + logy = study of

²kinesio = movement + logy = study of

corresponding differences in how freely the bones can move. Authorities differ in their classification schemes, but one common view places the joints in four major categories: *bony*, *fibrous*, *cartilaginous*, and *synovial joints*. This section will describe the first three of these and the subclasses of each. The remainder of the chapter will then be concerned primarily with synovial joints.

Bony Joints

A **bony joint**, or **synostosis**³ (SIN-oss-TOE-sis), is an immovable joint formed when the gap between two bones ossifies and they become, in effect, a single bone. Bony joints can form by ossification of either fibrous or cartilaginous joints. An infant is born with right and left frontal and mandibular bones, for example, but these

soon fuse seamlessly into a single frontal bone and mandible. In old age, some cranial sutures become obliterated by ossification and the adjacent cranial bones, such as the parietal bones, fuse. The epiphyses and diaphyses of the long bones are joined by cartilaginous joints in childhood and adolescence, and these become synostoses in early adulthood. The attachment of the first rib to the sternum also becomes a synostosis with age.

Fibrous Joints

A **fibrous joint** is also called a **synarthrosis**⁴ (SIN-ar-THRO-sis) or **synarthrodial joint**. It is a point at which adjacent bones are bound by collagen fibers that emerge from one bone, cross the space between them, and penetrate into the other (fig. 9.2). There are three kinds of

³syn = together + ost = bone + osis = condition

⁴syn = together + arthr = joined + osis = condition

FIGURE 9.2 Fibrous Joints. (a) A suture between the parietal bones. (b) A gomphosis between a tooth and the jaw. (c) A syndesmosis between the tibia and fibula.

Which of these is not a joint between two bones? Why?

fibrous joints: *sutures*, *gomphoses*, and *syndesmoses*. In sutures and gomphoses, the fibers are very short and allow for little or no movement. In syndesmoses, the fibers are longer and the attached bones are more movable.

Sutures

Sutures are immovable or only slightly movable fibrous joints that closely bind the bones of the skull to each other; they occur nowhere else. In chapter 8 we did not take much notice of the differences between one suture and another, but some differences may have caught your attention as you studied the diagrams in that chapter or examined laboratory specimens. Sutures can be classified as *serrate*, *lap*, and *plane* sutures. Readers with some knowledge of woodworking may recognize that the structures and functional properties of these sutures have something in common with basic types of carpentry joints (fig. 9.3).

Serrate sutures appear as wavy lines along which the adjoining bones firmly interlock with each other by their serrated margins, like pieces of a jigsaw puzzle. Serrate sutures are analogous to a dovetail wood joint. Examples include the coronal, sagittal, and lambdoid sutures that border the parietal bones.

Lap (squamous) sutures occur where two bones have overlapping beveled edges, like a miter joint in carpentry. On the surface, a lap suture appears as a relatively smooth (nonserrated) line. An example is the squamous suture between the temporal and parietal bones. The beveled edge of the temporal bone can be seen in figure 8.10b (p. 251).

Plane (butt) sutures occur where two bones have straight nonoverlapping edges. The two bones merely border on each other, like two boards glued together in a butt joint. This type of suture is seen between the palatine processes of the maxillae in the roof of the mouth.

FIGURE 9.3 Sutures. Serrate, lap, and plane sutures compared to some common wood joints.

Gomphoses

Even though the teeth are not bones, the attachment of a tooth to its socket is classified as a joint called a **gomphosis** (gom-FOE-sis). The term refers to its similarity to a nail hammered into wood.⁵ The tooth is held firmly in place by a fibrous **periodontal ligament**, which consists of collagen fibers that extend from the bone matrix of the jaw into the dental tissue (see fig. 9.2b). The periodontal ligament allows the tooth to move or give a little under the stress of chewing. This allows us to sense how hard we are biting or to sense a particle of food stuck between the teeth.

Syndesmoses

A **syndesmosis**⁶ (SIN-dez-MO-sis) is a fibrous joint at which two bones are bound by longer collagenous fibers

than in a suture or gomphosis, giving the bones more mobility. While the range of motion differs greatly among syndesmoses, all of them are more mobile than sutures or gomphoses. One of the less movable syndesmoses is the joint that binds the distal ends of the tibia and fibula together, side by side. A more movable one exists between the shafts of the radius and ulna, which are joined by a broad fibrous sheet called an **interosseous membrane** that allows for movements such as pronation and supination of the forearm (see fig. 9.2c).

Cartilaginous Joints

A **cartilaginous joint** is also called an **amphiarthrosis**⁷ (AM-fee-ar-THRO-sis) or **amphiarthrodial joint**. In these joints, two bones are linked by cartilage (fig. 9.4).

⁵gomph = nail, bolt + osis = condition

⁶syn = together + desm = band + osis = condition

⁷amphi = on all sides + arthr = joined + osis = condition

FIGURE 9.4 Cartilaginous Joints.

(a) A synchondrosis, represented by the costal cartilage joining rib 1 to the sternum. (b) The pubic symphysis. (c) Intervertebral discs, which join adjacent vertebrae to each other by symphyses.

❏ What is the difference between the pubic symphysis and the interpubic disc?

The two types of cartilaginous joints are *synchondroses* and *symphyses*.

Synchondroses

A **synchondrosis**⁸ (SIN-con-DRO-sis) is a joint in which the bones are bound by hyaline cartilage. An example is the temporary joint between the epiphysis and diaphysis of a long bone in a child, formed by the cartilage of the epiphyseal plate. Another is the attachment of the first rib to the sternum by a hyaline costal cartilage (fig. 9.4a). (The other costal cartilages are joined to the sternum by synovial joints.)

Symphyses

In a **symphysis**⁹ (SIM-fih-sis), two bones are joined by fibrocartilage (fig. 9.4b, c). One example is the pubic symphysis, in which the right and left pubic bones are joined by the cartilaginous interpubic disc. Another is the joint between the bodies of two vertebrae, united by an intervertebral disc. The surface of each vertebral body is covered with hyaline cartilage. Between the vertebrae, this cartilage becomes infiltrated with collagen bundles to form fibrocartilage. Each intervertebral disc permits only slight movement between adjacent vertebrae, but the collective effect of all 23 discs gives the spine considerable flexibility.

Think About It

The intervertebral joints are symphyses only in the cervical through the lumbar region. How would you classify the intervertebral joints of the sacrum and coccyx in a middle-aged adult?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What is the difference between arthrology and kinesiology?
2. Distinguish between a synostosis, synarthrosis, and amphiarthrosis.
3. Define suture, gomphosis, and syndesmosis, and explain what these three joints have in common.
4. Name the three types of sutures and describe how they differ.
5. Name two synchondroses and two symphyses.
6. Give some examples of joints that become synostoses with age.

⁸syn = together + chondr = cartilage + osis = condition

⁹sym = together + physis = growth

9.2 Synovial Joints

Objectives

When you have completed this section, you should be able to

- identify the anatomical components of a typical synovial joint;
- classify any given joint action as a first-, second-, or third-class lever;
- explain how mechanical advantage relates to the power and speed of joint movement;
- discuss the factors that determine a joint's range of motion;
- describe the primary axes of rotation that a bone can have and relate this to a joint's degrees of freedom;
- name and describe six classes of synovial joints; and
- use the correct standard terminology for various joint movements.

The most familiar type of joint is the **synovial** (sih-NO-vee-ul) **joint**, also called a **diarthrosis**¹⁰ (DY-ar-THRO-sis) or **diarthrodial joint**. Ask most people to point out any joint in the body, and they are likely to point to a synovial joint such as the elbow, knee, or a knuckle. Many synovial joints, like these examples, are freely movable. Others, such as the joints between the wrist and ankle bones and between the articular processes of the vertebrae, have more limited mobility.

Synovial joints are the most structurally complex type of joint and are the most likely type to develop uncomfortable and crippling dysfunctions. They are the most important joints for such professionals as physical and occupational therapists, athletic coaches, nurses, and fitness trainers to understand well. Their mobility makes the synovial joints especially important to the quality of life. Reflect, for example, on the performance extremes of a young athlete, the decline in flexibility that comes with age, and the crippling effect of rheumatoid arthritis. The rest of this chapter is concerned with synovial joints.

General Anatomy

In synovial joints, the facing surfaces of the two bones are covered with **articular cartilage**, a layer of hyaline cartilage usually about 2 or 3 mm thick. These surfaces are separated by a narrow space, the **joint (articular) cavity**, containing a slippery lubricant called **synovial fluid** (fig. 9.5). This fluid, for which the joint is named, is rich in albumin and hyaluronic acid, which give it a viscous,

¹⁰dia = separate, apart + arthr = joint + osis = condition

FIGURE 9.5 Structure of a Simple Synovial Joint.

❖ Why is a meniscus unnecessary in an interphalangeal joint?

slippery texture similar to raw egg white.¹¹ It nourishes the articular cartilages, removes their wastes, and makes movements at synovial joints almost friction-free. A connective tissue **joint (articular) capsule** encloses the cavity and retains the fluid. It has an outer **fibrous capsule** continuous with the periosteum of the adjoining bones, and an inner, cellular **synovial membrane**. The synovial membrane is composed mainly of fibroblast-like cells that secrete the fluid, and is populated by macrophages that remove debris from the joint cavity.

In a few synovial joints, fibrocartilage grows inward from the joint capsule and forms a pad between the articulating bones. In the jaw (temporomandibular) and distal radioulnar joints, and at both ends of the clavicle (sternoclavicular and acromioclavicular joints), the pad crosses the entire joint capsule and is called an **articular disc** (see fig. 9.23c). In the knee, two cartilages extend inward from the left and right but do not entirely cross the joint (see fig. 9.29d). Each is called a **meniscus**¹² because of its crescent shape. These cartilages absorb shock and pressure, guide the bones across each other, improve the fit between the bones, and stabilize the joint, reducing the chance of dislocation.

Accessory structures associated with a synovial joint include tendons, ligaments, and bursae. A **tendon** is a strip or sheet of tough collagenous connective tissue that attaches a muscle to a bone. Tendons are often the most important structures in stabilizing a joint. A **ligament** is a similar tissue that attaches one bone to another. Several ligaments are named and illustrated in our later discussion of individual joints, and tendons are more fully considered in chapter 10 along with the gross anatomy of muscles.

A **bursa**¹³ is a fibrous sac filled with synovial fluid, located between adjacent muscles, where a tendon passes over a bone, or between bone and skin (see fig. 9.24). Bursae cushion muscles, help tendons slide more easily over the joints, and sometimes enhance the mechanical effect of a muscle by modifying the direction in which its tendon pulls. **Tendon sheaths** are elongated cylindrical bursae wrapped around a tendon, seen especially in the hand and foot (fig. 9.6).

Joints and Lever Systems

Long bones act as levers to enhance the speed or power of limb movements. A lever is any elongated, rigid object that rotates around a fixed point called the fulcrum (fig. 9.7). Rotation occurs when an effort applied to one point on the lever overcomes a resistance (load) at some other point. The portion of a lever from the fulcrum to the

INSIGHT 9.1

Clinical Application

Exercise and Articular Cartilage

When synovial fluid is warmed by exercise, it becomes thinner (less viscous) and more easily absorbed by the articular cartilage. The cartilage then swells and provides a more effective cushion against compression. For this reason, a warm-up period before vigorous exercise helps protect the articular cartilage from undue wear and tear.

Because cartilage is nonvascular, repetitive compression during exercise is important to its nutrition and waste removal. Each time a cartilage is compressed, fluid and metabolic wastes are squeezed out of it. When weight is taken off the joint, the cartilage absorbs synovial fluid like a sponge, and the fluid carries oxygen and nutrients to the chondrocytes. Without exercise, articular cartilages deteriorate more rapidly from inadequate nutrition, oxygenation, and waste removal.

Weight-bearing exercise builds bone mass and strengthens the muscles that stabilize many of the joints, thus reducing the risk of joint dislocations. Excessive joint stress, however, can hasten the progression of osteoarthritis by damaging the articular cartilage (see Insight 9.5, p. 314). Swimming is a good way of exercising the joints with minimal damage.

¹¹ovi = egg

¹³bursa = purse

FIGURE 9.6 Tendon Sheaths and Other Bursae in the Hand and Wrist.

FIGURE 9.7 The Basic Components of a Lever. This example is a first-class lever.

What would be the mechanical advantage of the lever shown here? Where would you put the fulcrum to increase the mechanical advantage without changing the lever class?

point of effort is called the **effort arm**, and the part from the fulcrum to the point of resistance is called the **resistance arm**. In skeletal anatomy, the fulcrum is a joint; the effort is applied by a muscle; and the resistance can be an object against which the body is working (as in weight lifting), the weight of the limb itself, or the tension in an opposing muscle.

Mechanical Advantage

The advantage conferred by a lever can be either of two kinds: (1) to exert more force against a resisting object than the force applied to the lever—for example, when a crowbar is used to move a heavy object; or (2) to move the resisting object farther or faster than the effort arm is moved, as in rowing a boat, where the blade of the oar moves much farther and faster than the handle. A single lever cannot confer both advantages. There is a trade-off between force on one hand and speed or distance on the other—as one increases, the other decreases.

The **mechanical advantage (MA)** of a lever is the ratio of its output force to its input force. If L_E is the length of the effort arm and L_R is the length of the resistance arm, $MA = L_E/L_R$. If MA is greater than 1.0, the lever produces more force, but less speed or distance, than the force exerted on it. If MA is less than 1.0, the lever produces more speed or distance, but less force, than the input.

Consider the forearm, for example (fig. 9.8a). Its resistance arm is longer than its effort arm, so we know from the preceding formula that MA must be less than 1.0. The figure shows some representative values for L_E and L_R that yield $MA = 0.15$. The biceps brachii muscle puts more

FIGURE 9.8 Mechanical Advantage (MA). MA is calculated from the length of the effort arm divided by the length of the resistance arm. (a) The forearm acts as a third-class lever during flexion of the elbow. (b) The mandible acts as a second-class lever when the jaw is forcibly opened. The digastric muscle and others provide the effort, while tension in the temporalis muscle and others provide resistance.

power into the lever than we get out of it, but the hand moves farther and faster than the point where the biceps tendon inserts on the radius. Most musculoskeletal levers operate with an MA much less than 1, but figure 9.8b shows a case with MA greater than 1.

In chapter 10, you will find that two or more muscles often act on the same joint, seemingly producing the same effect. This may seem redundant, but it makes sense if the tendinous insertions of the muscles are at different points on a bone and produce different mechanical advantages. A sprinter taking off from the starting line, for example, uses “low-gear” (high-MA) muscles that do not generate maximum speed, but have the power to overcome the inertia of the body. The runner then “shifts into high gear” by using muscles with different insertions that have a lower mechanical advantage but produce more speed. This is analogous to the way an automobile transmission uses one gear to get a car moving and other gears to cruise at higher speeds.

Types of Levers

Physicists recognize three classes of levers that differ with respect to the relative locations of the fulcrum (F), effort (E), and resistance (R) (fig. 9.9).

1. A **first-class lever** is one with the fulcrum in the middle (RFE). A seesaw is a common example. An anatomical example is the atlanto–occipital joint of the neck, where the muscles of the back of the neck pull down on the occipital bone of the skull and oppose the tendency of the head to tip forward. Loss of muscle tone here can be embarrassing if you nod off in class. Rocking of the foot on the tibia as the toes are raised and lowered also exemplifies a first-class lever. (It is often misinterpreted as a second-class lever because of a superficial resemblance between standing on tiptoes and the wheelbarrow example that follows.)
2. A **second-class lever** has the resistance in the middle (FRE). Lifting the handles of a wheelbarrow, for example, causes it to pivot on the axle of the wheel at the opposite end and lift a load in the middle. The mandible acts as a second-class lever when the *digastric muscle* pulls down on the chin to open the mouth. The fulcrum is the temporomandibular (jaw) joint, the effort is applied at the chin by the digastric muscle, and the resistance is the tension in muscles such as the *temporalis*, which tends to hold the mouth shut. This example is upside down

FIGURE 9.9 The Three Classes of Levers. Left: The lever classes defined by the relative positions of the resistance (load), fulcrum, and effort. Center: Mechanical examples. Right: Anatomical examples. (a) Muscles of the back of the neck pull down on the occipital bone to oppose the tendency of the head to drop forward. The fulcrum is the occipital condyles. (b) To open the mouth, the digastric muscle pulls down on the chin. It is resisted by the temporalis muscle on the side of the head. The fulcrum is the temporomandibular (jaw) joint. (c) In flexing the elbow, the biceps brachii muscle exerts an effort on the radius. Resistance is provided by the weight of the forearm or anything held in the hand. The fulcrum is the elbow joint.

relative to a wheelbarrow, but the mechanics remain the same.

3. In a **third-class lever**, the effort is applied between the fulcrum and resistance (REF). A pair of forceps, for example, consists of two third-class levers joined at the fulcrum. Most musculoskeletal levers are third-class. The forearm acts as a third-class lever when you flex your elbow. The fulcrum is the joint between the ulna and humerus, the effort is applied in part by the

biceps brachii muscle, and the resistance can be any weight in the hand or the weight of the forearm itself.

The classification of a lever changes as it makes different actions. We use the forearm as a third-class lever when we flex the elbow, as in weight lifting, but we use it as a first-class lever when we extend it, as in hammering nails. The mandible is a second-class lever when we open the mouth and a third-class lever when we close it to bite off a piece of food.

Range of Motion

One aspect of joint performance and physical assessment of a patient is a joint's flexibility, or **range of motion (ROM)**—the degrees through which a joint can move. The knee, for example, can flex through an arc of 130° to 140°, the metacarpophalangeal joint of the index finger about 90°, and the ankle about 74°. ROM obviously affects a person's functional independence and quality of life. It is also an important consideration in training for athletics or dance, in clinical diagnosis, and in monitoring the progress of rehabilitation. The ROM of a joint is normally determined by the following factors:

- **Structure of the articular surfaces of the bones.** In many cases, joint movement is limited by the shapes of the bone surfaces. For example, you cannot straighten your elbow beyond 180° or so because, as it straightens, the olecranon of the ulna swings into the olecranon fossa of the humerus and the fossa prevents it from moving any farther.
- **Strength and tautness of ligaments and joint capsules.** Some bone surfaces impose little if any limitation on joint movement. The articulations of the phalanges are an example; as one can see by examining a dry skeleton, an interphalangeal joint can bend through a broad arc. In life, however, these bones are joined by ligaments that limit their movement. As you flex one of your knuckles, ligaments on the anterior (palmar) side of the joint go slack, but ligaments on the posterior (dorsal) side tighten and prevent the joint from flexing beyond 90° or so. The knee is another case in point. In kicking a football, the knee rapidly extends to about 180°, but it can go no farther. Its motion is limited in part by a *cruciate ligament* and other knee ligaments described later. Gymnasts, dancers, and acrobats increase the ROM of their synovial joints by gradually stretching their ligaments during training. “Double-jointed” people have unusually large ROMs at some joints, not because the joint is actually double or fundamentally different from normal in its anatomy, but because the ligaments are unusually long or slack.
- **Action of the muscles and tendons.** Extension of the knee is also limited by the *hamstring muscles* on the posterior side of the thigh. In many other joints, too, pairs of muscles oppose each other and moderate the speed and range of joint motion. Even a resting muscle maintains a state of tension called *muscle tone*, which serves in many cases to stabilize a joint. One of the major factors preventing dislocation of the shoulder joint, for example, is tension in the *biceps brachii* muscle, whose tendons cross the joint, insert on the scapula, and hold the head of the humerus against the glenoid cavity. The nervous system continually moni-

tors and adjusts joint angles and muscle tone to maintain joint stability and limit unwanted movements.

Axes of Rotation

In solid geometry, we recognize three mutually perpendicular axes, *x*, *y*, and *z*. In anatomy, these correspond to the transverse, frontal, and sagittal planes of the body. Just as we can describe any point in space by its *x*, *y*, and *z* coordinates, we can describe any joint movement by reference to these three anatomical planes.

A moving bone has a relatively stationary **axis of rotation** that passes through the bone in a direction perpendicular to the plane of movement. Think of a door for comparison; it moves horizontally as it opens and closes and it rotates on hinges that are oriented on the vertical axis. Now consider the shoulder joint, where the convex head of the humerus inserts into the concave glenoid cavity of the scapula. If you raise your arm to one side of your body (*abduction*, a motion defined later), the head of the humerus rotates on an axis that passes from anterior to posterior; the arm rises in the frontal plane whereas its axis of rotation is in the sagittal plane (fig. 9.10a). If you lift your arm to point straight in front of you, it moves through the sagittal plane whereas its axis of rotation is on the frontal plane, passing through the shoulder from lateral to medial (fig. 9.10b). And if you swing your arm in a horizontal arc, for example to fold it across your chest, the humeral head rotates in the transverse plane and its axis of rotation passes vertically through the joint (fig. 9.10c).

Because the arm can move in all three anatomical planes, the shoulder joint is said to have three **degrees of freedom**, or to be a **multiaxial** joint. Other joints move through only one or two planes; they have one or two degrees of freedom and are called **monaxial** and **biaxial** joints, respectively. Degrees of freedom are a factor used in classifying the synovial joints.

Classes of Synovial Joints

There are six fundamental types of synovial joints, distinguished by the shapes of their articular surfaces and their degrees of freedom. We will begin by looking at these six types in simple terms, but then see that this is an imperfect classification for reasons discussed at the end. All six types can be found in the upper limb (fig. 9.11). They are listed here in descending order of mobility: one multiaxial type (ball-and-socket), three biaxial types (condylar, saddle, and plane), and two monaxial types (hinge and pivot).

1. **Ball-and-socket joints.** These are the shoulder and hip joints—the only multiaxial joints in the body. In both cases, one bone (the humerus or femur) has a smooth hemispherical head that fits into a cuplike socket on the other (the glenoid cavity of the scapula or the acetabulum of the hip bone).

FIGURE 9.10 Axes of Joint Rotation. All three axes are represented in movements of the multiaxial ball-and-socket joint of the shoulder.

2. **Condylar (ellipsoid) joints.** These joints exhibit an oval convex surface on one bone that fits into a complementary shaped depression on the other. The radiocarpal joint of the wrist and metacarpophalangeal (MET-uh-CAR-po-fah-LAN-jee-ul) joints at the bases of the fingers are examples. They are biaxial joints,

capable of movement in two planes. To demonstrate this, hold your hand with the palm facing you. Make a fist, and these joints flex in the sagittal plane. Fan your fingers apart, and they move in the frontal plane.

3. **Saddle joints.** Here, both bones have a saddle-shaped surface—concave in one direction (like the

FIGURE 9.11 The Six Types of Synovial Joints. All six have representatives in the forelimb. Mechanical models show the types of motion possible at each joint.

front-to-rear curvature of a horse's saddle) and convex in the other (like the left-to-right curvature of a saddle). The clearest example of this is the trapezometacarpal joint at the base of the thumb. Saddle joints are biaxial. The thumb, for example, moves in a frontal plane when you spread the fingers apart, and in a sagittal plane when you move it as

if to grasp a tool such as a hammer. This range of motion gives us and other primates that anatomical hallmark, the opposable thumb. Another saddle joint is the sternoclavicular joint, where the clavicle articulates with the sternum. The clavicle moves vertically in the frontal plane at this joint when you lift a suitcase, and moves horizontally in the

transverse plane when you reach forward to push open a door.

4. **Plane (gliding) joints.** Here the bone surfaces are flat or only slightly concave and convex. The adjacent bones slide over each other and have relatively limited movement. Plane joints are found between the carpal bones of the wrist, the tarsal bones of the ankle, and the articular processes of the vertebrae. Their movements, although slight, are complex. They are usually biaxial. For example, when the head is tilted forward and back, the articular facets of the vertebrae slide anteriorly and posteriorly; when the head is tilted from side to side, the facets slide laterally. Although any one joint moves only slightly, the combined action of the many joints in the wrist, ankle, and vertebral column allows for a significant amount of overall movement.
5. **Hinge joints.** These are essentially monaxial joints, moving freely in one plane with very little movement in any other. Examples include the elbow, knee, and interphalangeal (finger and toe) joints. In these cases, one bone has a convex (but not hemispherical) surface, such as the trochlea of the humerus and the condyles of the femur. This fits into a concave depression on the other bone, such as the trochlear notch of the ulna and the condyles of the tibia.
6. **Pivot joints.** These are monaxial joints in which a bone spins on its longitudinal axis. There are two principal examples: the atlantoaxial joint between the first two vertebrae, and the radioulnar joint at the elbow. At the atlantoaxial joint, the dens of the axis projects into the vertebral foramen of the atlas and is held against the anterior arch of the atlas by the transverse ligament (see fig. 8.24, p. 262). As the head rotates left and right, the skull and atlas pivot around the dens. At the radioulnar joint, the annular ligament of the ulna wraps around the neck of the radius. During pronation and supination of the forearm, the disc-like radial head pivots like a wheel turning on its axle. The edge of the wheel spins against the radial notch of the ulna like a car tire spinning in snow.

Some joints cannot be easily classified into any one of these six categories. The temporomandibular joint, for example, has some aspects of condylar, hinge, and plane joints. It clearly has an elongated condyle where it meets the temporal bone of the cranium, but it moves in a hingelike fashion when the mandible moves up and down in speaking, biting, and chewing; it glides slightly forward when the jaw juts (protracts) to take a bite; and it glides from side to side to grind food between the molars. The knee is a classic hinge joint, but has an element of the pivot type; when we lock our knees to stand more effortlessly, the femur pivots slightly on the tibia.

The humeroradial joint (between humerus and radius) acts as a hinge joint when the elbow flexes and a pivot joint when the forearm pronates.

Movements of Synovial Joints

Kinesiology, physical therapy, and other medical and scientific fields have a specific vocabulary for the movements of synovial joints. The following terms form a basis for describing the muscle actions in chapter 10 and may also be indispensable to your advanced coursework or intended career. This section introduces the terms for joint movements, many of which are presented in pairs or groups with opposite or contrasting meanings. This section relies on familiarity with the three cardinal anatomical planes and the directional terms in atlas A. All directional terms used here refer to a person in standard anatomical position. When one is standing in anatomical position, each joint is said to be in its **zero position**. Joint movements can be described as deviating from the zero position or returning to it.

Flexion and Extension

Flexion (fig. 9.12) is a movement that decreases a joint angle, usually in the sagittal plane. This is particularly common at hinge joints—for example, bending of the elbow or knee—but it occurs in other types of joints as well. For example, if you hold out your hands with the palms up, flexion of the wrist tips your palms toward you. The meaning of *flexion* is perhaps least obvious in the ball-and-socket joints of the shoulder and hip. At the shoulder, it means to raise your arm as if pointing at something directly in front of you or to continue in that arc and point toward the sky. At the hip, it means to raise the thigh, for example to place your foot on the next higher step when ascending a flight of stairs.

Extension (fig. 9.12) is a movement that straightens a joint and generally returns a body part to the zero position—for example, straightening the elbow, wrist, or knee, or returning the arm or thigh back to zero position. In stair climbing, both the hip and knee extend when lifting the body to the next higher step.

Further extension of a joint beyond the zero position is called **hyperextension**.¹⁴ For example, if you hold your hand in front of you with the palm down, then raise the back of your hand as if you were admiring a new ring, you hyperextend the wrist. Hyperextension of the upper or lower limb means to move the limb to a position behind the frontal plane of the trunk, as if reaching around with your arm to scratch your back. Each back-swing of the lower limb when you walk hyperextends the hip.

¹⁴*hyper* = excessive, beyond normal

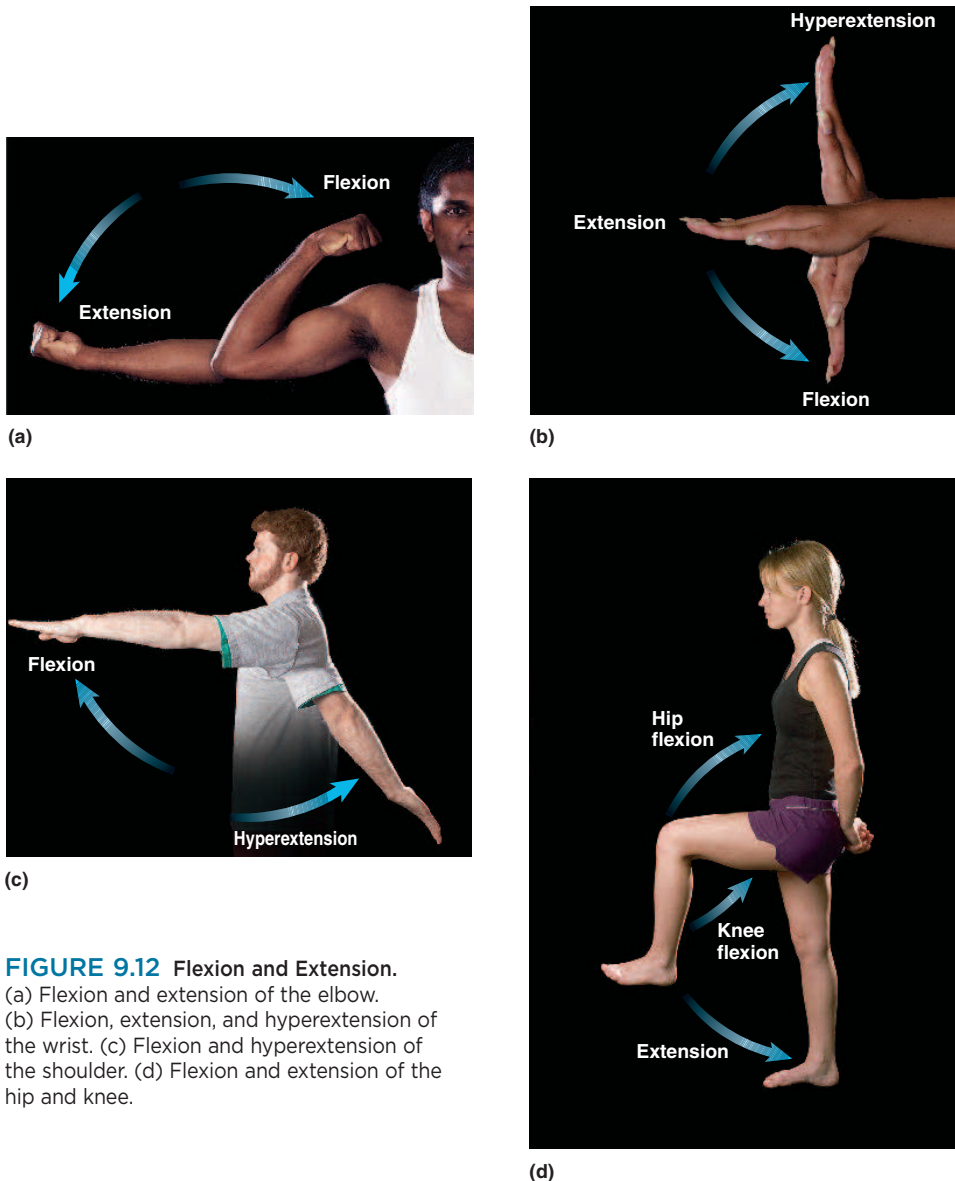

FIGURE 9.12 Flexion and Extension. (a) Flexion and extension of the elbow. (b) Flexion, extension, and hyperextension of the wrist. (c) Flexion and hyperextension of the shoulder. (d) Flexion and extension of the hip and knee.

Flexion and extension occur at nearly all diarthroses, but hyperextension is limited to only a few. At most diarthroses, ligaments or bone structure prevents hyperextension.

Abduction and Adduction

Abduction¹⁵ (ab-DUC-shun) (fig. 9.13a) is the movement of a body part in the frontal plane away from the midline of the body—for example, moving the feet apart to stand spread-legged, or raising an arm to one side of the body.

¹⁵ab = away + duc = to lead or carry

Adduction¹⁶ (fig. 9.13b) is movement in the frontal plane back toward the midline. Some joints can be **hyperadducted**, as when you stand with your ankles crossed, cross your fingers, or hyperadduct the shoulder to stand with your elbows straight and your hands clasped below your waist. You **hyperabduct** the arm if you raise it high enough to cross slightly over the front or back of your head.

Elevation and Depression

Elevation (fig. 9.14a) is a movement that raises a body part vertically in the frontal plane. **Depression** (fig. 9.14b) lowers a body part in the same plane. For example, to lift a suitcase from the floor, you elevate your scapula; in setting it down again, you depress the scapula. These are also important movements in chewing, as described in a later discussion of movements of the mandible.

Protraction and Retraction

Protraction¹⁷ (fig. 9.15a) is the anterior movement of a body part in the transverse (horizontal) plane, and **retraction**¹⁸ (fig. 9.15b) is posterior movement. Your shoulder protracts, for example, when you reach in front of you to push a door

open. It retracts when you return it to the resting (zero) position or pull the shoulders back to stand at military attention. Such exercises as rowing a boat, bench presses, and push-ups involve repeated protraction and retraction of the shoulders.

Circumduction

In **circumduction**¹⁹ (fig. 9.16), one end of an appendage remains fairly stationary while the other end makes a circular motion. If an artist standing at an easel reaches

¹⁶ad = toward + duc = to lead or carry

¹⁷pro = forward + trac = to pull or draw

¹⁸re = back + trac = to pull or draw

¹⁹circum = around + duc = to carry, lead

(a) Abduction

(b) Adduction

FIGURE 9.13 Abduction and Adduction.

(a) Elevation

(b) Depression

FIGURE 9.14 Elevation and Depression.

forward and draws a circle on a canvas, she circumducts the upper limb; the shoulder remains stationary while the hand moves in a circle. A baseball player winding up for the pitch circumducts the upper limb in a more extreme “windmill” fashion. One can also circumduct an individual finger, the hand, the thigh, the foot, the trunk, and the head.

Think About It

Choose any example of circumduction and explain why this motion is actually a sequence of flexion, abduction, extension, and adduction.

(a) Protraction

(b) Retraction

FIGURE 9.15 Protraction and Retraction.

FIGURE 9.16 Circumduction.

Rotation

In one sense, the term *rotation* applies to any bone turning around a fixed axis, as described earlier. But in the terminology of specific joint movements, **rotation** (fig. 9.17) is a movement in which a bone spins on its longitudinal axis. For example, if you stand with bent elbow and move your forearm to place your palm against your abdomen,

FIGURE 9.17 Medial (Internal) and Lateral (External) Rotation. Shows rotation of both the humerus and femur.

FIGURE 9.18 Supination and Pronation.

your humerus spins in a motion called **medial (internal) rotation** (fig. 9.17a). If you make the opposite motion, so the forearm points away from the body, your humerus exhibits **lateral (external) rotation** (fig. 9.17b). If you turn your right foot so your toes are pointing away from your left foot, and then turn it so your toes are pointing toward your left foot, your femur undergoes lateral and medial rotation, respectively. Other examples are given in the ensuing discussions of forearm and head movements.

Supination and Pronation

Supination and pronation are known primarily as forearm movements, but see also the later discussion of foot movements. **Supination**²⁰ (SOO-pih-NAY-shun) (fig. 9.18a) of the forearm is a movement that turns the palm to face anteriorly or upward; in anatomical position, the forearm is supinated and the radius is parallel to the ulna. **Pronation**²¹ (fig. 9.18b) is the opposite movement, causing the palm to face posteriorly or downward, and the radius to cross the ulna like an X. During these movements, the concave end of the disc-shaped head of the radius spins on the capitulum of the humerus, and the edge of the disc spins in the radial notch of the ulna. The ulna remains relatively stationary.

As an aid to remembering these terms, think of it this way: You are *prone* to stand in the most comfortable position, which is with the forearm *pronated*. But if you were holding a bowl of *soup* in your hand, you would need to *supinate* the forearm to keep from spilling it.

Chapter 10 describes the muscles that perform these actions. Of these, the *supinator* is the most powerful. Supination is the type of movement you would usually make with your right hand to turn a doorknob clockwise or to drive a screw into a piece of wood. The threads of screws and bolts are designed with the relative strength of the supinator in mind, so the greatest power can be applied when driving them with a screwdriver in the right hand.

We will now consider a few body regions that combine the foregoing motions, or that have unique movements and terminology.

Special Movements of the Head and Trunk

Flexion of the vertebral column produces forward-bending movements, as in tilting the head forward or bending at the waist in a toe-touching exercise (fig. 9.19a). *Extension* of

²⁰*supin* = to lay back

²¹*pron* = to bend forward

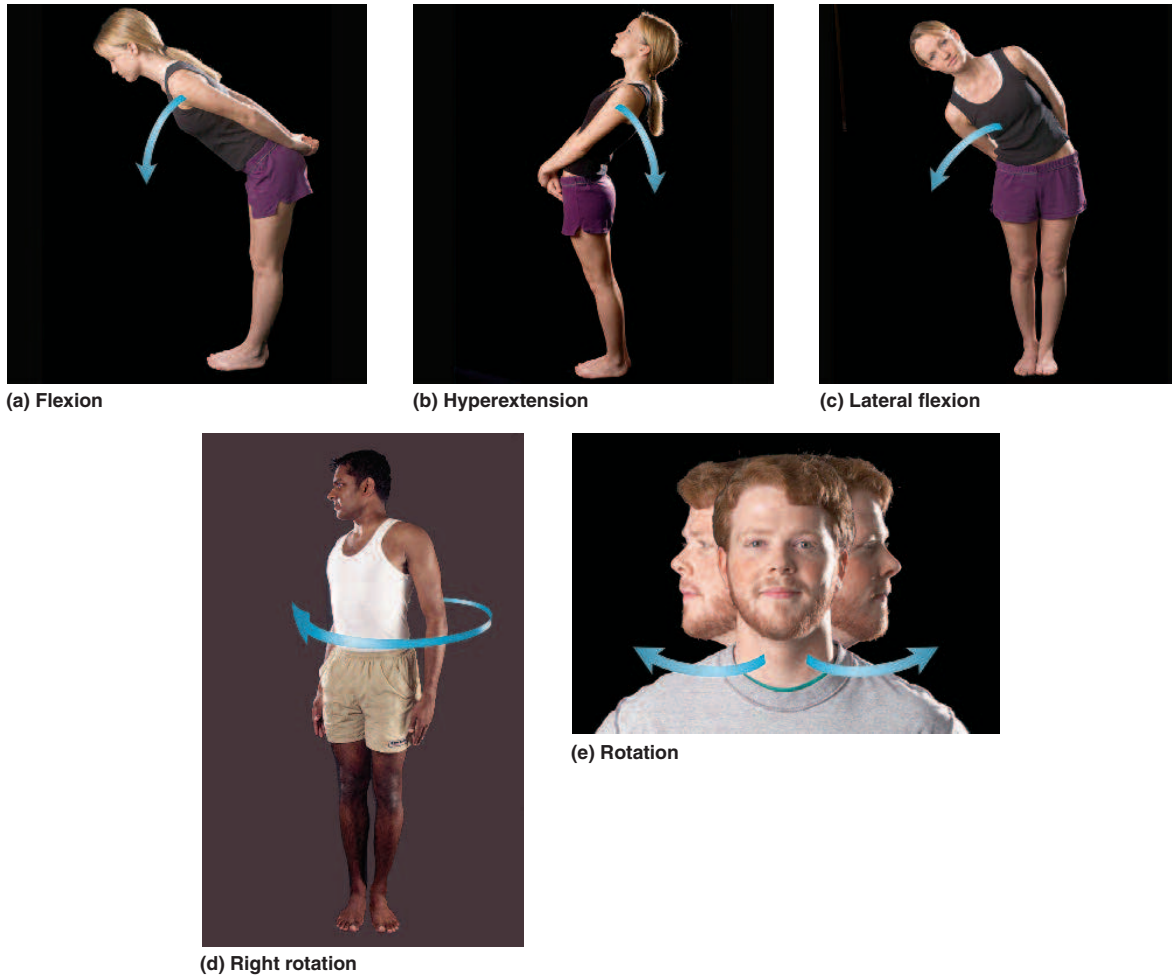

FIGURE 9.19 Movements of the Head and Trunk.

● In rotation of the head (e), what bone spins on its axis?

the vertebral column straightens the trunk or the neck, as in standing up or returning the head to a forward-looking (zero) position. *Hyperextension* is employed in looking up toward the sky or bending over backward (fig. 9.19b).

Lateral flexion is tilting the head or trunk to the right or left of the midline (fig. 9.19c). Twisting at the waist or turning of the head is called **right rotation** or **left rotation** when the chest or the face turns to the right or left of the forward-facing zero position (fig. 9.19d, e). Powerful right and left rotation at the waist is important in baseball pitching, discus throwing, and other sports.

Special Movements of the Mandible

Movements of the mandible are concerned especially with biting and chewing. Imagine taking a bite of raw carrot. Most people have some degree of overbite; at rest,

the upper incisors (front teeth) overhang the lower ones. For effective biting, however, the chisel-like edges of the incisors must meet. In preparation to bite, we therefore *protract* the mandible to bring the lower incisors forward. After the bite is taken, we *retract* it (fig. 9.20a, b). To actually take the bite, we must *depress* the mandible to open the mouth, then *elevate* it so the incisors can cut off the piece of food.

Next, to chew the food, we do not simply raise and lower the mandible as if hammering away at the food between the teeth; rather, we exercise a grinding action that shreds the food between the broad, bumpy surfaces of the premolars and molars. This entails a side-to-side movement of the mandible called **lateral excursion** (movement to the left or right of the zero position) and **medial excursion** (movement back to the median, zero position) (fig. 9.20c, d).

FIGURE 9.20 Movements of the Mandible.

Special Movements of the Hand and Digits

The hand moves anteriorly and posteriorly by flexion and extension of the wrist. It can also move in the frontal plane. **Ulnar flexion** tilts the hand toward the little finger, and **radial flexion** tilts it toward the thumb (fig. 9.21a, b). We often use such motions when waving hello to someone with a side-to-side wave of the hand, or when washing windows, polishing furniture, or keyboarding.

Movements of the digits are more varied, especially those of the thumb. *Flexion* of the fingers is curling them; *extension* is straightening them. Most people cannot hyperextend their fingers. Spreading the fingers apart is *abduction* (fig. 9.21c), and bringing them together again so they touch along their surfaces is *adduction* (as in fig. 9.21a, b).

The thumb is different, however, because in embryonic development it rotates nearly 90° from the rest of the hand. If you hold your hand in a completely relaxed position, you will probably see that the plane that contains your thumb and index finger is about 90° to the plane that contains the index through little finger. Much of the terminology of thumb movement therefore differs from that of the other four fingers. *Flexion* of the thumb is bending the joints so the tip of the thumb is directed toward the palm, and *extension* is

FIGURE 9.21 Movements of the Hand and Digits. (a) Radial flexion of the wrist. (b) Ulnar flexion of the wrist. (c) Abduction of the fingers. The thumb position in this figure is called *radial abduction*. Parts (a) and (b) show adduction of the fingers. (d) Palmar abduction of the thumb. (e) Opposition of the thumb; reposition is shown in parts (a) and (b).

straightening the thumb. If you place the palm of your hand on a table top with all five digits parallel and touching, the thumb is extended. Keeping your hand there, if you move your thumb away from the index finger so they form a 90° angle (but both are on the plane of the table top), the thumb movement is called **radial abduction** (as in fig. 9.21c). Another movement, **palmar abduction**, moves the thumb away from the plane of the hand so it points anteriorly, as you would do if you were about to wrap your hand around a tool handle (fig. 9.21d). From either position—radial or palmar abduction—**adduction** of the thumb means to bring it back to zero position, touching the base of the index finger.

Two terms are unique to the thumb: **Opposition**²² means to move the thumb to touch the tip of any of the other four fingers (fig. 9.21e). **Reposition**²³ is the return to zero position.

Special Movements of the Foot

A few additional movement terms are unique to the foot. **Dorsiflexion** (DOR-sih-FLEC-shun) is a movement in which the toes are elevated, as one might do in applying toenail polish (fig. 9.22a). In each step you take, the foot dorsiflexes as it comes forward. This prevents you from scraping your toes on the ground and results in the characteristic *heel strike* of human locomotion when the foot touches down in front of you. **Plantar flexion** is movement of the foot so the toes point downward, as in pressing the gas pedal of a car or standing on tiptoes. This motion also produces the *toe-off* in each step you take, as the heel of the foot behind you lifts off the ground. Plantar flexion can be a very powerful motion, epitomized by high jumpers and the jump shots of basketball players.

²²op = against + posit = to place

²³re = back + posit = to place

Inversion²⁴ is a foot movement that tips the soles medially, somewhat facing each other and **eversion**²⁵ is a movement that tips the soles laterally, away from each other (fig. 9.22b, c). These movements are common in fast sports such as tennis and football, and sometimes cause ankle sprains. These terms also refer to congenital deformities of the feet, which are often corrected by orthopedic shoes or braces.

Pronation and **supination**, referring mainly to forearm movements, also apply to the feet but refer here to a more complex combination of movements. Pronation of the foot is a combination of dorsiflexion, eversion, and abduction—that is, the toes are elevated and turned away from the other foot and the sole is tilted away from the other foot. Supination of the foot is a combination of plantar flexion, inversion, and adduction—the toes are lowered and turned toward the other foot and the sole is tilted toward it. These may seem a little difficult to visualize and perform, but they are ordinary motions during walking, running, and crossing uneven surfaces such as stepping stones.

You can perhaps understand why these terms apply to the feet if you place the palms of your hands on a table and pretend they are your soles. Tilt your hands so the inner edge (thumb side) of each is raised from the table. This is like raising the medial edge of your foot from the ground, and as you can see, it involves a slight supination of your forearms. Resting your hands palms down on a table, your forearms are already pronated; but if you raise the outer edges of your hands (the little finger side), like pronating the feet, you will see that it involves a continuation of the pronation movement of the forearm.

²⁴in = inward + version = turning

²⁵e = outward + version = turning

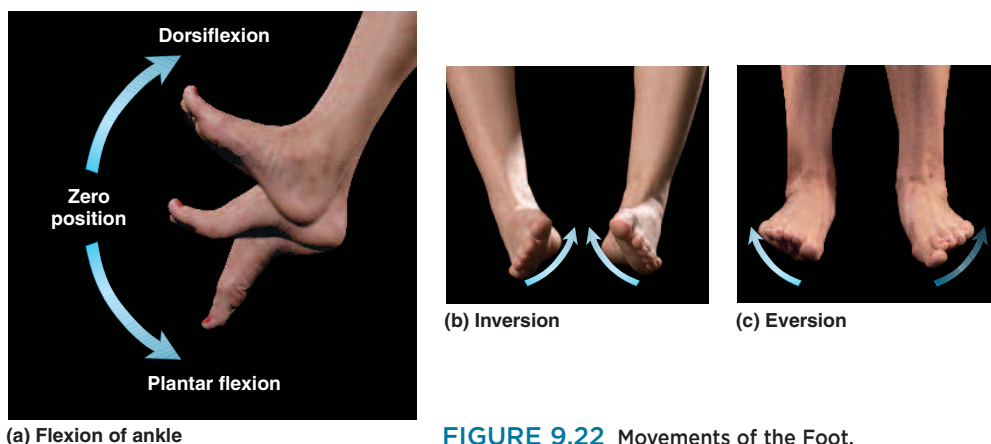

FIGURE 9.22 Movements of the Foot.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Describe the roles of articular cartilage and synovial fluid in joint mobility.
- Give an anatomical example of each class of levers and explain why each example belongs in that class.
- Give an example of each of the six classes of synovial joints and state how many axes of rotation each example has.
- Suppose you reach overhead and screw a lightbulb into a ceiling fixture. Name each joint that would be involved and the joint actions that would occur.
- Where are the effort, fulcrum, and resistance in the act of dorsiflexion? What class of lever does the foot act as during dorsiflexion? Would you expect it to have a mechanical advantage greater or less than 1.0? Why?

9.3 Anatomy of Selected Diarthroses

Objectives

When you have completed this section, you should be able to

- identify the major anatomical features of the jaw, shoulder, elbow, hip, knee, and ankle joints; and
- explain how the anatomical differences between these joints are related to differences in function.

We now examine the gross anatomy of certain diarthroses. It is beyond the scope of this book to discuss all of them, but the ones selected here most often require medical attention and many of them have a strong bearing on athletic performance and everyday mobility.

The Jaw Joint

The **temporomandibular (jaw) joint (TMJ)** is the articulation of the condyle of the mandible with the mandibular fossa of the temporal bone (fig. 9.23). You can feel its action by pressing your fingertips against the jaw immediately anterior to the ear while opening and closing your mouth. This joint combines elements of condylar, hinge, and plane joints. It functions in a hingelike fashion when the mandible is elevated and depressed, it glides slightly forward when the jaw is protracted to take a bite, and it glides from side to side to grind food between the molars.

The synovial cavity of the TMJ is divided into superior and inferior chambers by an articular disc, which permits lateral and medial excursion of the mandible.

Two ligaments support the joint. The **lateral ligament** prevents posterior displacement of the mandible. If the jaw receives a hard blow, this ligament normally prevents the condylar process from being driven upward and fracturing the base of the skull. The **sphenomandibular ligament** on the medial side of the joint extends from the sphenoid bone to the ramus of the mandible. A **stylomandibular ligament** extends from the styloid process to the angle of the mandible but is not part of the TMJ proper.

A deep yawn or other strenuous depression of the mandible can dislocate the TMJ by making the condyle pop out of the fossa and slip forward. The joint can be relocated by pressing down on the molars while pushing the jaw backward.

The Shoulder Joint

The **glenohumeral (humeroscapular) joint**, or shoulder joint, is where the hemispherical head of the humerus articulates with the glenoid cavity of the scapula (fig. 9.24). Together, the shoulder and elbow joints serve to position the hand for the performance of a task; without a hand, shoulder and elbow movements are almost useless. The relatively loose shoulder joint capsule and shallow glenoid cavity sacrifice joint stability for freedom of movement. The cavity, however, has a ring of fibrocartilage called the **glenoid labrum**²⁶ around its margin, making it somewhat deeper than it looks on a dried skeleton.

The shoulder is stabilized mainly by the biceps brachii muscle on the anterior side of the arm. One of its tendons arises from the *long head* of the muscle (see chapter 10), passes through the intertubercular groove of the humerus, and inserts on the superior margin of the glenoid cavity. It acts as a taut strap that presses the humeral head against the glenoid cavity. Four additional

INSIGHT 9.2 Clinical Application

TMJ Syndrome

Temporomandibular joint (TMJ) syndrome has received medical recognition only recently, although it may affect as many as 75 million Americans. It can cause moderate intermittent facial pain, clicking sounds in the jaw, limitation of jaw movement, and in some people, more serious symptoms—severe headaches, vertigo (dizziness), tinnitus (ringing in the ears), and pain radiating from the jaw down the neck, shoulders, and back. It seems to be caused by a combination of psychological tension and malocclusion (misalignment of the teeth). Treatment may involve psychological management, physical therapy, analgesic and anti-inflammatory drugs, and sometimes corrective dental appliances to align the teeth properly.

²⁶labrum = lip

FIGURE 9.23 The Temporomandibular Joint (TMJ).

muscles help to stabilize this joint: the *supraspinatus*, *infraspinatus*, *teres minor*, and *subscapularis*. Their tendons form the **rotator cuff**, which is fused to the joint capsule on all sides except the inferior (see fig. 10.26, p. 356). Chapter 10 further describes the rotator cuff and its injuries (p. 381).

Five principal ligaments also support this joint. Three of them, called the **glenohumeral ligaments**, are relatively weak and sometimes absent. The other two are the **coracohumeral ligament**, which extends from the coracoid process of the scapula to the greater tubercle of the humerus, and the **transverse humeral ligament**, which extends from the greater to the lesser tubercle of the humerus and forms a tunnel housing the tendon from the long head of the biceps.

Four bursae occur at the shoulder. Their names describe their locations: the **subdeltoid**, **subacromial**, **subcoracoid**, and **subscapular bursae**. The *deltoid* is the large muscle that caps the shoulder, and the other bursae are named for parts of the scapula described in chapter 8.

INSIGHT 9.3 Clinical Application

Shoulder Dislocation

Shoulder dislocations are very painful and sometimes cause permanent damage. The most common dislocation is downward displacement of the humerus, because (1) the rotator cuff protects the joint in all directions except inferiorly, and (2) the joint is protected from above by the coracoid process, acromion, and clavicle. Dislocations most often occur when the arm is abducted and then receives a blow from above—for example, when the outstretched arm is struck by heavy objects falling off a shelf. They also occur in children who are jerked off the ground by one arm or forced to follow by a hard tug on the arm. Children are especially prone to such injury not only because of the inherent stress caused by such abuse, but also because a child's shoulder is not fully ossified and the rotator cuff is not strong enough to withstand very much stress. Because this joint is so easily dislocated, one should never attempt to move an immobilized person by pulling on his or her arm.

FIGURE 9.24 The Glenohumeral (Shoulder) Joint.

The Elbow Joint

The elbow is a hinge joint composed of two articulations: the **humeroulnar joint** where the trochlea of the humerus joins the trochlear notch of the ulna, and the **humeroradial joint** where the capitulum of the humerus meets the head of the radius (fig. 9.25). Both are enclosed in a single joint capsule. On the posterior side of the elbow, there is a prominent **olecranon bursa** to ease the movement of tendons over the joint. Side-to-side motions of the elbow joint

are restricted by a pair of ligaments: the **radial (lateral) collateral ligament** and **ulnar (medial) collateral ligament**.

Another joint occurs in the elbow region, the **proximal radioulnar joint**, but it is not involved in the hinge. At this joint, the edge of the disclike head of the radius fits into the radial notch of the ulna. It is held in place by the **annular ligament**, which encircles the radial head and is attached at each end to the ulna. The radial head rotates like a wheel against the ulna as the forearm is pronated or supinated.

FIGURE 9.25 The Elbow Joint. This region includes two joints that form the elbow hinge—the humeroulnar and humeroradial—and one joint, the radioulnar, not involved in the hinge.

The Hip Joint

The **coxal (hip) joint** is the point where the head of the femur inserts into the acetabulum of the hip bone (fig. 9.26). Because the coxal joints bear much of the body's weight, they have deep sockets and are much more stable than the shoulder joint. The depth of the socket is somewhat greater than you see on dried bones because of a horseshoe-shaped ring of fibrocartilage, the **acetabular labrum**, attached to its rim. Dislocations of the hip are rare, but some infants suffer congenital dislocations because the acetabulum is not deep enough to hold the head of the femur in place. This condition can be treated by placing the infant in traction until

the acetabulum develops enough strength to support the body's weight (fig. 9.27).

Think About It

Where else in the body is there a structure similar to the acetabular labrum? What do those two locations have in common?

Ligaments that support the coxal joint include the **iliofemoral** (ILL-ee-oh-FEM-oh-rul) and **pubofemoral** (PYU-bo-FEM-or-ul) ligaments on the anterior side and the **ischiofemoral** (ISS-kee-oh-FEM-or-ul) ligament on

FIGURE 9.26 The Coxal (Hip) Joint.

the posterior side. The name of each ligament refers to the bones to which it attaches—the femur and the ilium, pubis, or ischium. When you stand up, these ligaments become twisted and pull the head of the femur tightly into the acetabulum. The head of the femur has a conspicuous pit called the **fovea capitis**. The **round ligament**, or **ligamentum teres**²⁷ (TERR-eez), arises here

and attaches to the lower margin of the acetabulum. This is a relatively slack ligament, so it is doubtful that it plays a significant role in holding the femur in its socket. It does, however, contain an artery that supplies blood to the head of the femur. A **transverse acetabular ligament** bridges a gap in the inferior margin of the acetabular labrum.

²⁷teres = round

FIGURE 9.27 Treatment of Congenital Hip Dislocation. Infants are sometimes placed in traction to treat this condition.

The Knee Joint

The **tibiofemoral (knee) joint** is the largest and most complex diarthrosis of the body (figs. 9.28 and 9.29). It is primarily a hinge joint, but when the knee is flexed it is also capable of slight rotation and lateral gliding. The patella and patellar ligament also articulate with the femur to form a gliding **patellofemoral joint**.

The joint capsule encloses only the lateral and posterior aspects of the knee joint, not the anterior. The anterior aspect is covered by the patellar ligament and the *lateral* and *medial patellar retinacula* (not illustrated). These are extensions of the tendon of the *quadriceps femoris muscle*, the large anterior muscle of the thigh. The knee is stabilized mainly by the quadriceps tendon in front and the tendon of the *semimembranosus muscle* on the rear of the thigh. Developing strength in these muscles therefore reduces the risk of knee injury.

The joint cavity contains two C-shaped cartilages called the **lateral meniscus** and **medial meniscus**, joined by a **transverse ligament**. The menisci absorb the shock of the body weight jostling up and down on the knee and prevent the femur from rocking from side to side on the tibia.

The posterior **popliteal** (pop-LIT-ee-ul) **region** of the knee is supported by a complex array of *extracapsular ligaments* external to the joint capsule and two *intracapsular ligaments* within it. The extracapsular ligaments include two collateral ligaments that prevent the knee from rotating when the joint is extended—the **fibular (lateral) collateral ligament** and the **tibial (medial) collateral ligament**—and other ligaments not illustrated.

The two intracapsular ligaments lie deep within the joint. The synovial membrane folds around them, however, so that they are excluded from the fluid-filled synovial cavity. These ligaments cross each other in the form of an X; hence, they are called the **anterior cruciate**²⁸

²⁸*cruci* = cross + *ate* = characterized by

FIGURE 9.28 The Right Knee, Anterior Dissection. The quadriceps tendon has been cut and folded (reflected) downward to expose the joint cavity and the posterior surface of the patella.

(CROO-she-ate) **ligament (ACL)** and **posterior cruciate ligament (PCL)**. These are named according to whether they attach to the anterior or posterior side of the tibia, not for their attachments to the femur. When the knee is extended, the ACL is pulled tight and prevents hyperextension. The PCL prevents the femur from sliding off the front of the tibia and prevents the tibia from being displaced backward. The ACL is one of the most common sites of knee injury (see Insight 9.4).

Think About It

What structure in the elbow joint serves the same function as the ACL of the knee?

FIGURE 9.29 The Right Tibiofemoral (Knee) Joint.

INSIGHT 9.4 Clinical Application

Knee Injuries and Arthroscopic Surgery

Although the knee can bear a lot of weight, it is highly vulnerable to rotational and horizontal stress, especially when the knee is flexed (as in skiing or running) and receives a blow from behind or from the side. The most common injuries are to a meniscus or the anterior cruciate ligament (ACL) (fig. 9.30). Knee injuries heal slowly because ligaments and tendons have a very scanty blood supply and cartilage usually has no blood vessels at all.

The diagnosis and surgical treatment of knee injuries has been greatly improved by *arthroscopy*, a procedure in which the interior of a joint is viewed with a pencil-thin instrument, the *arthroscope*, inserted through a small incision. The arthroscope has a light source, a lens, and fiber optics that allow a viewer to see into the cavity, take photographs or videotapes of the joint, and withdraw samples of synovial fluid. Saline is often introduced through one incision to expand the joint and provide a clearer view of its structures. If surgery is required, additional small incisions can be made for the surgical instruments and the procedures can be observed through the arthroscope or on a monitor. Arthroscopic surgery produces much less tissue damage than conventional surgery and enables patients to recover more quickly.

Orthopedic surgeons now often replace a damaged ACL with a graft from the patellar ligament or a hamstring tendon. The surgeon “harvests” a strip from the middle of the patient’s ligament (or tendon), drills a hole into the femur and tibia within the joint cavity, threads the ligament through the holes, and fastens it with screws. The grafted ligament is more taut and “competent” than the damaged ACL. It becomes ingrown with blood vessels and serves as a substrate for the deposition of more collagen, which further strengthens it in time. Following arthroscopic ACL reconstruction, a patient typically must use crutches for 7 to 10 days and undergo supervised physical therapy for 6 to 10 weeks, followed by self-directed exercise therapy. Healing is completed in about 9 months.

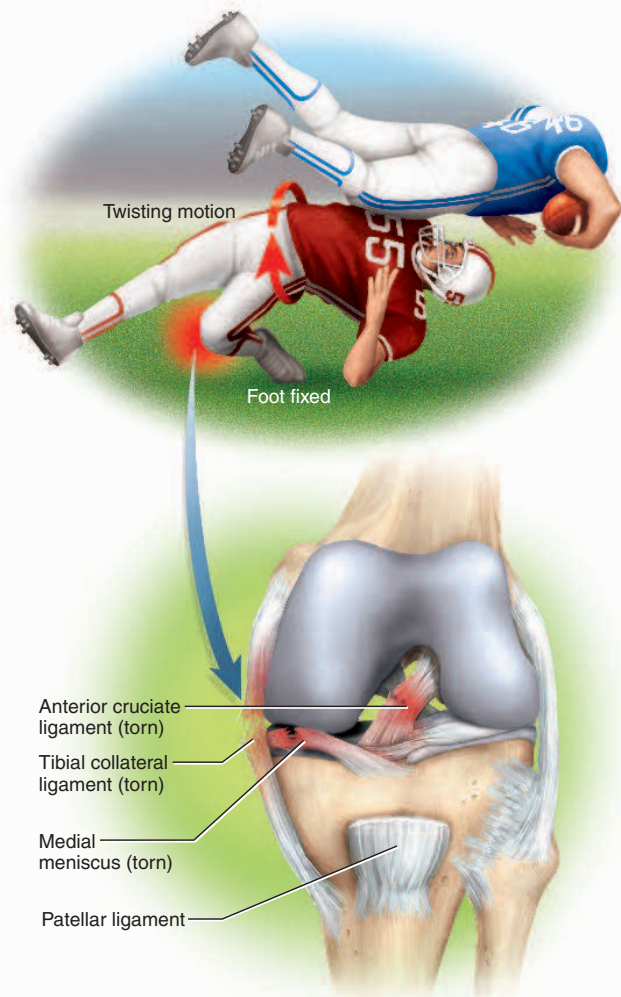

FIGURE 9.30 Knee Injuries.

An important aspect of human bipedalism is the ability to “lock” the knees and stand erect without tiring the extensor muscles of the leg. When the knee is extended to the fullest degree allowed by the ACL, the femur rotates medially on the tibia. This action locks the knee, and in this state, all the major knee ligaments are twisted and taut. To unlock the knee, the *popliteus* muscle rotates the femur laterally and untwists the ligaments.

The knee joint has at least 13 bursae. Four of these are anterior: the **superficial infrapatellar**, **suprapatellar**, **prepatellar**, and **deep infrapatellar**. Located in the popliteal region are the *popliteal bursa* and *semimembranosus bursa* (not illustrated). At least seven more bursae are found on the lateral and medial sides of the knee joint. From figure 9.29c, your knowledge of the relevant word

elements (*infra-*, *supra-*, *pre-*), and the terms *superficial* and *deep*, you should be able to work out the reasoning behind most of these names and develop a system for remembering the locations of these bursae.

The Ankle Joint

The **talocrural**²⁹ (ankle) joint includes two articulations—a medial joint between the tibia and talus and a lateral joint between the fibula and talus, both enclosed in one joint capsule (fig. 9.31). The malleoli of the tibia and fibula overhang the talus on each side like a cap and prevent most side-to-side motion. The ankle therefore has a more restricted range of motion than the wrist.

²⁹*talo* = ankle + *crural* = pertaining to the leg

FIGURE 9.31 The Talocrural (Ankle) Joint and Ligaments of the Right Foot.

The ligaments of the ankle include (1) **anterior and posterior tibiofibular ligaments**, which bind the tibia to the fibula; (2) a multipart **medial (deltoid³⁰) ligament**, which binds the tibia to the foot on the medial side; and (3) a multipart **lateral (collateral) ligament**, which binds the fibula to the foot on the lateral side. The **calcaneal (Achilles) tendon** extends from the calf muscles to the calcaneus. It plantarflexes the foot and limits dorsiflexion. Plantar flexion is limited by extensor tendons on the anterior side of the ankle and by the anterior part of the joint capsule.

Sprains (torn ligaments and tendons) are common at the ankle, especially when the foot is suddenly inverted or everted to excess. They are painful and usually accompanied by immediate swelling. They are best treated by

immobilizing the joint and reducing swelling with an ice pack, but in extreme cases may require a cast or surgery. Sprains and other joint disorders are briefly described in table 9.1.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

12. What keeps the mandibular condyle from slipping out of its fossa in a posterior direction?
13. Explain how the biceps tendon braces the shoulder joint.
14. Identify the three joints found at the elbow and name the movements in which each joint is involved.
15. What keeps the femur from slipping backward off the tibia?
16. What keeps the tibia from slipping sideways off the talus?

³⁰delt = triangular, Greek letter delta (Δ) + oid = resembling

TABLE 9.1 Some Common Joint Disorders

Arthritis	Broad term embracing more than 100 types of joint rheumatism.
Bursitis	Inflammation of a bursa, usually due to overexertion of a joint.
Dislocation	Displacement of a bone from its normal position at a joint, usually accompanied by a sprain of the adjoining connective tissues. Most common at the fingers, thumb, shoulder, and knee.
Gout	A hereditary disease, most common in men, in which uric acid crystals accumulate in the joints and irritate the articular cartilage and synovial membrane. Causes gouty arthritis, with swelling, pain, tissue degeneration, and sometimes fusion of the joint. Most commonly affects the great toe.
Rheumatism	Broad term for any pain in the supportive and locomotory organs of the body, including bones, ligaments, tendons, and muscles.
Sprain	Torn ligament or tendon, sometimes with damage to a meniscus or other cartilage.
Strain	Painful overstretching of a tendon or muscle without serious tissue damage. Often results from inadequate warm-up before exercise.
Synovitis	Inflammation of a joint capsule, often as a complication of a sprain.
Tendinitis	A form of bursitis in which a tendon sheath is inflamed.

Rheumatoid arthritis p. 314Rotator cuff injury p. 381
Shoulder dislocation p. 306**INSIGHT 9.5** Clinical Application**Arthritis and Artificial Joints**

Arthritis³¹ is a broad term for pain and inflammation of a joint and embraces more than a hundred different diseases of largely obscure or unknown causes. In all of its forms, it is the most common crippling disease in the United States; nearly everyone past middle age develops arthritis to some degree. Physicians who treat arthritis and other joint disorders are called *rheumatologists*.

The most common form of arthritis is *osteoarthritis (OA)*, also called “wear-and-tear arthritis” because it is apparently a normal consequence of years of wear on the joints. As joints age, the articular cartilage softens and degenerates. As the cartilage becomes roughened by wear, joint movement may be accompanied by crunching or crackling sounds called *crepitus*. OA affects especially the fingers, intervertebral joints, hips, and knees. As the articular cartilage wears away, exposed bone tissue often develops spurs that grow into the joint cavity, restrict movement, and cause pain. OA rarely occurs before age 40, but it affects about 85% of people older than 70, especially those who are overweight. It usually does not cripple, but in severe cases it can immobilize the hip.

Rheumatoid arthritis (RA), which is far more severe than osteoarthritis, results from an autoimmune attack against the joint tissues. It begins when the body produces antibodies to fight an infection. Failing to recognize the body’s own tissues, a misguided antibody known as *rheumatoid factor* also attacks the synovial membranes. Inflammatory cells accumulate in the synovial fluid and produce enzymes that degrade the articular cartilage. The synovial membrane thickens and adheres to the articular cartilage, fluid accumulates in the joint capsule, and the capsule is invaded by fibrous connective tissue. As articular cartilage degenerates, the joint begins to ossify, and sometimes the bones become solidly fused and immobilized, a condition called *ankylosis*³² (fig. 9.32). The disease tends to develop symmetrically— if the right wrist or hip develops RA, so does the left.

(a)

(b)

FIGURE 9.32 Rheumatoid Arthritis (RA). (a) A severe case with ankylosis of the joints. (b) X-ray of severe RA of the hands.³¹*arthr* = joint + *itis* = inflammation³²*ankyl* = bent, crooked + *osis* = condition

Rheumatoid arthritis is named for the fact that symptoms tend to flare up and subside (go into remission) periodically.³³ It affects women far more often than men, and because RA typically begins as early as age 30 to 40, it can cause decades of pain and disability. There is no cure, but joint damage can be slowed with hydrocortisone or other steroids. Because long-term use of steroids weakens the bone, however, aspirin is the treatment of first choice to control the inflammation. Physical therapy is also used to preserve the joint's range of motion and the patient's functional ability.

Arthroplasty,³⁴ a treatment of last resort, is the replacement of a diseased joint with an artificial device called a *prosthesis*.³⁵ Joint prostheses were first developed to treat injuries in World War II and the Korean War. Total hip replacement (THR), first performed in 1963 by English orthopedic surgeon Sir John Charnley, is now the most common orthopedic procedure for the elderly. The first knee replacements were performed in the 1970s. Joint prostheses are now available for finger, shoulder, and elbow joints, as well as the hip and knee. Arthroplasty is performed on over 250,000 patients per year in the United States, primarily to relieve pain and restore function in elderly people with OA or RA.

Arthroplasty presents ongoing challenges for biomedical engineering. An effective prosthesis must be strong, nontoxic,

and corrosion-resistant. In addition, it must bond firmly to the patient's bones and enable a normal range of motion with a minimum of friction. The heads of long bones are usually replaced with prostheses made of a metal alloy such as cobalt-chrome, titanium alloy, or stainless steel. Joint sockets are made of polyethylene (fig. 9.33). Prostheses are bonded to the patient's bone with screws or bone cement.

Improvements in technology have resulted in long-lasting prostheses. Over 75% of artificial knees last 20 years, nearly 85% last 15 years, and over 90% last 10 years. The most common form of failure is detachment of the prosthesis from the bone. This problem has been reduced by using *porous-coated prostheses*, which become infiltrated by the patient's own bone and create a firmer bond. A prosthesis is not as strong as a natural joint, however, and is not an option for many young, active patients.

Arthroplasty has been greatly improved by *computer-assisted design and manufacture (CAD/CAM)*. A computer scans X-rays from the patient and presents several design possibilities for review. Once a design is selected, the computer generates a program to operate the machinery that produces the prosthesis. CAD/CAM has reduced the waiting period for a prosthesis from 12 weeks to about 2 weeks and has lowered the cost dramatically.

³⁵prosthesis = something added

CHAPTER REVIEW

Review of Key Concepts

9.1 Joints and Their Classification (p. 286)

1. A *joint (articulation)* is any point at which two bones meet. Not all joints are movable.
2. The sciences dealing with joints include arthrology, kinesiology, and biomechanics.
3. Joints are typically named for the bones involved, such as the glenohumeral joint.
4. Joints are classified according to the manner in which the bones are joined and corresponding differences in how freely the bones can move.
5. *Bony joints (synostoses)* are joints at which the original gap between two bones becomes ossified and adjacent bones become, in effect, a single bone—for example, union of the two frontal bones into a single bone.
6. *Fibrous joints (synarthroses)* are joints at which two bones are united by collagenous fibers. The three types of fibrous joints are *sutures* (which are of *serrate*, *lap*, and *plane* types), *gomphoses* (teeth in their sockets), and *syndesmoses* (exemplified by long bones joined along their shafts by interosseous membranes).
7. *Cartilaginous joints (amphiarthroses)* are joints at which two bones are united by cartilage. In *synchondroses*, the cartilage is hyaline (as in the epiphyseal plates of juvenile bones), and in *symphyses*, it is fibrocartilage (as in the intervertebral discs and pubic symphysis).

9.2 Synovial Joints (p. 290)

1. In a *synovial joint*, two bones are separated by a *joint cavity* containing lubricating *synovial fluid*. The articulating surfaces of the adjacent bones are covered by a hyaline *articular cartilage* and are sometimes held apart by a cartilaginous *articular disc* or a pair of *menisci*.
2. Synovial joints commonly exhibit *tendons* (which join muscle to bone), *ligaments* (which join one bone to another), and *bursae* (sacs of synovial fluid outside the joint cavity).
3. A long bone acts as a lever, with a stationary *fulcrum*, an *effort arm*, and a *resistance arm*.
4. The *mechanical advantage (MA)* of a lever is equal to the ratio of the length of the effort arm to the length of the resistance arm. A lever with an $MA > 1$ puts out more force than is put into it, and one with an $MA < 1$ puts out less force, but produces movements of greater speed or distance than the input.
5. Levers of the body are classified as *first-*, *second-*, or *third-class* depending on the relative positions of the fulcrum, effort, and resistance.
6. Joints vary in their *range of motion*, determined by the structure of the articulating bones, the tautness of ligaments and joint capsules, and the action of muscles and tendons.
7. A bone can rotate on as many as three mutually perpendicular *axes of rotation* (*x*, *y*, and *z*) corresponding to the three anatomical planes of the body. A joint has one to three *degrees of freedom* depending on how many of these axes of rotation it has. A joint is classified as *monaxial*, *biaxial*, or *multiaxial* depending on its degrees of freedom.
8. *Ball-and-socket joints* at the shoulder and hip are the only multiaxial joints.
9. *Condylar joints*, for example, at the articulation of the proximal phalanges with the metacarpals, are biaxial.
10. *Saddle joints* are also biaxial, occurring at the articulations of metacarpal I with the trapezium, and the clavicle with the sternum.
11. *Plane joints* are biaxial and have limited gliding movement, for example between the carpal bones and the articular facets of the vertebrae.
12. *Hinge joints* are monaxial and represented by the elbow and knee.
13. *Pivot joints* are monaxial and occur where a bone spins on its longitudinal axis, such as the head of the radius articulating with the ulna.
14. Joint movements are described by a specific terminology that is widely used in kinesiology, physical therapy,

and other fields. Many are described in reference to the *zero position* that a joint has when a person stands in anatomical position.

15. *Flexion* is a movement that decreases the angle between two bones, as in flexing the elbow; *extension* straightens a joint, usually returning a body part to zero position; and *hyperextension* extends a joint beyond the zero position. The vertebral column exhibits flexion and extension in bending forward and returning to zero position, respectively; hyperextension when bending backward; and *lateral flexion* when bending to one side.
16. *Abduction* moves a bone away from the median plane of the body, as in spreading the legs, and *adduction* moves it back. Abduction beyond a 180° angle is *hyperabduction*, as in lifting an arm to cross behind the head, and adduction beyond the zero position is *hyperadduction*, as in standing with the ankles crossed.
17. *Elevation* raises a bone such as the scapula and *depression* lowers it.
18. *Protraction* thrusts a bone such as the clavicle or mandible forward and *retraction* draws it back.
19. *Circumduction* moves the distal end of a bone in a circle while the proximal end remains relatively stationary.
20. *Rotation* turns a bone on its longitudinal axis. For example, folding the forearm across the abdomen and then rotating it in the opposite direction, with the elbow bent, cause *medial* and *lateral rotation* of the humerus. Turning the head or twisting at the waist is called *right rotation* and *left rotation*.
21. *Supination* rotates the forearm so the palm faces forward or upward, and *pronation* turns it so the palm faces toward the rear or downward.
22. The mandible exhibits some of the foregoing movements when biting and chewing, such as protraction, retraction, elevation, and depression; but also *lateral* and *medial excursion* when grinding food between the molars.

23. The wrist exhibits unique movements called *ulnar* and *radial flexion* when it bends medially and laterally, and the thumb exhibits unique movements called *opposition* and *reposition* when it crosses the palm to approach the fingertips and then returns to zero position. Thumb abduction and adduction occur in a plane 90° to the other digits because of embryonic rotation of the thumb to the sagittal plane.
 24. The foot exhibits *dorsiflexion* and *plantar flexion* in the sagittal plane; *inversion* and *eversion* in the frontal plane; and a complex combination of movements collectively called *pronation* and *supination*, but with only slight resemblance to the same-named movements of the forearm.
- 9.3 Anatomy of Selected Diarthroses (p. 305)**
1. The *temporomandibular (jaw) joint* of the skull is the point at which the condyle of the mandible articulates with the mandibular fossa of the temporal bone. It is stabilized by two ligaments and contains an articular disc to absorb some of the pressure of a bite.
 2. The *glenohumeral joint* is a ball-and-socket joint at which the head of the humerus articulates with the glenoid cavity of the scapula. It is supported by a cartilaginous *glenoid labrum*, two major ligaments and three minor (weak) ones, the biceps brachii tendon, and tendons of the four *rotator cuff* muscles. It has four bursae.
 3. The elbow has three joints of the hinge and pivot types: the *humeroulnar joint* where the trochlear notch of the ulna wraps around the trochlea of the humerus; the *humeroradial joint* where the head of the radius pivots on the capitulum of the humerus; and the *proximal radioulnar joint* where the edge of the radial head spins against the radial notch of the ulna. The first and second joints are involved in the hinge action of the elbow, and the second and third in the pivot action. An *anular ligament* arises from the ulna and encircles the neck of the radius. The joint is also stabilized by *radial* and *ulnar collateral ligaments* and has a posterior *olecranon bursa*.
 4. The *coxal joint* is a ball-and-socket joint where the head of the femur articulates with the acetabulum of the hip bone. The acetabulum is deepened by a cartilaginous *acetabular labrum*. Three major ligaments attach the femur to the pubis, ischium, and ilium.
 5. The knee has two principal joints, the *tibiofemoral* hinge joint and the *patellofemoral* gliding joint. It is enclosed laterally and posteriorly by the joint capsule and anteriorly by a pair of *patellar retinacula*. The joint is stabilized mainly by the *quadriceps femoris* and *semimembranosus* muscles of the thigh. The most important structures within the joint cavity are the two *menisci* and the *anterior* and *posterior cruciate ligaments*, but the knee has several other stabilizing ligaments and at least 13 bursae.
 6. The *talocrural (ankle) joint* is a meeting of three bones—tibia, fibula, and talus—supported by numerous tight ligaments and crossed by the calcaneal tendon of the calf muscles.

Testing Your Recall

1. Internal and external rotation of the humerus are made possible by a _____ joint.
 - a. pivot
 - b. condylar
 - c. ball-and-socket
 - d. saddle
 - e. hinge
2. Which of the following is the least movable?
 - a. a diarthrosis
 - b. a synostosis
 - c. a symphysis
 - d. a synovial joint
 - e. a condylar joint
3. Which of the following movements are unique to the foot?
 - a. dorsiflexion and inversion
 - b. elevation and depression
 - c. circumduction and rotation
 - d. abduction and adduction
 - e. opposition and reposition
4. Which of the following joints cannot be circumducted?
 - a. carpometacarpal
 - b. metacarpophalangeal
 - c. glenohumeral
 - d. coxal
 - e. interphalangeal
5. Which of the following terms denotes a general condition that includes the other four?
 - a. gout
 - b. arthritis
 - c. rheumatism
 - d. osteoarthritis
 - e. rheumatoid arthritis
6. In the adult, the ischium and pubis are united by
 - a. a synchondrosis.
 - b. a diarthrosis.
 - c. a synostosis.
 - d. an amphiarthrosis.
 - e. a symphysis.
7. In a second-class lever, the effort
 - a. is applied to the end opposite the fulcrum.
 - b. is applied to the fulcrum itself.
 - c. is applied between the fulcrum and resistance.
 - d. always produces an MA less than 1.0.
 - e. is applied on one side of the fulcrum to move a resistance on the other side.
8. Which of the following joints has anterior and posterior cruciate ligaments?
 - a. the shoulder
 - b. the elbow
 - c. the hip
 - d. the knee
 - e. the ankle
9. To bend backward at the waist involves _____ of the vertebral column.
 - a. rotation
 - b. hyperextension
 - c. dorsiflexion
 - d. abduction
 - e. flexion
10. The rotator cuff includes the tendons of all of the following muscles *except*
 - a. the subscapularis.
 - b. the supraspinatus.
 - c. the infraspinatus.
 - d. the biceps brachii.
 - e. the teres minor.

318 PART TWO Support and Movement

11. The lubricant of a diarthrosis is called _____.
12. A fluid-filled sac that eases the movement of a tendon over a bone is called a/an _____.
13. A _____ joint allows one bone to swivel on another.
14. _____ is the science of movement.
15. The joint between a tooth and the mandible is called a/an _____.
16. In a _____ suture, the articulating bones have interlocking wavy margins, somewhat like a dovetail joint in carpentry.
17. In kicking a football, what type of action does the knee joint exhibit?
18. The angle through which a joint can move is called its _____.
19. The menisci of the knee are functionally similar to the _____ of the temporomandibular joint.
20. At the ankle, both the tibia and fibula articulate with what tarsal bone?

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. More people get rheumatoid arthritis than osteoarthritis.
2. A doctor who treats arthritis is called a kinesiologist.
3. Synovial joints are also known as synarthroses.
4. There is no meniscus in the elbow joint.
5. Reaching behind you to take something out of your hip pocket involves hyperextension of the shoulder.
6. The anterior cruciate ligament normally prevents hyperextension of the knee.
7. The femur is held tightly in the acetabulum mainly by the round ligament.
8. The knuckles are diarthroses.
9. Synovial fluid is secreted by the bursae.
10. Unlike most ligaments, the periodontal ligaments do not attach one bone to another.

Answers in appendix B

Testing Your Comprehension

1. All second-class levers produce a mechanical advantage greater than 1.0 and all third-class levers produce a mechanical advantage less than 1.0. Explain why.
2. For each of the following joint movements, state what bone the axis of rotation passes through and which of the three anatomical planes contains the axis of rotation. You might find it helpful to produce some of these actions on an articulated laboratory skeleton so you can more easily visualize the axis of rotation. (a) Plantar flexion; (b) flexion of the hip; (c) abduction of the thigh; (d) flexion of the knee; (e) flexion of the first interphalangeal joint of the index finger. (Do not bend the fingers of a wired laboratory skeletal hand, because they can break off.)
3. In order of occurrence, list the joint actions (flexion, pronation, etc.) and the joints where they would occur as you (a) sit down at a table, (b) reach out and pick up an apple, (c) take a bite, and (d) chew it. Assume that you start in anatomical position.
4. The deltoid muscle inserts on the deltoid tuberosity of the humerus and abducts the arm. Imagine a person holding a weight in the hand and abducting the arm. On a laboratory skeleton, identify the fulcrum; measure the effort arm and resistance arm; determine the mechanical advantage of this movement; and determine which of the three lever types the upper limb acts as when performing this movement.
5. List the six types of synovial joints, and for each one, if possible, identify a joint in the upper limb and a joint in the lower limb that falls into each category. Which of these six joints have no examples in the lower limb?

- 10.5 Clinical Application:** Athletic Injuries 381

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Gross anatomy of the skeleton (chapter 8)
- Terms for synovial joint movements (pp. 298-304)

Muscles constitute nearly half of the body's weight and occupy a place of central interest in several fields of health care and fitness. Physical and occupational therapists must be well acquainted with the muscular system to design and carry out rehabilitation programs. Athletes and trainers, dancers and acrobats, and amateur fitness enthusiasts follow programs of resistance training to strengthen individual muscle groups through movement regimens based on knowledge of muscle, bone, and joint anatomy. Nurses employ their knowledge of the muscular system to give intramuscular injections correctly and to safely and effectively move patients who are physically incapacitated. Gerontological nurses are keenly aware of how deeply a person's muscular condition affects the quality of life in old age. The muscular system is highly important to biomedical disciplines even beyond the scope of the movement sciences. It is the primary source of body heat in the moving individual, and through its absorption, storage, and use of glucose, it is a major factor in control of blood glucose levels. Indeed, loss of muscle mass is often a significant factor in the onset of diabetes mellitus.

The muscular system is closely related to what we have covered in the preceding chapters. This chapter relates muscle attachments to the bone structures described in chapter 8 and muscle function to the joint movements described in chapter 9. After this, we will examine the mechanisms of muscle contraction at the cellular and molecular levels in chapter 11, and chapter 12 will shed light on the relationship of the muscles to the nerves that control them.

10.1 The Structural and Functional Organization of Muscles

Objectives

When you have completed this section, you should be able to

- describe the varied functions of muscles;
- describe the connective tissue components of a muscle and their relationship to the bundling of muscle fibers;
- describe the various shapes of skeletal muscles and relate this to their functions;
- explain what is meant by the origin, insertion, belly, action, and innervation of a muscle;
- describe the ways that muscles work in groups to aid, oppose, or moderate each other's actions;
- distinguish between intrinsic and extrinsic muscles;
- describe in general terms the nerve supply to the muscles and where these nerves originate; and
- explain how the Latin names of muscles can aid in visualizing and remembering them.

As we saw in chapter 5, there are three kinds of muscular tissue in the human body—skeletal, cardiac, and smooth. All types, however, are specialized for one fundamental purpose: to convert the chemical energy of ATP into the mechanical energy of motion. Muscle cells exert a useful force on other tissues and organs, either to produce desirable movements or to prevent undesirable ones.

Our focus in this chapter is on the **muscular system**, composed of the skeletal muscles only. The study of this system is called **myology**.¹ There are about 600 muscles in the human muscular system, but we survey fewer than one-third of them in this chapter, and most introductory anatomy and physiology courses cover an even smaller number of those.

The Functions of Muscles

The functions of muscles are as follows:

- **Movement.** Muscles enable us to move from place to place and to move individual body parts. Muscular contractions also move body contents in the course of breathing, blood circulation, feeding and digestion, defecation, urination, and childbirth. Muscular movements also serve various roles in communication: speech, writing, and nonverbal body language such as facial expressions.
- **Stability.** Muscles maintain posture by preventing unwanted movements. Some are called *antigravity muscles* because, at least part of the time, they resist the pull of gravity and prevent us from falling or slumping over. Many muscles also stabilize the joints by maintaining tension on tendons and bones.
- **Control of body openings and passages.** Muscles encircling the mouth serve not only for speech but also for food intake and retention of food while chewing. In the eyelid and pupil, they regulate the admission of light to the eye. Internal muscular rings control the movement of food, bile, blood, and other materials within the body. Muscles encircling the urethra and anus control the elimination of waste. (Some of these muscles are called *sphincters*, and others are not; this is discussed later.)
- **Heat production.** The skeletal muscles produce as much as 85% of one's body heat, which is vital to the functioning of enzymes and therefore to all metabolism.

¹myo = muscle + logy = study of

FIGURE 10.1 Connective Tissues of a Muscle. (a) The muscle-bone attachment. (b) A cross section of the thigh showing the relationship of neighboring muscles to fasciae and bone. (c) Muscle fascicles in the tongue. Vertical fascicles passing between the superior and inferior surfaces of the tongue are seen alternating with cross-sectioned horizontal fascicles that pass from the tip to the rear of the tongue. A fibrous perimysium can be seen between the fascicles, and endomysium can be seen between the muscle fibers within each fascicle. (c.s. = cross section; l.s. = longitudinal section)

Connective Tissues and Fascicles

A skeletal muscle is more than muscular tissue. It also contains connective tissue, nervous tissue, and blood vessels. In this section, we will examine the connective tissue components. From the smallest to largest and from deep to superficial, these are as follows (fig. 10.1):

- **Endomysium**² (EN-doe-MIZ-ee-um). This is a thin sleeve of loose connective tissue that surrounds each

muscle fiber. It creates room for blood capillaries and nerve fibers to reach every muscle fiber, ensuring that no muscle cell is without stimulation and nourishment. The endomysium also provides the extracellular chemical environment for the muscle fiber and its associated nerve ending. Excitation of a muscle fiber is based on the exchange of calcium, sodium, and potassium ions between the endomysial tissue fluid and the nerve and muscle fibers.

²endo = within + mys = muscle

FIGURE 10.2 Classification of Muscles According to Fascicle Orientation. The fascicles are the “grain” visible in each illustration.

- **Perimysium.**³ This is a thicker connective tissue sheath that wraps muscle fibers together in bundles called **fascicles**⁴ (FASS-ih-culs). Fascicles are visible to the naked eye as parallel strands—the “grain” in a cut of meat; tender roast beef is easily pulled apart along its fascicles. The perimysium carries the larger nerves and blood vessels as well as stretch receptors called muscle spindles (see p. 504).
- **Epimysium.**⁵ This is a fibrous sheath that surrounds the entire muscle. On its outer surface, the epimysium grades into the fascia; on its inner surface, it issues projections between the fascicles to form the perimysium.
- **Fascia**⁶ (FASH-ee-uh). This is a sheet of connective tissue that separates neighboring muscles or muscle groups from each other and from the subcutaneous tissue. As we will see later in this chapter, muscles of the limbs, especially, are grouped in *compartments* separated from each other by fascia.
- **Parallel muscles** have a fairly uniform width and parallel fascicles. Some of these are elongated straps, such as the *rectus abdominis* of the abdomen, *sartorius* of the thigh, and *zygomaticus major* of the face. Others are more squarish and are called *quadrilateral* (four-sided) muscles, such as the *masseter* of the jaw. Parallel muscles can span long distances, such as from hip to knee, and they shorten more than other muscle types. However, having fewer muscle fibers than a fusiform muscle of the same mass, they produce less force.
- **Triangular (convergent) muscles** are fan-shaped—broad at the origin and converging toward a narrower insertion. Examples include the *pectoralis major* in the chest and the *temporalis* on the side of the head. Despite their small localized insertions on a bone, these muscles are relatively strong because they contain a large number of fibers in the wider part of the muscle.
- **Pennate**⁸ muscles are feather-shaped. Their fascicles insert obliquely on a tendon that runs the length of the muscle, like the shaft of a feather. There are three types of pennate muscles: *unipennate*, in which all fascicles approach the tendon from one side (for example, the *palmar interosseous muscles* of the hand and *semimembranosus* of the thigh); *bipennate*, in which fascicles approach the tendon from both sides (for example, the *rectus femoris* of the thigh); and *multipennate*, shaped like a bunch of feathers with their quills converging on a single point (for example, the *deltoid* of the shoulder). These muscles generate more force than the preceding types because they fit more muscle fibers into a given length of muscle.

Fascicles and Muscle Shapes

The strength of a muscle and the direction of its pull are determined partly by the orientation of its fascicles. Muscles can be classified according to fascicle orientation as follows (fig. 10.2):

- **Fusiform**⁷ muscles are thick in the middle and tapered at each end. The *biceps brachii* of the arm and *gastrocnemius* of the calf are examples of this type.

³peri = around + mys = muscle

⁴fasc = bundle + icle = little

⁵epi = upon, above + mys = muscle

⁶fascia = band

⁷fusi = spindle + form = shape

⁸penna = feather + ate = characterized by

FIGURE 10.3 Synergistic and Antagonistic Muscle Pairs. The biceps brachii and brachialis muscles are synergists in elbow flexion. The triceps brachii is an antagonist of those two muscles and is the prime mover in elbow extension.

Which of these muscles have direct attachments to the bones, and which have indirect attachments?

- **Circular muscles (sphincters)** form rings around certain body openings. When they contract, they constrict the opening and tend to prevent the passage of material through it. Examples include the *orbicularis oculi* of the eyelids and the *external urethral* and *anal sphincters*. Smooth muscle can also form sphincters—for example, the *pyloric valve* at the passage from the stomach to the small intestine and the *internal urethral* and *anal sphincters*.

Muscle Attachments

Skeletal muscles are attached to bones through extensions of their connective tissue components. There are two forms of attachment—*indirect* and *direct*.

In an **indirect attachment**, the muscle ends conspicuously short of its bony destination, and the gap is bridged by a fibrous band or sheet called a **tendon**. See, for example, the two ends of the biceps brachii in figure 10.3 and the photographs in figures 10.32b and 10.38. You can easily palpate tendons and feel their texture just above the heel (your *calcaneal* or *Achilles tendon*) and on the anterior side of the wrist (tendons of the *palmaris longus* and *flexor carpi radialis* muscles). Collagen fibers of the muscle (the endo-, peri-, and epimysium) continue into the tendon and from there into the periosteum and matrix of

the bone, creating very strong structural continuity from muscle to bone.

In some cases, the tendon is a broad sheet called an **aponeurosis**⁹ (AP-oh-new-RO-sis). This term originally referred to the tendon located beneath the scalp, but now it also refers to similar tendons associated with certain abdominal, lumbar, hand, and foot muscles. For example, the palmaris longus tendon passes through the wrist and then expands into a fanlike *palmar aponeurosis* beneath the skin of the palm (see fig. 10.29a).

In some places, groups of tendons from separate muscles pass under a band of connective tissue called a **retinaculum**.¹⁰ One of these covers each surface of the wrist like a bracelet, for example. The tendons of several forearm muscles pass under them on their way to the hand.

In a **direct (fleshy) attachment**, there is so little separation between muscle and bone that to the naked eye, the red muscular tissue seems to emerge directly from the bone—for example, along the margins of the *brachialis* and lateral head of the *triceps brachii* in figure 10.3. At a microscopic level, however, the muscle fibers stop slightly short of the bone, and the gap between muscle and bone is spanned by collagen fibers.

Some muscles insert not on bone but on the fascia or tendon of another muscle or on collagen fibers of the dermis of the skin. The distal tendon of the biceps brachii, for example, inserts partly on the fascia of the forearm. Many facial muscles insert in the skin, enabling them to produce facial expressions such as a smile.

Muscle Origins and Insertions

Most skeletal muscles are attached to a different bone at each end, so either the muscle or its tendon spans at least one joint. When the muscle contracts, it moves one bone relative to the other. The bony site of attachment at the relatively stationary end is called its **origin**. The attachment site at its more mobile end is called the **insertion**. For the biceps brachii, for example, the origin is on the scapula and the insertion is on the radius (fig. 10.3). The thicker middle region between the origin and insertion is called the **belly** of the muscle.

The terminology of origins and insertions, however, is imperfect and sometimes misleading. One end of a muscle might function as its stationary origin during one action, but as its moving insertion during a different action. For example, consider the *quadriceps femoris* muscle on the anterior side of the thigh. It is a powerful extensor of the knee, connected at its proximal end mainly to the femur and at its distal end to the tibia, just below the knee. If you kick a soccer ball, the tibia moves more than the femur, so the tibia would be considered the insertion of

⁹apo = upon, above + neuro = nerve

¹⁰retinac = retainer, bracelet + cul = little

the quadriceps and the femur would be considered its origin. But as you sit down in a chair, the tibia remains stationary and the femur moves, with the quadriceps acting as a brake so you don't sit down too abruptly and hard. By the foregoing definitions, the tibia would now be considered the origin of the quadriceps and the femur would be its insertion.

There are many other cases in which the moving and nonmoving ends of the muscle are reversed when different actions are performed. Consider the difference, for example, in the relative movements of the humerus and ulna when flexing the elbow to lift dumbbells as compared with flexing the elbow to perform chin-ups or scale a climbing wall. For such reasons, some anatomists are abandoning origin and insertion terminology and speaking instead of a muscle's proximal and distal or superior and inferior attachments, especially in the limbs. Nevertheless, this book uses the traditional, admittedly imperfect descriptions.

Functional Groups of Muscles

The effect produced by a muscle, whether it is to produce or prevent a movement, is called its **action**. Skeletal muscles seldom act independently; instead, they function in groups whose combined actions produce the coordinated motion of a joint. Muscles can be classified into four categories according to their actions, but it must be stressed that a particular muscle can act in a certain way during one joint action and in a different way during other actions of the same joint. The following examples are illustrated in figure 10.3:

1. The **prime mover (agonist)** is the muscle that produces most of the force during a particular joint action. In flexing the elbow, for example, the prime mover is the *brachialis*.
2. A **synergist**¹¹ (SIN-ur-jist) is a muscle that aids the prime mover. Several synergists acting on a joint can produce more power than a single larger muscle. The biceps brachii, for example, overlies the brachialis and works with it as a synergist to flex the elbow. The actions of a prime mover and its synergist are not necessarily identical and redundant. If the prime mover worked alone at a joint, it might cause rotation or other undesirable movements of a bone. A synergist may stabilize a joint and restrict these movements, or modify the direction of a movement so that the action of the prime mover is more coordinated and specific.
3. An **antagonist**¹² is a muscle that opposes the prime mover. In some cases, it relaxes to give the prime

mover almost complete control over an action.

More often, however, the antagonist maintains some tension on a joint and thus limits the speed or range of the prime mover, preventing excessive movement, joint injury, or inappropriate actions. If you extend your arm to reach out and pick up a cup of tea, for example, your *triceps brachii* serves as the prime mover of elbow extension, and your brachialis acts as an antagonist to slow the extension and stop it at the appropriate point. If you extend your arm rapidly to throw a dart, however, the brachialis must be quite relaxed. The brachialis and triceps represent an **antagonistic pair** of muscles that act on opposite sides of a joint. We need antagonistic pairs at a joint because a muscle can only pull, not push—for example, a single muscle cannot flex *and* extend the elbow. Which member of the pair acts as the prime mover depends on the motion under consideration. In flexion of the elbow, the brachialis is the prime mover and the triceps is the antagonist; when the elbow is extended, their roles are reversed.

4. A **fixator** is a muscle that prevents a bone from moving. To *fix* a bone means to hold it steady, allowing another muscle attached to it to pull on something else. For example, consider again the flexion of the elbow by the biceps brachii. The biceps originates on the scapula, crosses both the shoulder and elbow joints, and inserts on the radius. The scapula is loosely attached to the axial skeleton, so when the biceps contracts, it seems that it would pull the scapula laterally. There are fixator muscles (the *rhomboids*) that attach the scapula to the vertebral column, however. They contract at the same time as the biceps, holding the scapula firmly in place and ensuring that the force generated by the biceps moves the radius rather than the scapula.

Intrinsic and Extrinsic Muscles

In places such as the tongue, larynx, back, hand, and foot, anatomists distinguish between intrinsic and extrinsic muscles. An **intrinsic muscle** is entirely contained within a particular region, having both its origin and insertion there. An **extrinsic muscle** acts upon a designated region but has its origin elsewhere. For example, some movements of the fingers are produced by extrinsic muscles in the forearm, whose long tendons reach to the phalanges; other finger movements are produced by the intrinsic muscles of the hand, located between the metacarpal bones.

Muscle Innervation

The **innervation** of a muscle refers to the identity of the nerve that stimulates it. Knowing the innervation to each

¹¹syn = together + erg = work

¹²ant = against + agonist = actor, competitor

muscle enables clinicians to diagnose nerve, spinal cord, and brainstem injuries from their effects on muscle function, and to set realistic goals for rehabilitation. The innervations described in this chapter will be more meaningful after you have studied the peripheral nervous system (chapters 13 and 14), but a brief orientation will be helpful here. The muscles are innervated by two groups of nerves:

- **Spinal nerves** arise from the spinal cord, emerge through the intervertebral foramina, and innervate muscles below the neck. Spinal nerves are identified by letters and numbers that refer to the adjacent vertebrae—for example, T6 for the sixth thoracic nerve and S2 for the second sacral nerve. Immediately after emerging from an intervertebral foramen, each spinal nerve branches into a *posterior* and *anterior ramus*. You will note references to nerve numbers and rami in many of the muscle tables. The term *plexus* in some of the tables refers to weblike networks of spinal nerves adjacent to the vertebral column. All of the spinal nerves named here are illustrated, and most are also discussed, in chapter 13 (see tables 13.3–13.6).
- **Cranial nerves** arise from the base of the brain, emerge through the skull foramina, and innervate muscles of the head and neck. Cranial nerves are identified by roman numerals (CN I to CN XII) and by names given in chapter 14 (see table 14.1), although not all 12 of them innervate skeletal muscles.

How Muscles Are Named

Figure 10.4 shows an overview of the major superficial muscles. Learning the names of these and other muscles may seem a forbidding task at first, especially when some of them have such long Latin names as *depressor labii inferioris* and *flexor digiti minimi brevis*. Such names, however, typically describe some distinctive aspects of the structure, location, or action of a muscle, and become very helpful once we grow familiar with a few common Latin words. For example, the *depressor labii inferioris* is a muscle that lowers (depresses) the bottom (inferior) lip (labium), and the *flexor digiti minimi brevis* is a short (*brevis*) muscle that flexes the smallest (*minimi*) finger (*digit*). Muscle names are interpreted in footnotes throughout the chapter. Familiarity with these terms and attention to the footnotes will help you translate muscle names and remember the location, appearance, and action of the muscles. You can listen to pronunciations of these muscle names on the CD-ROM or online version of *Anatomy & Physiology| Revealed*.

A Learning Strategy

In the remainder of this chapter, we consider about 160 muscles. The following suggestions may help you develop a rational strategy for learning the muscular system:

- Examine models, cadavers, dissected animals, or a photographic atlas as you read about these muscles. Visual images are often easier to remember than words, and direct observation of a muscle may stick in your memory better than descriptive text or two-dimensional drawings.
- When studying a particular muscle, palpate it on yourself if possible. Contract the muscle to feel it bulge and sense its action. This makes muscle locations and actions less abstract. Atlas B, following this chapter, shows where you can see and palpate several of these muscles on the living body.
- Locate the origins and insertions of muscles on an articulated skeleton. Some study skeletons are painted and labeled to show these. This helps you visualize the locations of muscles and understand how they produce particular joint actions.
- Study the derivation of each muscle name; the name usually describes the muscle's location, appearance, origin, insertion, or action.
- Say the names aloud to yourself or a study partner. It is harder to remember and spell terms you cannot pronounce, and silent pronunciation is not nearly as effective as speaking and hearing the names. Pronunciation guides are provided in the muscle tables for all but the most obvious cases.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. List some functions of the muscular system other than movement of the body.
2. Describe the relationship of endomysium, perimysium, and epimysium to each other. Which of these separates one fascicle from another? Which separates one muscle from another?
3. Distinguish between direct and indirect muscle attachments to bones.
4. Define origin, insertion, belly, action, and innervation.
5. Describe the five basic muscle shapes (*fascicle arrangements*).
6. Distinguish between a synergist, antagonist, and fixator. Explain how each of these may affect the action of a prime mover.

(a) Anterior view

FIGURE 10.4 The Muscular System. In each figure, major superficial muscles are shown on the anatomical right and some of the deeper muscles are shown on the left. Muscles not labeled here are shown in more detail in later figures.

FIGURE 10.4 The Muscular System (continued).

(b) Posterior view

10.2 Muscles of the Head and Neck

Objectives

When you have completed this section, you should be able to

- name and locate the muscles that produce facial expressions;
- name and locate the muscles used for chewing and swallowing;
- name and locate the neck muscles that move the head; and
- identify the origin, insertion, action, and innervation of any of these muscles.

Figure 10.5 shows some of the muscles of the head and neck. We will treat the muscles of this region from a regional and functional perspective, thus placing them in the following groups: muscles of facial expression, muscles of chewing and swallowing, and muscles that move the head as a whole (tables 10.1–10.3).

In these tables and throughout the rest of the chapter, each muscle entry provides the following information:

- the name of the muscle;
- the pronunciation of the name, unless it is self-evident or uses words whose pronunciations have been provided in a recent entry;
- the actions of the muscle;
- the muscle's origin, indicated by the letter O;
- the muscle's insertion, indicated by the letter I; and
- the muscle's innervation, indicated by the letter N.

FIGURE 10.5 Some Facial Muscles of the Cadaver. Boldface labels indicate muscles employed in facial expression.

TABLE 10.1 Muscles of Facial Expression

Humans have much more expressive faces than other mammals because of a complex array of muscles that insert in the dermis and subcutaneous tissues. These muscles tense the skin and produce such expressions as a pleasant smile, a threatening scowl, a puzzled frown, or a flirtatious wink (fig. 10.6). They add subtle shades of meaning to our spoken words. Facial muscles also contribute directly to speech, chewing, and other oral functions. All but one of these muscles are innervated by the facial nerve (cranial nerve VII). This nerve is especially vulnerable to injury from lacerations and skull fractures, which can paralyze the muscles and cause parts of the face to sag. The only muscle in this table not innervated by the facial nerve is the levator palpebrae superioris, innervated by the oculomotor nerve (CN III).

FIGURE 10.6 Expressions Produced by Several of the Facial Muscles. The ordinary actions of these muscles are usually more subtle than these demonstrations.

Name an antagonist of each of these muscles: the depressor anguli oris, orbicularis oculi, and levator labii superioris.

TABLE 10.1 Muscles of Facial Expression (*cont.*)

<p>The Scalp. The <i>occipitofrontalis</i> overlies the dome of the cranium. It is divided into the <i>frontalis</i> of the forehead and <i>occipitalis</i> at the rear of the head, named for the frontal and occipital bones underlying them. They are connected to each other by a broad aponeurosis, the galea aponeurotica¹³ (GAY-lee-uh APO-oh-new-ROT-ih-cuh) (fig. 10.7).</p>		
<p>Frontalis (frun-TAY-lis) Elevates eyebrows in glancing upward and expressions of surprise or fright; draws scalp forward and wrinkles skin of forehead</p> <p>O: Galea aponeurotica I: Subcutaneous tissue of eyebrows N: Facial n.</p>		
<p>Occipitalis (oc-SIP-ih-TAY-lis) Retracts scalp; fixes galea aponeurotica so frontalis can act on eyebrows</p> <p>O: Superior nuchal line and temporal bone I: Galea aponeurotica N: Facial n.</p>		
<p>The Orbital and Nasal Regions. The <i>orbicularis oculi</i> is a sphincter of the eyelid that encircles and closes the eye. The <i>levator palpebrae superioris</i> lies deep to the orbicularis oculi, in the eyelid and orbital cavity (see fig. 16.23, p. 615), and opens the eye. Other muscles in this group move the eyelids and skin of the forehead and dilate the nostrils. Muscles within the orbit that move the eyeball itself are discussed in chapter 16.</p>		
<p>Orbicularis Oculi¹⁴ (or-BIC-you-LERR-is OC-you-lye) Sphincter of the eyelids; closes eye in blinking, squinting, and sleep; aids in flow of tears across eye</p> <p>O: Lacrimal bone, adjacent regions of frontal bone and maxilla, medial angle of eyelids I: Upper and lower eyelids, skin around margin of orbit N: Facial n.</p>		
<p>Levator Palpebrae Superioris¹⁵ (leh-VAY-tur pal-PEE-bree soo-PEER-ee-OR-is) Elevates upper eyelid, opens eye</p> <p>O: Lesser wing of sphenoid in posterior wall of orbit I: Upper eyelid N: Oculomotor n.</p>		
<p>Corrugator Supercilii¹⁶ (COR-oo-GAY-tur SOO-per-SIL-ee-eye) Draws eyebrows medially and downward in frowning and concentration; reduces glare of bright sunlight</p> <p>O: Medial end of supraorbital margin I: Skin of eyebrow N: Facial n.</p>		
<p>Nasalis¹⁷ (nay-ZAIL-is) Widens nostrils; narrows internal air passage between vestibule and nasal cavity</p> <p>O: Maxilla just lateral to nose I: Bridge and alar cartilages of nose N: Facial n.</p>		
<p>The Oral Region. The mouth is the most expressive part of the face, and lip movements are necessary for intelligible speech; thus, it is not surprising that the muscles here are especially diverse. The <i>orbicularis oris</i> is a complex of muscles in the lips that encircle the mouth; until recently it was misinterpreted as a sphincter, or circular muscle, but it is actually composed of four independent quadrants that interlace and give only an appearance of circularity. Other muscles in this region approach the lips from all directions and thus draw the lips or angles (corners) of the mouth upward, laterally, and downward. Some of these have origins or insertions in a complex cord called the modiolus¹⁸ just lateral to each angle of the lips (see fig. 10.7). Named for the hub of a cartwheel, the modiolus is a point of convergence of several muscles of the lower face. You can palpate it by inserting one finger just inside the corner of your lips and pinching the corner between the finger and thumb, feeling for a thick knot of tissue.</p>		
<p>Orbicularis Oris¹⁹ (or-BIC-you-LERR-is OR-is) Encircles mouth, closes lips, protrudes lips as in kissing; uniquely developed in humans for speech</p> <p>O: Modiolus of mouth I: Submucosa and dermis of lips N: Facial n.</p>		
<p>Levator Labii Superioris²⁰ (leh-VAY-tur LAY-bee-eye soo-PEER-ee-OR-is) Elevates and everts upper lip in sad, sneering, or serious expressions</p> <p>O: Zygomatic bone and maxilla near inferior margin of orbit I: Muscles of upper lip N: Facial n.</p>		
<p>Levator Anguli Oris²¹ (leh-VAY-tur ANG-you-lye OR-is) Elevates angle of mouth as in smiling</p> <p>O: Maxilla just below infraorbital foramen I: Muscles at angle of mouth N: Facial n.</p>		
<p>Zygomaticus Major (ZY-go-MAT-ih-cus) Draws angle of mouth upward and laterally in laughing</p> <p>O: Zygomatic bone I: Superolateral angle of mouth N: Facial n.</p>		
<p>Zygomaticus Minor Elevates upper lip, exposes upper teeth in smiling or sneering</p> <p>O: Zygomatic bone I: Muscles of upper lip N: Facial n.</p>

TABLE 10.1 Muscles of Facial Expression (*cont.*)

FIGURE 10.7 Muscles of Facial Expression. Boldface labels indicate muscles employed in facial expression.

TABLE 10.1 Muscles of Facial Expression (*cont.*)

Risorius ²³ (rih-SOR-ee-us) Draws angle of mouth laterally in expressions of laughing, horror, or disdain	O: Zygomatic arch, fascia near ear	I: Modiolus of mouth	N: Facial n.
Depressor Anguli Oris ²⁴ Draws angle of mouth laterally and downward in opening mouth or sad expressions	O: Inferior margin of mandibular body	I: Modiolus of mouth	N: Facial n.
Depressor Labii Inferioris ²⁵ Draws lower lip downward and laterally in chewing and expressions of melancholy or doubt	O: Mandible near mental protuberance	I: Skin and mucosa of lower lip	N: Facial n.
The Mental and Buccal Regions. Adjacent to the oral orifice are the mental region (chin) and buccal region (cheek). In addition to muscles already discussed that act directly on the lower lip, the mental region has a pair of small <i>mentalis muscles</i> extending from the upper margin of the mandible to the skin of the chin. In some people, these muscles are especially thick and have a visible dimple between them called the <i>mental cleft</i> (see fig. 4.18, p. 144). The <i>buccinator</i> is the muscle in the cheek. It has multiple functions in chewing, sucking, and blowing. If the cheek is inflated with air, compression of the buccinator blows it out. Sucking is achieved by contracting the buccinators to draw the cheeks inward, and then relaxing them. This action is especially important to nursing infants. To feel this action, hold your fingertips lightly on your cheeks as you make a kissing noise. You will notice the relaxation of the buccinators at the moment air is sharply drawn in through the pursed lips.			
Mentalis (men-TAY-lis) Elevates and protrudes lower lip in drinking, pouting, and expressions of doubt or disdain; elevates and wrinkles skin of chin	O: Mandible near inferior incisors	I: Skin of chin at mental protuberance	N: Facial n.
Buccinator ²⁶ (BUC-sin-AY-tur) Compresses cheek against teeth and gums; directs food between molars; retracts cheek from teeth when mouth is closing to prevent biting cheek; expels air and liquid	O: Alveolar processes on lateral surfaces of maxilla and mandible	I: Orbicularis oris; submucosa of cheek and lips	N: Facial n.
The Cervical and Mental Region. The <i>platysma</i> is a thin superficial muscle of the upper chest and lower face. It is relatively unimportant, but when men shave they tend to tense the platysma to make the concavity between the jaw and neck shallower and the skin tauter.			
Platysma ²⁷ (plah-TIZ-muh) Draws lower lip and angle of mouth downward in expressions of horror or surprise; may aid in opening mouth widely	O: Fascia of deltoid and pectoralis major	I: Mandible; skin and subcutaneous tissue of lower face	N: Facial n.

²³*risor* = laughter²⁴*depress* = to lower + *angul* = angle, corner + *or* = mouth²⁵*labi* = lip + *inferior* = lower²⁶*buccinator* = trumpeter²⁷*platy* = flat

TABLE 10.2 Muscles of Chewing and Swallowing

The following muscles contribute to facial expression and speech but are primarily concerned with the manipulation of food, including tongue movements, chewing, and swallowing.

Extrinsic Muscles of the Tongue. The tongue is a very agile organ. It pushes food between the molars for chewing (mastication) and later forces the food into the pharynx for swallowing (deglutition); it is also, of course, of crucial importance to speech. Both intrinsic and extrinsic muscles are responsible for its complex movements. The intrinsic muscles consist of a variable number of vertical fascicles that extend from the superior to the inferior sides of the tongue, transverse fascicles that extend from right to left, and longitudinal fascicles that extend from root to tip (see figs. 10.1c and 25.5b, p. 971). The extrinsic muscles listed here connect the tongue to other structures in the head (fig. 10.8). Three of these are innervated by the hypoglossal nerve (CN XII), whereas the fourth is innervated by both the vagus (CN X) and accessory (CN XI) nerves.

FIGURE 10.8 Muscles of the Tongue and Pharynx.

Genioglossus²⁸ (JEE-nee-oh-GLOSS-us) Unilateral action draws tongue to one side; bilateral action depresses midline of tongue or protrudes tongue

O: Superior mental spine on posterior surface of mental protuberance

I: Inferior surface of tongue from root to apex

N: Hypoglossal n.

Hyoglossus²⁹ (HI-oh-GLOSS-us) Depresses tongue

O: Body and greater horn of hyoid bone

I: Lateral and inferior surfaces of tongue

N: Hypoglossal n.

Styloglossus³⁰ (STY-lo-GLOSS-us) Draws tongue upward and posteriorly

O: Styloid process of temporal bone and ligament from styloid process to mandible

I: Superolateral surface of tongue

N: Hypoglossal n.

Palatoglossus³¹ (PAL-a-toe-GLOSS-us) Elevates root of tongue and closes oral cavity off from pharynx; forms palatoglossal arch at rear of oral cavity

O: Soft palate

I: Lateral surface of tongue

N: Accessory and vagus nn.

²⁸genio = chin + gloss = tongue

²⁹hyo = hyoid bone + gloss = tongue

³⁰stylo = styloid process + gloss = tongue

³¹palato = palate + gloss = tongue

TABLE 10.2 Muscles of Chewing and Swallowing (*cont.*)

Muscles of Chewing. Four pairs of muscles produce the biting and chewing movements of the mandible: the *temporalis*, *masseter*, and two pairs of *pterygoid muscles* (fig. 10.9). Their actions include *depression* to open the mouth for receiving food; *elevation* for biting off a piece of food or crushing it between the teeth; *protraction* so that the incisors meet in cutting off a piece of food; *retraction* to draw the lower incisors behind the upper incisors and make the rear teeth meet; and *lateral* and *medial excursion*, the side-to-side movements that grind food between the rear teeth. The last four of these movements are shown in figure 9.20 (p. 303). All of these muscles are innervated by the mandibular nerve, which is a branch of the trigeminal (CN V).

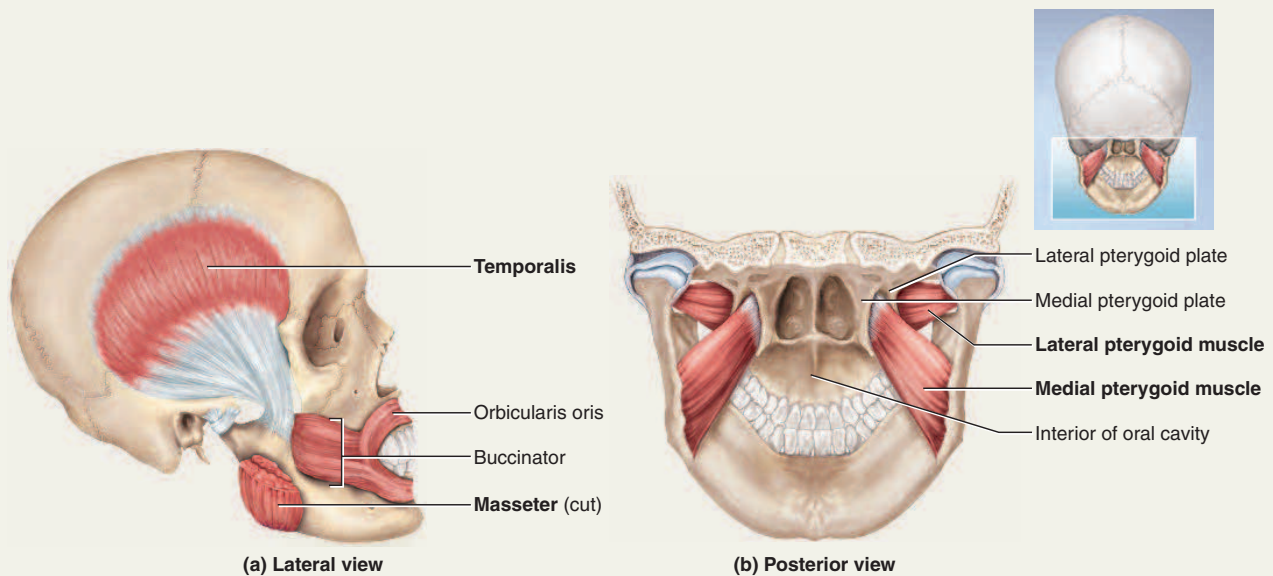

FIGURE 10.9 Muscles of Chewing. Boldface labels indicate muscles that act on the mandible in its chewing movements. (a) Right lateral view. In order to expose the insertion of the temporalis muscle on the mandible, part of the zygomatic arch and masseter muscle are removed. (b) View of the pterygoid muscles looking into the oral cavity from behind the skull.

Temporalis³² (**TEM-po-RAY-liss**) Elevation, retraction, and lateral and medial excursion of the mandible

O: Temporal lines and temporal fossa of cranium

I: Coronoid process and anterior border of mandibular ramus

N: Mandibular n.

Masseter³³ (**ma-SEE-tur**) Elevation of the mandible, with smaller roles in protraction, retraction, and lateral and medial excursion

O: Zygomatic arch

I: Lateral surface of mandibular ramus and angle

N: Mandibular n.

Medial Pterygoid³⁴ (**TERR-ih-goyd**) Elevation, protraction, and lateral and medial excursion of the mandible

O: Medial surface of lateral pterygoid plate, palatine bone, lateral surface of maxilla near molar teeth

I: Medial surface of mandibular ramus and angle

N: Mandibular n.

Lateral Pterygoid Depression (in wide opening of the mouth), protraction, and lateral and medial excursion of the mandible

O: Lateral surfaces of lateral pterygoid plate and greater wing of sphenoid

I: Neck of mandible (just below condyle); articular disc and capsule of temporomandibular joint

N: Mandibular n.

Hyoid Muscles—Suprahyoid Group. Several aspects of chewing, swallowing, and vocalizing are aided by eight pairs of *hyoid muscles* associated with the hyoid bone (fig. 10.10). The *suprahyoid group* is composed of the four pairs superior to the hyoid—the *digastric*, *geniohyoid*, *mylohyoid*, and *stylohyoid*. The digastric is an unusual muscle, named for its two bellies. Its *posterior belly* arises from the mastoid notch of the cranium and slopes downward and forward. The *anterior belly* arises from a trench called the *digastric fossa* on the inner surface of the mandibular body. It slopes downward and backward. The two bellies meet at a constriction, the *intermediate tendon*. This tendon passes through a connective tissue loop, the *fascial sling*, attached to the hyoid bone. Thus, when the two bellies of the digastric contract, they pull upward on the hyoid; but if the hyoid is fixed from below, the digastric aids in wide opening of the mouth. The lateral pterygoids are more important in wide mouth opening, with

³²*temporalis* = of the temporal region of the head

³³*masset* = chew

³⁴*pteryg* = wing + *oid* = resembling; pterygoid plate of sphenoid

TABLE 10.2 Muscles of Chewing and Swallowing (*cont.*)

the digastrics coming into play only in extreme opening, as in yawning or taking a large bite of an apple. Cranial nerves V (trigeminal), VII (facial), and XII (hypoglossal) innervate these muscles; the trigeminal nerve gives rise to the mylohyoid nerve of the digastric and mylohyoid muscles.

Digastric³⁵ Depresses mandible when hyoid is fixed; opens mouth widely, as when ingesting food or yawning; elevates hyoid when mandible is fixed

O: Mastoid notch of temporal bone, digastric fossa of mandible

I: Hyoid bone via fascial sling

N: Posterior belly: facial n.
Anterior belly: mylohyoid n.

Geniohyoid³⁶ (**JEE-nee-oh-HY-oyd**) Depresses mandible when hyoid is fixed; elevates and protracts hyoid when mandible is fixed

O: Inferior mental spine of mandible

I: Hyoid bone

N: Spinal nerve C1 via hypoglossal n.

Mylohyoid³⁷ Spans mandible from side to side and forms floor of mouth; elevates floor of mouth in initial stage of swallowing

O: Mylohyoid line near inferior margin of mandible

I: Hyoid bone

N: Mylohyoid n.

Stylohyoid Elevates and retracts hyoid, elongating floor of mouth; roles in speech, chewing, and swallowing are not yet clearly understood

O: Styloid process of temporal bone

I: Hyoid bone

N: Facial n.

Hyoid Muscles—Infrahyoid Group. The infrahyoid muscles are inferior to the hyoid bone. By fixing the hyoid from below, they enable the suprahyoid muscles to open the mouth. The *omohyoid* is unusual in that it arises from the shoulder, passes under the sternocleidomastoid, and then ascends to the hyoid bone. Like the digastric, it has two bellies. The *thyrohyoid*, named for the hyoid bone and the large shield-shaped *thyroid cartilage* of the larynx, helps prevent choking. It elevates the larynx during swallowing so that its superior opening is sealed by a flap of tissue, the *epiglottis*. You can feel this effect by placing your finger on the “Adam’s apple” (the anterior prominence of the thyroid cartilage) and feeling it bob up as you swallow. The *sternothyroid* muscle then pulls the larynx down again so you can resume breathing; it is the only infrahyoid muscle with no connection to the hyoid bone. The sternohyoid lowers the hyoid bone after it has been elevated.

The infrahyoid muscles that act on the larynx are regarded as its *extrinsic muscles*. The *intrinsic muscles*, considered in chapter 22, are concerned with control of the vocal cords and laryngeal opening. The *ansa cervicalis*,³⁸ which innervates three of these muscles, is a loop of nerve on the side of the neck formed by certain fibers from cervical nerves 1 to 3. Cranial nerves IX (glossopharyngeal), X (vagus), and XII (hypoglossal) also innervate these muscles.

Omohyoid³⁹ Depresses hyoid after it has been elevated

O: Superior border of scapula

I: Hyoid bone

N: Ansa cervicalis

Sternohyoid⁴⁰ Depresses hyoid after it has been elevated

O: Manubrium of sternum, medial end of clavicle

I: Hyoid bone

N: Ansa cervicalis

Thyrohyoid⁴¹ Depresses hyoid; with hyoid fixed, elevates larynx as in singing high notes

O: Thyroid cartilage of larynx

I: Hyoid bone

N: Spinal nerve C1 via hypoglossal n.

Sternothyroid Depresses larynx after it has been elevated in swallowing and vocalization; aids in singing low notes

O: Manubrium of sternum, costal cartilage 1

I: Thyroid cartilage of larynx

N: Ansa cervicalis

Muscles of the Pharynx. The three pairs of *pharyngeal constrictors* encircle the pharynx on its posterior and lateral sides, forming a muscular funnel (see fig. 10.8).

Pharyngeal Constrictors (Three Muscles) During swallowing, contract in order from *superior* to *middle* to *inferior constrictor* to drive food into esophagus

O: Medial pterygoid plate, mandible, hyoid, stylohyoid ligament, cricoid and thyroid cartilages of larynx

I: Median pharyngeal raphe (seam on posterior side of pharynx); basilar part of occipital bone

N: Glossopharyngeal and vagus nn.

TABLE 10.2 Muscles of Chewing and Swallowing (*cont.*)**FIGURE 10.10** Muscles of the Neck. Boldface labels indicate muscles of the suprahyoid and infrahyoid groups. Another muscle of the suprahyoid group, the geniohyoid, lies deep to the mylohyoid and can be seen in figure 10.8.

TABLE 10.3 Muscles Acting on the Head

Muscles that move the head originate on the vertebral column, thoracic cage, and pectoral girdle and insert on the cranial bones. Their actions include flexion (tipping the head forward), extension (holding the head erect), hyperextension (as in looking upward), lateral flexion (tilting the head to one side), and rotation (turning the head to look left or right). Flexion, extension, and hyperextension involve simultaneous action of the right and left muscles of a pair; the other actions require the muscle on one side to contract more strongly than its mate. Many head actions result from a combination of these movements—for example, looking up over the shoulder involves a combination of rotation and hyperextension.

Depending on the relations of the muscle origins and insertions, a muscle may cause a **contralateral** movement of the head (toward the opposite side, as when contraction of a muscle on the left turns the face toward the right) or an **ipsilateral** movement (toward the same side as the muscle, as when contraction of a muscle on the left tilts the head to the left).

Flexors of the Neck. The prime mover of neck flexion is the *sternocleidomastoid*, a thick muscular cord that extends from the upper chest (sternum and clavicle) to the mastoid process behind the ear (see fig. 10.10). This is most easily seen when the head is rotated to one side and slightly extended. To visualize the action of a single sternocleidomastoid, place the index finger of your left hand on your left mastoid process and the index finger of your right hand on your suprasternal notch. Now contract your left sternocleidomastoid to bring your two fingertips as close together as possible. You will see that this tilts your face upward and to the right.

As the sternocleidomastoid passes obliquely across the neck, it divides it into *anterior* and *posterior triangles* (fig. 10.11). Other muscles and landmarks subdivide each of these into smaller triangles of surgical importance.

The three *scalenes*,⁴² located on the side of the neck, are named for being arranged somewhat like a staircase. Their actions are similar so they are considered collectively.

Sternocleidomastoid⁴³ (**STIR-no-CLY-do-MAST-oyd**) Unilateral action tilts head slightly upward and toward the opposite side, as in looking over one's contralateral shoulder. The most common action is probably rotating the head to the left or right. Bilateral action draws the head straight forward and down, as when eating or reading. Aids in deep breathing when head is fixed.

O: Manubrium of sternum, medial one-third of clavicle

I: Mastoid process and lateral half of superior nuchal line

N: Accessory n., spinal nerves C2–C3

Scalenes (SCAY-leens) (Anterior, Middle, and Posterior) Unilateral contraction causes ipsilateral flexion or contralateral rotation (tilts head toward same shoulder, or rotates face away), depending on action of other muscles. Bilateral contraction flexes neck. If spine is fixed, scalenes elevate ribs 1–2 and aid in breathing.

O: Transverse processes of all cervical vertebrae (C1–C7)

I: Ribs 1–2

N: Anterior rami of C3–C8

Extensors of the Neck. The extensors are located mainly in the nuchal region (back of the neck; fig. 10.12) and therefore tend to hold the head erect or draw it back. The *trapezius* is the most superficial of these. It extends from the nuchal region over the shoulders and halfway down the back. It is named for the fact that the right and left trapezii together form a diamond or trapezoidal shape (see fig. 10.4b). The *splenius* is a deeper, elongated muscle with *splenius capitis* and *splenius cervicis* regions in the head and neck, respectively. It is nicknamed the “bandage muscle” because of the way it wraps around still deeper neck muscles. One of those deeper muscles is the semispinalis, another elongated muscle with head, neck, and thoracic regions. Only the *semispinalis capitis* and *cervicis* are tabulated here; the semispinalis thoracis does not act on the neck, but is included in table 10.6.

Trapezius⁴⁴ (**tra-PEE-zee-us**) Extends and laterally flexes neck. See also roles in scapular movement in table 10.8

O: External occipital protuberance, medial one-third of superior nuchal line, nuchal ligament, spinous processes of vertebrae C7–T3 or T4

I: Acromion and spine of scapula, lateral one-third of clavicle

O: Articular processes of vertebrae C4–C7, transverse processes of T1–T6

I: Occipital bone between nuchal lines, spinous processes of vertebrae C2–C5

N: Posterior rami of cervical and thoracic nn.

**FIGURE 10.12** Muscles of the Shoulder and Nuchal Regions.**Think About It**

Of the muscles you have studied so far, name three that you would consider intrinsic muscles of the head and three that you would classify as extrinsic. Explain your reason for each.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. Name two muscles that elevate the upper lip and two that depress the lower lip.
8. Name the four paired muscles of mastication and state where they insert on the mandible.
9. Distinguish between the functions of the suprahyoid and infrahyoid muscles.
10. List the muscles of neck extension and flexion.

⁴⁵splenius = bandage + capitis = of the hand

⁴⁶cervicis = of the neck

10.3 Muscles of the Trunk

Objectives

When you have completed this section, you should be able to

- name and locate the muscles of respiration and explain how they affect airflow and abdominal pressure;
- name and locate the muscles of the abdominal wall, back, and pelvic floor; and
- identify the origin, insertion, action, and innervation of any of these muscles.

In this section, we will examine muscles of the trunk of the body in three functional groups concerned with respiration, support of the abdominal wall and pelvic floor, and movement of the vertebral column (tables 10.4–10.7). In the illustrations, you will note some major muscles that are not discussed in the associated tables—for example, the pectoralis major and serratus anterior. Although they are *located* in the trunk, they *act upon* the limbs and limb girdles, and are further discussed in tables 10.8 and 10.9.

TABLE 10.4 Muscles of Respiration

We breathe primarily by means of muscles that enclose the thoracic cavity—the diaphragm, external intercostal, internal intercostal, and innermost intercostal muscles (fig. 10.13).

The *diaphragm* is a muscular dome between the thoracic and abdominal cavities, bulging upward against the base of the lungs. It has openings for passage of the esophagus, major blood and lymphatic vessels, and nerves between the two cavities. Its fibers converge from the margins toward a fibrous **central tendon**. When the diaphragm contracts, it flattens slightly and enlarges the thoracic cavity, causing air intake (*inspiration*); when it relaxes, it rises and shrinks the thoracic cavity, expelling air (*expiration*).

Three layers of muscle lie between the ribs: the external, internal, and innermost intercostal muscles. The 11 pairs of *external intercostal muscles* constitute the most superficial layer. They extend from the rib tubercle posteriorly almost to the beginning of the costal cartilage anteriorly. Each one slopes downward and anteriorly from one rib to the next inferior one. The 11 pairs of *internal intercostal muscles* lie deep to the external intercostals and extend from the margin of the sternum to the angles of the ribs. They are thickest in the region between the costal cartilages and grow thinner in the region where they overlap the internal intercostals. Their fibers slope downward and posteriorly from each rib to the one below, at nearly right angles to the external intercostals. Each is divided into an *intercartilaginous part* between the costal cartilages and an *interosseous part* between the bony part of the ribs. The two parts differ in their respiratory roles. The *innermost intercostal muscles* vary in number, as they are sometimes absent from the upper thoracic cage. Their fibers run in the same direction as the internal intercostals, and they are presumed to serve the same function. The internal and innermost intercostals are separated by a fascia that allows passage for intercostal nerves and blood vessels (see fig. 13.13b, p. 496).

Many other muscles of the chest and abdomen contribute significantly to breathing: the sternocleidomastoid and scalenes of the neck; pectoralis major and serratus anterior of the chest; latissimus dorsi of the lower back; internal and external abdominal obliques and transverse abdominal muscle; and even some of the anal muscles. The respiratory actions of all these muscles are described in chapter 22.

Diaphragm⁴⁷ (**DY-ah-fragm**) Prime mover of inspiration (responsible for about two-thirds of air intake); contracts in preparation for sneezing, coughing, crying, laughing, and weight lifting; contraction compresses abdominal viscera and aids in childbirth and expulsion of urine and feces.

O: Xiphoid process of sternum; ribs and costal cartilages 7–12; lumbar vertebrae

I: Central tendon of diaphragm

N: Phrenic nn.

External Intercostals⁴⁸ (**IN-tur-COSS-tulz**) When scalenes fix rib 1, external intercostals elevate and protract ribs 2–12, expanding the thoracic cavity and creating a partial vacuum causing inflow of air; exercise a braking action during expiration so that expiration is not overly abrupt

O: Inferior margins of ribs 1–11

I: Superior margin of next lower rib

N: Intercostal nn.

Internal Intercostals In inspiration, the intercartilaginous part aids in elevating the ribs and expanding the thoracic cavity; in expiration, the interosseous part depresses and retracts the ribs, compressing the thoracic cavity and expelling air; the latter occurs only in forceful expiration, not in relaxed breathing

O: Superior margins and costal cartilages of ribs 2–12; margin of sternum

I: Inferior margin of next higher rib

N: Intercostal nn.

Innermost Intercostals Presumed to have the same action as the internal intercostals

O: Superomedial surface of ribs 2–12; may be absent from upper ribs

I: Medial edge of costal groove of next higher rib

N: Intercostal nn.

⁴⁷*dia* = across + *phragm* = partition

⁴⁸*inter* = between + *costa* = rib

TABLE 10.4 Muscles of Respiration (cont.)

**Think About It**

What muscles are eaten as “spare ribs”? What is the tough fibrous membrane between the meat and the bone?

TABLE 10.5 Muscles of the Anterior Abdominal Wall

Unlike the thoracic cavity, the abdominal cavity has little skeletal support. It is enclosed, however, in layers of broad flat muscles whose fibers run in different directions, strengthening the abdominal wall on the same principle as the alternating layers of plywood. Three layers of muscle enclose the lumbar region and extend about halfway across the anterior abdomen (fig. 10.14). The most superficial layer is the *external abdominal oblique*. Its fibers pass downward and anteriorly. The next deeper layer is the *internal abdominal oblique*, whose fibers pass upward and anteriorly, roughly perpendicular to those of the external oblique. The deepest layer is the *transverse abdominal* (*transversus abdominis*), with horizontal fibers. Anteriorly, a pair of vertical *rectus abdominis* muscles extend from sternum to pubis. These are divided into segments by three transverse **tendinous intersections**, giving them an appearance that body builders nickname the “six pack.”

The tendons of the oblique and transverse muscles are *aponeuroses*—broad fibrous sheets that continue medially and inferiorly (figs. 10.15 and 10.16). At the rectus abdominis, they diverge and pass around its anterior and posterior sides, enclosing the muscle in a vertical sleeve called the **rectus sheath**. They meet again at a median line called the **linea alba** between the rectus muscles. Another line, the **linea semilunaris**, marks the lateral boundary where the rectus sheath meets the aponeurosis. The aponeurosis of the external oblique also forms a cordlike **inguinal ligament** at its inferior margin. This extends obliquely from the anterior superior spine of the ilium to the pubis. The linea alba, linea semilunaris, and inguinal ligament are externally visible on a person with good muscle definition (see fig. B.2, p. 390).

FIGURE 10.14 Cross Section of the Anterior Abdominal Wall.

External Abdominal Oblique Supports abdominal viscera against pull of gravity; stabilizes vertebral column during heavy lifting; maintains posture; compresses abdominal organs, thus aiding in forceful expiration of contents during childbirth, urination, defecation, and vomiting; unilateral contraction causes contralateral rotation of waist

O: Ribs 5–12

I: Anterior half of iliac crest, pubic symphysis, and superior margin of pubis

N: Anterior rami of spinal nerves T7–T12

Internal Abdominal Oblique Same as external oblique except that unilateral contraction causes ipsilateral rotation of waist

O: Inguinal ligament, iliac crest, and thoracolumbar fascia

I: Ribs 10–12, costal cartilages 7–10, pubis

N: Anterior rami of spinal nerves T7–L1

Transverse Abdominal Compresses abdominal contents, with same effects as external oblique, but does not contribute to movements of vertebral column

O: Inguinal ligament, iliac crest, thoracolumbar fascia, costal cartilages 7–12

I: Linea alba, pubis, aponeurosis of internal oblique

N: Anterior rami of spinal nerves T7–L1

Rectus⁴⁹ Abdominis (REC-tus ab-DOM-ih-nis) Flexes lumbar region of vertebral column, producing forward bending at the waist

O: Pubic symphysis and superior margin of pubis

I: Xiphoid process, costal cartilages 5–7

N: Anterior rami of spinal nerves T6–T12

⁴⁹rectus = straight

TABLE 10.5

Muscles of the Anterior Abdominal Wall (*cont.*)

FIGURE 10.15 Thoracic and Abdominal Muscles. (a) Superficial muscles. The left rectus sheath is cut away to expose the rectus abdominis muscle. (b) Deep muscles. On the anatomical right, the external oblique has been removed to expose the internal oblique and the pectoralis major has been removed to expose the pectoralis minor. On the anatomical left, the internal oblique has been cut to expose the transverse abdominal, and the middle of the rectus abdominis has been cut out to expose the posterior rectus sheath.

• Name at least three muscles that lie deep to the pectoralis major.

TABLE 10.5

Muscles of the Anterior Abdominal Wall (cont.)

TABLE 10.6 Muscles of the Back

Muscles of the back primarily extend, rotate, and laterally flex the vertebral column. The most prominent superficial back muscles are the latissimus dorsi and trapezius (fig. 10.17), but they are concerned with upper limb movements and covered in tables 10.8 and 10.9. Deep to these are the *serratus posterior superior* and *inferior* (fig. 10.18). They extend from the vertebrae to the ribs. Their function and significance remain unknown, so we will not consider them further.

Deep to these is a prominent muscle, the **erector spinae**, which runs vertically for the entire length of the back from the cranium to the sacrum. It is a thick muscle, easily palpated on each side of the vertebral column in the lumbar region. (Pork chops and T-bone steaks are erector spinae muscles.) As it ascends, it divides in the upper lumbar region into three parallel columns (figs. 10.18 and 10.19). The most lateral of these is the **iliocostalis**, which from inferior to superior is divided into the *iliocostalis lumborum*, *iliocostalis thoracis*, and *iliocostalis cervicis* (lumbar, thoracic, and cervical regions). The next medial column is the **longissimus**, divided from inferior to superior into the *longissimus thoracis*, *longissimus cervicis*, and *longissimus capitis* (thoracic, cervical, and cephalic regions). The most medial column is the **spinalis**, divided into *spinalis thoracis*, *spinalis cervicis*, and *spinalis capitis*. The functions of all three columns are sufficiently similar that we will treat them collectively as the erector spinae.

FIGURE 10.17 Neck, Back, and Gluteal Muscles. The most superficial muscles are shown on the left and the next deeper layer on the right.

TABLE 10.6 Muscles of the Back (*cont.*)

The major deep muscles are the *semispinalis thoracis* in the thoracic region and *quadratus lumborum* in the lumbar region. The erector spinae and quadratus lumborum are enclosed in a fibrous sheath called the **thoracolumbar fascia**, which is the origin of some of the abdominal and lumbar muscles. The **multifidus** is a collective name for a series of tiny muscles that connect adjacent vertebrae to each other from the cervical to lumbar region.

Erector Spinae (eh-REC-tur SPY-nee) Extension and lateral flexion of vertebral column; the longissimus capitis also produces ipsilateral rotation of the head.

O: Nuchal ligament, ribs 3-12, thoracic and lumbar vertebrae, median and lateral sacral crests, thoracolumbar fascia

I: Mastoid process, cervical and thoracic vertebrae, and all ribs

N: Posterior rami of cervical to lumbar spinal nerves

Semispinalis Thoracis (SEM-ee-spy-NAY-liss tho-RA-sis) Extension and contralateral rotation of vertebral column

O: Vertebrae T6-T10

I: Vertebrae C6-T4

N: Posterior rami of cervical and thoracic spinal nerves

FIGURE 10.18 Muscles Acting on the Vertebral Column. These are deeper than the muscles in figure 10.17, and those on the right are deeper than those on the left.

TABLE 10.6

Muscles of the Back (*cont.*)

Quadratus Lumborum⁵⁰ (**quad-RAY-tus lum-BORE-um**) Aids respiration by fixing rib 12 and stabilizing inferior attachments of diaphragm. Unilateral contraction causes ipsilateral flexion of lumbar vertebral column; bilateral contraction extends lumbar vertebral column.

O: Iliac crest, iliolumbar ligament

I: Rib 12 and vertebrae L1-L4

N: Anterior rami of spinal nerves T12-L4

Multifidus⁵¹ (**mul-TIFF-ih-dus**) Stabilization of adjacent vertebrae, maintenance of posture, control of vertebral movement when erector spinae acts on vertebral column

O: Vertebrae C4-L5, posterior superior iliac spine, sacrum, aponeurosis of erector spinae

I: Laminae and spinous processes of vertebrae superior to origins

N: Posterior rami of cervical to lumbar spinal nerves

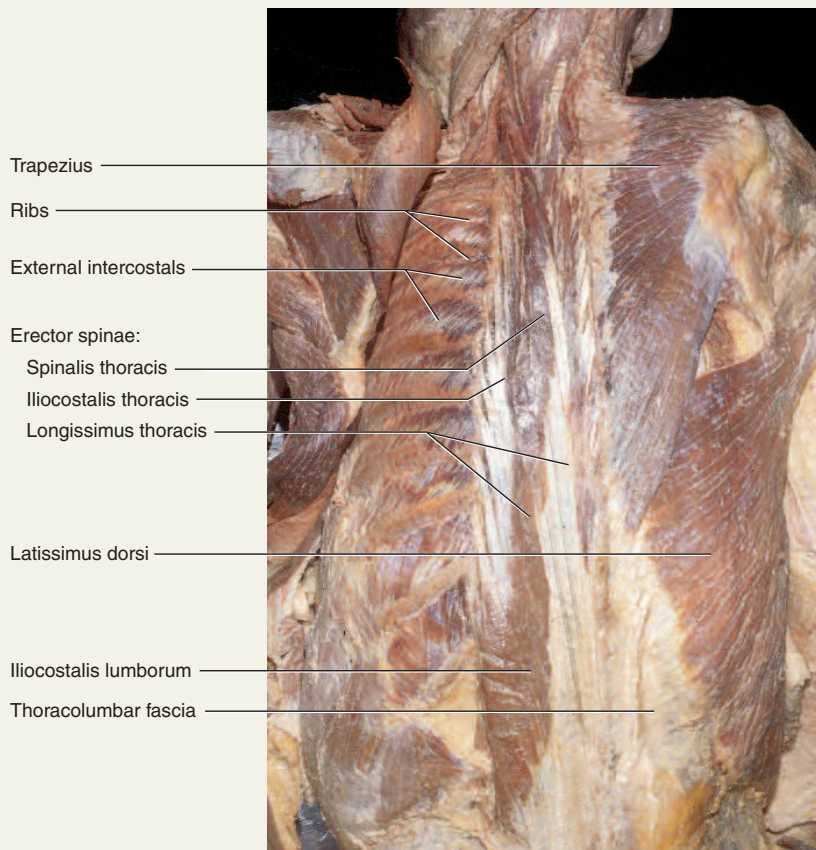

FIGURE 10.19 Deep Back Muscles of the Cadaver.

INSIGHT 10.1 Clinical Application

Heavy Lifting and Back Injuries

When you are fully bent over forward, as in touching your toes, the erector spinae is fully stretched. Because of the *length-tension relationship* explained in chapter 11, muscles that are stretched to such extremes cannot contract very effectively. Standing up from such a position is therefore initiated by the hamstring muscles on the back of the thigh and the gluteus

maximus of the buttocks. The erector spinae joins in the action when it is partially contracted.

Standing too suddenly or improperly lifting a heavy weight, however, can strain the erector spinae, cause painful muscle spasms, tear tendons and ligaments of the lower back, and rupture intervertebral discs. The lumbar muscles are adapted for maintaining posture, not for lifting. This is why it is important, in heavy lifting, to kneel and use the powerful extensor muscles of the thighs and buttocks to lift the load.

⁵⁰*quadrat* = four-sided + *lumborum* = of the lumbar region

⁵¹*multi* = many + *fid* = branched, sectioned

TABLE 10.7 Muscles of the Pelvic Floor

The floor of the pelvic cavity is formed by three layers of muscles and fasciae that span the pelvic outlet and support the viscera. It is penetrated by the anal canal, urethra, and vagina, which open into a diamond-shaped region between the thighs called the **perineum** (PERR-ih-NEE-um). The perineum is bordered by four bony landmarks: the pubic symphysis anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally. The anterior half of the perineum is the **urogenital triangle** and the posterior half is the **anal triangle** (fig. 10.20). These are especially important landmarks in obstetrics.

Superficial Perineal Space. The pelvic floor is divided into three layers or *compartments*. The one just deep to the skin, called the **superficial perineal space** (fig. 10.20a), contains three muscles: the ischiocavernosus, bulbospongiosus, and superficial transverse perineal. The *ischiocavernosus* muscles converge like a V from the ischial tuberosities toward the penis or clitoris. In males, the *bulbospongiosus* (*bulbocavernosus*) forms a sheath around the base (bulb) of the penis, and in females it encloses the vagina like a pair of parentheses. *Cavernosus* in these names refers to the spongy, cavernous structure of the tissues in the penis and clitoris. The *superficial transverse perineal muscle* extends from the ischial tuberosities to a strong median fibromuscular anchorage, the **perineal body**. It is a weakly developed muscle and not always present, so it is not tabulated below. The other two muscles of this layer primarily serve sexual functions.

Ischiocavernosus⁵² (**ISS-kee-oh-CAV-er-NO-sus**) Maintains erection of the penis or clitoris by compressing deep structures of the organ and forcing blood forward into its body.

O: Ramus and tuberosity of ischium **I:** Ensheathes deep structures of penis or clitoris **N:** Pudendal n.

Bulbospongiosus⁵³ (**BUL-bo-SPUN-jee-OH-sus**) Expels remaining urine from urethra after bladder has emptied. Aids in erection of penis or clitoris. In male, spasmodic contractions expel semen during ejaculation. In female, contractions constrict vaginal orifice and expel secretions of greater vestibular glands (see fig. 28.8b, p. 1084).

O: Perineal body and median raphe **I:** Ensheathes root of penis or clitoris **N:** Pudendal n.

The Middle Compartment. In the middle compartment, the urogenital triangle is spanned by a thin triangular sheet called the **urogenital diaphragm**. This is composed of a fibrous membrane and two or three muscles: the *deep transverse perineal muscle* and the *external urethral sphincter* (fig. 10.20b), and in females only, a *compressor urethrae* muscle. The deep transverse perineal muscle, like its superficial counterpart mentioned earlier, is weakly developed and not tabulated; the two of them serve to anchor the perineal body on the median plane, and the perineal body, in turn, anchors other pelvic muscles. The anal triangle has one muscle at this level, the *external anal sphincter*.

External Urethral Sphincter Retains urine in bladder until voluntarily voided.

O: Right and left ischiopubic rami **I:** Encircles urethral orifice **N:** Pudendal n., S2-S4, pelvic splanchnic n.

Compressor Urethrae Aids in urine retention; found in females only

O: Right and left ischiopubic rami **I:** Right and left compressor urethrae meet as muscular sheet inferior to external urethral sphincter **N:** Pudendal n., S2-S4, pelvic splanchnic n.

External Anal Sphincter Retains feces in rectum until voluntarily voided

O: Coccyx, perineal body **I:** Encircles anal canal and orifice **N:** Pudendal n., S2-S4, pelvic splanchnic n.

The Pelvic Diaphragm. The deepest compartment, the **pelvic diaphragm**, consists of two muscle pairs shown in figure 10.20c: the *levator ani* and *coccygeus*. The levator ani forms most of the pelvic floor. It is a composite of three muscles. The greatest part of it is a broad, triangular *iliococcygeus*. It arises from a *tendinous arch* that forms the medial margin of the fascia over the obturator internus muscle. Medial and anterior to this are a pair of narrow muscles, the *pubococcygeus* and *puborectalis*, which arise from the pubis and flank the urethra, the rectum, and (in females) the vagina. The left and right levator ani muscles converge on the fibrous *anococcygeal body*, which, in turn, inserts on the coccyx. Posterior to the levator ani is the coccygeus muscle, extending from the ischial spine to the coccyx and forming about one-quarter of the pelvic diaphragm.

Levator Ani⁵⁴ (**leh-VAY-tur AY-nye**) Compresses anal canal and reinforces external anal and urethral sphincters; supports uterus and other pelvic viscera; aids in the falling away of the feces; vertical movements affect pressure differences between abdominal and thoracic cavities and thus aid in breathing

O: Inner surface of lesser pelvis from pubis through tendinous arch of obturator internus to spine of ischium **I:** Coccyx via anococcygeal body, walls of urethra, vagina, and anal canal **N:** Pudendal n., S2-S3

Coccygeus (coc-SIDJ-ee-us) Aids levator ani

O: Spine of ischium **I:** Coccyx and adjacent border of sacrum **N:** S3-S4

⁵²*ischio* = ischium of hip bone + *cavernosus* = corpus cavernosum of the penis or clitoris

⁵⁴*levat* = to elevate + *ani* = of the anus

⁵³*bulbo* = bulb of the penis + *spongiosus* = corpus spongiosum of the penis

INSIGHT 10.2 Clinical Application

Hernias

A hernia is any condition in which the viscera protrude through a weak point in the muscular wall of the abdominopelvic cavity. The most common type to require treatment is an *inguinal hernia* (fig. 10.21). In the male fetus, each testis descends from the pelvic cavity into the scrotum by way of a passage called the *inguinal canal* through the muscles of the groin. This canal remains a weak point in the pelvic floor, especially in infants and children. When pressure rises in the abdominal cavity, it can force part of the intestine or bladder into this canal or even into the scrotum. This also sometimes occurs in men who hold their breath while lifting heavy weights. When the diaphragm and abdominal muscles contract, pressure in the abdominal cavity can soar to 1,500 pounds per square inch—more than 100 times the normal pressure and quite sufficient to produce an inguinal hernia, or “rupture.” Inguinal hernias rarely occur in women.

Two other sites of hernia are the diaphragm and navel. A *hiatal hernia* is a condition in which part of the stomach protrudes through the diaphragm into the thoracic cavity. This is most common in overweight people over 40. It may cause heartburn due to the regurgitation of stomach acid into the esophagus, but most cases go undetected. In an *umbilical hernia*, abdominal viscera protrude through the navel.

FIGURE 10.21 Inguinal Hernia. A loop of small intestine has protruded through the inguinal canal into a space beneath the skin.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Which muscles are used more often, the external intercostals or internal intercostals? Explain.
- Explain how pulmonary ventilation affects abdominal pressure and vice versa.
- Name a major superficial muscle and two major deep muscles of the back.
- Define perineum, urogenital triangle, and anal triangle.
- Name one muscle in the superficial perineal space, one in the urogenital diaphragm, and one in the pelvic diaphragm. State the function of each.

- describe the origin, insertion, and innervation of each muscle.

10.4 Muscles Acting on the Shoulder and Upper Limb

Objectives

When you have completed this section, you should be able to

- name and locate the muscles that act on the pectoral girdle, shoulder, elbow, wrist, and hand;
- relate the actions of these muscles to the joint movements described in chapter 9; and

The upper and lower limbs have numerous muscles that serve primarily for movement of the body and manipulation of objects. These muscles are organized into spaces called muscle **compartments** separated by fasciae—fibrous connective tissue sheets. Each compartment contains one or more functionally related muscles along with their nerve and blood supplies (fig. 10.22). We have already seen such compartmentalization in such regions as the thoracic wall (the three layers of intercostal muscles), the abdominal wall, and the pelvic floor. In the ensuing tables, you will find muscles of the upper limb divided into anterior and posterior compartments, and those of the lower limb divided into anterior, posterior, medial, and lateral compartments. These major compartments are separated from each other by the interosseous membranes of the forearm and leg (see pp. 271 and 278) and by especially thick fasciae called **intermuscular septa**. In most limb regions, the muscle groups are further subdivided by thinner fasciae into superficial and deep layers. A serious problem called *compartment syndrome* can occur when one of the muscles or blood vessels in a compartment is injured, partly because of the fact that the muscles are so tightly bound by these fasciae (see Insight 10.3).

The upper limb is used for a broad range of both powerful and subtle actions, ranging from climbing, grasping,

FIGURE 10.22 Muscle Compartments. A cross section of the left leg slightly above midcalf, oriented the same way as the reader's.

and throwing to writing, playing musical instruments, and manipulating small objects. It therefore has an especially complex array of muscles, but the muscles fall into logical groups that make their functional relationships and names easier to understand. Tables 10.8 through 10.12 group these into muscles that act on the scapula, those that act on the humerus and shoulder joint, those that act on the forearm and elbow joint, extrinsic (forearm) muscles that act on the wrist and hand, and intrinsic (hand) muscles that act on the fingers.

INSIGHT 10.3 Clinical Application

Compartment Syndrome

The fasciae of the upper and lower limbs enclose the muscle compartments very snugly. If a blood vessel in a compartment is damaged by overuse or contusion (a bruising injury), blood and tissue fluid accumulate in the compartment. The fasciae prevent the compartment from expanding to relieve the pressure. Mounting pressure on the muscles, nerves, and blood vessels triggers a sequence of degenerative events called *compartment syndrome*. Blood flow to the compartment is obstructed by pressure on its arteries. If *ischemia* (poor blood flow) persists for more than 2 to 4 hours, nerves begin to die, and after 6 hours, so does muscle tissue. Nerves can regenerate after the pressure is relieved, but muscle necrosis is irreversible. The breakdown of muscle releases myoglobin into the blood. *Myoglobinuria*, the presence of myoglobin in the urine, gives the urine a dark color and is one of the key signs of compartment syndrome and some other degenerative muscle disorders. Compartment syndrome is treated by immobilizing and resting the limb and, if necessary, making an incision (*fasciotomy*) to relieve the compartment pressure.

TABLE 10.8 Muscles Acting on the Shoulder

Muscles that act on the pectoral girdle originate on the axial skeleton and insert on the clavicle and scapula. The scapula is only loosely attached to the thoracic cage and is capable of considerable movement (fig. 10.23)—rotation (as in raising and lowering the apex of the shoulder), elevation and depression (as in shrugging and lowering the shoulders), and protraction and retraction (pulling the shoulders forward and back). The clavicle braces the shoulder and moderates these movements.

FIGURE 10.23 Actions of Some Thoracic Muscles on the Scapula. Note that an individual muscle can contribute to multiple actions, depending on which fibers contract and what synergists act with it.

TABLE 10.8 Muscles Acting on the Shoulder (*cont.*)

<p>Anterior Group. Muscles of the pectoral girdle fall into anterior and posterior groups (see figs. 10.24 and 10.25 in table 10.9). The major muscles of the anterior group are the <i>pectoralis minor</i> and <i>serratus anterior</i> (see fig. 10.15b). The pectoralis minor arises by three heads from ribs 3 to 5 and converges on the coracoid process of the scapula. The serratus anterior arises from separate heads on all or nearly all of the ribs, wraps laterally around the chest, passes across the back between the rib cage and scapula, and inserts on the medial (vertebral) border of the scapula. Thus, when it contracts, the scapula glides laterally and slightly forward around the ribs.</p>		
<p>Pectoralis Minor (PECK-toe-RAY-liss) With serratus anterior, draws scapula laterally and forward around chest wall; with other muscles, rotates scapula and depresses apex of shoulder, as in reaching down to pick up a suitcase</p>		
O: Ribs 3–5 and overlying fascia	I: Coracoid process of scapula	N: Medial and lateral pectoral nn.
<p>Serratus⁵⁵ Anterior (serr-AY-tus) With pectoralis minor, draws scapula laterally and forward around chest wall; protracts scapula, and is the prime mover in all forward-reaching and pushing actions; aids in rotating scapula to elevate apex of shoulder; fixes scapula during abduction of arm</p>		
O: All or nearly all ribs	I: Medial border of scapula	N: Long thoracic n.
<p>Posterior Group. The posterior muscles that act on the scapula include the large, superficial trapezius, already discussed (table 10.3), and three deep muscles: the <i>levator scapulae</i>, <i>rhomboides minor</i>, and <i>rhomboides major</i> (the <i>rhomboids</i>). The action of the trapezius depends on whether its superior, middle, or inferior fibers contract and whether it acts alone or with other muscles. The levator scapulae and superior fibers of the trapezius rotate the scapula in opposite directions if either of them acts alone. If both act together, their opposite rotational effects balance each other and they elevate the scapula and shoulder, as when you lift a suitcase from the floor. Depression of the scapula occurs mainly by gravitational pull, but the trapezius and serratus anterior can depress it more rapidly and forcefully, as in swimming, hammering, and rowing.</p>		
<p>Trapezius (tra-PEE-zee-us) Stabilizes scapula and shoulder during arm movements; elevates and depresses apex of shoulder; acts with other muscles to rotate and retract scapula (see also roles in head and neck movements in table 10.3)</p>		
O: External occipital protuberance, medial one-third of superior nuchal line, nuchal ligament, spinous processes of vertebrae C7–T3 or T4	I: Acromion and spine of scapula, lateral one-third of clavicle	N: Accessory n., anterior rami of C3–C4
<p>Levator Scapulae (leh-VAY-tur SCAP-you-lee) Elevates scapula if cervical vertebrae are fixed; flexes neck laterally if scapula is fixed; retracts scapula and braces shoulder; rotates scapula and depresses apex of shoulder</p>		
O: Transverse processes of vertebrae C1–C4	I: Superior angle to medial border of scapula	N: C3–C4, and C5 via dorsal scapular n.
<p>Rhomboides Minor (rom-BOY-dee-us) Retracts scapula and braces shoulder; fixes scapula during arm movements</p>		
O: Spinous processes of vertebrae C7–T1, nuchal ligament	I: Medial border of scapula	N: Dorsal scapular n.
<p>Rhomboides Major Same as rhomboides minor</p>		
O: Spinous processes of vertebrae T2–T5	I: Medial border of scapula	N: Dorsal scapular n.

⁵⁵ *serrate* = scalloped, zigzag

TABLE 10.9 Muscles Acting on the Arm

Axial Muscles. Nine muscles cross the shoulder joint and insert on the humerus. Two are considered **axial muscles** because they originate primarily on the axial skeleton—the *pectoralis major* and *latissimus dorsi* (figs. 10.15, 10.24, and 10.25). The pectoralis major is the thick, fleshy muscle of the mammary region, and the latissimus dorsi is a broad muscle of the back that extends from the waist to the axilla. These muscles bear the primary responsibility for attaching the arm to the trunk and are the prime movers of the shoulder joint.

Pectoralis Major (PECK-toe-RAY-liss) Flexes, adducts, and medially rotates humerus, as in climbing or hugging. Aids in deep inspiration.

O: Medial half of clavicle, costal cartilages 1–7, aponeurosis of external oblique

I: Lateral lip of intertubercular sulcus of humerus

N: Medial and lateral pectoral nn.

Latissimus Dorsi⁵⁶ (**la-TISS-ih-mus DOR-sye**) Adducts and medially rotates humerus; extends the shoulder joint as in pulling on the oars of a rowboat; produces backward swing of arm in such actions as walking and bowling; with hands grasping overhead objects, pulls body forward and upward, as in climbing; aids in deep inspiration, sudden expiration such as sneezing and coughing, and prolonged forceful expiration as in singing or blowing a sustained note on a wind instrument

O: Vertebrae T7–L5, lower three or four ribs, iliac crest, thoracolumbar fascia

I: Floor of intertubercular sulcus of humerus

N: Thoracodorsal n.

Scapular Muscles. The other seven muscles of the shoulder are considered **scapular muscles** because they originate on the scapula. Four of them form the rotator cuff and are treated in the next section. The most conspicuous scapular muscle is the *deltoid*, the thick triangular muscle that caps the shoulder. This is a commonly used site of drug injections. Its anterior, lateral, and posterior fibers act like three different muscles.

Deltoid Anterior fibers flex and medially rotate arm; lateral fibers abduct arm; posterior fibers extend and laterally rotate arm; involved in arm swinging during such actions as walking or bowling, and in adjustment of hand height for various manual tasks

O: Acromion and spine of scapula; clavicle

I: Deltoid tuberosity of humerus

N: Axillary n.

Teres Major (TERR-eez) Extends and medially rotates humerus; contributes to arm swinging

O: Inferior angle of scapula

I: Medial lip of intertubercular sulcus of humerus

N: Lower subscapular n.

Coracobrachialis (COR-uh-co-BRAY-kee-AL-iss) Flexes and medially rotates arm; resists deviation of arm from frontal plane during abduction

O: Coracoid process

I: Medial aspect of humeral shaft

N: Musculocutaneous n.

⁵⁶*latissimus* = broadest + *dorsi* = of the back

TABLE 10.9 Muscles Acting on the Arm (*cont.*)

FIGURE 10.24 Pectoral and Brachial Muscles. (a) Superficial muscles, anterior view. (b) Superficial muscles, posterior view. (c) The biceps brachii, the superficial flexor of the elbow. (d) The brachialis, the deep flexor of the elbow, and the coracobrachialis and subscapularis, which act on the humerus.

TABLE 10.9

Muscles Acting on the Arm (cont.)

FIGURE 10.25 Pectoral, Brachial, and Upper Back Muscles of the Cadaver.

TABLE 10.9 Muscles Acting on the Arm (*cont.*)

The Rotator Cuff Tendons of the remaining four scapular muscles form the **rotator cuff** (fig. 10.26). These muscles are nicknamed the “SITS muscles” for the first letters of their names—*supraspinatus*, *infraspinatus*, *teres minor*, and *subscapularis*. The first three muscles lie on the posterior side of the scapula (see fig. 10.24b). The supraspinatus and infraspinatus occupy the supraspinous and infraspinous fossae, above and below the scapular spine. The teres minor lies inferior to the infraspinatus. The subscapularis occupies the subscapular fossa on the anterior surface of the scapula, between the scapula and ribs (see fig. 10.24d). The tendons of these muscles merge with the joint capsule of the shoulder as they cross it en route to the humerus. They insert on the proximal end of the humerus, forming a partial sleeve around it. The rotator cuff reinforces the joint capsule and holds the head of the humerus in the glenoid cavity. The rotator cuff, especially the supraspinatus tendon, is easily damaged by strenuous circumduction or hard blows to the shoulder (see Insight 10.5).

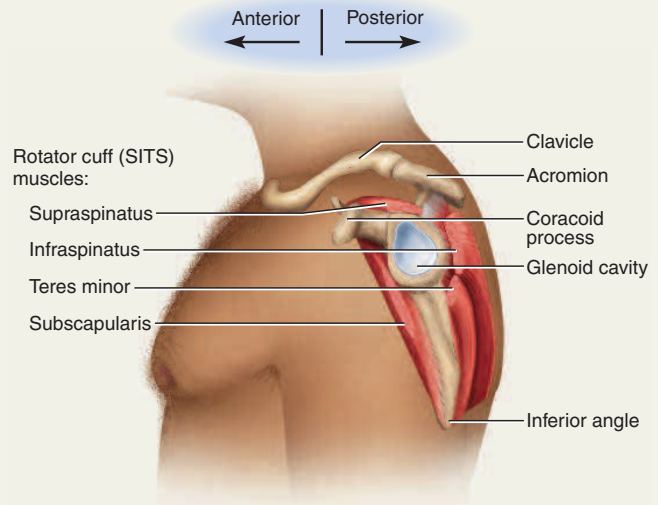

FIGURE 10.26 Rotator Cuff Muscles in Relation to the Scapula. Lateral view. For posterior and anterior views of these muscles, see figure 10.24b, d.

Supraspinatus⁵⁷ (**SOO-pra-spy-NAY-tus**) Aids deltoid in abduction of arm; resists downward slippage of humeral head when arm is relaxed or when carrying weight

O: Supraspinous fossa of scapula

I: Greater tubercle of humerus

N: Suprascapular n.

Infraspinatus⁵⁸ (**IN-fra-spy-NAY-tus**) Modulates action of deltoid, preventing humeral head from sliding upward; rotates humerus laterally

O: Infraspinous fossa of scapula

I: Greater tubercle of humerus

N: Suprascapular n.

Teres Minor (**TERR-eez**) Modulates action of deltoid, preventing humeral head from sliding upward as arm is abducted; rotates humerus laterally

O: Lateral border and adjacent posterior surface of scapula

I: Greater tubercle of humerus; posterior surface of joint capsule

N: Axillary n.

Subscapularis⁵⁹ (**SUB-SCAP-you-LERR-iss**) Modulates action of deltoid, preventing humeral head from sliding upward as arm is abducted; rotates humerus medially

O: Subscapular fossa of scapula

I: Lesser tubercle of humerus, anterior surface of joint capsule

N: Upper and lower subscapular nn.

⁵⁷ *supra* = above + *spin* = spine of scapula

⁵⁸ *infra* = below, under + *spin* = spine of scapula

⁵⁹ *sub* = below, under

TABLE 10.10 Muscles Acting on the Forearm

The elbow and forearm are capable of four motions—flexion, extension, pronation, and supination—carried out by muscles in both the brachium and antebrachium (arm and forearm).

Muscles with Bellies in the Arm (Brachium). The principal elbow flexors are in the anterior compartment of the arm—the brachialis and biceps brachii (see fig. 10.24c–d). The *biceps brachii* appears as a large anterior bulge on the arm and commands considerable interest among body builders, but the *brachialis* underlying it generates about 50% more power and is thus the prime mover of elbow flexion. The biceps is not only a flexor but also a powerful forearm supinator. It is named for its two heads: a *short head* whose tendon arises from the coracoid process of the scapula, and a *long head* whose tendon originates on the superior margin of the glenoid cavity, loops over the shoulder, and braces the humerus against the glenoid cavity (see p. 305). The two heads converge close to the elbow on a single distal tendon that inserts on the radius and on the fascia of the medial side of the upper forearm. Note that *biceps* is the singular term; there is no such word as *bicep*. To refer to the biceps muscles of both arms, the plural is *bicipites* (by-SIP-ih-teez).

The triceps brachii is a three-headed muscle on the posterior side of the humerus, and is the prime mover of elbow extension (see fig. 10.24b).

Brachialis (BRAY-kee-AL-iss) Prime mover of elbow flexion

O: Anterior surface of distal half of humerus **I:** Coronoid process and tuberosity of ulna **N:** Musculocutaneous n., radial n.

Biceps Brachii (BY-seps BRAY-kee-eye) Rapid or forceful supination of forearm; synergist in elbow flexion; slight shoulder flexion; tendon of long head stabilizes shoulder by holding humeral head against glenoid cavity

O: Long head: superior margin of glenoid cavity **I:** Tuberosity of radius, fascia of forearm **N:** Musculocutaneous n.
Short head: coracoid process

Triceps Brachii (TRI-seps BRAY-kee-eye) Extends elbow; long head extends and adducts humerus

O: Long head: inferior margin of glenoid cavity and joint capsule **I:** Olecranon, fascia of forearm **N:** Radial n.
Lateral head: posterior surface of proximal end of humerus
Medial head: posterior surface of entire humeral shaft

Muscles with Bellies in the Forearm (Antebrachium). Most forearm muscles act on the wrist and hand, but two of them are synergists in elbow flexion and extension and three of them function in pronation and supination. The *brachioradialis* is the large fleshy mass of the lateral (radial) side of the forearm just distal to the elbow (see figs. 10.24a and 10.29a). Its origin is on the distal end of the humerus and its insertion on the distal end of the radius. With the insertion so far from the fulcrum of the elbow, it does not generate as much force as the brachialis and biceps; it is effective mainly when those muscles have already partially flexed the elbow. The *anconeus* is a weak synergist of elbow extension on the posterior side of the elbow (see fig. 10.30). Pronation is achieved by the *pronator teres* near the elbow and *pronator quadratus* (the prime mover) near the wrist. Supination is usually achieved by the *supinator* of the upper forearm, with the biceps brachii aiding when additional speed or power is required (fig. 10.27).

Brachioradialis (BRAY-kee-oh-RAY-dee-AL-iss) Flexes elbow

O: Lateral supracondylar ridge of humerus **I:** Lateral surface of radius near styloid process **N:** Radial n.

Anconeus⁶⁰ (an-CO-nee-us) Extends elbow; may help to control ulnar movement during pronation

O: Lateral epicondyle of humerus **I:** Olecranon and posterior surface of ulna **N:** Radial n.

Pronator Quadratus (PRO-nay-tur quad-RAY-tus) Prime mover of forearm pronation; also resists separation of radius and ulna when force is applied to forearm through wrist, as in doing push-ups

O: Anterior surface of distal ulna **I:** Anterior surface of distal radius **N:** Median n.

Pronator Teres (PRO-nay-tur TERR-eez) Assists pronator quadratus in pronation, but only in rapid or forceful action; weakly flexes elbow

O: Humeral shaft near medial epicondyle; coronoid process of ulna **I:** Lateral surface of radial shaft **N:** Median n.

Supinator (SOO-pih-NAY-tur) Supinates forearm

O: Lateral epicondyle of humerus; supinator crest and fossa of ulna just distal to radial notch; anular and radial collateral ligaments of elbow **I:** Proximal one-third of radius **N:** Posterior interosseous n.

⁶⁰*anconeus* = elbow

TABLE 10.10 Muscles Acting on the Forearm (*cont.*)

FIGURE 10.27 Actions of the Rotator Muscles on the Forearm. (a) Supination. (b) Cross section just distal to the elbow, showing the synergistic action of the biceps brachii and supinator. (c) Pronation.

• What do the names of the pronator teres and pronator quadratus muscles indicate about their shapes?

TABLE 10.11 Muscles Acting on the Wrist and Hand

The hand is acted upon by extrinsic muscles in the forearm and intrinsic muscles in the hand itself. The bellies of the extrinsic muscles form the fleshy roundness of the upper forearm (along with the brachioradialis); their tendons extend into the wrist and hand. Their actions are mainly flexion and extension of the wrist and digits, but also include radial and ulnar flexion, finger abduction and adduction, and thumb opposition. These muscles are numerous and complex, but their names often describe their location, appearance, and function.

Many of them act on the **metacarpophalangeal joints** between the metacarpal bones of the hand and the proximal phalanges of the fingers, and the **interphalangeal joints** between the proximal and middle or the middle and distal phalanges (or proximal-distal in the thumb, which has no middle phalanx). The metacarpophalangeal joints form the knuckles at the bases of the fingers, and the interphalangeal joints form the second and third knuckles. Some tendons cross multiple joints before inserting on a middle or distal phalanx, and can flex or extend all the joints they cross.

Most tendons of the extrinsic muscles pass under a fibrous, braceletlike sheet called the **flexor retinaculum** on the anterior side of the wrist or the **extensor retinaculum** on the posterior side. These ligaments prevent the tendons from standing up like taut bowstrings when the muscles contract. The **carpal tunnel** is a tight space between the flexor retinaculum and carpal bones. The flexor tendons passing through the tunnel are enclosed in tendon sheaths that enable them to slide back and forth quite easily, although this region is subject to painful inflammation—*carpal tunnel syndrome*—resulting from repetitive motion (see Insight 10.4 and fig. 10.31).

Fasciae divide the forearm muscles into anterior and posterior compartments and each compartment into superficial and deep layers (fig. 10.28). The muscles will be described below in these four groups.

Anterior (Flexor) Compartment, Superficial Layer. Most muscles of the anterior compartment are wrist and finger flexors that arise from a common tendon on the humerus (fig. 10.29). At the distal end, the tendon of the *palmaris longus* passes over the flexor retinaculum, whereas the other tendons pass beneath it, through the carpal tunnel. The two prominent tendons you can palpate at the wrist belong to the palmaris longus on the medial side and the *flexor carpi radialis* on the lateral side (see fig. B.8, p. 395). The latter is an important landmark for finding the radial artery, where the pulse is usually taken. The palmaris longus is absent on one or both sides (most commonly the left) in about 14% of people. To see if you have one, flex your wrist and touch the tips of your thumb and little finger together. If present, the palmaris longus tendon will stand up prominently on the wrist.

Flexor Carpi Radialis⁶¹ (FLEX-ur CAR-pye RAY-dee-AL-iss) Flexes wrist anteriorly; aids in radial flexion of wrist

O: Medial epicondyle of humerus **I:** Base of metacarpals II–III **N:** Median n.

Flexor Carpi Ulnaris⁶² (ul-NAY-ris) Flexes wrist anteriorly; aids in ulnar flexion of wrist

O: Medial epicondyle of humerus; medial margin of olecranon; posterior surface of ulna **I:** Pisiform, hamate, metacarpal V **N:** Ulnar n.

Flexor Digitorum Superficialis⁶³ (DIDJ-ih-TOE-rum SOO-per-FISH-ee-AY-lis) Flexes wrist, metacarpophalangeal, and interphalangeal joints depending on action of other muscles

O: Medial epicondyle of humerus; ulnar collateral ligament; coronoid process; superior half of radius **I:** Middle phalanges II–V **N:** Median n.

Palmaris Longus (pal-MERR-iss) Anchors skin and fascia of palmar region; resists shearing forces when stress is applied to skin by such actions as climbing and tool use. Weakly developed and sometimes absent.

O: Medial epicondyle of humerus **I:** Flexor retinaculum, palmar aponeurosis **N:** Median n.

Anterior (Flexor) Compartment, Deep Layer. The following two flexors constitute the deep layer (fig. 10.29c). The *flexor digitorum profundus* flexes fingers II–V, but the thumb (pollex) has a flexor of its own—one of several muscles serving exclusively for thumb movements.

Flexor Digitorum Profundus Flexes wrist, metacarpophalangeal, and interphalangeal joints; sole flexor of the distal interphalangeal joints

O: Proximal three-quarters of ulna; coronoid process; interosseous membrane **I:** Distal phalanges II–V **N:** Median n., ulnar n.

Flexor Pollicis Longus (PAHL-ih-sis) Flexes phalanges of thumb

O: Radius, interosseous membrane **I:** Distal phalanx I **N:** Median n.

⁶¹*carpi* = of the wrist + *radialis* = of the radius

⁶²*ulnaris* = of the ulna

⁶³*digitorum* = of the digits + *superficialis* = shallow. near the surface

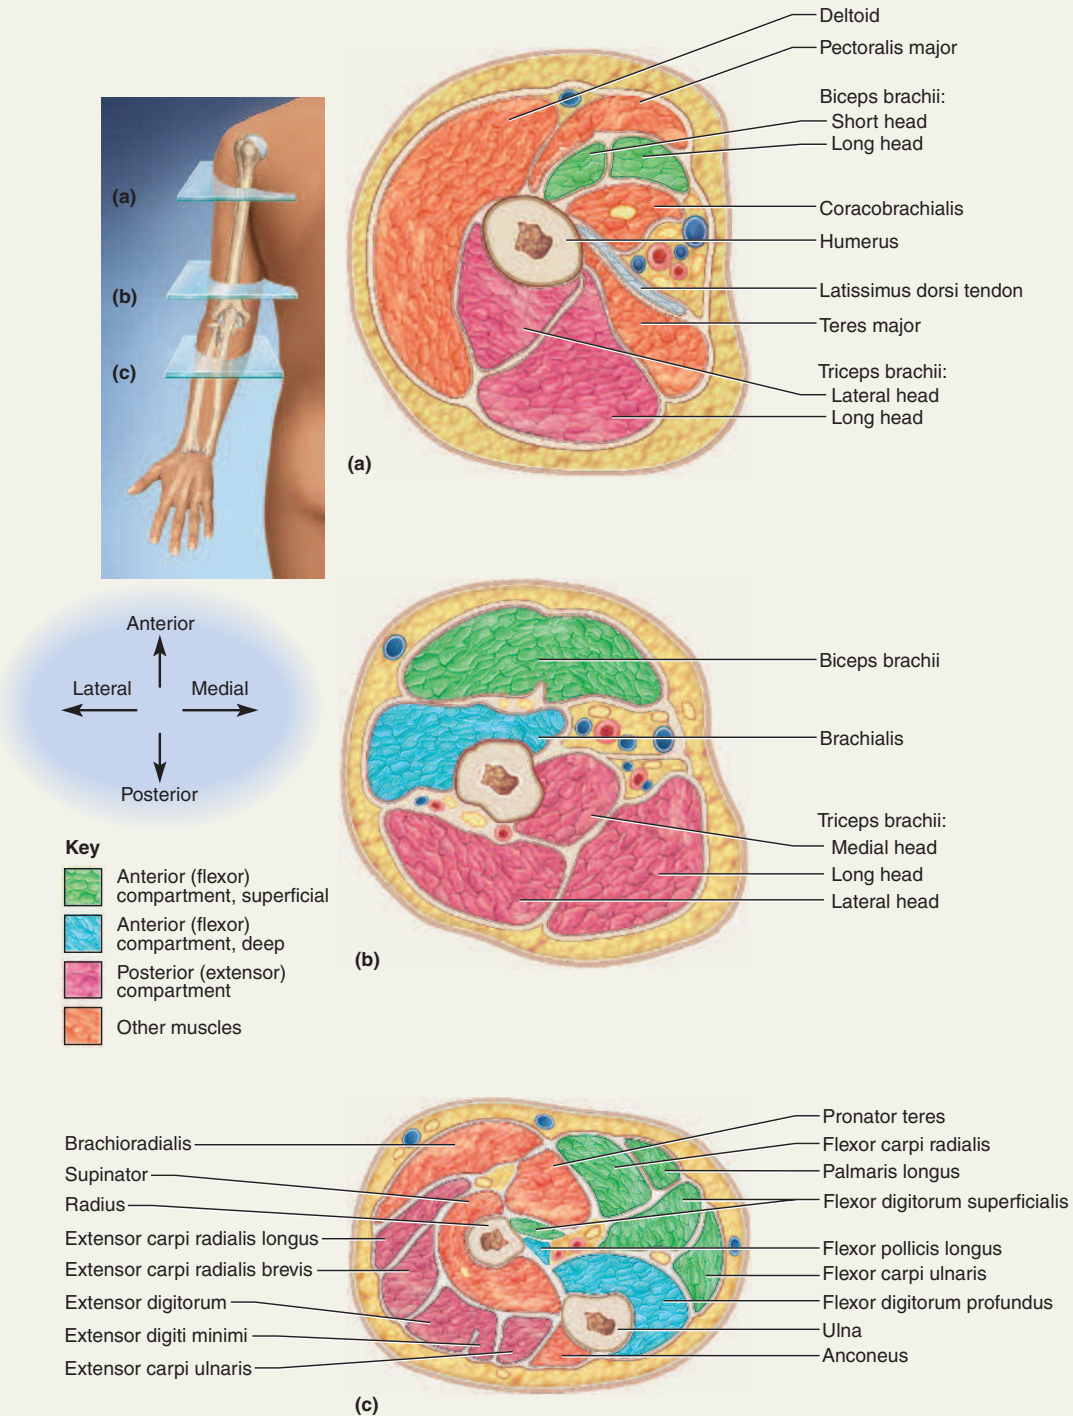

TABLE 10.11 Muscles Acting on the Wrist and Hand (*cont.*)

FIGURE 10.28 Serial Cross Sections Through the Upper Limb. Each section is taken at the correspondingly lettered level in the figure at the left and is pictured with the posterior muscle compartment facing the bottom of the page, as if viewing a person's right limb extended toward you with the palm up.

❗ Why are the extensor pollicis longus and extensor indicis not seen in part (c)?

TABLE 10.11 Muscles Acting on the Wrist and Hand (*cont.*)

FIGURE 10.29 Flexors of the Wrist and Hand. Anterior views of the forearm. (a) Superficial flexors. (b) The flexor digitorum superficialis, deep to the muscles in part (a) but also classified as a superficial flexor. (c) Deep flexors. Flexor muscles of each compartment are labeled in boldface.

Posterior (Extensor) Compartment, Superficial Layer. Superficial muscles of the posterior compartment are mostly wrist and finger extensors, and share a single tendon arising from the humerus (fig. 10.30a). The first of these, the *extensor digitorum*, has four distal tendons that can easily be seen and palpated on the back of the hand when the fingers are strongly extended (see fig. B.8, p. 395). It serves digits II through V, and the other muscles in this group each serve a single digit. From lateral to medial, these extensors are as follows.

Extensor Carpi Radialis Longus	Extends wrist; aids in radial flexion of wrist
O: Lateral supracondylar ridge of humerus	I: Base of metacarpal II N: Radial n.
Extensor Carpi Radialis Brevis (BREV-iss)	Extends wrist; aids in radial flexion of wrist
O: Lateral epicondyle of humerus	I: Base of metacarpal III N: Posterior interosseous n.
Extensor Digitorum	Extends wrist, metacarpophalangeal, and interphalangeal joints; tends to spread digits apart when extending metacarpophalangeal joints
O: Lateral epicondyle of humerus	I: Dorsal surfaces of phalanges II-V N: Posterior interosseous n.
Extensor Digiti Minimi⁶⁴ (DIDJ-ih-ty MIN-ih-my)	Extends wrist and all joints of little finger
O: Lateral epicondyle of humerus	I: Proximal phalanx V N: Posterior interosseous n.
Extensor Carpi Ulnaris	Extends and fixes wrist when fist is clenched or hand grips an object; aids in ulnar flexion of wrist
O: Lateral epicondyle of humerus; posterior surface of ulnar shaft	I: Base of metacarpal V N: Posterior interosseous n.

⁶⁴digit = finger + minim = smallest

TABLE 10.11 Muscles Acting on the Wrist and Hand (*cont.*)

Posterior (Extensor) Compartment, Deep Layer. The deep muscles that follow serve only the thumb and index finger (fig. 10.30b). By strongly abducting and extending the thumb into a hitchhiker's position, you may see a deep dorsolateral pit at the base of the thumb, with a taut tendon on each side of it (see fig. B.8, p. 395). This depression is called the *anatomical snuffbox* because it was once fashionable to place a pinch of snuff here and inhale it. It is bordered laterally by the tendons of the *abductor pollicis longus* and *extensor pollicis brevis*, and medially by the tendon of the *extensor pollicis longus*. The extensor muscles from lateral to medial are as follows.

Abductor Pollicis Longus Abducts thumb in frontal (palmar) plane (radial abduction); extends thumb at carpometacarpal joint

O: Posterior surfaces of radius and ulna; interosseous membrane

I: Trapezium, base of metacarpal I

N: Posterior interosseous n.

Extensor Pollicis Brevis Extends metacarpal I and proximal phalanx of thumb

O: Shaft of radius, interosseous membrane

I: Proximal phalanx I

N: Posterior interosseous n.

Extensor Pollicis Longus Extends distal phalanx I; aids in extending proximal phalanx I and metacarpal I; adducts and laterally rotates thumb

O: Posterior surface of ulna, interosseous membrane

I: Distal phalanx I

N: Posterior interosseous n.

Extensor Indicis (IN-dih-sis) Extends wrist and index finger

O: Posterior surface of ulna, interosseous membrane

I: Middle and distal phalanges of index finger

N: Posterior interosseous n.

FIGURE 10.30 Extensors of the Wrist and Hand. Posterior views of the forearm. Extensor muscles of each compartment are labeled in boldface.

INSIGHT 10.4 Clinical Application

Carpal Tunnel Syndrome

Prolonged, repetitive motions of the wrist and fingers can cause tissues in the carpal tunnel to become inflamed, swollen, or fibrotic. Since the carpal tunnel cannot expand, swelling puts pressure on the median nerve of the wrist, which passes through the carpal tunnel with the flexor tendons (fig. 10.31).

This pressure causes tingling and muscular weakness in the palm and medial side of the hand and pain that may radiate to the arm and shoulder. This condition, called *carpal tunnel syndrome*, is common among keyboard operators, pianists, meat cutters, and others who spend long hours making repetitive wrist motions. Carpal tunnel syndrome is treated with aspirin and other anti-inflammatory drugs, immobilization of the wrist, and sometimes surgical removal of part or all of the flexor retinaculum to relieve pressure on the nerve.

FIGURE 10.31 The Carpal Tunnel. (a) Dissection of the wrist (anterior aspect) showing the tendons, nerve, and bursae that pass under the flexor retinaculum. (b) Cross section of the wrist, viewed as if from the distal end of a person's right forearm extended toward you with the palm up. Note how the flexor tendons and median nerve are confined in the tight space between the carpal bones and flexor retinaculum. That tight packing and repetitive sliding of the flexor tendons through the tunnel contribute to carpal tunnel syndrome.

TABLE 10.12 Intrinsic Muscles of the Hand

The intrinsic muscles of the hand assist the flexors and extensors in the forearm and make finger movements more precise. They are divided into three groups: the *thenar group* at the base of the thumb, the *hypothener group* at the base of the little finger, and the *midpalmar group* between these (fig. 10.32).

Thenar Group. The thenar group of muscles forms the thick fleshy mass (*thenar eminence*) at the base of the thumb, and the *adductor pollicis* forms the web between the thumb and palm. All are concerned with thumb movements. The adductor pollicis has an *oblique head* that extends from the capitate bone of the wrist to the ulnar side of the base of the thumb, and a *transverse head* that extends from metacarpal III to the same insertion as the oblique head.

Adductor Pollicis Draws thumb toward palm as in gripping a tool

O: Capitate; bases of metacarpals II–III; anterior ligaments of wrist; tendon sheath of flexor carpi radialis

I: Medial surface of proximal phalanx I

N: Ulnar n.

Abductor Pollicis Brevis Abducts thumb in sagittal plane

O: Mainly flexor retinaculum; also scaphoid, trapezium, and abductor pollicis longus tendon

I: Lateral surface of proximal phalanx I

N: Median n.

Flexor Pollicis Brevis Flexes metacarpophalangeal joint of thumb

O: Trapezium, trapezoid, capitate, anterior ligaments of wrist, flexor retinaculum

I: Proximal phalanx I

N: Median n., ulnar n.

Opponens Pollicis (op-PO-nenz) Flexes metacarpal I to oppose thumb to fingertips

O: Trapezium, flexor retinaculum

I: Metacarpal I

N: Median n.

Hypothener Group. The hypothener group forms the fleshy mass (*hypothener eminence*) at the base of the little finger. All of these muscles are concerned with movement of that digit.

Abductor Digiti Minimi Abducts little finger, as in spreading fingers apart

O: Pisiform, tendon of flexor carpi ulnaris

I: Medial surface of proximal phalanx V

N: Ulnar n.

Flexor Digiti Minimi Brevis Flexes little finger at metacarpophalangeal joint

O: Hamulus of hamate bone, flexor retinaculum

I: Medial surface of proximal phalanx V

N: Ulnar n.

Opponens Digiti Minimi Flexes metacarpal V at carpometacarpal joint when little finger is moved into opposition with tip of thumb; deepens palm of hand

O: Hamulus of hamate bone, flexor retinaculum

I: Medial surface of metacarpal V

N: Ulnar n.

Midpalmar Group. The midpalmar group occupies the hollow of the palm. It has 11 small muscles divided into three groups.

Dorsal Interosseous⁶⁵ Muscles (IN-tur-OSS-ee-us) (Four Muscles) Abduct fingers; strongly flex metacarpophalangeal joints but extend interphalangeal joints, depending on action of other muscles; important for grip strength

O: Each with two heads arising from facing surfaces of adjacent metacarpals

I: Proximal phalanges II–IV

N: Ulnar n.

Palmar Interosseous Muscles (Three Muscles) Adduct fingers; other actions same as for dorsal interosseous muscles

O: Metacarpals I, II, IV, V

I: Proximal phalanges II, IV, V

N: Ulnar n.

Lumbricals⁶⁶ (LUM-brick-ulz) (Four Muscles) Extend interphalangeal joints; contribute to ability to pinch objects between fleshy pulp of thumb and finger, instead of these digits meeting by the edges of their nails

O: Tendons of flexor digitorum profundus

I: Proximal phalanges II–V

N: Median n., ulnar n.

⁶⁵*inter* = between + *osse* = bones

⁶⁶*lumbrical* = resembling an earthworm

TABLE 10.12 Intrinsic Muscles of the Hand (*cont.*)

FIGURE 10.32 Intrinsic Muscles of the Hand. The boldface labels in parts (a), (c), and (d) indicate the muscles that belong to the respective layer.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. Name a muscle that inserts on the scapula and plays a significant role in each of the following actions:
 - (a) pushing a stalled car, (b) paddling a canoe,
 - (c) squaring the shoulders in military attention,
 - (d) lifting the shoulder to carry a heavy box on it, and
 - (e) lowering the shoulder to lift a suitcase.
17. Describe three contrasting actions of the deltoid muscle.
18. Name the four rotator cuff muscles and describe the scapular surfaces against which they lie.
19. Name the prime movers of elbow flexion and extension.
20. Identify three functions of the biceps brachii.
21. Name three extrinsic muscles and two intrinsic muscles that flex the phalanges.

10.5 Muscles Acting on the Hip and Lower Limb

Objectives

When you have completed this section, you should be able to

- name and locate the muscles that act on the hip, knee, ankle, and toe joints;
- relate the actions of these muscles to the joint movements described in chapter 9; and
- describe the origin, insertion, and innervation of each muscle.

The largest muscles are found in the lower limb. Unlike those of the upper limb, they are adapted less for precision than for the strength needed to stand, maintain balance, walk, and run. Several of them cross and act upon two or more joints, such as the hip and knee. To avoid confusion in this discussion, remember that in the anatomical sense the word *leg* refers only to that part of the limb between the knee and ankle. The term *foot* includes the tarsal region (ankle), metatarsal region, and toes. Tables 10.13 through 10.16 group the muscles of the lower limb into those that act on the femur and hip joint, those that act on the leg and knee joint, extrinsic (leg) muscles that act on the foot and ankle joint, and intrinsic (foot) muscles that act on the arches and toes.

TABLE 10.13 Muscles Acting on the Hip and Femur

Anterior Muscles of the Hip. Most muscles that act on the femur originate on the hip bone. The two principal anterior muscles are the *iliacus*, which fills most of the broad iliac fossa of the pelvis, and the *psoas major*, a thick rounded muscle that arises mainly from the lumbar vertebrae (fig. 10.33). Collectively, they are called the **iliopsoas** and share a common tendon to the femur.

Iliacus⁶⁷ (**ih-LY-uh-cus**) Flexes thigh at hip when trunk is fixed; flexes trunk at hip when thigh is fixed, as in bending forward in a chair or sitting up in bed; balances trunk during sitting

O: Iliac crest and fossa, superolateral region of sacrum, anterior sacroiliac and iliolumbar ligaments

I: Lesser trochanter and nearby shaft of femur

N: Femoral n.

Psoas⁶⁸ **Major (SO-ass)** Same as iliacus

O: Bodies and intervertebral discs of vertebrae T12-L5, transverse processes of lumbar vertebrae

I: Lesser trochanter and nearby shaft of femur

N: Anterior rami of lumbar spinal nn.

FIGURE 10.33 Muscles That Act on the Hip and Femur. Anterior view.

⁶⁷*ili* = loin, flank

⁶⁸*psoa* = loin

TABLE 10.13 Muscles Acting on the Hip and Femur (*cont.*)

Lateral and Posterior Muscles of the Hip. On the lateral and posterior sides of the hip are the *tensor fasciae latae* and three gluteal muscles. The **fascia lata** is a fibrous sheath that encircles the thigh like a subcutaneous stocking and tightly binds its muscles. On the lateral surface, it combines with the tendons of the gluteus maximus and tensor fasciae latae to form the **iliotibial band**, which extends from the iliac crest to the lateral condyle of the tibia (see fig. 10.35, table 10.14). The tensor fasciae latae tautens the iliotibial band and braces the knee, especially when the opposite foot is lifted.

The gluteal muscles are the *gluteus maximus*, *gluteus medius*, and *gluteus minimus* (fig. 10.34). The gluteus maximus is the largest of these and forms most of the lean mass of the buttock. It is an extensor of the hip joint that produces the backswing of the leg in walking and provides most of the lift when you climb stairs. It generates its maximum force when the thigh is flexed at a 45° angle to the trunk. This is the advantage in starting a foot race from a crouched position. The gluteus medius is deep and lateral to the gluteus maximus. Its name refers to its size, not its position. The gluteus minimus is the smallest and deepest of the three.

Tensor Fasciae Latae⁶⁹ (**TEN-sur FASH-ee-ee LAY-tee**) Extends knee, laterally rotates tibia, aids in abduction and medial rotation of femur; during standing, steadies pelvis on femoral head and steadies femoral condyles on tibia

O: Iliac crest, anterior superior spine, deep surface of fascia lata

I: Lateral condyle of tibia via iliotibial band

N: Superior gluteal n.

Gluteus Maximus⁷⁰ Extends thigh at hip as in stair climbing (rising to next step) or running and walking (backswing of limb); abducts thigh; elevates trunk after stooping; prevents trunk from pitching forward during walking and running; helps stabilize femur on tibia

O: Posterior gluteal line of ilium, on posterior surface from iliac crest to posterior superior spine; coccyx; posterior surface of lower sacrum; aponeurosis of erector spinae

I: Gluteal tuberosity of femur; lateral condyle of tibia via iliotibial band

N: Inferior gluteal n.

FIGURE 10.34 Gluteal Muscles. Posterior view.

Describe two everyday movements of the body that employ the power of the gluteus maximus.

⁶⁹fasc = band + lat = broad

⁷⁰glut = buttock + maxim = largest

TABLE 10.13 Muscles Acting on the Hip and Femur (*cont.*)

Gluteus Medius and Gluteus Minimus Abduct and medially rotate thigh; during walking, shift weight of trunk toward limb with foot on the ground as other foot is lifted

O: Most of lateral surface of ilium between crest and acetabulum **I:** Greater trochanter of femur **N:** Superior gluteal n.

Lateral Rotators. Inferior to the gluteus minimus and deep to the other two gluteal muscles are six muscles called the **lateral rotators**, named for their action on the femur (fig. 10.34). Their action is most clearly visualized when you cross your legs to rest an ankle on your knee, causing your femur to rotate and the knee to point laterally. Thus, they oppose medial rotation by the gluteus medius and minimus. Most of them also abduct or adduct the femur. The abductors are important in walking because when we lift one foot from the ground, they shift the body weight to the other leg and prevent us from falling.

Gemellus⁷¹ Superior (jeh-MEL-us) Laterally rotates extended thigh; abducts flexed thigh; sometimes absent

O: Ischial spine **I:** Greater trochanter of femur **N:** Nerve to obturator internus

Gemellus Inferior Same actions as gemellus superior

O: Ischial tuberosity **I:** Greater trochanter of femur **N:** Nerve to quadratus femoris

Obturator⁷² Externus (OB-too-RAY-tur) Not well understood; thought to laterally rotate thigh in climbing

O: External surface of obturator membrane; pubic and ischial rami **I:** Femur between head and greater trochanter **N:** Obturator n.

Obturator Internus Not well understood; thought to laterally rotate extended thigh and abduct flexed thigh

O: Ramus of ischium; inferior ramus of pubis; anteromedial surface of lesser pelvis **I:** Greater trochanter of femur **N:** Nerve to obturator internus

Piriformis⁷³ (PIR-ih-FOR-mis) Laterally rotates extended thigh; abducts flexed thigh

O: Anterior surface of sacrum; gluteal surface of ilium; capsule of sacroiliac joint **I:** Greater trochanter of femur **N:** Spinal nn. L5-S2

Quadratus Femoris⁷⁴ (quad-RAY-tus FEM-oh-ris) Laterally rotates thigh

O: Ischial tuberosity **I:** Intertrochanteric crest of femur **N:** Nerve to quadratus femoris

Medial (Adductor) Compartment of the Thigh. Fasciae divide the thigh into three compartments: the *anterior (extensor) compartment*, *posterior (flexor) compartment*, and *medial (adductor) compartment*. Muscles of the anterior and posterior compartments function mainly as extensors and flexors of the knee, respectively, and are treated in table 10.14. The five muscles of the medial compartment act primarily as adductors of the thigh (see fig. 10.33), but some of them cross both the hip and knee joints and have additional actions as follows.

Adductor Brevis Adducts thigh

O: Body and inferior ramus of pubis **I:** Linea aspera and spiral line of femur **N:** Obturator n.

Adductor Longus Adducts and medially rotates thigh; flexes thigh at hip

O: Body and inferior ramus of pubis **I:** Linea aspera of femur **N:** Obturator n.

Adductor Magnus Adducts and medially rotates thigh; extends thigh at hip

O: Inferior ramus of pubis; ramus and tuberosity of ischium **I:** Linea aspera, gluteal tuberosity, and medial supracondylar line of femur **N:** Obturator n., tibial n.

Gracilis⁷⁵ (GRASS-ih-lis) Flexes and medially rotates tibia at knee

O: Body and inferior ramus of pubis; ramus of ischium **I:** Medial surface of tibia just below condyle **N:** Obturator n.

Pectineus⁷⁶ (pec-TIN-ee-us) Flexes and adducts thigh

O: Superior ramus of pubis **I:** Spiral line of femur **N:** Femoral n.

⁷¹gemellus = twin

⁷²obtur = to close, stop up

⁷³piri = pear + form = shaped

⁷⁴quadrat = four-sided + femoris = of the thigh or femur

⁷⁵gracil = slender

⁷⁶pectin = comb

TABLE 10.14 Muscles Acting on the Knee and Leg

The following muscles form most of the mass of the thigh and produce their most obvious actions on the knee joint. Some of them, however, cross both the hip and knee joints and produce actions at both, moving the femur, tibia, and fibula.

Anterior (Extensor) Compartment of the Thigh. The anterior compartment of the thigh contains the large quadriceps femoris muscle, the prime mover of knee extension and the most powerful muscle of the body (figs. 10.35 and 10.36). As the name implies, it has four heads: the *rectus femoris*, *vastus lateralis*, *vastus medialis*, and *vastus intermedius*. All four converge on a single **quadriceps (patellar) tendon**, which extends to the patella, then continues as the **patellar ligament** and inserts on the tibial tuberosity. (Remember that a tendon usually extends from muscle to bone, and a ligament from bone to bone.) The patellar ligament is struck with a rubber reflex hammer to test the knee-jerk reflex. The quadriceps extends the knee when you stand up, take a step, or kick a ball. One head, the rectus femoris, contributes to running by acting with the iliopsoas to flex the hip in each airborne phase of the leg's cycle of motion. The rectus femoris also flexes the hip in such actions as high kicks, stair climbing, or simply in drawing the leg forward during a stride.

Crossing the quadriceps from the lateral side of the hip to the medial side of the knee is the narrow, straplike *sartorius*, the longest muscle of the body. It flexes the hip and knee joints and laterally rotates the thigh, as in crossing the legs. It is colloquially called the "tailor's muscle" after the cross-legged posture of a tailor supporting his work on the raised knee.

**FIGURE 10.35** Superficial Anterior Thigh Muscles of the Cadaver. Right thigh.

Quadriceps Femoris (QUAD-rih-seps FEM-oh-ris) All heads insert on tibia through a common tendon and extend the knee, in addition to the actions of individual heads below

Rectus femoris Extends knee; flexes thigh at hip; flexes trunk on hip if thigh is fixed

O: Ilium at anterior inferior spine and superior margin of acetabulum; capsule of hip joint

I: Patella, tibial tuberosity, lateral and medial condyles of tibia

N: Femoral n.

Vastus⁷⁷ lateralis Extends knee; retains patella in groove on femur during knee movements

O: Femur at greater trochanter and intertrochanteric line, gluteal tuberosity, and linea aspera

I: Same as rectus femoris

N: Same as rectus femoris

Vastus medialis Same as vastus lateralis

O: Femur at intertrochanteric line, spiral line, linea aspera, and medial supracondylar line

I: Same as rectus femoris

N: Same as rectus femoris

Vastus intermedius Extends knee

O: Anterior and lateral surfaces of femoral shaft

I: Same as rectus femoris

N: Same as rectus femoris

Sartorius⁷⁸ Aids in knee and hip flexion, as in sitting or climbing; abducts and laterally rotates thigh

O: On and near anterior superior spine of ilium

I: Medial surface of proximal end of tibia

N: Femoral n.

⁷⁷vastus = large, extensive

⁷⁸sartor = tailor

TABLE 10.14 Muscles Acting on the Knee and Leg (*cont.*)

Posterior (Flexor) Compartment of the Thigh. The posterior compartment contains three muscles colloquially known as the **hamstring muscles**; from lateral to medial, they are the *biceps femoris*, *semitendinosus*, and *semimembranosus* (see fig. 10.37). The pit at the back of the knee, known anatomically as the popliteal fossa, is colloquially called the *ham*. The tendons of these muscles can be felt as prominent cords on both sides of the pit—the biceps tendon on the lateral side and the semimembranosus and semitendinosus tendons on the medial side. When wolves attack large prey, they often attempt to sever the hamstring tendons, because this renders the prey helpless. The hamstrings flex the knee, and aided by the gluteus maximus, they extend the hip during walking and running. The semitendinosus is named for its unusually long tendon. This muscle also is usually bisected by a transverse or oblique tendinous band. The semimembranosus is named for the flat shape of its superior attachment.

TABLE 10.14 Muscles Acting on the Knee and Leg (*cont.*)

FIGURE 10.37 Posterior Muscles of the Hip and Thigh.

Biceps Femoris Flexes knee; extends hip; elevates trunk from stooping posture; laterally rotates tibia on femur when knee is flexed; laterally rotates femur when hip is extended; counteracts forward bending at hips

O: Long head: ischial tuberosity
Short head: linea aspera and lateral supracondylar line of femur

I: Head of fibula

N: Tibial n., common fibular n.

Semitendinosus⁷⁹ (**SEM-ee-TEN-din-OH-sus**) Flexes knee; medially rotates tibia on femur when knee is flexed; medially rotates femur when hip is extended; counteracts forward bending at hips

O: Ischial tuberosity

I: Medial surface of upper tibia

N: Tibial n.

Semimembranosus⁸⁰ (**SEM-ee-MEM-bran-OH-sus**) Same as semitendinosus

O: Ischial tuberosity

I: Medial condyle and nearby margin of tibia; intercondylar line and lateral condyle of femur; ligament of popliteal region

N: Tibial n.

Posterior Compartment of the Leg. Most muscles in the posterior compartment of the leg act on the ankle and foot and are reviewed in table 10.15, but the *popliteus* acts on the knee (see fig. 10.41a).

Popliteus⁸¹ (**pop-LIT-ee-us**) Rotates tibia medially on femur if femur is fixed (as in sitting down), or rotates femur laterally on tibia if tibia is fixed (as in standing up); unlocks knee to allow flexion; may prevent forward dislocation of femur during crouching

O: Lateral condyle of femur; lateral meniscus and joint capsule

I: Posterior surface of upper tibia

N: Tibial n.

⁷⁹*semi* = half + *tendinosus* = tendinous

⁸⁰*semi* = half + *membranous* = membranous

⁸¹*poplit* = ham (pit) of the knee

TABLE 10.15 Muscles Acting on the Foot

The fleshy mass of the leg is formed by a group of **crural muscles**, which act on the foot (fig. 10.38). These muscles are tightly bound by fasciae that compress them and aid in the return of blood from the legs. The fasciae separate the crural muscles into anterior, lateral, and posterior compartments (see fig. 10.42b).

Anterior (Extensor) Compartment of the Leg. Muscles of the anterior compartment dorsiflex the ankle and prevent the toes from scuffing the ground during walking. From lateral to medial, these muscles are the *fibularis tertius*, *extensor digitorum longus* (extensor of toes II–V), *extensor hallucis longus* (extensor of the great toe), and *tibialis anterior*. Their tendons are held tightly against the ankle and kept from bowing by two **extensor retinacula** similar to the one at the wrist (fig. 10.39a).

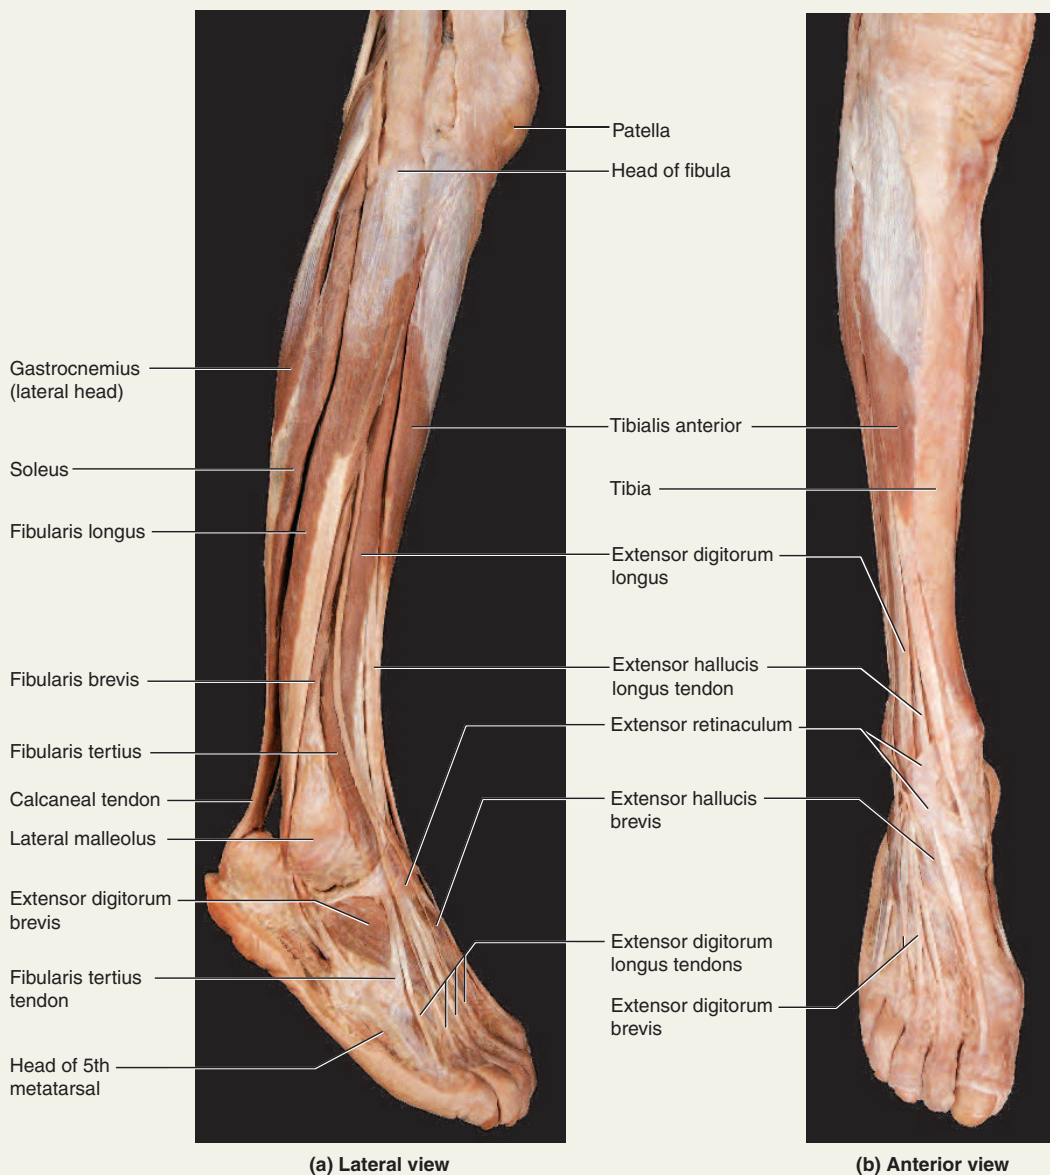

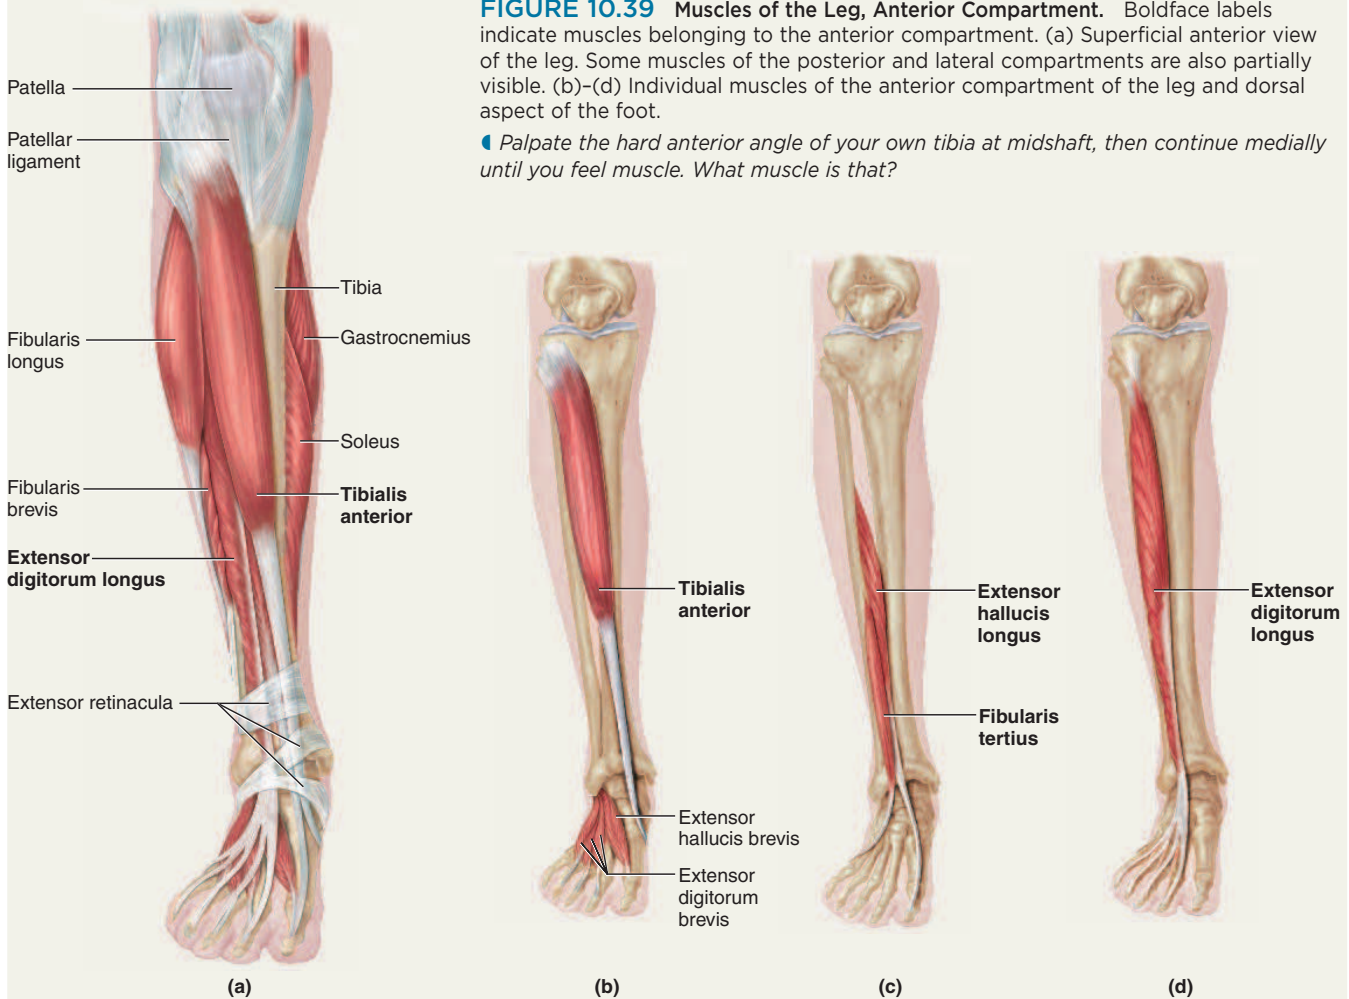

FIGURE 10.38 Superficial Crural Muscles. Right leg of the cadaver.

TABLE 10.15 Muscles Acting on the Foot (*cont.*)

Fibularis (Peroneus)⁸² Tertius⁸³ (FIB-you-LERR-iss TUR-she-us) Dorsiflexes and everts foot during walking, helps toes clear the ground during forward swing

O: Medial surface of lower one-third of fibula, interosseous membrane

I: Metatarsal V

N: Deep fibular (peroneal) n.

Extensor Digitorum Longus (DIDJ-ih-TOE-rum) Extends toes, dorsiflexes foot, tautens plantar aponeurosis

O: Lateral condyle of tibia, shaft of fibula, interosseous membrane

I: Middle and distal phalanges II–V

N: Deep fibular (peroneal) n.

Extensor Hallucis Longus (ha-LOO-sis) Extends great toe, dorsiflexes foot

O: Anterior surface of middle of fibula, interosseous membrane

I: Distal phalanx I

N: Deep fibular (peroneal) n.

Tibialis⁸⁴ Anterior (TIB-ee-AY-lis) Dorsiflexes and inverts foot; resists backward tipping of body (as when standing on a moving boat deck); helps support medial longitudinal arch of foot

O: Lateral condyle and lateral margin of proximal half of tibia; interosseous membrane

I: Medial cuneiform, metatarsal I

N: Deep fibular (peroneal) n.

⁸²perone = pinlike (fibula)

⁸³fibularis = of the fibula + tert = third

⁸⁴tibialis = of the tibia

TABLE 10.15 Muscles Acting on the Foot (*cont.*)

Posterior (Flexor) Compartment of the Leg, Superficial Group. The posterior compartment has superficial and deep muscle groups. The three muscles of the superficial group are plantar flexors: the *gastrocnemius*, *soleus*, and *plantaris* (fig. 10.40). The first two of these, collectively known as the *triceps surae*,⁸⁵ insert on the calcaneus by way of the **calcaneal (Achilles) tendon**. This is the strongest tendon of the body but is nevertheless a common site of sports injuries resulting from sudden stress. The plantaris, a weak synergist of the triceps surae, is a relatively unimportant muscle and is absent from many people; it is not tabulated here. Surgeons often use the plantaris tendon for tendon grafts needed in other parts of the body.

FIGURE 10.40 Superficial Muscles of the Leg, Posterior Compartment. (a) The gastrocnemius. (b) The soleus, deep to the gastrocnemius and sharing the calcaneal tendon with it.

⁸⁵sura = calf of leg

TABLE 10.15 Muscles Acting on the Foot (*cont.*)

Gastrocnemius ⁸⁶ (GAS-trock-NEE-me-us) Plantar flexes foot, flexes knee; active in walking, running, and jumping		
O: Condyles and popliteal surface of femur, lateral supracondylar line, capsule of knee joint	I: Calcaneus	N: Tibial n.
Soleus ⁸⁷ (SO-lee-us) Plantar flexes foot; steadies leg on ankle during standing		
O: Posterior surface of head and proximal one-fourth of fibula; middle one-third of tibia; interosseous membrane	I: Calcaneus	N: Tibial n.
Posterior (Flexor) Compartment of the Leg, Deep Group. There are four muscles in the deep group (fig. 10.41). The <i>flexor digitorum longus</i> , <i>flexor hallucis longus</i> , and <i>tibialis posterior</i> are plantar flexors. The fourth muscle, the <i>popliteus</i> , is described in table 10.14 because it acts on the knee rather than on the foot.		
Flexor Digitorum Longus Flexes phalanges of digits II–V as foot is raised from ground; stabilizes metatarsal heads and keeps distal pads of toes in contact with ground in toe-off and tiptoe movements		
O: Posterior surface of tibial shaft	I: Distal phalanges II–V	N: Tibial n.
Flexor Hallucis Longus Same actions as flexor digitorum longus, but for great toe (digit I)		
O: Distal two-thirds of fibula and interosseous membrane	I: Distal phalanx I	N: Tibial n.
Tibialis Posterior Inverts foot; may assist in strong plantar flexion or control pronation of foot during walking		
O: Posterior surface of proximal half of tibia, fibula, and interosseous membrane	I: Navicular, medial cuneiform, metatarsals II–IV	N: Tibial n.
Lateral (Fibular) Compartment of the Leg. The lateral compartment includes the <i>fibularis brevis</i> and <i>fibularis longus</i> (see figs. 10.38a, 10.39a, 10.42b). They plantar flex and evert the foot. Plantar flexion is important not only in standing on tiptoes but in providing lift and forward thrust each time you take a step.		
Fibularis (Peroneus) Brevis Maintains concavity of sole during toe-off and tiptoeing; may evert foot and limit inversion and help steady leg on foot		
O: Lateral surface of distal two-thirds of fibula	I: Base of metatarsal V	N: Superficial fibular (peroneal) n.
Fibularis (Peroneus) Longus Maintains concavity of sole during toe-off and tiptoeing; everts and plantar flexes foot		
O: Head and lateral surface of proximal two-thirds of fibula	I: Medial cuneiform, metatarsal I	N: Superficial fibular (peroneal) n.

⁸⁶*gastro* = belly + *cnem* = leg⁸⁷Named for its resemblance to a flatfish (sole)

TABLE 10.15 Muscles Acting on the Foot (*cont.*)

FIGURE 10.42 Serial Cross Sections Through the Lower Limb. Each section is taken at the correspondingly lettered level in the figure at the left.

TABLE 10.16 Intrinsic Muscles of the Foot

The intrinsic muscles of the foot help to support the arches and act on the toes in ways that aid locomotion. Several of them are similar in name and location to the intrinsic muscles of the hand.

Dorsal Aspect of Foot. Only one of the intrinsic muscles, the *extensor digitorum brevis*, is on the dorsal (superior) side of the foot. The medial slip of this muscle, serving the great toe, is sometimes called the *extensor hallucis brevis*.

Extensor Digitorum Brevis Extends proximal phalanx I and all phalanges of digits II–IV

O: Calcaneus, inferior extensor retinaculum of ankle

I: Proximal phalanx I, tendons of extensor digitorum longus to II–IV

N: Deep fibular (peroneal) n.

Ventral Layer 1 (Most superficial). All remaining intrinsic muscles are on the ventral (inferior) aspect of the foot or between the metatarsal bones. They are grouped in four layers (fig. 10.43). Dissecting into the foot from the plantar surface, one first encounters a tough fibrous sheet, the **plantar aponeurosis**, between the skin and muscles. It diverges like a fan from the calcaneus to the bases of all the toes, and serves as an origin for several ventral muscles. The ventral muscles include the stout *flexor digitorum brevis* on the midline of the foot, with four tendons that supply all digits except the hallux. It is flanked by the *abductor digiti minimi* laterally and the *abductor hallucis* medially.

Flexor Digitorum Brevis Flexes digits II–IV; supports arches of foot

O: Calcaneus, plantar aponeurosis

I: Middle phalanges II–V

N: Medial plantar n.

Abductor Digiti Minimi⁸⁸ Abducts and flexes little toe; supports arches of foot

O: Calcaneus, plantar aponeurosis

I: Proximal phalanx V

N: Lateral plantar n.

Abductor Hallucis Abducts great toe; supports arches of foot

O: Calcaneus, plantar aponeurosis, flexor retinaculum

I: Proximal phalanx I

N: Medial plantar n.

Ventral Layer 2. The next deeper layer consists of the thick *quadratus plantae* in the middle of the foot and the four *lumbrical* muscles located between the metatarsals.

Quadratus Plantae⁸⁹ (**quad-RAY-tus PLAN-tee**) Same as flexor digitorum longus (table 10.15); flexion of digits II–V and associated locomotor functions

O: Two heads on the medial and lateral sides of calcaneus

I: Distal phalanges II–V via flexor digitorum longus tendons

N: Lateral plantar n.

Lumbricals (LUM-brick-ulz) (Four Muscles) Flex toes II–V

O: Tendon of flexor digitorum longus

I: Proximal phalanges II–V

N: Lateral and medial plantar nn.

Ventral Layer 3. The muscles of this layer serve only the great and little toes. They are the *flexor digiti minimi brevis*, *flexor hallucis brevis*, and *adductor hallucis*. The adductor hallucis has an *oblique head* that extends diagonally from the midplantar region to the base of the great toe, and a transverse head that passes across the bases of digits II–IV and meets the long head at the base of the great toe.

Flexor Digiti Minimi Brevis Flexes little toe

O: Metatarsal V, sheath of fibularis longus

I: Proximal phalanx V

N: Lateral plantar n.

Flexor Hallucis Brevis Flexes great toe

O: Cuboid, lateral cuneiform, tibialis posterior tendon

I: Proximal phalanx I

N: Medial plantar n.

Adductor Hallucis Adducts great toe

O: Metatarsals II–IV, fibularis longus tendon, ligaments at bases of digits III–V

I: Proximal phalanx I

N: Lateral plantar n.

Ventral Layer 4 (Deepest). This layer consists only of the small interosseous muscles located between the metatarsal bones—four dorsal and three plantar. Each dorsal interosseous muscle is bipennate and originates on two adjacent metatarsals. The plantar interosseous muscles are unipennate and originate on only one metatarsal each.

Dorsal Interosseous Muscles (Four Muscles) Abduct toes II–IV

O: Each with two heads arising from facing surfaces of two adjacent metatarsals

I: Proximal phalanges II–IV

N: Lateral plantar n.

Plantar Interosseous Muscles (Three Muscles) Adduct toes III–V

O: Medial aspect of metatarsals III–V

I: Proximal phalanges III–V

N: Lateral plantar n.

⁸⁸*digit* = toe + *minim* = smallest

⁸⁹*quadrat* = four-sided + *plantae* = of the plantar region

TABLE 10.16 Intrinsic Muscles of the Foot (*cont.*)

FIGURE 10.43 Intrinsic Muscles of the Foot. (a)–(d) First through fourth layers, respectively, in ventral (plantar) views. (e) Fourth layer, dorsal view. The muscles belonging to each layer are shown in color and with boldface labels.

Think About It

Not everyone has the same muscles. From the information provided in this chapter, identify at least three muscles that are lacking in some people.

INSIGHT 10.5 Clinical Application

Athletic Injuries

Although the muscular system is subject to fewer diseases than most organ systems, it is particularly vulnerable to injuries resulting from sudden and intense stress placed on muscles and tendons. Each year, thousands of athletes from the high school to professional level sustain some type of injury to their muscles, as do the increasing numbers of people who have taken up running and other forms of physical conditioning. Overzealous exertion without proper conditioning and warm-up is frequently the cause. Compartment syndrome is one common sports injury (see Insight 10.3). Others include:

- Baseball finger**—tears in the extensor tendons of the fingers resulting from the impact of a baseball with the extended fingertip.
- Blocker's arm**—abnormal calcification in the lateral margin of the forearm as a result of repeated impact with opposing players.
- Charley horse**—any painful tear, stiffness, and blood clotting in a muscle. A charley horse of the quadriceps femoris is often caused by football tackles.
- Pitcher's arm**—inflammation at the origin of the flexor carpi muscles resulting from hard wrist flexion in releasing a baseball.
- Pulled groin**—strain in the adductor muscles of the thigh; common in gymnasts and dancers who perform splits and high kicks.
- Pulled hamstrings**—strained hamstring muscles or a partial tear in their tendinous origins, often with a hematoma (blood clot) in the fascia lata. This condition is frequently caused by repetitive kicking (as in football and soccer) or long, hard running.
- Rider's bones**—abnormal calcification in the tendons of the adductor muscles of the medial thigh. It results from prolonged abduction of the thighs when riding horses.
- Rotator cuff injury**—a tear in the tendon of any of the SITS (rotator cuff) muscles, most often the tendon of the supraspinatus. Such injuries are caused by strenuous circumduction of the arm, shoulder dislocation, hard falls or blows

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

22. In the middle of a stride, you have one foot on the ground and you are about to swing the other leg forward. What muscles produce the movements of that leg?
23. Name the muscles that cross both the hip and knee joints and produce actions at both.
24. List the major actions of the muscles of the anterior, medial, and posterior compartments of the thigh.
25. Describe the role of plantar flexion and dorsiflexion in walking. What muscles produce these actions?

to the shoulder, or repetitive use of the arm in a position above horizontal. They are common among baseball pitchers and third basemen, bowlers, swimmers, weight lifters, and in racquet sports. Recurrent inflammation of a SITS tendon can cause a tendon to degenerate and then to rupture in response to moderate stress. Injury causes pain and makes the shoulder joint unstable and subject to dislocation.

Shinsplints—a general term embracing several kinds of injury with pain in the crural region: tendinitis of the tibialis posterior muscle, inflammation of the tibial periosteum, and anterior compartment syndrome. Shinsplints may result from unaccustomed jogging, walking on snowshoes, or any vigorous activity of the legs after a period of relative inactivity.

Tennis elbow—inflammation at the origin of the extensor carpi muscles on the lateral epicondyle of the humerus. It occurs when these muscles are repeatedly tensed during backhand strokes and then strained by sudden impact with the tennis ball. Any activity that requires rotary movements of the forearm and a firm grip of the hand (for example, using a screwdriver) can cause the symptoms of tennis elbow.

Tennis leg—a partial tear in the lateral origin of the gastrocnemius muscle. It results from repeated strains put on the muscle while supporting the body weight on the toes.

Most athletic injuries can be prevented by proper conditioning. A person who suddenly takes up vigorous exercise may not have sufficient muscle and bone mass to withstand the stresses such exercise entails. These must be developed gradually. Stretching exercises keep ligaments and joint capsules supple and therefore reduce injuries. Warm-up exercises promote more efficient and less injurious musculoskeletal function in several ways, discussed in chapter 11. Most of all, moderation is important, as most injuries simply result from overuse of the muscles. “No pain, no gain” is a dangerous misconception.

Muscular injuries can be treated initially with “RICE”: rest, ice, compression, and elevation. Rest prevents further injury and allows repair processes to occur; ice reduces swelling; compression with an elastic bandage helps to prevent fluid accumulation and swelling; and elevation of an injured limb promotes drainage of blood from the affected area and limits further swelling. If these measures are not enough, anti-inflammatory drugs may be employed, including corticosteroids as well as aspirin and other nonsteroidal agents. Serious injuries, such as compartment syndrome, require emergency attention by a physician.

CONNECTIVE ISSUES

Interactions Between the MUSCULAR SYSTEM and Other Organ Systems

■ indicates ways in which this system affects other systems

■ indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

Facial muscles pull on skin to provide facial expressions

Covers and protects superficial muscles; initiates synthesis of calcitriol, which promotes absorption of Ca^{2+} needed for muscle contraction; dissipates heat generated by muscles

SKELETAL SYSTEM

Muscles move and stabilize joints and produce stress that affects ossification, bone remodeling, and shapes of bones

Provides levers on which muscles act; can be a source of Ca^{2+} needed for muscle contraction

NERVOUS SYSTEM

Muscles give expression to thoughts, emotions, and motor commands that arise in the central nervous system

Stimulates muscle contraction; monitors and adjusts muscle tension; adjusts cardiopulmonary functions to meet needs of muscles during exercise

ENDOCRINE SYSTEM

Skeletal muscles protect some endocrine organs

Hormones stimulate growth and development of muscles and regulate levels of glucose and electrolytes important for muscle contraction

CIRCULATORY SYSTEM

Muscle contractions help to move blood through veins; exercise stimulates growth of new blood vessels

Delivers O_2 and nutrients; removes muscle wastes and heat; cardiovascular efficiency, RBC count, hemoglobin level, and density of blood capillaries in muscle greatly affect muscular endurance

LYMPHATIC AND IMMUNE SYSTEMS

Muscle contractions promote lymph flow; exercise elevates level of immune cells and antibodies; excess exercise inhibits immune responses

Lymphatic system drains fluid from muscles; immune system protects muscles from pathogens and promotes tissue repair

RESPIRATORY SYSTEM

Muscle contractions ventilate lungs; muscles of larynx and pharynx regulate air flow; CO_2 generated by exercise stimulates respiratory rate and depth

Provides O_2 and removes CO_2 ; respiratory efficiency greatly affects muscular endurance

URINARY SYSTEM

Muscles control voluntary urination; muscles of pelvic floor support bladder

Eliminates wastes generated by muscles; regulates levels of electrolytes important for muscle contraction

DIGESTIVE SYSTEM

Muscles enable chewing and swallowing; control voluntary defecation; abdominal and lumbar muscles protect lower digestive organs

Absorbs nutrients needed by muscles; liver regulates blood glucose levels and metabolizes lactic acid generated by anaerobic muscle metabolism

REPRODUCTIVE SYSTEM

Muscles contribute to erection and ejaculation; abdominal and pelvic muscles aid childbirth

Gonadal steroids affect muscular growth and development

CHAPTER REVIEW

Review of Key Concepts

10.1 The Structural and Functional Organization of Muscles (p. 320)

- The muscular system consists of the skeletal muscles. The study of this system is *myology*.
- The muscular system serves for body movements, stability, communication, control of body openings and passages, and heat production.
- Each skeletal muscle fiber (cell) is enclosed in a fibrous *endomysium*. A *fascicle* is a bundle of muscle fibers enclosed in a fibrous *perimysium*. The muscle as a whole is enclosed in a fibrous *epimysium*. Connective tissue *fasciae* separate muscles from each other and from the skin.
- Muscles are classified according to the orientation of their fascicles as *fusiform*, *parallel*, *triangular*, *pen-nate*, and *circular*. Circular muscles are also called *sphincters*.
- A muscle may have an *indirect attachment* in which a tendon intervenes between the muscle and bone or a *direct attachment* to a bone in which the muscle fibers reach all the way to the bone.
- A muscle typically has a stationary *origin (head)* on one bone, a mobile *insertion* on another bone, and a thicker *belly* between the origin and insertion. However, a given muscle attachment may serve as the origin during one joint action and the insertion during a different action.
- The *action* of a muscle is either the motion it produces or its role in preventing an unwanted motion. Muscles work in groups across a joint. In a given joint action, the *prime mover* produces most of the force, a *synergist* aids the prime mover or modifies its action, an *antagonist* opposes that action, and a *fixator* prevents a bone from moving. These muscles may change roles in different actions at the same joint.
- Intrinsic muscles* are entirely contained in a region of study such as the head or hand; *extrinsic muscles* have their origin in a region other than the

- site of their action, such as forearm muscles that move the fingers.
- Muscles are innervated by spinal nerves and cranial nerves.
 - Muscle names, often in Latin, usually refer to their size, shape, location, number of heads, orientation, or action.

10.2 Muscles of the Head and Neck (p. 328)

- Humans and other primates have much more expressive faces than other animals, and they have correspondingly complex facial muscles.
- The *frontalis* and *occipitalis* move the scalp, eyebrows, and forehead (table 10.1).
- The eyelid and other tissues around the eye are moved by the *orbicularis oculi*, *levator palpebrae superioris*, and *corrugator supercilii* (table 10.1).
- The *nasalis* muscle flares and compresses the nostrils (table 10.1).
- The lips are acted upon by the *orbicularis oris*, *levator labii superioris*, *levator anguli oris*, *zygomaticus major* and *minor*, *risorius*, *depressor anguli oris*, *depressor labii inferioris*, and *mentalis* (table 10.1).
- The *buccinator muscles* act upon the cheeks (table 10.1).
- The *platysma* acts upon the mandible and the skin of the neck (table 10.1).
- The tongue is controlled by a set of unnamed *intrinsic muscles* and several *extrinsic muscles*: the *genioglossus*, *hyoglossus*, *styloglossus*, and *palatoglossus* (table 10.2).
- Biting and chewing are achieved by the actions of the *temporalis*, *masseter*, *medial pterygoid*, and *lateral pterygoid* muscles on the mandible (table 10.2).
- Four muscles are associated with the hyoid bone and located superior to it, and are thus called the *suprahyoid group*: the *digastric*, *geniohyoid*, *mylohyoid*, and *stylohyoid* (table 10.2). These muscles act on the mandible and hyoid bone to forcibly open the mouth and to aid in swallowing.

- Another four muscles associated with the hyoid bone are inferior to it and therefore called the *infrahyoid group*: the *omohyoid*, *sternohyoid*, *thyrohyoid*, and *sternothyroid* (table 10.2). These muscles depress or fix the hyoid and elevate or depress the larynx, especially in association with swallowing.
- The *superior*, *middle*, and *inferior pharyngeal constrictors* contract in sequence to force food down and into the esophagus (table 10.2).
- The *sternocleidomastoid* and three *scalene* muscles flex the neck. The *trapezius*, *splenius capitis*, and *semispinalis capitis* are the major extensors of the neck. Some of these are also employed in rotation of the head (table 10.3).

10.3 Muscles of the Trunk (p. 339)

- Breathing is achieved by the muscles of respiration, especially the *diaphragm*, *external intercostals*, *internal intercostals*, and *innermost intercostals* (table 10.4).
- The abdominal wall is supported by the sheetlike *external abdominal oblique*, *internal abdominal oblique*, and *transverse abdominal* muscles, and by the *rectus abdominis*. These support the abdominal viscera, stabilize the vertebral column during lifting, and aid in respiration, urination, defecation, vomiting, and childbirth (table 10.5).
- The back has numerous complex muscles that extend, rotate, and flex the vertebral column and aid in breathing. The major superficial muscle is the *erector spinae* (which is subdivided into the *iliocostalis*, *longissimus*, and *spinalis* muscle columns). The deep back muscles include the *semispinalis thoracis*, *quadratus lumborum*, and *multifidus* (table 10.6).
- The pelvic floor is spanned by three layers of muscles and fasciae (table 10.7). The anal canal, urethra, and vagina penetrate the pelvic floor

muscles and open into the *perineum*, a diamond-shaped space between the thighs bordered by the pubic symphysis, coccyx, and ischial tuberosities. The anterior half of the perineum is the *urogenital triangle*, and the posterior half is the *anal triangle*.

5. The most superficial compartment of the pelvic floor is the *superficial perineal space*. It contains two major muscles: the *ischiocavernosus* and *bulbospongiosus*.
6. The middle compartment of the pelvic floor contains the *external urethral sphincter* and *external anal sphincter*, and in females, the *compressor urethrae*.
7. The deepest compartment of the pelvic floor is the *pelvic diaphragm*. It consists of two muscles: the *levator ani* and *coccygeus*.

10.4 Muscles Acting on the Shoulder and Upper Limb (p. 349)

1. The limbs afford especially good demonstrations of the organization of muscle groups into *compartments*, each with its own nerve and blood supply and separated from others by interosseous membranes and *intermuscular septa*.
2. Muscles that act on the pectoral girdle originate on the axial skeleton and insert on the clavicle and scapula. They fall into an anterior group that includes the *pectoralis minor* and *serratus anterior*, and a posterior group that includes the superficial *trapezius* and three deeper muscles, the *levator scapulae*, *rhomboideus major*, and *rhomboideus minor* (table 10.8).
3. Muscles that act on the arm (humerus) originate mainly on the pectoral girdle and axial skeleton and cross the shoulder joint. These include the *pectoralis major*, *latissimus dorsi*, *deltoid*, *teres major*, *coracobrachialis*, and four *rotator cuff (SITS)* muscles: the *supraspinatus*, *infraspinatus*, *teres minor*, and *subscapularis* (table 10.9).
4. Muscles that act on the forearm and elbow are located in both the arm (the *brachialis*, *biceps brachii*, and *triceps brachii*) and the forearm (the *brachioradialis*, *anconeus*, *pronator quadratus*, *pronator teres*, and *supinator*) (table 10.10).
5. Most tendons of the forearm muscles pass under a *flexor retinaculum* on the anterior side of the wrist or an *extensor retinaculum* on the posterior side of the wrist. The space between the flexor retinaculum and carpal bones is called the *carpal tunnel*.
6. Most muscles whose origins and bellies are in the forearm have insertions in, and act upon, the wrist and hand. Several of them, however, have origins on the humerus and also cross the elbow joint. Therefore, they also contribute slightly to actions of the elbow. Deep fasciae divide the forearm muscles into *anterior* and *posterior compartments* and separate those of each compartment into superficial and deep layers.
7. Anterior compartment muscles are mainly flexors of the wrist and hand. Superficial muscles of the anterior compartment include the *palmaris longus* and *flexor carpi radialis*, which form the two most prominent tendons of the anterior wrist, and the *flexor carpi ulnaris* and *flexor digitorum superficialis*. The deep muscles of the anterior compartment include the *flexor digitorum profundus* and *flexor pollicis longus* (table 10.11).
8. Posterior compartment muscles are mainly extensors of the wrist and hand. Superficial muscles of the posterior compartment include the *extensor carpi radialis longus*, *extensor carpi radialis brevis*, *extensor digitorum*, *extensor digiti minimi*, and *extensor carpi ulnaris*. Deep muscles of the posterior compartment include the *abductor pollicis longus*, *extensor pollicis brevis*, *extensor pollicis longus*, and *extensor indicis*.
9. Intrinsic muscles of the hand assist the forearm muscles and make movements of the digits more precise. They are divided into a thenar, hypothenar, and midpalmar group (table 10.12).
10. The *thenar group* of muscles form the thick fleshy mass at the base of the thumb and the web between the thumb and palm. They move the thumb. They include the *adductor pollicis*, *abductor pollicis brevis*, *flexor pollicis brevis*, and *opponens pollicis*.
11. The *hypothenar group* muscles form the fleshy *hypothenar eminence* at the base of the little finger, and are

concerned with movements of that digit. They include the *abductor digiti minimi*, *flexor digiti minimi brevis*, and *opponens digiti minimi*.

12. The *midpalmar group* of muscles span the palm and include four *dorsal interosseous muscles*, three *palmar interosseous muscles*, and four *lumbrical muscles*, located between the metacarpal bones. They act on digits II through V.

10.5 Muscles Acting on the Hip and Lower Limb (p. 366)

1. Most muscles that act on the femur originate on the hip bone (table 10.13). The two major anterior muscles of this group are the *iliacus* and the *psaos major*, collectively called the *iliopsoas*.
2. Superficial muscles on the lateral and posterior sides of the hip include the *tensor fasciae latae*, *gluteus maximus*, *gluteus medius*, and *gluteus minimus*. The tendons of the first two of these muscles join the *fascia lata* to form the fibrous *iliotibial band* on the lateral aspect of the thigh.
3. Deep muscles on the lateral aspect of the hip, known as the *lateral rotators*, include the *gemellus superior*, *gemellus inferior*, *obturator externus*, *obturator internus*, *piriformis*, and *quadratus femoris*. The principal actions of these muscles are abduction and lateral rotation of the femur.
4. Deep fasciae divide the thigh muscles into an *anterior (extensor) compartment*, *medial (adductor) compartment*, and *posterior (flexor) compartment*.
5. Muscles of the medial compartment act as adductors of the femur. These include the *adductor brevis*, *adductor longus*, *adductor magnus*, *gracilis*, and *pectineus*.
6. Muscles of the anterior compartment act mainly as extensors of the knee. These include the four heads of the *quadriceps femoris*—*rectus femoris*, *vastus lateralis*, *vastus medialis*, and *vastus intermedius*—and the *sartorius* (table 10.14).
7. Muscles of the posterior compartment act as extensors of the hip and flexors of the knee. These are the *biceps femoris*, *semitendinosus*, and *semimembranosus*, known colloquially as the *hamstring muscles*.

8. Muscles of the leg are divided into anterior, posterior, and lateral compartments (table 10.15). Most of them act on the foot.
9. Anterior compartment muscles of the leg include the *fibularis tertius*, *extensor digitorum longus*, *extensor hallucis longus*, and *tibialis anterior*.
10. Superficial posterior compartment muscles include the *popliteus*, which acts on the knee, and two muscles, the *gastrocnemius* and *soleus*, collectively also known as the *triceps surae* (these share the calcaneal tendon to the heel).
11. Deep posterior compartment muscles include the *flexor digitorum longus*, *flexor hallucis longus*, and *tibialis posterior*.
12. Lateral compartment muscles include the *fibularis brevis* and *fibularis longus*.
13. Intrinsic muscles of the foot support the arches and act on the toes, and resemble intrinsic muscles of the hand. The *extensor digitorum brevis* is located dorsally. The others are ventral and are arranged in layers (table 10.16).
14. The layer 1 (most superficial) intrinsic muscles of the foot are the *flexor digitorum brevis*, *abductor digiti minimi*, and *abductor hallucis*; layer 2 comprises the *quadratus plantae* and four *lumbrical muscles*; layer 3 includes the *flexor digiti minimi brevis*, *flexor hallucis brevis*, and *adductor hallucis*; and layer 4 (deepest) includes four *dorsal interosseous muscles* and three *plantar interosseous muscles*.

Testing Your Recall

1. Which of the following muscles is the prime mover in spitting out a mouthful of liquid?
 - a. platysma
 - b. buccinator
 - c. risorius
 - d. masseter
 - e. palatoglossus
2. Each muscle fiber has a sleeve of areolar connective tissue around it called
 - a. the fascia.
 - b. the endomysium.
 - c. the perimysium.
 - d. the epimysium.
 - e. the intermuscular septum.
3. Which of these is *not* a suprahyoid muscle?
 - a. genioglossus
 - b. geniohyoid
 - c. stylohyoid
 - d. mylohyoid
 - e. digastric
4. Which of these muscles is an extensor of the neck?
 - a. external oblique
 - b. sternocleidomastoid
 - c. splenius capitis
 - d. iliocostalis
 - e. latissimus dorsi
5. Which of these muscles of the pelvic floor is the deepest?
 - a. superficial transverse perineal
 - b. bulbospongiosus
 - c. ischiocavernosus
 - d. deep transverse perineal
 - e. levator ani
6. Which of these actions is *not* performed by the trapezius?
 - a. extension of the neck
 - b. depression of the scapula
 - c. elevation of the scapula
 - d. rotation of the scapula
 - e. adduction of the humerus
7. Both the hands and feet are acted upon by a muscle or muscles called
 - a. the extensor digitorum.
 - b. the abductor digiti minimi.
 - c. the flexor digitorum profundus.
 - d. the abductor hallucis.
 - e. the flexor digitorum longus.
8. Which of the following muscles does *not* extend the hip joint?
 - a. quadriceps femoris
 - b. gluteus maximus
 - c. biceps femoris
 - d. semitendinosus
 - e. semimembranosus
9. Both the gastrocnemius and _____ muscles insert on the heel by way of the calcaneal tendon.
 - a. semimembranosus
 - b. tibialis posterior
 - c. tibialis anterior
 - d. soleus
 - e. plantaris
10. Which of the following muscles raises the upper lip?
 - a. levator palpebrae superioris
 - b. orbicularis oris
 - c. zygomaticus minor
 - d. masseter
 - e. mentalis
11. The _____ of a muscle is the point where it attaches to a relatively stationary bone.
12. A bundle of muscle fibers surrounded by perimysium is called a/an _____.
13. The _____ is the muscle that generates the most force in a given joint movement.
14. The three large muscles on the posterior side of the thigh are commonly known as the _____ muscles.
15. Connective tissue bands called _____ prevent flexor tendons of the forearm and leg from rising like bowstrings.
16. The anterior half of the perineum is a region called the _____.
17. The abdominal aponeuroses converge on a median fibrous band on the abdomen called the _____.
18. A muscle that works with another to produce the same or similar movement is called a/an _____.
19. A muscle somewhat like a feather, with fibers obliquely approaching its tendon from both sides, is called a/an _____ muscle.
20. A circular muscle that closes a body opening is called a/an _____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Cutting the phrenic nerves would paralyze the prime mover of respiration.
- The orbicularis oculi is a sphincter.
- The origin of the sternocleidomastoid muscle is the mastoid process of the skull.
- To push someone away from you, you would use the serratus anterior more than the trapezius.
- Both the extensor digitorum and extensor digiti minimi extend the little finger.
- Curling the toes employs the quadratus plantae.
- The scalenes are superficial to the trapezius.
- Exhaling requires contraction of the internal intercostal muscles.
- Hamstring injuries often result from rapid flexion of the knee.
- The tibialis anterior and tibialis posterior are synergists.

Answers in appendix B

Testing Your Comprehension

- Radical mastectomy, once a common treatment for breast cancer, involved removal of the pectoralis major along with the breast. What functional impairments would result from this? What synergists could a physical therapist train a patient to use to recover some lost function?
- Removal of cancerous lymph nodes from the neck sometimes requires removal of the sternocleidomastoid on that side. How would this affect a patient's range of head movement?
- Poorly conditioned, middle-aged people may suffer a rupture of the calcaneal tendon when the foot is suddenly dorsiflexed. Explain each of the following signs of a ruptured calcaneal tendon: (a) a prominent lump typically appears in the calf; (b) the foot can be dorsiflexed farther than usual; and (c) the patient cannot plantar flex the foot very effectively.
- Women who habitually wear high heels may suffer painful "high heel syndrome" when they go barefoot or wear flat shoes. What muscle(s) and tendon(s) are involved? Explain.
- A student moving out of a dormitory kneels down, in correct fashion, to lift a heavy box of books. What prime movers are involved as he straightens his legs to lift the box?

B.6 Muscle Test (fig. B.15) 402

B.1 The Importance of External Anatomy

In the study of human anatomy, it is easy to become so preoccupied with internal structure that we forget the importance of what we can see and feel externally. Yet external anatomy and appearance are major concerns in giving a physical examination and in many aspects of patient care. A knowledge of the body's surface landmarks is essential to one's competence in physical therapy, cardiopulmonary resuscitation, surgery, making X-rays and electrocardiograms, giving injections, drawing blood, listening to heart and respiratory sounds, measuring the pulse and blood pressure, and finding pressure points to stop arterial bleeding, among other procedures. A misguided attempt to perform some of these procedures while disregarding or misunderstanding external anatomy can be very harmful and even fatal to a patient.

Having just studied skeletal and muscular anatomy in the preceding chapters, this is an opportune time for you to study the body surface. Much of what we see there reflects the underlying structure of the superficial bones and muscles. A broad photographic overview of surface anatomy is given in atlas A (see fig. A.5, p. 33). In the following pages, we examine the body literally from head (fig. B.1) to toe (fig. B.14), studying its regions in more detail. To make the most profitable use of this atlas, refer to the skeletal and muscular anatomy in chapters 8 to 10. Relate drawings of the clavicles in chapter 8 to the photograph in figure B.1, for example. Study the shape of the scapula in chapter 8 and see how much of it you can trace

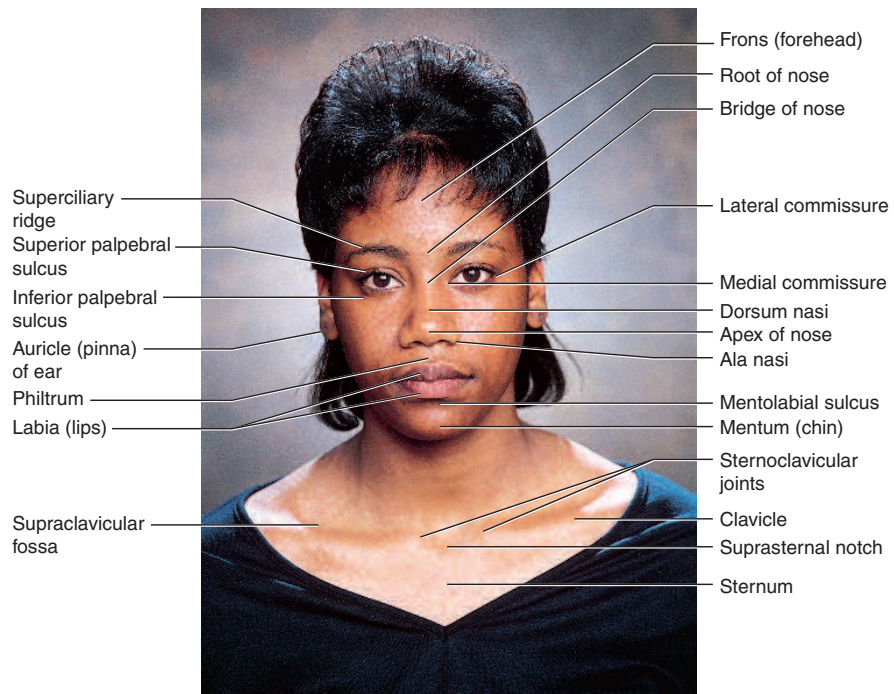

on the photographs in figure B.3. See if you can relate the tendons visible on the hand (fig. B.8) to the muscles of the forearm illustrated in chapter 10, and the external markings of the pelvis (fig. B.4) to bone structure in chapter 8.

For learning surface anatomy, there is a resource available to you that is far more valuable than any laboratory model or textbook illustration—your own body. For the best understanding of human structure, compare the art and photographs in this book with your body or with structures visible on a study partner. In addition to bones and muscles, you can palpate a number of superficial arteries, veins, tendons, ligaments, and cartilages, among other structures. By palpating regions such as the shoulder, elbow, or ankle, you can develop a mental image of the subsurface structures better than you can obtain by looking at two-dimensional textbook images. And the more you can study with other people, the more you will appreciate the variations in human structure and be able to apply your knowledge to your future patients or clients, who will not look quite like any textbook diagram or photograph you have ever seen. Through comparisons of art, photography, and the living body, you will get a much deeper understanding of the body than if you were to study this atlas in isolation from the earlier chapters.

At the end of this atlas, you can test your knowledge of externally visible muscle anatomy. The two photographs in figure B.15 have 30 numbered muscles and a list of 26 names, some of which are shown more than once in the photographs and some of which are not shown at all. Identify the muscles to your best ability without looking back at the previous illustrations, and then check your answers in appendix B at the back of the book.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Aerobic and anaerobic metabolism (pp. 81–82)
- Plasma membrane proteins as receptors (p. 94)
- Voltage- and ligand-regulated ion gates in the plasma membrane (p. 94)
- Structure of a neuron (p. 170)
- General histology of the three types of muscle (p. 172)
- Desmosomes and gap junctions (p. 173)
- Connective tissues of a muscle (p. 321)

Muscular System

Movement is a fundamental characteristic of all living organisms, from bacteria to humans. Even plants and other seemingly immobile organisms move cellular components from place to place. Across the entire spectrum of life, the molecular mechanisms of movement are very similar, involving motor proteins such as myosin and dynein. But in animals, movement has developed to the highest degree, with the evolution of **muscle cells** specialized for this function. A muscle cell is essentially a device for converting the chemical energy of ATP into the mechanical energy of movement.

The three types of muscular tissue—skeletal, cardiac, and smooth—were described and compared in chapter 5. Cardiac and smooth muscle are further described in this chapter, and cardiac muscle is discussed most extensively in chapter 19. Most of the present chapter, however, concerns **skeletal muscle**, the type that holds the body erect against the pull of gravity and produces its outwardly visible movements.

This chapter treats the structure, contraction, and metabolism of skeletal muscle at the molecular, cellular, and tissue levels of organization. Understanding muscle at these levels provides an indispensable basis for understanding such aspects of motor performance as warm-up, quickness, strength, endurance, and fatigue. Such factors have obvious relevance to athletic performance, and they become very important when a lack of physical conditioning, old age, or injury interferes with a person's ability to carry out everyday tasks or meet the extra demands for speed or strength that we all occasionally encounter.

11.1 Types and Characteristics of Muscular Tissue

Objectives

When you have completed this section, you should be able to

- describe the physiological properties that all muscle types have in common;
- list the defining characteristics of skeletal muscle; and
- discuss the possible elastic functions of the connective tissue components of a muscle.

Universal Characteristics of Muscle

The functions of the muscular system were detailed in the preceding chapter: movement, stability, communication, control of body openings and passages, and heat production. To carry out those functions, all muscle cells have the following characteristics:

- **Responsiveness (excitability).** Responsiveness is a property of all living cells, but muscle and nerve cells have developed this property to the highest degree. When stimulated by chemical signals (neurotransmitters), stretch, and other stimuli, muscle cells respond with electrical changes across the plasma membrane.
- **Conductivity.** Stimulation of a muscle fiber produces more than a local effect. The local electrical change triggers a wave of excitation that travels rapidly along the fiber and initiates processes leading to muscle contraction.
- **Contractility.** Muscle fibers are unique in their ability to shorten substantially when stimulated. This enables them to pull on bones and other tissues and create movements of the body and its parts.
- **Extensibility.** In order to contract, a muscle cell must also be extensible—able to stretch again between contractions. Most cells rupture if they are stretched even a little, but skeletal muscle fibers can stretch to as much as three times their contracted length.
- **Elasticity.** When a muscle cell is stretched and then the tension is released, it recoils to its original resting length. Elasticity, commonly misunderstood as the ability to stretch, refers to this tendency of a muscle cell (or other structures) to return to the original length when tension is released.

Skeletal Muscle

Skeletal muscle may be defined as voluntary striated muscle that is usually attached to one or more bones. A skeletal muscle exhibits alternating light and dark transverse bands, or **striations** (fig. 11.1), that result from an overlapping arrangement of their internal contractile proteins. Skeletal muscle is called **voluntary** because it is usually subject to conscious control. The other types of muscle are **involuntary** (not usually under conscious control), and they are never attached to bones.

A typical skeletal muscle cell is about 100 μm in diameter and 3 cm (30,000 μm) long; some are as thick as 500 μm and as long as 30 cm. Because of their extraordinary length, skeletal muscle cells are usually called **muscle fibers** or **myofibers**.

Recall from chapter 10 that a skeletal muscle is composed not only of muscular tissue, but also of fibrous connective tissue: the *endomysium* that surrounds each

FIGURE 11.1 Skeletal Muscle Fibers.

• What tissue characteristics evident in this photo distinguish this from cardiac and smooth muscle?

muscle fiber, the *perimysium* that bundles muscle fibers together into fascicles, and the *epimysium* that encloses the entire muscle (see fig. 10.1, p. 321). These connective tissues are continuous with the collagen fibers of tendons and those, in turn, with the collagen of the bone matrix. Thus, when a muscle fiber contracts, it pulls on these collagen fibers and usually moves a bone.

Collagen is neither excitable nor contractile, but it is somewhat extensible and elastic. When a muscle lengthens, for example during extension of a joint, its collagenous components resist excessive stretching and protect the muscle from injury. When a muscle relaxes, elastic recoil of the collagen may help to return the muscle to its resting length and keep it from becoming too flaccid. Some authorities contend that recoil of the tendons and other collagenous tissues contribute significantly to the power output and efficiency of a muscle. When you are running, for example, recoil of the calcaneal tendon may help to lift the heel and produce some of the thrust as your toes push off from the ground. (Such recoil contributes significantly to the long, energy-efficient leaping of kangaroos.) Others feel that the elasticity of these components is negligible in humans and that the recoil is produced entirely by components within the muscle fibers.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Define responsiveness, conductivity, contractility, extensibility, and elasticity. State why each of these properties is necessary for muscle function.
2. How is skeletal muscle different from the other types of muscle?
3. Name and define the three layers of collagenous connective tissue in a skeletal muscle.

11.2 Microscopic Anatomy of Skeletal Muscle

Objectives

When you have completed this section, you should be able to

- describe the structural components of a muscle fiber;
- relate the striations of a muscle fiber to the overlapping arrangement of its protein filaments; and
- name the major proteins of a muscle fiber and state the function of each.

The Muscle Fiber

In order to understand muscle function, you must know how the organelles and macromolecules of a muscle fiber are arranged. Perhaps more than any other cell, a muscle fiber exemplifies the adage, Form follows function. It has a complex, tightly organized internal structure in which even the spatial arrangement of protein molecules is closely tied to its contractile function.

The plasma membrane of a muscle fiber is called the **sarcolemma**,¹ and its cytoplasm is called the **sarcoplasm**. The sarcoplasm is occupied mainly by long protein bundles called **myofibrils** about 1 μm in diameter (fig. 11.2)—not to be confused with *myofibers*, the muscle cells themselves. It also contains an abundance of **glycogen**, a starchlike carbohydrate that provides energy for the cell during heightened levels of exercise, and the red pigment **myoglobin**, which stores oxygen until needed for muscular activity.

Muscle fibers have multiple flattened or sausage-shaped nuclei pressed against the inside of the sarcolemma. Their unusual multinuclear condition results from their embryonic development—several stem cells called **myoblasts**² fuse to produce each muscle fiber, with each myoblast contributing a nucleus to the mature fiber. Some myoblasts remain as unspecialized **satellite cells** between the muscle fiber and endomysium. When a muscle is injured, satellite cells can multiply and produce new muscle fibers to some degree. Most muscle repair, however, is by fibrosis rather than by regeneration of functional muscle.

Most other organelles of the cell, such as mitochondria, are packed into the spaces between the myofibrils. The smooth endoplasmic reticulum, here called the **sarcoplasmic reticulum (SR)**, forms a network around each myofibril. It periodically exhibits dilated end-sacs called **terminal cisternae**, which cross the muscle fiber from one side to the other. The sarcolemma has tubular

¹sarco = flesh, muscle + lemma = husk

²myo = muscle + blast = precursor

FIGURE 11.2 Structure of a Skeletal Muscle Fiber. This is a single cell containing 11 myofibrils (9 shown at the left end and 2 cut off at midfiber). A few myofilaments are shown projecting from the myofibril at the left. Their finer structure is shown in figure 11.3.

Why is it important for the transverse tubule to be so closely associated with the terminal cisternae?

infoldings called **transverse (T) tubules**, which penetrate through the cell and emerge on the other side. Each T tubule is closely associated with two terminal cisternae, running alongside it on each side. A T tubule and the two terminal cisternae associated with it constitute a **triad**. The SR is a reservoir of calcium ions; it has gated channels in its membrane that open at the right times to release a flood of Ca^{2+} into the cytosol, where the calcium activates the muscle contraction process. The T tubule signals the SR when to release these calcium bursts.

Myofilaments

Let's return to the myofibrils just mentioned—the long protein cords that fill most of the muscle cell—and look at their structure at a finer, molecular level. It is here that the key to muscle contraction lies. Each myofibril is a bundle of parallel protein microfilaments called

myofilaments (see the left end of figure 11.2). There are three kinds of myofilaments:

1. **Thick filaments** (fig. 11.3a, b, d) are about 15 nm in diameter. Each is made of several hundred molecules of a protein called **myosin**. A myosin molecule is shaped like a golf club, with two chains intertwined to form a shaftlike *tail* and a double globular *head* projecting from it at an angle. A thick filament may be likened to a bundle of 200 to 500 such “golf clubs,” with their heads directed outward in a helical array around the bundle. The heads on one half of the thick filament angle to the left, and the heads on the other half angle to the right; in the middle is a *bare zone* with no heads.
2. **Thin filaments** (fig. 11.3c, d), 7 nm in diameter, are composed primarily of two intertwined strands of a protein called **fibrous (F) actin**. Each F actin is like

FIGURE 11.3 Molecular Structure of Thick and Thin Filaments. (a) A single myosin molecule consists of two intertwined polypeptides forming a twisted filamentous tail and a double globular head. (b) A thick filament consists of 200 to 500 myosin molecules bundled together with the heads projecting outward in a helical array. (c) A thin filament consists of two intertwined chains of G actin molecules, smaller filamentous tropomyosin molecules, and a calcium-binding protein called troponin associated with the tropomyosin. (d) A region of overlap between the thick and thin myofilaments.

a bead necklace—a string of subunits called **globular (G) actin**. Each G actin has an **active site** that can bind to the head of a myosin molecule. A thin filament also has 40 to 60 molecules of yet another protein called **tropomyosin**. When a muscle fiber is relaxed, tropomyosin blocks the active sites of six or seven G actins and prevents myosin from binding to them. Each tropomyosin molecule, in turn, has a smaller calcium-binding protein called **troponin** bound to it.

3. **Elastic filaments** (see fig. 11.5b), 1 nm in diameter, are made of a huge springy protein called **titin³ (connectin)**. They flank each thick filament and anchor it to a structure called the **Z disc**. This helps to stabilize the thick filament, center it between the thin filaments, and prevent overstretching.

Myosin and actin are called **contractile proteins** because they do the work of shortening the muscle fiber. Tropomyosin and troponin are called **regulatory proteins** because they act like a switch to determine when the fiber can contract and when it cannot. Several clues as to how they do this may be apparent from what has already been said—calcium ions are released into the sarcoplasm to activate contraction; calcium binds to troponin; troponin is also bound to tropomyosin; and tropomyosin blocks the active sites of actin, so that myosin cannot bind to it when the muscle is not stimulated. Perhaps you are already forming some idea of the contraction mechanism to be explained shortly.

At least seven other accessory proteins occur in the thick and thin filaments or are associated with them. Among other functions, they anchor the myofilaments, regulate their length, and keep them aligned with each other for optimal contractile effectiveness. The most clinically important of these is **dystrophin**, an enormous protein located between the sarcolemma and the outermost myofilaments. It links actin filaments to a peripheral protein on the inner face of the sarcolemma (fig. 11.4). That protein, in turn, is linked to a complex of transmembrane proteins; they are linked to proteins external to the muscle fiber; and ultimately, these linkages lead to a collagen-glycoprotein layer, the **basal lamina**, and to the fibrous endomysium surrounding the entire muscle fiber. Thus, dystrophin is a key element transferring the forces of the myofilament movement to the connective tissues of the muscle as a whole. Genetic defects in dystrophin are responsible for the disabling disease, **muscular dystrophy** (see Insight 11.5).

Striations

Myosin and actin are not unique to muscle; these proteins occur in all cells, where they function in cellular motility, mitosis, and transport of intracellular materials. In skeletal and cardiac muscle they are especially abundant, however,

³tit = giant + in = protein.

FIGURE 11.4 Dystrophin. One end of this large protein is linked to the actin of a thin myofilament near the surface of the muscle fiber. The other is linked to a peripheral protein on the inside of the sarcolemma. Through a complex of transmembrane and extracellular proteins, dystrophin transfers the force of myofilament movement to the basal lamina, endomysium, and other extracellular components of the muscle.

and are organized in a precise array that accounts for the striations of these two muscle types (fig. 11.5).

Striated muscle has dark **A bands** alternating with lighter **I bands**. (*A* stands for *anisotropic* and *I* for *isotropic*, which refers to the way these bands affect polarized light. To help remember which band is which, think “dArk” and “lIght.”) Each A band consists of thick filaments lying side by side. Part of the A band, where thick and thin filaments overlap, is especially dark. In this region, each thick filament is surrounded by thin filaments. In the middle of the A band, there is a lighter region called the **H band**,⁴ into which the thin filaments do not reach. The thick filaments originate at a dark **M line** in the middle of the H band.

Each light I band is bisected by a dark narrow **Z disc**⁵ (**Z line**), which provides anchorage for the thin filaments and elastic filaments. Each segment of a myofibril from one Z disc to the next is called a **sarcomere**⁶ (SAR-co-meer),

⁴H = *helle* = bright

⁵Z = *Zwischenscheibe* = “between disc”

⁶*sarco* = muscle + *mere* = part, segment

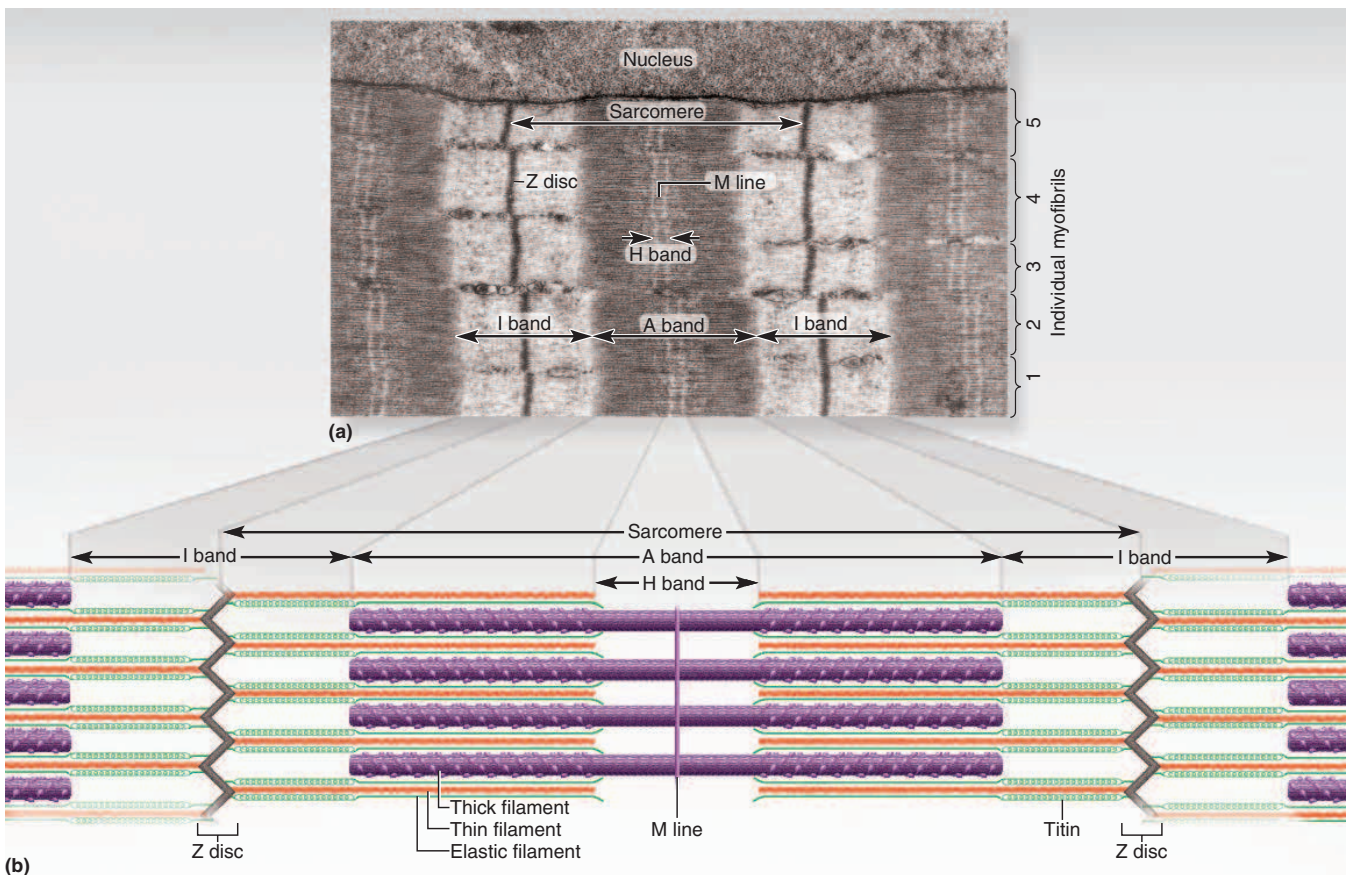

FIGURE 11.5 Muscle Striations and Their Molecular Basis. (a) Five myofibrils of a single muscle fiber, showing the striations in the relaxed state (TEM). (b) The overlapping pattern of thick and thin myofilaments that accounts for the striations seen in part (a).

TABLE 11.1 Structural Components of a Muscle Fiber

Term	Definition
<i>General structure and contents of the muscle fiber</i>	
Sarcolemma	The plasma membrane of a muscle fiber
Sarcoplasm	The cytoplasm of a muscle fiber
Glycogen	An energy-storage polysaccharide abundant in muscle
Myoglobin	An oxygen-storing red pigment of muscle
T tubule	A tunnel-like extension of the sarcolemma extending from one side of the muscle fiber to the other; conveys electrical signals from the cell surface to its interior
Sarcoplasmic reticulum	The smooth ER of a muscle fiber; a Ca ²⁺ reservoir
Terminal cisternae	The dilated ends of sarcoplasmic reticulum adjacent to a T tubule
<i>Myofibrils</i>	
Myofibril	A bundle of protein microfilaments (myofilaments)
Myofilament	A threadlike complex of several hundred contractile protein molecules
Thick filament	A myofilament about 11 nm in diameter composed of bundled myosin molecules
Elastic filament	A myofilament about 1 nm in diameter composed of a giant protein, titin, that flanks a thick filament and anchors it to a Z disc
Thin filament	A myofilament about 5 to 6 nm in diameter composed of actin, troponin, and tropomyosin
Myosin	A protein with a long shaftlike tail and a globular head; constitutes the thick myofilament
F actin	A fibrous protein made of a long chain of G actin molecules twisted into a helix; main protein of the thin myofilament
G actin	A globular subunit of F actin with an active site for binding a myosin head
Regulatory proteins	Troponin and tropomyosin, proteins that do not directly engage in the sliding filament process of muscle contraction but regulate myosin-actin binding
Tropomyosin	A regulatory protein that lies in the groove of F actin and, in relaxed muscle, blocks the myosin-binding active sites
Troponin	A regulatory protein associated with tropomyosin that acts as a calcium receptor
Titin	A springy protein that forms the elastic filaments
Dystrophin	A large protein that links thin filaments to transmembrane proteins; transfers the force of sarcomere contraction to the extracellular proteins of the muscle
<i>Striations and sarcomeres</i>	
Striations	Alternating light and dark transverse bands across a myofibril
A band	Dark band formed by parallel thick filaments that partly overlap the thin filaments
H band	A lighter region in the middle of an A band that contains thick filaments only; thin filaments do not reach this far into the A band in relaxed muscle
M line	A dark line in the middle of an H band; origin of the thick filaments
I band	A light band composed of thin filaments only
Z disc	A protein disc to which thin filaments and elastic filaments are anchored at each end of a sarcomere; appears as a narrow dark line in the middle of the I band
Sarcomere	The distance from one Z disc to the next; the contractile unit of a muscle fiber

the functional contractile unit of the muscle fiber. A muscle shortens because its individual sarcomeres shorten and pull the Z discs closer to each other, and dystrophin and the linking proteins pull on the extracellular proteins of the muscle. As the Z discs are pulled closer together during

contraction, they pull on the sarcolemma to achieve overall shortening of the cell.

The terminology of muscle fiber structure is reviewed in table 11.1; this table may be a useful reference as you study the mechanism of contraction.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

4. What special terms are given to the plasma membrane, cytoplasm, and smooth ER of a muscle cell?
5. What is the difference between a myofilament and a myofibril?
6. List five proteins of the myofilaments and describe their physical arrangement.
7. Sketch the overlapping pattern of myofilaments to explain how they account for the A bands, I bands, H bands, and Z discs.

11.3 The Nerve–Muscle Relationship

Objectives

When you have completed this section, you should be able to

- explain what a motor unit is and how it relates to muscle contraction;
- describe the structure of the junction where a nerve fiber meets a muscle fiber; and
- explain why a cell has an electrical charge difference across its plasma membrane, and in general terms, how this relates to muscle contraction.

Skeletal muscle never contracts unless it is stimulated by a nerve (or artificially with electrodes). If its nerve connections are severed or poisoned, a muscle is paralyzed. If the connection is not restored, the paralyzed muscle undergoes a shrinkage called *denervation atrophy*. Thus, muscle contraction cannot be understood without first understanding the relationship between nerve and muscle cells.

Motor Neurons and Motor Units

Skeletal muscles are served by nerve cells called *somatic motor neurons*, whose cell bodies are in the brainstem and spinal cord. Their axons, called **somatic motor fibers**, lead to the skeletal muscles (fig. 11.6). Each nerve fiber branches out to a number of muscle fibers, but each muscle fiber is supplied by only one motor neuron.

When a nerve signal approaches the end of an axon, it spreads out over all of its terminal branches and stimulates all the muscle fibers supplied by them. Thus, these muscle fibers contract in unison. Since they behave as a single functional unit, one nerve fiber and all the muscle fibers innervated by it are called a **motor unit**. The muscle fibers of a single motor unit are not clustered together but are dispersed throughout a muscle. Thus, when they are

FIGURE 11.6 Motor Units. A motor unit consists of one motor neuron and all skeletal muscle fibers that it innervates. Two motor units are here represented by the red and blue nerve and muscle fibers. Note that the muscle fibers of a motor unit are not clustered together, but distributed through the muscle and commingled with the fibers of other motor units.

stimulated, they cause a weak contraction over a wide area—not just a localized twitch in one small region. An effective muscle contraction usually requires the activation of several motor units at once.

On average, about 200 muscle fibers are innervated by each motor neuron, but motor units can be much smaller or larger than this to serve different purposes. Where fine control is needed, we have *small motor units*. In the muscles of eye movement, for example, each neuron controls only 3 to 6 muscle fibers. Where strength is more important than fine control, we have *large motor units*. In the gastrocnemius muscle of the calf, for example, one motor neuron may control up to 1,000 muscle fibers. Another way to look at this is that 1,000 muscle fibers may be innervated by 200 neurons in a muscle with small motor units, but by only 1 or 2 neurons in a muscle with large motor units. Consequently, small motor units provide a relatively fine degree of control. Turning a few motor neurons on or off produces a small, subtle change in the action of such a muscle. Large motor units generate more strength but less subtlety of action. Activating just a few motor neurons produces a very large change in a muscle with large motor units. Fine movements of the eye and hand thus depend on small motor units, while powerful movements of the gluteal or quadriceps muscles depend on large motor units.

In addition to adjustments in strength and control, another advantage of having multiple motor units in a

FIGURE 11.7 Innervation of Skeletal Muscle. (a) Neuromuscular junctions, with muscle fibers slightly teased apart (LM; compare the SEM on p. 403). (b) Structure of a single neuromuscular junction.

muscle is that they are able to work in shifts. Muscle fibers fatigue when subjected to continual stimulation. If all of the fibers in one of your postural muscles fatigued at once, for example, you might collapse. To prevent this, other motor units take over while the fatigued ones recover, and the muscle as a whole can sustain long-term contraction. The role of motor units in muscular strength is further discussed later in the chapter.

The Neuromuscular Junction

The point where a nerve fiber meets its target cell is called a **synapse** (SIN-aps). When the target cell is a muscle fiber, the synapse is called a **neuromuscular junction (NMJ)**,

or **motor end plate** (fig. 11.7). Each terminal branch of the nerve fiber within the NMJ forms a separate synapse with the muscle fiber. The sarcolemma of the NMJ is irregularly indented, a little like a handprint pressed into soft clay. If you imagine the nerve fiber to be like your forearm and your hand to be spread out on the handprint, the individual synapses would be like the points where your fingertips contact the clay. Thus, one nerve fiber stimulates the muscle fiber at several points within the NMJ.

At each synapse, the nerve fiber ends in a bulbous swelling called a **synaptic knob**. The knob doesn't directly touch the muscle fiber but is separated from it by a narrow space called the **synaptic cleft**, about 60 to 100 nm wide

(scarcely any wider than the thickness of one plasma membrane). A third cell, called a **Schwann cell**, envelops the entire junction and isolates it from the surrounding tissue fluid.

The synaptic knob contains spheroidal organelles called **synaptic vesicles**, which are filled with a chemical called **acetylcholine (ACh)** (ASS-eh-tul-CO-leen)—one of many *neurotransmitters* to be introduced in chapter 12. The electrical signal (nerve impulse) traveling down a nerve fiber cannot cross the synaptic cleft like a spark jumping between two electrodes—rather, it causes the synaptic vesicles to undergo exocytosis, releasing ACh into the cleft. ACh thus functions as a chemical messenger from the nerve cell to the muscle cell.

To respond to this chemical, the muscle fiber has about 50 million **ACh receptors**—proteins incorporated into its plasma membrane. Nearly all of these occur directly across from the synaptic knobs; very few are found anywhere else on the muscle fiber. To maximize the number of ACh receptors and thus its sensitivity to the neurotransmitter, the sarcolemma in this area has numerous infoldings, about 1 μm deep, called **junctional folds**, which increase the surface area of ACh-sensitive membrane. The muscle nuclei beneath the folds are specifically dedicated to the synthesis of ACh receptors and other proteins of the local sarcolemma. A deficiency of ACh receptors leads to muscle paralysis in the disease *myasthenia gravis* (see Insight 11.5, p. 435).

The entire muscle fiber and the Schwann cell of the NMJ are surrounded by a **basal lamina**, which separates them from the surrounding connective tissue. Composed partially of collagen and glycoproteins, the basal lamina passes through the synaptic cleft and virtually fills it. Both the sarcolemma and that part of the basal lamina in the cleft contain an enzyme called **acetylcholinesterase (AChE)** (ASS-eh-till-CO-lin-ESS-ter-ase). This enzyme breaks down ACh after the ACh has stimulated the muscle cell; thus, it is important in turning off muscle contraction and allowing the muscle to relax (see Insight 11.1).

You must be very familiar with the foregoing terms to understand how a nerve stimulates a muscle fiber and how the fiber contracts. They are summarized in table 11.2 for your later reference.

Electrically Excitable Cells

Muscle fibers and neurons are regarded as *electrically excitable cells* because their plasma membranes exhibit voltage changes in response to stimulation. The study of the electrical activity of cells, called **electrophysiology**, is a key to understanding nervous activity, muscle contraction, the heartbeat, and other physiological phenomena. The details of electrophysiology are presented in chapter 12, but a few fundamental principles must be introduced here so you can understand muscle excitation.

INSIGHT 11.1 Clinical Application

Neuromuscular Toxins and Paralysis

Toxins that interfere with synaptic function can paralyze the muscles. Some pesticides, for example, contain *cholinesterase inhibitors* that bind to AChE and prevent it from degrading ACh. This causes *spastic paralysis*, a state of continual contraction of the muscle, which poses the danger of suffocation if it affects the laryngeal and respiratory muscles. *Tetanus* (lockjaw) is a form of spastic paralysis caused by the toxin of a soil bacterium, *Clostridium tetani*. In the spinal cord, a chemical called glycine normally stops motor neurons from producing unwanted muscle contractions. The tetanus toxin blocks glycine release and thus causes overstimulation and spastic paralysis of the muscles.

Flaccid paralysis is a state in which the muscles are limp and cannot contract. This too can cause respiratory arrest if it affects the thoracic muscles. Flaccid paralysis can be caused by poisons, such as curare (cue-RAH-ree), that compete with ACh for receptor sites but do not stimulate the muscle. Curare is extracted from certain plants and used by some South American natives to poison blowgun darts. It has been used to treat

muscle spasms in some neurological disorders and to relax abdominal muscles for surgery, but other muscle relaxants have now replaced curare for most purposes.

Botulism is a type of food poisoning caused by a neuromuscular toxin secreted by the bacterium *Clostridium botulinum*. Botulinum toxin blocks the release of ACh and causes flaccid muscle paralysis. Purified botulinum toxin was approved by the U.S. Food and Drug Administration (FDA) in 2002 for cosmetically treating “frown lines” caused by muscle tautness between the eyebrows. Marketed as Botox Cosmetic (a prescription drug despite the name), it is injected in small doses into specific facial muscles. The wrinkles gradually disappear as muscle paralysis sets in over the next few hours. The effect lasts about 4 months until the muscles retighten and the wrinkles return. Botox treatment has become the fastest growing cosmetic medical procedure in the United States, with many people going for treatment every few months in their quest for a youthful appearance. It has begun to have some undesirable consequences, however, as it is sometimes administered by unqualified practitioners. Even some qualified physicians use it for treatments not yet approved by the FDA, and some host festive “Botox parties” for treatment of patients in assembly-line fashion.

TABLE 11.2 Components of the Neuromuscular Junction

Term	Definition
Neuromuscular junction	A functional connection between the distal end of a nerve fiber and the middle of a muscle fiber
Synaptic knob	The dilated tip of a nerve fiber; contains synaptic vesicles
Synaptic cleft	A gap of about 60 to 100 nm between the synaptic knob and sarcolemma
Synaptic vesicle	A secretory vesicle in the synaptic knob; contains acetylcholine
Junctional folds	Invaginations of the sarcolemma where ACh receptors are especially concentrated
Acetylcholine (ACh)	The neurotransmitter released by a somatic motor fiber that stimulates a skeletal muscle fiber (also used elsewhere in the nervous system)
ACh receptor	A transmembrane protein in the sarcolemma of the neuromuscular junction that binds to ACh
Acetylcholinesterase (AChE)	An enzyme in the sarcolemma and basal lamina of the muscle fiber in the synaptic region; responsible for degrading ACh and stopping the stimulation of the muscle fiber

In an unstimulated (resting) cell, there are more anions (negative ions) on the inside of the plasma membrane than on the outside. Thus, the plasma membrane is electrically **polarized**, or charged, like a little battery. In a resting muscle cell, there is an excess of sodium ions (Na^+) in the extracellular fluid (ECF) outside the cell and an excess of potassium ions (K^+) in the intracellular fluid (ICF) within the cell. Also in the ICF, and unable to penetrate the plasma membrane, are anions such as proteins, nucleic acids, and phosphates. These anions make the inside of the plasma membrane negatively charged by comparison to its outer surface.

A difference in electrical charge from one point to another is called an electrical potential, or voltage. The difference is typically 12 volts (V) for a car battery and 1.5 V for a flashlight battery, for example. On the sarcolemma of a muscle cell, the voltage is much smaller, about -90 millivolts (mV), but critically important to life. (The negative sign refers to the relatively negative charge on the intracellular side of the membrane.) This voltage is called the **resting membrane potential (RMP)**. It is maintained by the sodium–potassium pump, as noted in chapter 3.

When a nerve or muscle cell is stimulated, dramatic things happen electrically, as we shall soon see in the excitation of muscle. Ion gates in the plasma membrane open and Na^+ instantly diffuses down its concentration gradient into the cell. These cations override the negative charges in the ICF, so the inside of the plasma membrane briefly becomes positive. This change is called **depolarization** of the membrane. Immediately, Na^+ gates close and K^+ gates open. K^+ rushes out of the cell, partly because it is repelled by the positive sodium charge and partly because it is more concentrated in the ICF than in the ECF, so it diffuses down its concentration gradient when it has the opportunity. The loss of positive potassium ions from the cell turns the inside of the membrane

negative again (**repolarization**). This quick up-and-down voltage shift, from the negative RMP to a positive value and then back to a negative value again, is called an **action potential**. The RMP is a stable voltage seen in a “waiting” cell, whereas the action potential is a quickly fluctuating voltage seen in an active, stimulated cell. Chapter 12 explains the RMP and the mechanism of action potentials more fully.

Action potentials have a way of perpetuating themselves—an action potential at one point on a plasma membrane causes another one to happen immediately in front of it, which triggers another one a little farther along, and so forth. A wave of action potentials spreading along a nerve fiber like this is called a *nerve impulse* or *nerve signal*. Such signals also travel along the sarcolemma of a muscle fiber. We will see how this leads to muscle contraction.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

8. What differences would you expect to see between a motor unit where muscular strength is more important than fine control and another motor unit where fine control is more important?
9. Distinguish between acetylcholine, an acetylcholine receptor, and acetylcholinesterase. State where each is found and describe the function it serves.
10. What accounts for the resting membrane potential seen in unstimulated nerve and muscle cells?
11. What is the difference between a resting membrane potential and an action potential?

11.4 Behavior of Skeletal Muscle Fibers

Objectives

When you have completed this section, you should be able to

- explain how a nerve fiber stimulates a skeletal muscle fiber;
- explain how stimulation of a muscle fiber activates its contractile mechanism;
- explain the mechanism of muscle contraction;
- explain how a muscle fiber relaxes; and
- explain why the force of a muscle contraction depends on its length prior to stimulation.

The process of muscle contraction and relaxation has four major phases: (1) excitation, (2) excitation–contraction coupling, (3) contraction, and (4) relaxation. Each phase occurs in several smaller steps, which we now examine in detail. The steps are numbered in the following descriptions to correspond to those in figures 11.8 to 11.11.

Excitation

Excitation is the process in which action potentials in the nerve fiber lead to action potentials in the muscle fiber. The steps in excitation are shown in figure 11.8.

- 1 A nerve signal arrives at the synaptic knob and stimulates voltage-regulated calcium gates to open. Calcium ions enter the synaptic knob.
- 2 Calcium stimulates exocytosis of the synaptic vesicles, which release acetylcholine (ACh) into the synaptic cleft. One action potential causes exocytosis of about 60 synaptic vesicles, and each vesicle releases about 10,000 molecules of ACh.
- 3 ACh diffuses across the synaptic cleft and binds to receptor proteins on the sarcolemma.
- 4 These receptors are ligand-regulated ion gates. Two ACh molecules must bind to each receptor to open the gate. When this happens, Na^+ diffuses quickly into the cell and K^+ diffuses out. As a result of these ion movements, the sarcolemma reverses polarity—its voltage quickly jumps from the RMP of -90 mV to a peak of $+75$ mV as Na^+ enters, and then falls back to a level close to the RMP as K^+ diffuses out. This rapid fluctuation in membrane voltage at the motor end plate is called the **end-plate potential (EPP)**.
- 5 Areas of sarcolemma next to the motor end plate have voltage-regulated ion gates that open in

response to the EPP. Some of these are specific for Na^+ and admit it to the cell, while others are specific for K^+ and allow it to leave. These ion movements create an *action potential*. The muscle fiber is now excited.

Excitation–Contraction Coupling

Excitation–contraction coupling refers to the events that link the action potentials on the sarcolemma to activation of the myofilaments, thereby preparing them to contract. The steps in the coupling process are shown in figure 11.9.

- 6 A wave of action potentials spreads from the end plate in all directions, like ripples on a pond. When this wave of excitation reaches the T tubules, it continues down them into the sarcoplasm.
- 7 Action potentials open voltage-regulated ion gates in the T tubules. These are physically linked to calcium channels in the terminal cisternae of the sarcoplasmic reticulum (SR). Thus, gates in the SR open as well and calcium diffuses out of the SR, down its concentration gradient and into the cytosol.
- 8 Calcium binds to the troponin of the thin filaments.
- 9 The troponin–tropomyosin complex changes shape and sinks deeper into the groove of the thin filament. This exposes the active sites on the actin filaments and makes them available for binding to myosin heads.

Contraction

Contraction is the step in which the muscle fiber develops tension and may shorten. (Muscles often “contract,” or develop tension, without shortening, as we see later.) How a fiber shortens remained a mystery until sophisticated techniques in electron microscopy enabled cytologists to see the molecular organization of muscle fibers. In 1954, two researchers at the Massachusetts Institute of Technology—Jean Hanson and Hugh Huxley—reported convincing evidence for a model now called the **sliding filament theory**. This theory holds that the myofilaments do not become any shorter during contraction; rather, the thin filaments slide over the thick ones and pull the Z discs behind them, causing each sarcomere as a whole to shorten. The individual steps in this mechanism are shown in figure 11.10.

- 10 The myosin head must have an ATP molecule bound to it to initiate the contraction process. **Myosin ATPase**, an enzyme in the head, hydrolyzes this ATP. The energy released by this process activates the head, which “cocks” into an extended, high-energy position. The head temporarily keeps the ADP and phosphate group bound to it.

FIGURE 11.8 Excitation of a Muscle Fiber. These events link action potentials in a nerve fiber to the generation of action potentials in the muscle fiber. See the corresponding numbered steps in the text for explanation.

FIGURE 11.9 Excitation-Contraction Coupling. These events link action potentials in the muscle fiber to the release and binding of calcium ions. See the corresponding numbered steps in the text for explanation. The numbers in this figure begin where figure 11.8 ended.

FIGURE 11.10 The Sliding Filament Mechanism of Contraction. This is a cycle of repetitive events that cause a thin filament to slide over a thick filament and generate tension in the muscle. See the corresponding numbered steps in the text for explanation. The numbers in this figure begin where figure 11.9 ended. Lower left: Diagram of a contracted sarcomere, showing movement of the thin filaments across the thick filaments and narrowing of the I bands.

- 11 The cocked myosin binds to an exposed active site on the thin filament, forming a **cross-bridge** between the myosin and actin.
- 12 Myosin releases the ADP and phosphate and flexes into a bent, low-energy position, tugging the thin filament along with it. This is called the **power stroke**. The head remains bound to actin until it binds a new ATP.
- 13 Upon binding more ATP, myosin releases the actin. It is now prepared to repeat the whole process—it will hydrolyze the ATP, recock (the **recovery stroke**), attach to a new active site farther down the thin filament, and produce another power stroke.

It may seem as if releasing the thin filament at step 13 would simply allow it to slide back to its previous position, so that nothing would have been accomplished. Think of the sliding filament mechanism, however, as being similar to the way you would pull in a boat anchor hand over hand. When the myosin head cocks, it is like your hand reaching out to grasp the anchor rope. When it flexes back into the low-energy position, it is like your elbow flexing to pull on the rope and draw the anchor up a little bit. When you let go of the rope with one hand, you hold onto it with the other, alternating hands until the anchor is pulled in. Similarly, when one myosin head releases the actin in preparation for the recovery stroke, there are many other heads on the same thick filament holding onto the thin filament so that it doesn't slide back. At any given moment during contraction, about half of the heads are bound to the thin filament and the other half are extending forward to grasp the filament farther down. That is, the myosin heads of a thick filament do not all stroke at once but contract sequentially.

Each myosin head acts in a jerky manner, but hundreds of them working together produce a smooth, steady pull on the thin filament. This is similar to the locomotion of a millipede—a wormlike animal with a few hundred tiny legs. Each leg takes individual jerky steps, but all the legs working together produce a smooth gliding movement. Note that even though the muscle fiber contracts, the *myofilaments do not become shorter* any more than a rope becomes shorter as you pull in an anchor. The thin filaments slide over the thick ones, as the name of the theory implies.

A single cycle of power and recovery strokes by all the myosin heads in a muscle fiber would shorten the fiber by about 1%. A fiber, however, may shorten by as much as 40% of its resting length, so obviously the cycle of power and recovery must be repeated many times by each myosin head. Each head carries out about five strokes per second, and each stroke consumes one molecule of ATP.

Relaxation

When its work is done, a muscle fiber relaxes and returns to its resting length. This is achieved by the steps shown in figure 11.11.

- 14 Nerve signals stop arriving at the neuromuscular junction, so the synaptic knob stops releasing ACh.
- 15 As ACh dissociates (separates) from its receptor, AChE breaks it down into fragments that cannot stimulate the muscle. The synaptic knob reabsorbs these fragments for recycling. All of this happens continually while the muscle is being stimulated, too, but when nerve signals stop, no new ACh is released to replace that which is broken down. Therefore, stimulation of the muscle fiber by ACh ceases.
- 16 Active transport pumps in the SR begin to pump Ca^{2+} from the cytosol back into the cisternae. Here, the calcium binds to a protein called **calsequestrin** (CAL-see-QUES-trin) and is stored until the fiber is stimulated again. Since active transport requires ATP, you can see that *ATP is needed for muscle relaxation as well as for muscle contraction* (see Insight 11.2).
- 17 As calcium ions dissociate from troponin, they are pumped into the SR and are not replaced.
- 18 Tropomyosin moves back into the position where it blocks the active sites of the actin filament. Myosin can no longer bind to actin, and the muscle fiber ceases to produce or maintain tension.

A muscle returns to its resting length with the aid of two forces: (1) like a recoiling rubber band, its intracellular and perhaps extracellular elastic components stretch it; and (2) since muscles often occur in antagonistic pairs,

INSIGHT 11.2 Clinical Application

Rigor Mortis

*Rigor mortis*⁷ is the hardening of the muscles and stiffening of the body that begins 3 to 4 hours after death. It occurs partly because the deteriorating sarcoplasmic reticulum releases calcium into the cytosol, and the deteriorating sarcolemma admits more calcium from the extracellular fluid. The calcium activates myosin-actin cross-bridging. Once bound to actin, myosin cannot release it without first binding an ATP molecule, and of course no ATP is produced in a dead body. Thus, the thick and thin filaments remain rigidly cross-linked until the myofilaments begin to decay. Rigor mortis peaks about 12 hours after death and then diminishes over the next 48 to 60 hours.

⁷rigor = rigidity + mortis = of death

FIGURE 11.11 Relaxation of a Muscle Fiber. These events lead from the cessation of a nerve signal to the release of thin filaments by myosin. See the corresponding numbered steps in the text for explanation. The numbers in this figure begin where figure 11.10 ended.

the contraction of an antagonist lengthens the relaxed muscle. Contraction of the triceps brachii, for example, extends the elbow and lengthens the biceps brachii.

Think About It

Chapter 2 noted that one of the most important properties of proteins is their ability to change shape repeatedly. Identify at least two muscle proteins that must change shape in order for a muscle to contract and relax.

The Length-Tension Relationship and Muscle Tone

The amount of tension generated by a muscle, and therefore the force of its contraction, depends on how stretched or contracted it was before it was stimulated, among other factors. This principle is called the **length-tension relationship**. The reasons for it can be seen in figure 11.12. If a fiber is overly contracted at rest, its thick filaments are rather close to the Z discs. The stimulated muscle may contract a little, but then the thick filaments butt against the Z discs and can go no farther. The

contraction is therefore a weak one. On the other hand, if a muscle fiber is too stretched before it is stimulated, there is relatively little overlap between its thick and thin filaments. When the muscle is stimulated, the myosin heads cannot “get a good grip” on the thin filaments, and again the contraction is weak. (As mentioned in chapter 10, this is one reason you should not bend at the waist to pick up a heavy object. Muscles of the back become overly stretched and cannot contract effectively to straighten your spine against a heavy resistance.)

Between these extremes, there is an optimum resting length at which a muscle responds with the greatest force. The central nervous system continually monitors and adjusts the length of the resting muscles, maintaining a state of partial contraction called **muscle tone**. This maintains optimum length and makes the muscles ideally ready for action. The elastic filaments of the sarcomere also help to maintain enough myofilament overlap to ensure an effective contraction when the muscle is called into action.

Before You Go On

Answer the following questions to test your understanding of the preceding section:

12. What change does ACh cause in an ACh receptor? How does this electrically affect the muscle fiber?
13. How do troponin and tropomyosin regulate the interaction between myosin and actin?
14. Describe the roles played by ATP in the power and recovery strokes of myosin.
15. What steps are necessary for a contracted muscle to return to its resting length?

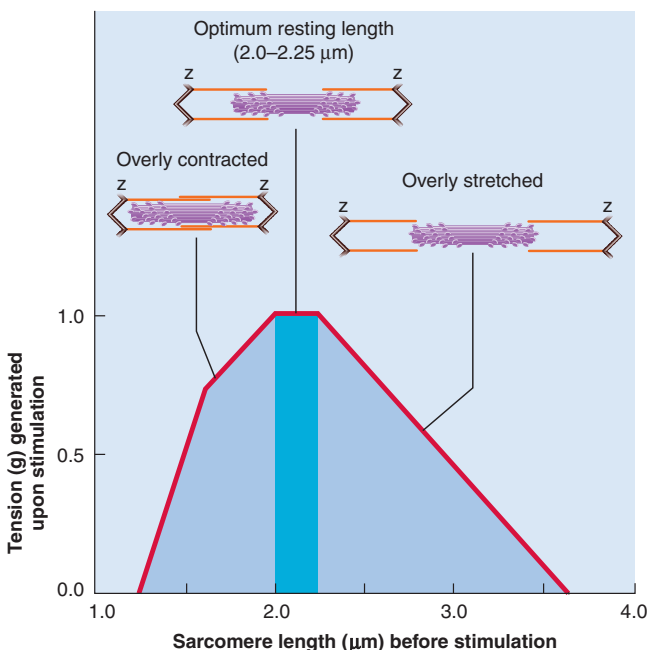

FIGURE 11.12 The Length-Tension Relationship. Center: In a resting muscle fiber, the sarcomeres are usually 2.0 to 2.25 μm long, the optimum length for producing maximum tension when the muscle is stimulated to contract. Note how this relates to the degree of overlap between the thick and thin filaments. Left: If the muscle is overly contracted, the thick filaments butt against the Z discs and the fiber cannot contract very much more when it is stimulated. Right: If the muscle is overly stretched, there is so little overlap between the thick and thin myofilaments that few cross-bridges can form between myosin and actin.

11.5 Behavior of Whole Muscles

Objectives

When you have completed this section, you should be able to

- describe the stages of a muscle twitch;
- explain why muscle does not contract in an all-or-none manner;
- explain how successive muscle twitches can add up to produce stronger muscle contractions;
- distinguish between isometric and isotonic contraction; and
- distinguish between concentric and eccentric contraction.

Now you know how an individual muscle cell shortens. Our next objective is to move up to the organ grade of construction and consider how this relates to the action of the muscle as a whole.

Threshold, Latent Period, and Twitch

Muscle contraction has often been studied and demonstrated using the gastrocnemius (calf) muscle of a frog, which can easily be isolated from the leg along with its connected sciatic nerve (see Insight 11.3). This nerve–muscle preparation can be attached to stimulating electrodes and to a recording device that produces a *myogram*, a chart of the timing and strength of the muscle's contraction.

A sufficiently weak (subthreshold) electrical stimulus to a muscle causes no contraction. By gradually increasing the voltage and stimulating the muscle again, we can determine the **threshold**, or minimum voltage necessary to generate an action potential in the muscle fiber and produce a contraction. The action potential triggers the release of a pulse of Ca^{2+} into the cytosol and activates the sliding filament mechanism. At threshold or higher, a stimulus thus causes a quick cycle of contraction and relaxation called a **twitch** (fig. 11.13).

There is a delay, or **latent period**, of about 2 milliseconds (msec) between the onset of the stimulus and the onset of the twitch. This is the time required for excitation, excitation–contraction coupling, and tensing of the elastic components of the muscle. The force generated during this time is called *internal tension*. It is not visible on the myogram because it causes no shortening of the muscle.

Once the elastic components are taut, the muscle begins to produce *external tension* and move a resisting object, or load. This is called the **contraction phase** of the twitch. In the frog gastrocnemius preparation, the load is the sensor of the recording apparatus; in the body, it is usually a bone. By analogy, imagine lifting a weight from a table with a rubber band. At first, internal tension would stretch the rubber band. Then as the rubber band became taut, external tension would lift the weight.

INSIGHT 11.3 Medical History

Galvani, Volta, and Animal Electricity

The invention of modern dry cells can be traced to studies of frog muscle by Italian anatomist Luigi Galvani (1737–98). He suspended isolated frog legs from a copper hook and noticed that they twitched when touched with an iron scalpel. He attributed this to “animal electricity” in the legs. The physicist Alessandro Volta (1745–1827) investigated Galvani's discovery further. He concluded that when two different metals (such as the copper hook and iron scalpel) are separated by an electrolyte solution (a frog's tissue fluids), a chemical reaction occurs that produces an electrical current. This current had stimulated the muscle in the legs of Galvani's frogs and caused the twitch. Based on this principle, Volta invented the first simple voltaic cell, the forerunner of today's dry cells.

FIGURE 11.13 A Muscle Twitch.

What role does ATP play during the relaxation phase?

The contraction phase is short-lived, because the SR quickly reabsorbs Ca^{2+} before the muscle develops maximal force. As the Ca^{2+} level in the cytoplasm falls, myosin releases the thin filaments and muscle tension declines. This is seen in the myogram as the **relaxation phase**. As shown by the asymmetry of the myogram, the muscle is quicker to contract than it is to relax. The entire twitch lasts from about 7 to 100 msec.

Contraction Strength of Twitches

We have seen that a subthreshold stimulus induces no muscle contraction at all, but at threshold intensity, a twitch is produced. Increasing the stimulus voltage still more, however, produces twitches no stronger than those at threshold. Superficially, the muscle fiber seems to be giving its maximum response once the stimulus intensity is at threshold or higher. For this reason, it has been common to say a muscle fiber obeys an *all-or-none law*, either contracting to its maximum possible extent or not at all. It is true that the electrical *excitation* of a muscle or nerve fiber follows an all-or-none law, and this is further discussed in chapter 12. But it is not true that muscle fibers exhibit all-or-none twitches in response to that excitation. On the contrary, even for a constant stimulus voltage, twitches vary in strength. This is so for a variety of reasons, some of which are causally linked to each other:

- Twitch strength varies with stimulation frequency; stimuli arriving close together produce stronger twitches than stimuli arriving at longer time intervals. See the phenomena of *treppe* and *tetanus* described shortly.
- Twitches vary with the concentration of Ca^{2+} in the sarcoplasm, which in turn can vary with stimulus frequency.

- Twitch strength depends on how stretched the muscle was just before it was stimulated, as we have already seen in the length–tension relationship.
- Twitches vary with the temperature of the muscle; a warmed-up muscle contracts more strongly because enzymes such as the myosin heads work more quickly.
- Twitches are weaker when the pH of the sarcoplasm falls below normal. This and other factors produce a weakening of muscle contraction called *fatigue*, discussed later in this chapter.
- Twitches vary with the state of hydration of a muscle, which affects the overlap between thick and thin filaments and the ability of myosin to form cross-bridges with actin.

It should not be surprising that muscle twitches vary in strength. Indeed, an individual twitch is not strong enough to do any useful work. Muscles must be able to contract with variable strength for different tasks, such as lifting a glass of champagne compared with lifting barbells at the gym.

Let us examine more closely the contrasting effects of stimulus *intensity* versus stimulus *frequency* on contraction strength. Suppose we apply a stimulating electrode to a motor nerve that supplies a muscle, such as the frog sciatic nerve–gastrocnemius preparation. Subthreshold stimulus voltages produce no response (fig. 11.14). At threshold, we see a weak twitch (at 3 in the top row of the figure), and if we continue to raise the voltage, we see stronger twitches. The reason for this is that higher voltages excite more and more nerve fibers in the motor nerve (middle row of the figure), and thus stimulate more and more motor units to contract. The process of bringing more motor units into play is called **recruitment**, or **multiple motor unit (MMU) summation**. This is seen not just in artificial stimulation, but is part of the way the nervous system behaves naturally to produce varying muscle contractions.

But even when stimulus intensity (voltage) remains constant, twitch strength can vary with stimulus frequency. High-frequency stimulation produces stronger twitches than low-frequency stimulation. In figure 11.15a, we see that when a muscle is stimulated at a low frequency (up to 10 stimuli/sec in this example), it produces an identical twitch for each stimulus and fully recovers between twitches.

Between 10 and 20 stimuli per second, the muscle still recovers fully between twitches, but each twitch develops more tension than the one before. This pattern of increasing tension with repetitive stimulation is called **treppe**⁸ (TREP-eh), or the *staircase phenomenon*, after the appearance of the myogram (fig. 11.15b). One cause of

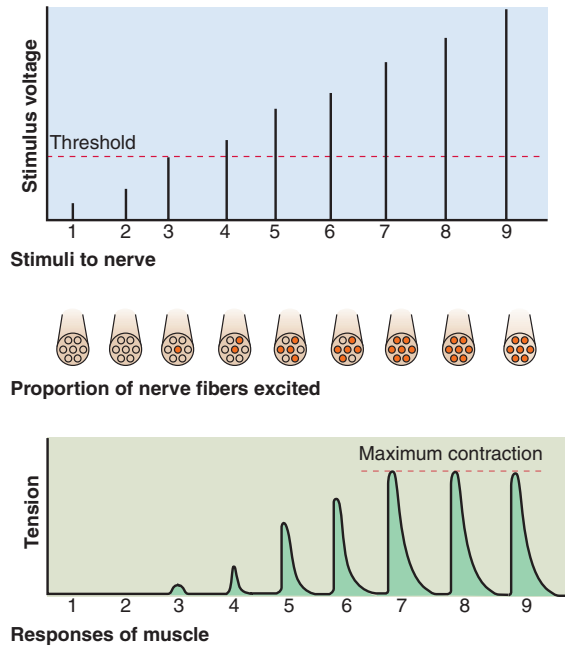

FIGURE 11.14 The Relationship Between Stimulus Intensity (Voltage) and Muscle Tension. Top row: Nine stimuli of increasing strength. The first two are subthreshold stimuli. Middle row: Cross section of a motor nerve with seven nerve fibers. The colored nerve fibers are the excited ones; note that none are excited by the subthreshold stimuli above. Bottom row: Graph of muscle tension. Subthreshold stimuli (1–2) produce no muscle contraction. When stimuli reach or exceed threshold (3–7), they excite more and more nerve fibers and motor units; thus, they produce stronger and stronger contractions. This is multiple motor unit summation (recruitment). Once all of the nerve fibers are stimulated (7–9), further increases in stimulus strength produce no further increase in muscle tension.

treppe is that when stimuli arrive so rapidly, the SR does not have time between stimuli to completely reabsorb all the Ca^{2+} it released. Thus, the calcium concentration in the cytosol rises higher and higher with each stimulus and causes subsequent twitches to be stronger. Another factor is that the heat released by each twitch causes muscle enzymes such as myosin ATPase to work more efficiently and produce stronger twitches as the muscle warms up.

Think About It

Explain why a rising concentration of Ca^{2+} in the sarcoplasm would enable more myosin–actin cross-bridges to form, and thus result in stronger twitches.

At a still higher stimulus frequency (20–40 stimuli/sec in fig. 11.15c), each new stimulus arrives before the previous twitch is over. Each new twitch “rides piggy-back” on the previous one and generates higher tension.

⁸treppe = staircase

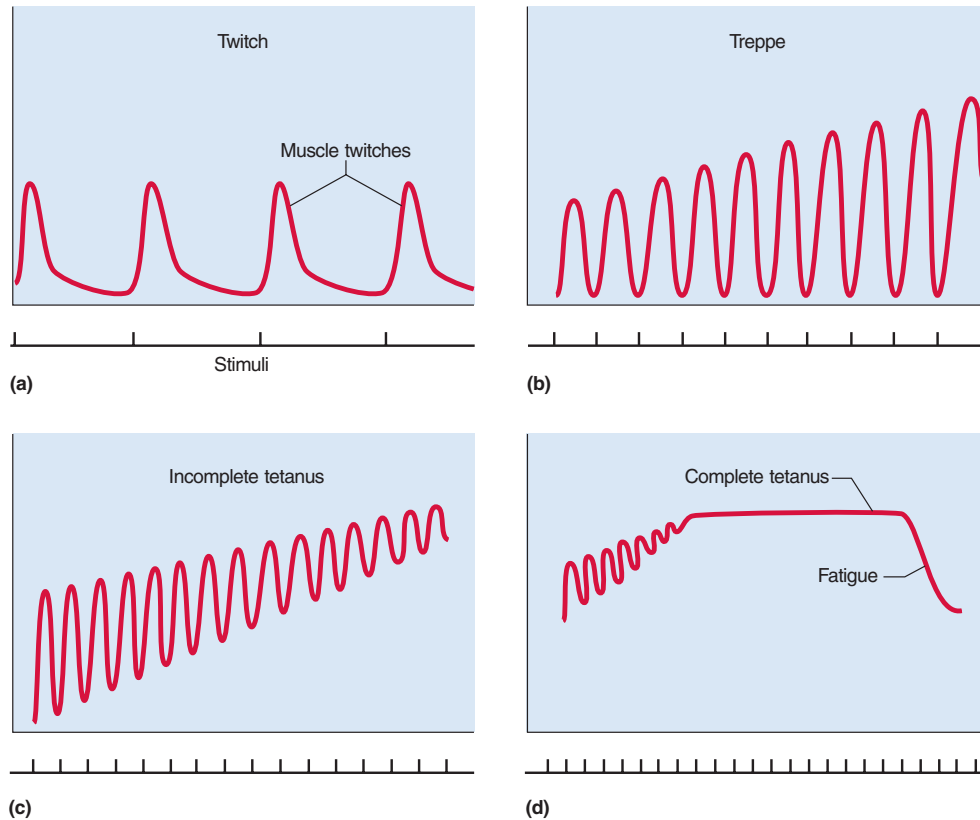

FIGURE 11.15 The Relationship Between Stimulus Frequency and Muscle Tension. (a) Twitch. At low frequency, the muscle relaxes completely between stimuli and shows twitches of uniform strength. (b) Treppe. At a moderate frequency of stimulation, the muscle relaxes fully between contractions, but successive twitches are stronger. (c) Wave summation and incomplete tetanus. At still higher stimulus frequency, the muscle does not have time to relax completely between twitches and the force of each twitch builds on the previous one. (d) Complete tetanus. At high stimulus frequency, the muscle does not have time to relax at all between stimuli and exhibits a state of continual contraction with about four times as much tension as a single twitch. Tension declines as the muscle fatigues. Only the conditions in parts (b) and (c) occur in the human body; those depicted in (a) and (d) are produced only by artificial stimulation below or above the range of nerve firing frequencies.

This phenomenon goes by two names: **temporal⁹ summation**, because it results from two stimuli arriving close together, or **wave summation**, because it results from one wave of contraction added to another. Wave is added upon wave, so each twitch reaches a higher level of tension than the one before, and the muscle relaxes only partially between stimuli. This effect produces a state of sustained fluttering contraction called **incomplete tetanus**.

At a still higher frequency, such as 40 to 50 stimuli per second, the muscle has no time to relax at all between stimuli, and the twitches fuse into a smooth, prolonged contraction called **complete tetanus** (fig. 11.15d). A muscle in complete tetanus produces about four times as much tension as a single twitch. This type of tetanus should not be confused with the disease of the same name caused by the tetanus toxin, explained in Insight 11.1.

Complete tetanus is a phenomenon seen in artificial stimulation of a muscle, however, and rarely if ever occurs in the body. Even during the most intense muscle contractions, the frequency of stimulation by a motor neuron rarely exceeds 25 per second, which is far from sufficient to produce complete tetanus. The reason for the smoothness of muscle contractions is that motor units function asynchronously; when one motor unit relaxes, another contracts and takes over so that the muscle does not lose tension.

Isometric and Isotonic Contraction

In muscle physiology, “contraction” does not always mean the shortening of a muscle—it may mean only that the muscle is producing internal tension while an external resistance causes it to stay the same length or even become longer. Thus, physiologists speak of different kinds of muscle contraction as *isometric* versus *isotonic* and *concentric* versus *eccentric*.

⁹tempor = time

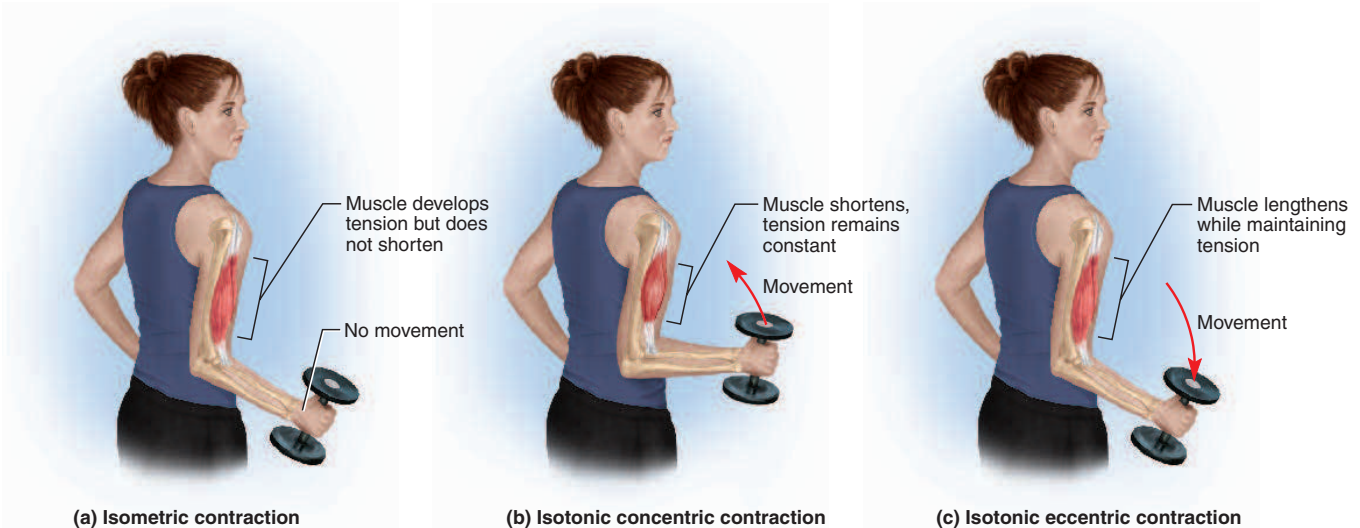

FIGURE 11.16 Isometric and Isotonic Contraction. (a) Isometric contraction, in which a muscle develops tension but does not shorten. This occurs at the beginning of any muscle contraction but is prolonged in actions such as lifting heavy weights. (b) Isotonic concentric contraction, in which the muscle shortens while maintaining a constant degree of tension. In this phase, the muscle moves a load. (c) Isotonic eccentric contraction, in which the muscle maintains tension while it lengthens, allowing a muscle to relax without going suddenly limp.

• Name a muscle that undergoes eccentric contraction as you sit down in a chair.

Suppose you lift a heavy dumbbell. When you first contract the muscles of your arms, you can feel the tension building in them even though the dumbbell is not yet moving. At this point, your muscles are contracting at a cellular level, but their tension is being absorbed by the elastic components and is resisted by the weight of the load; the muscle as a whole is not producing any external movement. This phase is called **isometric**¹⁰ **contraction**—contraction without a change in length (fig. 11.16a). Isometric contraction is not merely a prelude to movement. The isometric contraction of antagonistic muscles at a single joint is important in maintaining joint stability at rest, and the isometric contraction of postural muscles is what keeps us from sinking in a heap to the floor. **Isotonic**¹¹ **contraction**—contraction with a change in length but no change in tension—begins when internal tension builds to the point that it overcomes the resistance. The muscle now shortens, moves the load, and maintains essentially the same tension from then on (fig. 11.16b). Isometric and isotonic contraction are both phases of normal muscular action (fig. 11.17).

There are two forms of isotonic contraction: concentric and eccentric. In **concentric contraction**, a muscle shortens as it maintains tension—for example, when the biceps brachii contracts and flexes the elbow. In **eccentric contraction**, a muscle lengthens as it maintains tension.

FIGURE 11.17 Isometric and Isotonic Phases of Contraction. At the beginning of a contraction (isometric phase), muscle tension rises but the length remains constant (the muscle does not shorten). When tension overcomes the resistance of the load, the tension levels off and the muscle begins to shorten and move the load (isotonic phase).

• How would you extend this graph in order to show eccentric contraction?

¹⁰iso = same, uniform + metr = length

¹¹iso = same, uniform + ton = tension

If you set that dumbbell down again (fig. 11.16c), your biceps brachii lengthens as you extend your elbow, but it maintains tension to act as a brake and keep you from simply dropping the weight. A weight lifter uses concentric contraction when lifting a dumbbell and eccentric contraction when lowering it.

In summary, during isometric contraction, a muscle develops tension without changing length, and in isotonic contraction, it changes length while maintaining constant tension. In concentric contraction, a muscle maintains tension as it shortens, and in eccentric contraction, it maintains tension while it is lengthening.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. State three or more reasons why muscle twitch strength can vary even when stimulus intensity remains constant.
17. Explain the role of tetanus in normal muscle action.
18. Describe an everyday activity not involving the arms in which your muscles would switch from isometric to isotonic contraction.
19. Describe an everyday activity not involving the arms that would involve concentric contraction and one that would involve eccentric contraction.

11.6 Muscle Metabolism

Objectives

When you have completed this section, you should be able to

- explain how skeletal muscle meets its energy demands during rest and exercise;
- explain the basis of muscle fatigue and soreness;
- define *oxygen debt* and explain why extra oxygen is needed even after an exercise has ended;
- distinguish between two physiological types of muscle fibers, and explain their functional roles;
- discuss the factors that affect muscular strength; and
- discuss the effects of resistance and endurance exercises on muscle.

ATP Sources

All muscle contraction depends on ATP; no other energy source can serve in its place. The supply of ATP depends, in turn, on the availability of oxygen and organic energy sources such as glucose and fatty acids. To understand how muscle manages its ATP budget, you must be familiar with the two main pathways of ATP synthesis: *anaerobic*

fermentation and *aerobic respiration* (see fig. 2.31, p. 82). Each of these has advantages and disadvantages. Anaerobic fermentation enables a cell to produce ATP in the absence of oxygen, but the ATP yield is very limited and the process produces a toxic end product, lactic acid, which is a major factor in muscle fatigue. By contrast, aerobic respiration produces far more ATP and less toxic end products (carbon dioxide and water), but it requires a continual supply of oxygen. Although aerobic respiration is best known as a pathway for glucose oxidation, it is also used to extract energy from other organic compounds. In a resting muscle, most ATP is generated by the aerobic respiration of fatty acids.

During the course of exercise, different mechanisms of ATP synthesis are used depending on the exercise duration. We will view these mechanisms from the standpoint of immediate, short-term, and long-term energy, but it must be stressed that muscle does not make sudden shifts from one mechanism to another like an automobile transmission shifting gears. Rather, these mechanisms blend and overlap as the exercise continues (fig. 11.18).

Immediate Energy

In a short, intense exercise such as a 100 m dash, the myoglobin in a muscle fiber supplies oxygen for a limited amount of aerobic respiration at the outset, but this oxygen supply is quickly depleted. Until the respiratory and cardiovascular systems catch up with the heightened oxygen demand, the muscle meets most of its ATP needs by borrowing phosphate groups (P_i) from other molecules and transferring them to ADP. Two enzyme systems control these phosphate transfers (fig. 11.19):

1. **Myokinase** (MY-oh-KY-nase) transfers P_i from one ADP to another, converting the latter to ATP.
2. **Creatine kinase** (CREE-uh-tin KY-nase) obtains P_i from a phosphate-storage molecule, **creatine phosphate (CP)**, and donates it to ADP to make ATP. This is a fast-acting system that helps to maintain the ATP level while other ATP-generating mechanisms are being activated.

ATP and CP, collectively called the **phosphagen system**, provide nearly all the energy used for short bursts of intense activity. Muscle contains about 5 millimoles of ATP and 15 millimoles of CP per kilogram of tissue, which is enough to power about 1 minute of brisk walking or 6 seconds of sprinting or fast swimming. The phosphagen system is especially important in activities requiring brief but maximal effort, such as football, baseball, and weight lifting.

Short-Term Energy

As the phosphagen system is exhausted, the muscles shift to anaerobic fermentation to “buy time” until cardiopulmonary function can catch up with the muscles’ oxygen demand. During this period, the muscles obtain glucose

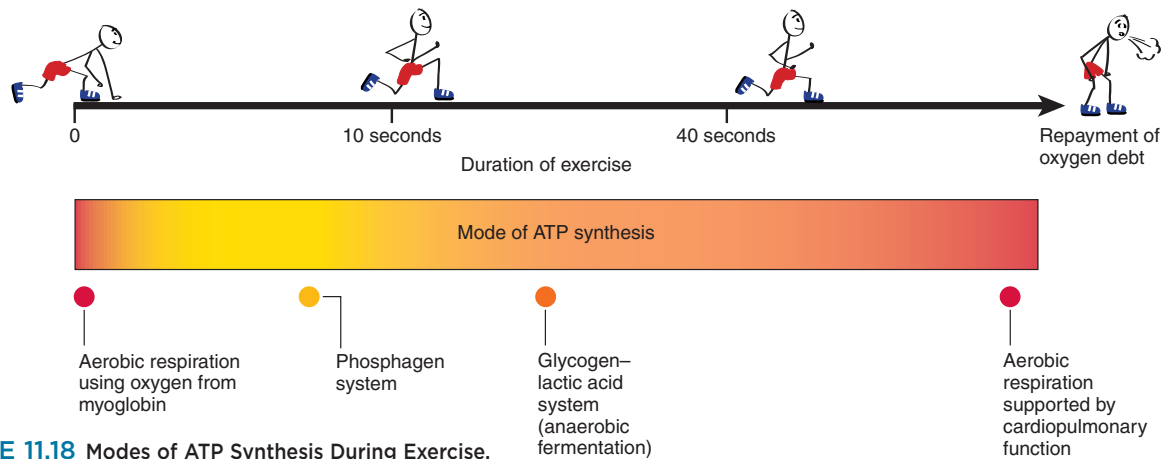

FIGURE 11.18 Modes of ATP Synthesis During Exercise.

FIGURE 11.19 The Phosphagen System. Two enzymes, myokinase and creatine kinase, generate ATP in the absence of oxygen. Myokinase borrows phosphate groups from ADP, and creatine kinase borrows them from creatine phosphate, to convert an ADP to ATP.

from the blood and their own stored glycogen. You may recall from chapter 2 that in the absence of oxygen, the pathway of glycolysis can generate a net gain of 2 ATP for every glucose molecule consumed, as it converts glucose to lactic acid. The pathway from glycogen to lactic acid, called the **glycogen–lactic acid system**, produces enough ATP for 30 to 40 seconds of maximum activity. To play basketball or to run completely around a baseball diamond, for example, depends heavily on this energy-transfer system.

Long-Term Energy

After 40 seconds or so, the respiratory and cardiovascular systems “catch up” and deliver oxygen to the muscles fast enough for aerobic respiration to meet most of the ATP demand. Aerobic respiration produces much more ATP than glycolysis does—typically another 36 ATP per glucose. Thus it is a very efficient means of meeting the ATP demands of prolonged exercise. One’s rate of oxygen consumption rises for 3 to 4 minutes and then levels off at a *steady state* in which aerobic ATP production keeps pace with the demand. In exercises lasting more than 10 minutes, over 90% of the ATP is produced aerobically.

Little lactic acid accumulates under steady state conditions, but this does not mean that aerobic exercise can continue indefinitely or that it is limited only by a person’s willpower. The depletion of glycogen and blood glucose, together with the loss of fluid and electrolytes through sweating, set limits to endurance and performance even when lactic acid does not.

Fatigue and Endurance

Muscle **fatigue** is the progressive weakness and loss of contractility that results from prolonged use of the muscles. For example, if you hold this book at arm’s length for a minute, you will feel your muscles growing weaker and eventually you will be unable to hold it up. Repeatedly squeezing a rubber ball, pushing a video game button, or trying to take lecture notes from a fast-talking professor produces fatigue in the hand muscles. Fatigue has multiple causes:

- ATP synthesis declines as glycogen is consumed.
- The ATP shortage slows down the sodium–potassium pumps, compromising their ability to maintain the resting membrane potential and excitability of the muscle fibers.

- Lactic acid lowers the pH of the sarcoplasm, which inhibits the enzymes involved in contraction, ATP synthesis, and other aspects of muscle function.
- Each action potential releases K^+ from the sarcoplasm to the extracellular fluid. The accumulation of extracellular K^+ lowers the membrane potential (hyperpolarizes the cell) and makes the muscle fiber less excitable.
- Motor nerve fibers use up their ACh, which leaves them less capable of stimulating muscle fibers. This is called *junctional fatigue*.
- The central nervous system, where all motor commands originate, fatigues by processes not yet understood, so there is less signal output to the skeletal muscles.

Think About It

Suppose you repeatedly stimulated the sciatic nerve in a frog nerve-muscle preparation until the muscle stopped contracting. What simple test could you do to determine whether this was due to junctional fatigue or to one of the other fatigue mechanisms?

The ability to maintain high-intensity exercise for more than 4 to 5 minutes is determined in large part by one's **maximum oxygen uptake (VO_{2max})**—the point at which the rate of oxygen consumption reaches a plateau and does not increase further with an added workload. VO_{2max} is proportional to body size; it peaks at around age 20; it is usually greater in males than in females; and it can be twice as great in a trained endurance athlete as in an untrained person (see the later discussion on effects of conditioning). A typical sedentary adult has a VO_{2max} of about 35 mL/min/kg. Such a person weighing 73 kg (160 pounds) and exercising at maximum intensity might therefore “burn” about 2.6 L of oxygen per minute, which sets a limit to his rate of ATP production. Elite endurance athletes can have a VO_{2max} of about 70 mL/min/kg. The world's top-rated endurance athlete of the early twenty-first century was Lance Armstrong, history's only seven-time winner of the grueling Tour de France bicycle race. Armstrong's VO_{2max} was measured at 83.8 mL/min/kg. Relating this to maximum ATP production, and ATP supply to muscle performance, it is easy to see why he had such outstanding endurance.

Oxygen Debt

You have probably noticed that you breathe heavily not only during a strenuous exercise but also for several minutes afterward (fig. 11.18). This is because your body accrues an oxygen debt that must be “repaid.” **Oxygen debt** is the difference between the resting rate of oxygen consumption and the elevated rate following an exercise; it is also known as *excess postexercise oxygen consump-*

INSIGHT 11.4 Clinical Application

Beating Fatigue—Some Athletic Strategies and Their Hazards

Muscle fatigue is one of the greatest limitations on athletic performance, and competitive athletes have resorted to various means to circumvent it. In recent years, creatine has been heavily promoted as a performance enhancer for power athletes. Taken orally, creatine increases the level of creatine phosphate (CP) in the muscles, and thus increases the speed of ATP regeneration. Some double-blind, placebo-controlled studies have shown that creatine supplements enhance performance on the treadmill and bicycle ergometer, and in weight-lifting and jumping exercises. However, the risks of creatine supplementation are still not well known. Creatine supplements have been implicated in muscle cramping, electrolyte imbalances, dehydration, gastrointestinal disturbances, water retention, weight gain, stroke, seizures, and severe kidney disease caused by overloading the kidneys with the creatine metabolite, creatinine. The role of creatine is being investigated in the deaths of several athletes who were using the supplement. Creatine supplements are not regulated by the Food and Drug Administration, and may vary widely in concentration and purity, making it difficult to know what dosage one is actually getting and whether it may include harmful impurities. Ironically, caffeine abolishes the effect of creatine, yet some companies market drink mixes that contain both caffeine and creatine. Physicians and athletic associations have warned against the use of creatine supplements until the adverse effects of long-term use are better known.

Creatine provides no known benefit for endurance athletes, who depend on aerobic respiration rather than the phosphagen system for long-term energy. Many endurance athletes, however, have used a strategy called *carbohydrate loading* to lessen fatigue. This is a dietary regimen that packs as much as 5 g of extra glycogen into every 100 g of muscle. Although the added glycogen can increase endurance, it is hydrophilic and retains an added 2.7 g of water per gram of glycogen. Some athletes feel that the resulting sense of heaviness and other side effects outweigh the benefit of carbohydrate loading.

tion (EPOC). The total amount of extra oxygen consumed after a strenuous exercise is typically about 11 L. It is used for the following purposes:

- *Replacing the body's oxygen reserves* that were depleted in the first minute of exercise. These include the oxygen bound to muscle myoglobin and blood hemoglobin, oxygen dissolved in the blood plasma and other extracellular fluids, and oxygen in the air in the lungs.
- *Replenishing the phosphagen system*. This involves synthesizing ATP and using some of it to donate phosphate groups back to creatine until the resting levels of ATP and CP are restored.
- *Oxidizing lactic acid*. About 80% of the lactic acid produced by muscle enters the bloodstream and is

TABLE 11.3		Classification of Skeletal Muscle Fibers	
Properties	Fiber Type		
	Slow Oxidative	Fast Glycolytic	
Twitch duration	As long as 100 msec	As short as 7.5 msec	
Relative diameter	Smaller	Larger	
ATP synthesis	Aerobic	Anaerobic	
Fatigue resistance	Good	Poor	
ATP hydrolysis	Slow	Fast	
Glycolysis	Moderate	Fast	
Myoglobin content	Abundant	Low	
Glycogen content	Low	Abundant

reconverted to pyruvic acid in the kidneys, the cardiac muscle, and especially the liver. Some of this pyruvic acid enters the aerobic (mitochondrial) pathway to make ATP, but the liver converts most of it back to glucose. Glucose is then available to replenish the glycogen stores of the muscle.

- *Serving the elevated metabolic rate.* As long as the body temperature remains elevated by exercise, the total metabolic rate remains high, and rapid metabolism consumes extra oxygen.

Physiological Classes of Muscle Fibers

Not all muscle fibers are metabolically alike or adapted to perform the same task. Some respond slowly but are relatively resistant to fatigue, while others respond more quickly but also fatigue quickly (table 11.3). Each primary type of fiber goes by several names:

- **Slow oxidative (SO), slow-twitch, red, or type I fibers.** These fibers have relatively abundant mitochondria, myoglobin, and blood capillaries, and therefore a relatively deep red color. They are well adapted to aerobic respiration, which does not generate lactic acid. Thus, these fibers do not fatigue easily. However, in response to a single stimulus, they exhibit a relatively long twitch, lasting about 100 msec. The soleus muscle of the calf and the

FIGURE 11.20 Muscle Stained to Distinguish Fast Glycolytic (FG) from Slow Oxidative (SO) Fibers. Cross section.

postural muscles of the back are composed mainly of these SO, high-endurance fibers.

- **Fast glycolytic (FG), fast-twitch, white, or type II fibers.** These fibers are well adapted for quick responses but not for fatigue resistance. They are rich in enzymes of the phosphagen and glycogen–lactic acid systems. Their sarcoplasmic reticulum releases and reabsorbs Ca^{2+} quickly, which partially accounts for their quick, forceful contractions. They are poorer than SO fibers in mitochondria, myoglobin, and blood capillaries, so they are relatively pale (hence the expression *white fibers*). These fibers produce twitches as short as 7.5 msec, but because of the lactic acid they generate, they fatigue more easily than SO fibers. Thus, they are especially important in sports such as basketball that require stop-and-go activity and frequent changes of pace. The gastrocnemius muscle of the calf, biceps brachii of the arm, and the muscles of eye movement consist mainly of FG fibers.

Some authorities recognize two subtypes of FG fibers called types IIA and IIB. Type IIB is the common type just described, while IIA, or **intermediate fibers**, combine fast-twitch responses with aerobic fatigue-resistant metabolism. Type IIA fibers, however, are relatively rare except in some endurance-trained athletes. The fiber types can be differentiated histologically by using stains for certain mitochondrial enzymes and other cellular components (fig. 11.20). All muscle fibers of one motor unit belong to the same physiological type.

Nearly all muscles are composed of both SO and FG fibers, but the proportions of these fiber types differ from one muscle to another. Muscles composed mainly of SO fibers are called *red muscles* and those composed mainly of FG fibers are called *white muscles*. People with different types and levels of physical activity differ in the proportion of one fiber type to another even in the same

TABLE 11.4

Proportion of Slow Oxidative (SO) and Fast Glycolytic (FG) Fibers in the Quadriceps Femoris Muscle of Male Athletes

Sample Population	SO	FG
Marathon runners	82%	18%
Swimmers	74	26
Average males	45	55
Sprinters and jumpers	37	63

muscle, such as the *quadriceps femoris* of the anterior thigh (table 11.4). It is thought that people are born with a genetic predisposition for a certain ratio of fiber types. Those who go into competitive sports discover the sports at which they can excel and gravitate toward those for which heredity has best equipped them. One person might be a “born sprinter” and another a “born marathoner.”

We noted earlier that sometimes two or more muscles act across the same joint and superficially seem to have the same function. We have already seen some reasons why such muscles are not as redundant as they seem. Another reason is that they may differ in the proportion of SO to FG fibers. For example, the gastrocnemius and soleus muscles of the calf both insert on the calcaneus through the same tendon, the calcaneal tendon, so they exert the same pull on the heel. The gastrocnemius, however, is a white, predominantly FG muscle adapted for quick, powerful movements such as jumping, whereas the soleus is a red, predominantly SO muscle that does most of the work in endurance exercises such as jogging and skiing.

Muscular Strength and Conditioning

We have far more muscular strength than we normally use. The gluteus maximus can generate 1,200 kg of tension, and all the muscles of the body can produce a total tension of 22,000 kg (nearly 25 tons). Indeed, the muscles can generate more tension than the bones and tendons can withstand—a fact that accounts for many injuries to the patellar and calcaneal tendons. Muscular strength depends on a variety of anatomical and physiological factors:

- **Muscle size.** The strength of a muscle depends primarily on its size; this is why weight lifting increases the size and strength of a muscle simultaneously. A muscle can exert a tension of about 3 to 4 kg per square cm of cross-sectional area.
- **Fascicle arrangement.** Pennate muscles such as the quadriceps femoris are stronger than parallel muscles such as the sartorius, which in turn are

stronger than circular muscles such as the orbicularis oculi.

- **Size of active motor units.** Large motor units produce stronger contractions than small ones.
- **Multiple motor unit summation.** When a stronger muscle contraction is desired, the nervous system activates more motor units. This process is the *recruitment*, or *MMU summation*, described earlier. It can produce extraordinary feats of strength under desperate conditions—rescuing a loved one pinned under an automobile, for example. Getting “psyched up” for athletic competition is also partly a matter of MMU summation.
- **Temporal summation.** Nerve impulses usually arrive at a muscle in a series of closely spaced action potentials. Because of the *temporal summation* described earlier, the greater the frequency of stimulation, the more strongly a muscle contracts.
- **The length–tension relationship.** As noted earlier, a muscle resting at optimum length is prepared to contract more forcefully than a muscle that is excessively contracted or stretched.
- **Fatigue.** Fatigued muscles contract more weakly than rested ones.

Resistance exercise, such as weight lifting, is the contraction of muscles against a load that resists movement. A few minutes of resistance exercise at a time, a few times each week, is enough to stimulate muscle growth. Growth results primarily from cellular enlargement, not cellular division. The muscle fibers synthesize more myofilaments and the myofibrils grow thicker. Myofibrils split longitudinally when they reach a certain size, so a well-conditioned muscle has more myofibrils than a poorly conditioned one. Muscle fibers themselves are incapable of mitosis, but there is some evidence that as they enlarge, they too may split longitudinally. A small part of muscle growth may therefore result from an increase in the number of fibers, but most results from the enlargement of fibers that have existed since childhood.

Think About It

Is muscle growth mainly the result of hypertrophy or hyperplasia?

Endurance (aerobic) exercise, such as jogging and swimming, improves the fatigue resistance of the muscles. Slow-twitch fibers, especially, produce more mitochondria and glycogen and acquire a greater density of blood capillaries as a result of conditioning. Endurance exercise also improves skeletal strength; increases the red blood cell count and the oxygen transport capacity of the blood; and enhances the function of the cardiovascular, respiratory, and nervous systems.

Endurance training does not significantly increase muscular strength, and resistance training does not improve endurance. Optimal performance and musculoskeletal health require **cross-training**, which incorporates elements of both types. If muscles are not kept sufficiently active, they become *deconditioned*—weaker and more easily fatigued.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

20. From which two molecules can ADP borrow a phosphate group to become ATP? What is the enzyme that catalyzes each transfer?
21. In a long period of intense exercise, why does muscle generate ATP anaerobically at first and then switch to aerobic respiration?
22. List four causes of muscle fatigue.
23. List three causes of oxygen debt.
24. What properties of fast glycolytic and slow oxidative fibers adapt them for different physiological purposes?

11.7 Cardiac and Smooth Muscle

Objectives

When you have completed this section, you should be able to

- describe the structural and physiological differences between cardiac muscle and skeletal muscle;
- explain why these differences are important to cardiac function;
- describe the structural and physiological differences between smooth muscle and skeletal muscle; and
- relate the unique properties of smooth muscle to its locations and functions.

In this section, we will compare cardiac muscle and smooth muscle to skeletal muscle. As you will find, cardiac and smooth muscle have special structural and physiological properties related to their distinctive functions. They also have certain properties in common with each other.

Any of the three types of muscle cells can be called **myocytes**. This term is preferable to *muscle fiber* for smooth and cardiac muscle because these two types of cells do not have the long fibrous shape of skeletal muscle cells. They are relatively short, and in further contrast to skeletal muscle fibers, they have only one nucleus. Cardiac myocytes are also called **cardiocytes**. Cardiac and smooth muscle are *involuntary* muscle tissues, not usually subject to our conscious control.

Cardiac Muscle

Cardiac muscle is limited to the heart, where its function is to pump blood. Knowing that, we can predict the properties that it must have: (1) It must contract with a regular rhythm; (2) the muscle cells of a given heart chamber must contract in unison so that the chamber can effectively expel blood; (3) each contraction must last long enough to expel blood from the chamber; (4) it must function in sleep and wakefulness, without fail and without need of conscious attention; and (5) it must be highly resistant to fatigue. These functional properties are the key to understanding how cardiac muscle differs structurally and physiologically from skeletal muscle (table 11.5).

Cardiac muscle is striated like skeletal muscle, but its myocytes (cardiocytes) are shorter and thicker, shaped like a log with uneven, notched ends (see fig. 19.11). Each myocyte is joined to several others at its ends through linkages called **intercalated** (in-TUR-kuh-LAY-ted) **discs**. These appear as thick dark lines in stained tissue sections. An intercalated disc has electrical *gap junctions* that allow each myocyte to directly stimulate its neighbors, and mechanical junctions that keep the myocytes from pulling apart when the heart contracts. The sarcoplasmic reticulum is less developed than in skeletal muscle, but the T tubules are larger and admit supplemental Ca^{2+} from the extracellular fluid. Damaged cardiac muscle is repaired by fibrosis. Cardiac muscle has no satellite cells, and even though mitosis has recently been detected in cardiac myocytes following heart attacks, it does not produce a significant amount of regenerated functional muscle.

Unlike skeletal muscle, cardiac muscle can contract without the need of nervous stimulation. It contains a built-in **pacemaker** that rhythmically sets off a wave of electrical excitation. This wave travels through the muscle and triggers the contraction of the heart chambers. Cardiac muscle is said to be **autorhythmic**¹² because of this ability to contract rhythmically and independently. The heart does, however, receive fibers from the *autonomic nervous system* that can either increase or decrease the heart rate and contraction strength. Cardiac muscle does not exhibit quick twitches like skeletal muscle. Rather, it maintains tension for about 200 to 250 msec, giving the heart time to expel blood.

Cardiac muscle uses aerobic respiration almost exclusively. It is very rich in myoglobin and glycogen, and it has especially large mitochondria that fill about 25% of the cell, compared with smaller mitochondria occupying about 2% of a skeletal muscle fiber. Cardiac muscle is very adaptable with respect to the fuel used, but very vulnerable to interruptions in oxygen supply. Because it makes little use of anaerobic fermentation, cardiac muscle is highly resistant to fatigue.

¹²auto = self

TABLE 11.5 Comparison of Skeletal, Cardiac, and Smooth Muscle

Feature	Skeletal Muscle	Cardiac Muscle	Smooth Muscle
Location	Associated with skeletal system	Heart	Walls of viscera and blood vessels, iris of eye, piloerector of hair follicles
Cell shape	Long threadlike fibers	Short, slightly branched cells	Short fusiform cells
Cell length	100 μm –30 cm	50–100 μm	30–200 μm
Cell width	10–500 μm	10–20 μm	5–10 μm
Striations	Present	Present	Absent
Nuclei	Multiple nuclei, adjacent to sarcolemma	Usually one nucleus, near middle of cell	One nucleus, near middle of cell
Connective tissues	Endomysium, perimysium, epimysium	Endomysium only	Endomysium only
Sarcoplasmic reticulum	Abundant	Present	Scanty
T tubules	Present, narrow	Present, wide	Absent
Gap junctions	Absent	Present in intercalated discs	Present in single-unit smooth muscle
Autorhythmicity	Absent	Present	Present in single-unit smooth muscle
Thin filament attachment	Z discs	Z discs	Dense bodies
Regulatory proteins	Tropomyosin, troponin	Tropomyosin, troponin	Calmodulin, myosin light-chain kinase
Ca ²⁺ source	Sarcoplasmic reticulum	Sarcoplasmic reticulum and extracellular fluid	Mainly extracellular fluid
Ca ²⁺ receptor	Troponin of thin filament	Troponin of thin filament	Calmodulin of thick filament
Innervation and control	Somatic motor fibers (voluntary)	Autonomic fibers (involuntary)	Autonomic fibers (involuntary)
Nervous stimulation required?	Yes	No	No
Effect of nervous stimulation	Excitatory only	Excitatory or inhibitory	Excitatory or inhibitory
Mode of tissue repair	Limited regeneration, mostly fibrosis	Limited regeneration, mostly fibrosis	Relatively good capacity for regeneration

Smooth Muscle

Smooth muscle is composed of myocytes with a fusiform shape, about 30 to 200 μm long, 5 to 10 μm wide at the middle, and tapering to a point at each end. There is only one nucleus, located near the middle of the cell. Although thick and thin filaments are both present, they are not aligned with each other and produce no visible striations or sarcomeres; this is the reason for the name *smooth* muscle. Z discs are absent. In their place are protein plaques on the inner face of the plasma membrane, and a well-ordered array of protein masses called **dense bodies** in the cytoplasm. The cytoplasm also contains an extensive cytoskeleton of intermediate filaments. These intermediate filaments as well as the thin myofilaments attach to the membrane plaques and dense bodies, thus providing mechanical linkages between the thin myofilaments and the plasma membrane (see fig. 11.24). The role of this linkage in smooth muscle contraction is explained later.

The sarcoplasmic reticulum is scanty, and there are no T tubules. The Ca²⁺ needed to activate smooth muscle contraction comes mainly from the extracellular fluid (ECF) by way of Ca²⁺ channels in the sarcolemma. During relaxation, Ca²⁺ is pumped back out of the cell. Some smooth muscle has no nerve supply, but when nerve fibers are present, they are autonomic (like those of cardiac muscle) and not somatic motor fibers.

Unlike skeletal and cardiac muscle, smooth muscle is capable of mitosis and hyperplasia. Thus, an organ such as the pregnant uterus can grow by adding more myocytes, and injured smooth muscle regenerates well.

Types of Smooth Muscle

There are two functional categories of smooth muscle called *multiunit* and *single-unit* types (fig. 11.21). **Multiunit smooth muscle** occurs in some of the largest arteries and pulmonary air passages, in the piloerector

FIGURE 11.21 Multiunit and Single-Unit Smooth Muscle.

(a) Multiunit smooth muscle, in which each muscle cell receives its own nerve supply and contracts independently. (b) Single-unit smooth muscle, in which a nerve fiber passes through the tissue without synapsing with any specific muscle cell, and muscle cells are coupled by electrical gap junctions.

muscles of the hair follicles, and in the iris of the eye. Its innervation, although autonomic, is otherwise similar to that of skeletal muscle—the terminal branches of a nerve fiber synapse with individual myocytes and form a motor unit. Each motor unit contracts independently of the others, hence the name of this muscle type.

Single-unit smooth muscle is more widespread. It occurs in most blood vessels and in the digestive, respiratory, urinary, and reproductive tracts—thus, it is also called **visceral muscle**. In many of the hollow viscera, it forms two or more layers—typically an *inner circular layer*, in which the myocytes encircle the organ, and an outer *longitudinal layer*, in which the myocytes run lengthwise along the organ (fig. 11.22). The name *single-unit* refers to the fact that the myocytes of this type of muscle are electrically coupled to each other by gap junctions. Thus, they directly stimulate each other and a large number of cells contract as a unit, almost as if they were a single cell.

Stimulation of Smooth Muscle

Like cardiac muscle, smooth muscle is involuntary and capable of contracting without nervous stimulation. Some smooth muscle contracts in response to chemical stimuli such as hormones, carbon dioxide, low pH, and oxygen

FIGURE 11.22 Layers of Visceral Muscle in a Cross Section of the Esophagus. Many hollow organs have adjacent circular and longitudinal layers of smooth muscle.

deficiency and in response to stretch (as in a full stomach or bladder). Some single-unit smooth muscle, especially in the stomach and intestines, has pacemaker cells that spontaneously depolarize and set off waves of contraction throughout an entire layer of muscle. Such smooth muscle is autorhythmic, like cardiac muscle, although with a much slower rhythm.

But like cardiac muscle, most smooth muscle is innervated by autonomic nerve fibers that can trigger or modify its contractions. Autonomic nerve fibers stimulate smooth muscle with either acetylcholine or norepinephrine. The nerve fibers have contrasting effects on smooth muscle in different locations. They relax the smooth muscle of arteries while contracting the smooth muscle in the bronchioles of the lungs, for example.

In single-unit smooth muscle, each autonomic nerve fiber has up to 20,000 beadlike swellings called **varicosities** along its length (figs. 11.21 and 11.23). Each varicosity contains synaptic vesicles and a few mitochondria. Instead of closely approaching any one myocyte, the nerve fiber passes amid several myocytes and stimulates all of them at once when it releases its neurotransmitter. The muscle cells do not have motor end plates or any other specialized area of sarcolemma to bind the neurotransmitter; rather, they have receptor sites scattered throughout the surface. Such nerve–muscle relationships are called **diffuse junctions** because there is no one-to-one relationship between a nerve fiber and a myocyte.

FIGURE 11.23 Varicosities of an Autonomic Nerve Fiber in Single-Unit Smooth Muscle.

Contraction and Relaxation

Smooth muscle resembles the other muscle types in that contraction is triggered by Ca^{2+} , energized by ATP, and achieved by the sliding of thin filaments over the thick filaments. The mechanism of excitation–contraction coupling, however, is very different. Little of the Ca^{2+} comes from the sarcoplasmic reticulum; most comes from the extracellular fluid and enters the cell through calcium channels in the sarcolemma. Some of these channels are voltage-regulated and open in response to changes in membrane voltage; some are ligand-regulated and open in response to hormones and neurotransmitters; and some are mechanically regulated and open in response to stretching of the cell.

Think About It

How is smooth muscle contraction affected by the drugs called calcium channel blockers? (See p. 95.)

Smooth muscle has no troponin. Calcium binds instead to a similar protein called **calmodulin**¹³ (cal-MOD-you-lin), associated with the thick filaments. Calmodulin then activates an enzyme called **myosin light-chain kinase**, which adds a phosphate group to a small regulatory protein on the myosin head. This activates the myosin ATPase, enabling it to bind to actin and hydrolyze ATP. The myosin then produces repetitive power and recovery strokes like those of skeletal muscle.

As thick filaments pull on the thin ones, the thin filaments pull on the dense bodies and membrane plaques. Through the dense bodies and cytoskeleton, force is transferred to the plasma membrane and the entire cell shortens.

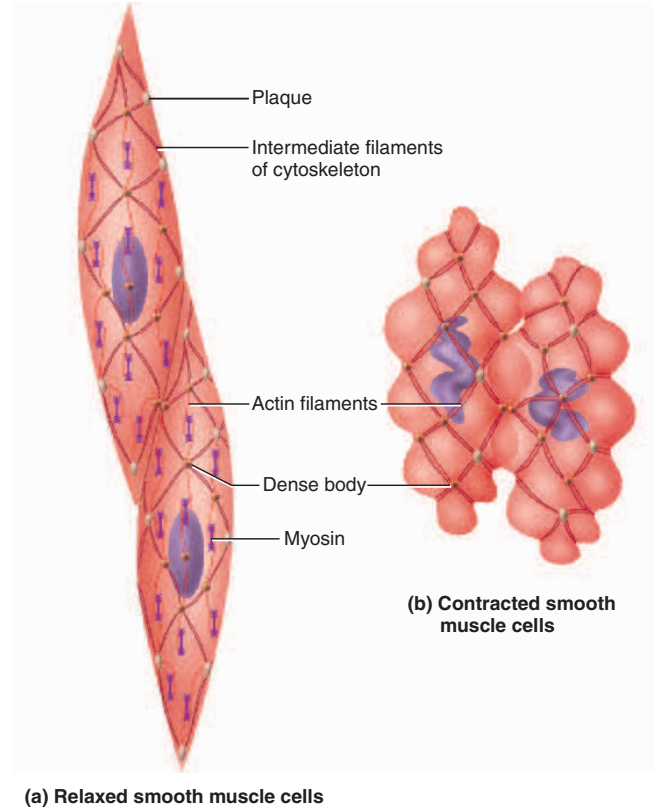

FIGURE 11.24 Smooth Muscle Contraction. (a) Relaxed cells. Actin myofilaments are anchored to plaques on the plasma membrane and to dense bodies in the sarcoplasm, rather than to Z discs. (b) Contracted cells.

When a smooth muscle cell contracts, it puckers and twists somewhat like wringing out a wet towel (fig. 11.24).

In skeletal muscle, there is typically a 2 msec latent period between stimulation and the onset of contraction. In smooth muscle, by contrast, the latent period is 50 to 100 msec long. Tension peaks about 500 msec (0.5 sec) after the stimulus and then declines over a period of 1 to 2 seconds. The effect of all this is that compared with skeletal muscle, smooth muscle is very slow to contract and relax. It is slow to contract because its myosin ATPase is a slow enzyme. It is slow to relax because the pumps that remove Ca^{2+} from the cell are also slow. As the Ca^{2+} level falls, myosin is dephosphorylated and is no longer able to hydrolyze ATP and execute power strokes. However, it does not necessarily detach from actin immediately. It has a *latch-bridge mechanism* that enables it to remain attached to actin for a prolonged time without consuming more ATP.

Smooth muscle often exhibits tetanus and is very resistant to fatigue. It makes most of its ATP aerobically, but its ATP requirement is small and it has relatively few mitochondria. Skeletal muscle requires 10 to 300 times as much ATP as smooth muscle to maintain the same amount of tension. The fatigue resistance and latch-bridge

¹³acronym for calcium modulating protein

mechanism of smooth muscle are important in enabling it to maintain a state of continual **smooth muscle tone** (tonic contraction). Tonic contraction keeps the arteries in a state of partial constriction called *vasomotor tone*. A loss of muscle tone in the arteries can cause a dangerous drop in blood pressure. Smooth muscle tone also keeps the intestines partially contracted. The intestines are much longer in a cadaver than they are in a living person because of the loss of muscle tone at death.

Response to Stretch

Stretch alone sometimes causes smooth muscle to contract by opening mechanically regulated calcium gates in the sarcolemma. Distension of the esophagus with food or the colon with feces, for example, evokes a wave of contraction called **peristalsis** (PERR-ih-STAL-sis) that propels the contents along the organ.

Smooth muscle exhibits a reaction called the **stress-relaxation** (or **receptive relaxation**) **response**. When stretched, it briefly contracts and resists, but then relaxes. The significance of this response is apparent in the urinary bladder, whose wall has three layers of smooth muscle. If the stretched bladder contracted and did not soon relax, it would expel urine almost as soon as it began to fill, thus failing to store the urine until an opportune time.

Remember that skeletal muscle cannot contract very forcefully if it is overstretched. Smooth muscle, however, is not subject to the limitations of the length–tension relationship. It must be able to contract forcefully even when greatly stretched, so that hollow organs such as the stomach and bladder can fill and then expel their contents efficiently. Skeletal muscle must be within 30% of optimum length in order to contract strongly when stimulated. Smooth muscle, by contrast, can be anywhere

from half to twice its resting length and still contract powerfully. There are three reasons for this: (1) there are no Z discs, so thick filaments cannot butt against them and stop the contraction; (2) since the thick and thin filaments are not arranged in orderly sarcomeres, stretching of the muscle does not cause a situation where there is too little overlap for cross-bridges to form; and (3) the thick filaments of smooth muscle have myosin heads along their entire length (there is no bare zone), so cross-bridges can form anywhere, not just at the ends. Smooth muscle also exhibits **plasticity**—the ability to adjust its tension to the degree of stretch. Thus, a hollow organ such as the bladder can be greatly stretched yet not become flabby when it is empty.

The muscular system suffers fewer diseases than any other organ system, but several of its more common dysfunctions are listed in table 11.6. The effects of aging on the muscular system are described on page 1141.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

25. Explain why intercalated discs are important to cardiac muscle function.
26. Explain why it is important for cardiac muscle to have longer-lasting contractions than skeletal muscle.
27. How do single-unit and multiunit smooth muscle differ in innervation and contractile behavior?
28. How does smooth muscle differ from skeletal muscle with respect to its source of calcium and its calcium receptor?
29. Explain why the stress-relaxation response is an important factor in smooth muscle function.

TABLE 11.6 Some Disorders of the Muscular System

Contracture	Abnormal muscle shortening not caused by nervous stimulation. Can result from failure of the calcium pump to remove Ca^{2+} from the sarcoplasm or from contraction of scar tissue, as in burn patients.	
Cramps	Painful muscle spasms triggered by heavy exercise, extreme cold, dehydration, electrolyte loss, low blood glucose, or lack of blood flow.	
Crush syndrome	A shocklike state following the massive crushing of muscles; associated with high and potentially fatal fever, cardiac irregularities resulting from K^+ released from the muscle, and kidney failure resulting from blockage of the renal tubules with myoglobin released by the traumatized muscle. Myoglobinuria (myoglobin in the urine) is a common sign.	
Delayed-onset muscle soreness	Pain, stiffness, and tenderness felt from several hours to a day after strenuous exercise. Associated with microtrauma to the muscles; with disrupted Z discs, myofibrils, and plasma membranes; and with elevated levels of myoglobin, creatine kinase, and lactate dehydrogenase in the blood.	
Disuse atrophy	Reduction in the size of muscle fibers as a result of nerve damage or muscular inactivity, for example in limbs in a cast and in patients confined to a bed or wheelchair. Muscle strength can be lost at a rate of 3% per day of bed rest.	
Fibromyalgia	Diffuse, chronic muscular pain and tenderness, often associated with sleep disturbances and fatigue; often misdiagnosed as chronic fatigue syndrome. Can be caused by various infectious diseases, physical or emotional trauma, or medications. Most common in women 30 to 50 years old.	
Myositis	Muscle inflammation and weakness resulting from infection or autoimmune disease.

INSIGHT 11.5 Clinical Application

Muscular Dystrophy and Myasthenia Gravis

*Muscular dystrophy*¹⁴ is a collective term for several hereditary diseases in which the muscles degenerate, weaken, and are gradually replaced by fat and fibrous scar tissue. The most common form of the disease is *Duchenne*¹⁵ *muscular dystrophy (DMD)*, a sex-linked recessive trait affecting about 1 out of every 3,500 live-born boys.

DMD is not evident at birth, but begins to exhibit its effects as a child shows difficulty keeping up with other children, falls frequently, and finds it hard to stand again. It is typically diagnosed between the ages of 2 and 10 years. It affects the muscles of the hips first; then the legs; and then progresses to the abdominal, spinal, and respiratory muscles as well as cardiac muscle. The muscles shorten as they atrophy, causing postural abnormalities such as scoliosis. Persons with DMD are usually wheelchair-dependent by the age of 10 or 12, and seldom live past the age of 20. For obscure reasons, they also frequently suffer a progressive decline in mental ability. Death usually results from respiratory insufficiency, pulmonary infection, or heart failure. DMD is incurable, but is treated with exercise to slow the atrophy of the muscles and with braces to reinforce the weakened hips and maintain posture.

The underlying cause of DMD is a mutation in the gene for the muscle protein dystrophin (see p. 407)—a large gene

highly vulnerable to mutation. Without dystrophin, there is no coupling between the thin myofilaments and the sarcolemma. The sarcomeres move independently of the sarcolemma, creating tears in the membrane. The torn membrane admits excess Ca^{2+} into the cell, which activates intracellular proteases (protein-digesting enzymes). These enzymes degrade the contractile proteins of the muscle, leading to weakness and cellular necrosis. Dying muscle fibers are replaced with scar tissue, which blocks blood circulation in the muscle and thereby contributes to still further necrosis. Muscle degeneration accelerates in a fatal spiral of positive feedback.

Genetic screening can identify heterozygous carriers of DMD, allowing for counseling of prospective parents on the risk of having a child with the disease. However, about one out of three cases arises by a new spontaneous mutation and therefore cannot be predicted by genetic testing.

A less severe form of muscular dystrophy is *facioscapulo-humeral (Landouzy-Déjérine)*¹⁶ *MD*, an autosomal dominant trait that begins in adolescence and affects both sexes equally. It involves the facial and shoulder muscles more than the pelvic muscles and cripples some individuals while it barely affects others. A third form, *limb-girdle dystrophy*, is a combination of several diseases of intermediate severity that affect the shoulder, arm, and pelvic muscles.

*Myasthenia gravis*¹⁷ (MY-ass-THÉE-nee-uh GRAV-is) (*MG*) usually occurs in women between the ages of 20 and 40. It is

¹⁴*dys* = bad, abnormal + *trophy* = growth

¹⁵Guillaume B. A. Duchenne (1806–75), French physician

¹⁶Louis T. J. Landouzy (1845–1917) and Joseph J. Déjérine (1849–1917), French neurologists

¹⁷*my* = muscle + *asthen* = weakness + *grav* = severe

an autoimmune disease in which antibodies attack the neuromuscular junctions and bind ACh receptors together in clusters. The muscle fiber then removes the clusters from the sarcolemma by endocytosis. As a result, the muscle fibers become less and less sensitive to ACh. The effects often appear first in the facial muscles and commonly include drooping eyelids (*ptosis*, fig. 11.25) and double vision (due to *strabismus*, inability to fixate on the same point with both eyes). The initial symptoms are often followed by difficulty in swallowing, weakness of the limbs, and poor physical endurance. Some people with MG die quickly as a result of respiratory failure, but others have normal life spans. One method of assessing the progress of the disease is to use *bungarotoxin*, a protein from cobra venom that binds to ACh receptors. The amount that binds is proportional to the number of receptors that are still functional. The muscle of an MG patient sometimes binds less than one-third as much bungarotoxin as normal muscle does.

Myasthenia gravis is often treated with cholinesterase inhibitors. These drugs retard the breakdown of ACh in the neuromuscular junction and enable it to stimulate the muscle longer. Immunosuppressive agents such as prednisone and azathioprine (Imuram) may be used to suppress the production of the antibodies that destroy ACh receptors. Since certain immune cells are stimulated by hormones from the thymus, removal of the thymus (*thymectomy*) helps to dampen the overactive immune response that causes myasthenia gravis. Also, a technique called *plasmapheresis* may be used to remove harmful antibodies from the blood plasma.

FIGURE 11.25 Myasthenia Gravis. These photographs were taken when the patient was first told to gaze upward (top photo) and then after 30, 60, and 90 seconds. Note the inability to keep the right eyelid open. This shows the ptosis that is diagnostic of myasthenia gravis.

CHAPTER REVIEW

Review of Key Concepts

11.1 Types and Characteristics of Muscular Tissue (p. 404)

1. Muscular tissue has the properties of responsiveness, conductivity, contractility, extensibility, and elasticity.
2. Skeletal muscle is voluntary striated muscle that is usually attached to one or more bones.
3. A skeletal muscle cell, or muscle fiber, is a threadlike cell typically 100 μm in diameter and 3 cm long.
4. Associated with the muscle fibers are the collagenous endomysium, perimysium, and epimysium, providing continuity from the muscle to the collagen of tendons and bones and transferring force from muscle contraction to bone movement.

11.2 Microscopic Anatomy of Skeletal Muscle (p. 405)

1. The plasma membrane of a muscle fiber is called the *sarcolemma* and its cytoplasm is the *sarcoplasm*. The sarcoplasm is mostly occupied by elongated protein bundles called *myofibrils*. It also contains an abundance of the energy-storage carbohydrate *glycogen*, the oxygen-storage pigment *myoglobin*, and mitochondria.
2. A muscle fiber forms by the fusion of many stem cells called *myoblasts*, each of which contributes one nucleus to the mature, multinuclear fiber. Some myoblasts become *satellite cells* external to the muscle fiber, and may later aid in muscle repair.
3. The *sarcoplasmic reticulum* (smooth ER) forms an extensive calcium-storage network around the myofibrils. Its dilated *terminal cisternae* are closely associated with tunnel-like *transverse tubules* that cross the fiber from side to side.
4. A myofibril is a bundle of two kinds of protein *myofilaments* called thick and thin filaments.
5. *Thick filaments* are composed of bundles of *myosin* molecules, each of which has a filamentous tail and a globular head.

6. Thin filaments are composed mainly of a double strand of *actin*, with a myosin-binding *active site* on each of its globular subunits. In the groove between the two actin strands are two regulatory proteins, *tropomyosin* and *troponin*.
7. Elastic filaments composed of *titin* flank each thick filament and attach to Z discs.
8. Several other accessory proteins are associated with the thick and thin filaments. One of these, *dystrophin*, links the thin filaments to the extracellular proteins of the muscle and thus links the movement of the contractile proteins to the pull exerted on a bone.
9. Skeletal and cardiac muscle exhibit alternating light and dark bands, or *striations*, that result from the pattern of overlap between thick and thin filaments. The principal striations are a dark *A band* with a light *H zone* in the middle, and a light *I band* with a dark line, the *Z disc*, in the middle.
10. The functional unit of a muscle fiber is the *sarcomere*, which is a segment from one Z disc to the next.

11.3 The Nerve–Muscle Relationship (p. 410)

1. Skeletal muscle contracts only when it is stimulated by a *somatic motor nerve fiber*.
2. One somatic motor fiber branches at the end and innervates from 3 to 1,000 muscle fibers. The nerve fiber and its muscle fibers are called a *motor unit*. Small motor units (few muscle fibers per nerve fiber) are found in muscles where fine control of movement is important, and large motor units in muscles where strength is more important than precision.
3. The point where a nerve fiber meets a muscle fiber is a type of synapse called the *neuromuscular junction*. It consists of the *synaptic knob* (a dilated tip of the nerve fiber) resting in a shallow folded depression in the sarcolemma. The gap between the knob and sarcolemma is the *synaptic cleft*. A collagen–glycoprotein layer

called the *basal lamina* fills the synaptic cleft and surrounds the muscle fiber and synapse.

4. *Synaptic vesicles* in the knob release a neurotransmitter called *acetylcholine (ACh)*, which diffuses across the cleft and binds to *ACh receptors* on the sarcolemma.
5. The sarcolemma and basal lamina have an enzyme called *acetylcholinesterase*, which breaks down ACh and ends stimulation of the muscle fiber.
6. An unstimulated nerve, muscle, or other cell has a difference in positive and negative charges on the two sides of its plasma membrane; it is *polarized*. The charge difference, called the *resting membrane potential*, is typically about -90 mV on a muscle fiber.
7. When a nerve or muscle fiber is stimulated, a quick, self-propagating voltage shift called an *action potential* occurs. Action potentials form nerve signals and activate muscle contraction.

11.4 Behavior of Skeletal Muscle Fibers (p. 414)

1. The first stage of muscle action is *excitation*. An arriving nerve signal triggers ACh release, ACh binds to receptors on the sarcolemma and triggers a voltage change called an *end-plate potential (EPP)*, and the EPP triggers action potentials in adjacent regions of the sarcolemma.
2. The second stage is *excitation–contraction coupling*. Action potentials spread along the sarcolemma and down the T tubules, and trigger Ca^{2+} release from the terminal cisternae of the SR. Ca^{2+} binds to troponin of the thin filaments, and tropomyosin shifts position to expose the active sites on the actin.
3. The third stage is *contraction*. A myosin head binds to an active site on actin, flexes, tugs the thin filament closer to the A band, then releases the actin and repeats the process. Each cycle of binding and release consumes one ATP.

- The fourth and final stage is *relaxation*. When nerve signals cease, ACh release ceases. Acetylcholinesterase degrades the ACh already present, halting stimulation of the muscle fiber. The SR pumps Ca^{2+} back into it for storage. In the absence of Ca^{2+} , tropomyosin blocks the active sites of actin so myosin can no longer bind to them, and the muscle relaxes.
- Overly contracted and overly stretched muscle fibers respond poorly to stimulation. A muscle responds best when it is slightly contracted before it is stimulated, so that there is optimal overlap between the resting thick and thin filaments. This is the *length-tension relationship*. *Muscle tone* maintains an optimal resting length and readiness to respond.

11.5 Behavior of Whole Muscles (p. 420)

- A stimulus must be of at least *threshold* strength to make a muscle contract. After a short *latent period*, the muscle responds to a single stimulus with a brief contraction called a *twitch*.
- Muscle twitches vary in strength even when stimulus intensity is constant. Reasons for such variation include stimulus frequency; varying Ca^{2+} concentration in the sarcoplasm; the length-tension relationship; and the temperature, pH, fatigue, and hydration of the muscle.
- A single twitch does no useful work for the body. In *recruitment*, however, multiple motor units are activated at once to produce a stronger muscle contraction. In high-frequency stimulation, successive twitches become progressively stronger; this is called *treppe* when the muscle completely relaxes between twitches and *incomplete tetanus* when it relaxes only partially and each twitch “piggybacks” on the previous ones to achieve greater tension.
- In *isometric contraction*, a muscle develops tension without changing length; in *isotonic contraction*, it changes length while maintaining constant tension. In *concentric contraction*, a muscle maintains tension as it shortens; in *eccentric contraction*, it maintains tension as it lengthens.

11.6 Muscle Metabolism (p. 425)

- A muscle must have ATP in order to contract. It generates ATP by different mechanisms over the duration of a period of exercise.
- At the outset, muscle uses oxygen from its myoglobin to generate ATP by aerobic respiration.
- As the stored oxygen is depleted, muscle regenerates ATP from ADP by adding a phosphate (P_i) to it. It gets this P_i either from another ADP, using the enzyme *myokinase* to transfer the phosphate, or from creatine phosphate, using the enzyme *creatine kinase* to do so. This is the *phosphagen system* for regenerating ATP.
- Further into an exercise, as the phosphagen system is depleted, a muscle shifts to anaerobic fermentation (the *glycogen-lactic acid system*) to generate ATP.
- Still later, the respiratory and circulatory systems may catch up with the demands of a muscle and deliver enough oxygen for aerobic respiration to meet the muscle’s ATP demand.
- Muscle fatigue results from several factors: ATP and ACh depletion, loss of membrane excitability, lactic acid accumulation, and central nervous system mechanisms.
- The ability to maintain high-intensity exercise depends partly on one’s *maximum oxygen uptake* ($\text{VO}_{2\text{max}}$), which varies with body size, age, sex, and physical condition.
- Prolonged exercise produces an *oxygen debt* that is “repaid” by continued heavy breathing after the exercise is over. The extra O_2 breathed during this time goes mainly to restore oxygen reserves in the myoglobin and blood, replenish the phosphagen system, oxidize lactic acid, and meet the needs of a metabolic rate elevated by the high postexercise body temperature.
- Slow oxidative* muscle fibers are adapted for aerobic respiration and are relatively resistant to fatigue, but produce relatively slow responses. *Fast glycolytic* muscle fibers respond more quickly but fatigue sooner. *Intermediate fibers* are relatively rare but combine fast responses with fatigue resistance.
- The strength of a muscle depends on its size, fascicle arrangement, size of its motor units, multiple motor unit summation, temporal summation of

twitches, prestimulation length, and fatigue.

- Resistance exercise stimulates muscle growth and increases strength; endurance exercise increases fatigue resistance.

11.7 Cardiac and Smooth Muscle (p. 430)

- Cardiac muscle consists of relatively short, slightly branched, striated cells joined physically and electrically by *intercalated discs*.
- Cardiac muscle is *autorhythmic* and thus contracts even without nervous stimulation.
- Cardiac muscle is rich in myoglobin, glycogen, and large mitochondria; uses aerobic respiration almost exclusively; and is very fatigue-resistant.
- Smooth muscle consists of short, fusiform, nonstriated cells.
- Smooth muscle has no T tubules and little sarcoplasmic reticulum; it gets Ca^{2+} mainly from the extracellular fluid.
- In multiunit smooth muscle, each cell is separately innervated by an autonomic nerve fiber and contracts independently. In single-unit smooth muscle, the muscle cells are connected by gap junctions and respond as a unit. Nerve fibers do not synapse with any specific muscle cells in the latter type.
- In smooth muscle, Ca^{2+} binds to calmodulin rather than troponin. This activates *myosin light-chain kinase*, which phosphorylates myosin and triggers contraction.
- Smooth muscle lacks Z discs. Its myofilaments indirectly pull on *dense bodies* and cause the cell to contract in a twisting fashion.
- Smooth muscle has a *latch-bridge mechanism* that enables it to maintain tonic contraction with little ATP expenditure.
- In tubular organs such as the esophagus and intestines, smooth muscle often produces waves of contraction called *peristalsis*, which propels the organ contents. Smooth muscle also has a *stress-relaxation response* that allows for the relaxation and filling of saccular organs such as the stomach and urinary bladder.
- Smooth muscle is not subject to the length-tension relationship. Its unusual ability to stretch and maintain responsiveness allows such organs as the stomach and bladder to expand greatly without losing contractility.

Testing Your Recall

- To make a muscle contract more strongly, the nervous system can activate more motor units. This process is called
 - recruitment.
 - summation.
 - incomplete tetanus.
 - twitch.
 - treppe.
- The functional unit of a muscle fiber is the _____, a segment from one Z disc to the next.
 - myofibril
 - I band
 - sarcomere
 - neuromuscular junction
 - striation
- Before a muscle fiber can contract, ATP must bind to
 - a Z disc.
 - the myosin head.
 - tropomyosin.
 - troponin.
 - actin.
- Before a muscle fiber can contract, Ca^{2+} must bind to
 - calsequestrin.
 - the myosin head.
 - tropomyosin.
 - troponin.
 - actin.
- Skeletal muscle fibers have _____, whereas smooth muscle cells do not.
 - T tubules
 - ACh receptors
 - thick myofilaments
 - thin myofilaments
 - dense bodies
- Smooth muscle cells have _____, whereas skeletal muscle fibers do not.
 - sarcoplasmic reticulum
 - tropomyosin
 - calmodulin
 - Z discs
 - myosin ATPase
- ACh receptors are found mainly in
 - synaptic vesicles.
 - terminal cisternae.
 - thick filaments.
 - thin filaments.
 - junctional folds.
- Single-unit smooth muscle cells can stimulate each other because they have
 - a latch-bridge.
 - diffuse junctions.
 - gap junctions.
 - tight junctions.
 - cross-bridges.
- A person with a high VO_2max
 - needs less oxygen than someone with a low VO_2max .
 - has stronger muscles than someone with a low VO_2max .
 - is less likely to show muscle tetanus than someone with a low VO_2max .
 - has fewer muscle mitochondria than someone with a low VO_2max .
 - experiences less muscle fatigue during exercise than someone with a low VO_2max .
- Slow oxidative fibers have all of the following *except*
 - an abundance of myoglobin.
 - an abundance of glycogen.
 - high fatigue resistance.
 - a red color.
 - a high capacity to synthesize ATP aerobically.
- The minimum stimulus intensity that will make a muscle contract is called _____.
- A state of prolonged maximum contraction is called _____.
- Parts of the sarcoplasmic reticulum called _____ lie on each side of a T tubule.
- Thick myofilaments consist mainly of the protein _____.
- The neurotransmitter that stimulates skeletal muscle is _____.
- Muscle contains an oxygen-binding pigment called _____.
- The _____ of skeletal muscle play the same role as dense bodies in smooth muscle.
- In autonomic nerve fibers that stimulate single-unit smooth muscle, the neurotransmitter is contained in swellings called _____.
- A state of continual partial muscle contraction is called _____.
- _____ is an end product of anaerobic fermentation that causes muscle fatigue.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- Each motor neuron supplies just one muscle fiber.
- To initiate muscle contraction, calcium ions must bind to the myosin heads.
- Slow oxidative fibers are relatively resistant to fatigue.
- Thin filaments are found in both the A bands and I bands of striated muscle.
- Thin filaments do not change length when a muscle contracts.
- Smooth muscle lacks striations because it does not have thick and thin myofilaments.
- A muscle must contract to the point of complete tetanus if it is to move a load.
- If no ATP were available to a muscle fiber, the excitation stage of muscle action could not occur.
- For the first 30 seconds of an intense exercise, muscle gets most of its energy from lactic acid.
- Cardiac and some smooth muscle are autorhythmic, but skeletal muscle is not.

Answers in appendix B

Testing Your Comprehension

- Without ATP, relaxed muscle cannot contract and a contracted muscle cannot relax. Explain why.
- Slight pH variations can cause enzymes to change conformation and can reduce enzyme activity. Explain how this relates to muscle fatigue.
- Why would skeletal muscle be unsuitable for the wall of the urinary bladder? Explain how this illustrates the complementarity of form and function at a cellular and molecular level.
- As skeletal muscle contracts, one or more bands of the sarcomere become narrower and disappear, and one or more of them remain the same width. Which bands will change—A, H, or I—and why?
- Botulism occurs when a bacterium, *Clostridium botulinum*, releases a neurotoxin that prevents motor neurons from releasing ACh. In view of this, what early signs of botulism would you predict? Explain why a person with botulism could die of suffocation.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Cations and anions (p. 56)
- Ligand- and voltage-regulated gates (p. 94)
- Cyclic AMP as a second messenger (p. 95)
- Simple diffusion (p. 100)
- Active transport and the sodium-potassium pump (p. 104)

The next five chapters are concerned with the science of **neurobiology**—the study of the nervous system. This is a system of great complexity and mystery. It is the foundation of all our conscious experience, personality, and behavior. It profoundly intrigues biologists, physicians, psychologists, and even philosophers. Understanding this fascinating system is regarded by many as the ultimate challenge facing the behavioral and life sciences.

We begin our study at the simplest organizational level—the nerve cells (*neurons*) and cells called *neuroglia* that support their function in various ways. We then progress to the organ level to examine the spinal cord (chapter 13), brain (chapter 14), autonomic nervous system (chapter 15), and sense organs (chapter 16).

12.1 Overview of the Nervous System

Objectives

When you have completed this section, you should be able to

- describe the overall function of the nervous system; and
- describe the major anatomical and functional subdivisions of the nervous system.

If the body is to maintain homeostasis and function effectively, its trillions of cells must work together in a coordinated fashion. If each cell behaved without regard to what others are doing, the result would be physiological chaos and death. We have two organ systems dedicated to maintaining internal coordination—the **endocrine system**, which communicates by means of chemical messengers (hormones) secreted into the blood, and the **nervous system** (fig. 12.1), which employs electrical and chemical means to send messages very quickly from cell to cell.

The nervous system carries out its coordinating task in three basic steps: (1) Through sense organs and simple sensory nerve endings, it receives information about changes in the body and the external environment and transmits coded messages to the spinal cord and brain. (2) The spinal cord and brain process this information, relate it to past experience, and determine what response, if any, is appropriate to the circumstances. (3) The spinal cord and brain issue commands primarily to muscle and gland cells to carry out such responses.

FIGURE 12.1 The Nervous System.

The nervous system has two major anatomical subdivisions (fig. 12.2):

- The **central nervous system (CNS)** consists of the brain and spinal cord, which are enclosed and protected by the cranium and vertebral column.
- The **peripheral nervous system (PNS)** consists of all the nervous system except the brain and spinal cord. It is composed of nerves and ganglia. A **nerve** is a bundle of nerve fibers (axons) wrapped in fibrous connective tissue. Nerves emerge from the CNS through foramina of the skull and vertebral column and carry signals to and from other organs of the body. A **ganglion**¹ (plural, *ganglia*) is a knotlike swelling in a nerve where the cell bodies of neurons are concentrated.

¹gangli = knot

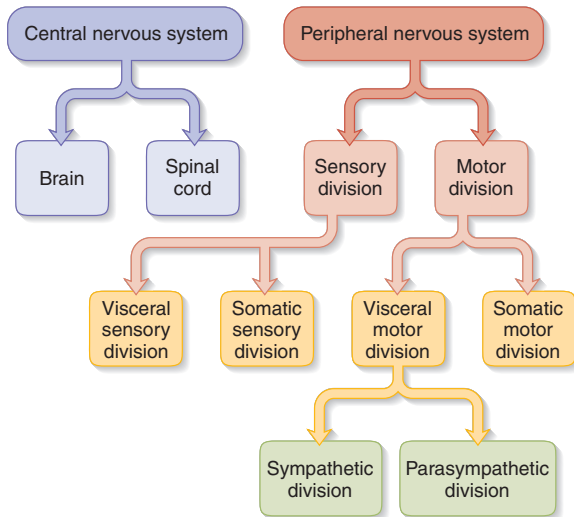

FIGURE 12.2 Subdivisions of the Nervous System.

The peripheral nervous system is functionally divided into *sensory* and *motor* divisions, and each of these is further divided into *somatic* and *visceral* subdivisions.

- The **sensory (afferent²) division** carries sensory signals from various **receptors** (sense organs and simple sensory nerve endings) to the CNS. This is the pathway that informs the CNS of stimuli within and around the body.
 - The **somatic³ sensory division** carries signals from receptors in the skin, muscles, bones, and joints.
 - The **visceral sensory division** carries signals mainly from the viscera of the thoracic and abdominal cavities, such as the heart, lungs, stomach, and urinary bladder.
- The **motor (efferent⁴) division** carries signals from the CNS to gland and muscle cells that carry out the body's responses. Cells and organs that respond to commands from the nervous system are called **effectors**.
 - The **somatic motor division** carries signals to the skeletal muscles. This output produces muscular contractions that are under voluntary control, as well as involuntary muscle contractions called *somatic reflexes*.
 - The **visceral motor division (autonomic⁵ nervous system)** carries signals to glands, cardiac muscle, and smooth muscle. We usually have no voluntary control over these effectors, and this system operates at an unconscious level.

²af = ad = toward + fer = to carry

³somat = body + ic = pertaining to

⁴ef = ex = out, away + fer = to carry

⁵auto = self + nom = law, governance

The responses of this system and its effectors are *visceral reflexes*. The autonomic nervous system has two further divisions:

- The **sympathetic division** tends to arouse the body for action, for example, by accelerating the heartbeat and increasing respiratory air-flow, but it inhibits digestion.
- The **parasympathetic division** tends to have a calming effect, slowing down the heartbeat, for example, but stimulating digestion.

The foregoing terminology may give the impression that the body has several nervous systems—central, peripheral, sensory, motor, somatic, and visceral. These are just terms of convenience, however. There is only one nervous system, and these subsystems are interconnected parts of the whole.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What is a receptor? Give two examples of effectors.
2. Distinguish between the central and peripheral nervous systems, and between visceral and somatic divisions of the sensory and motor systems.
3. What is another name for the visceral motor nervous system? What are the two subdivisions of this system?

12.2 Properties of Neurons

Objectives

When you have completed this section, you should be able to

- describe three functional properties found in all neurons;
- define the three most basic functional categories of neurons;
- identify the parts of a neuron; and
- explain how neurons transport materials between the cell body and tips of the axon.

Universal Properties

The communicative role of the nervous system is carried out by **nerve cells**, or **neurons**. These cells have three fundamental physiological properties that enable them to communicate with other cells:

1. **Excitability (irritability)**. All cells are excitable—that is, they respond to environmental changes called **stimuli**. Neurons have developed this property to the highest degree.

- Conductivity.** Neurons respond to stimuli by producing electrical signals that are quickly conducted to other cells at distant locations.
- Secretion.** When the electrical signal reaches the end of a nerve fiber, the neuron secretes a chemical *neurotransmitter* that crosses the gap and stimulates the next cell.

Think About It

What basic physiological properties do a nerve cell and a skeletal muscle fiber have in common? Name a physiological property of each that the other one lacks.

Functional Classes

There are three general classes of neurons (fig. 12.3) corresponding to the three major aspects of nervous system function listed earlier:

- Sensory (afferent) neurons** are specialized to detect stimuli such as light, heat, pressure, and chemicals, and transmit information about them to the CNS. Such neurons begin in almost every organ of the

FIGURE 12.3 Functional Classes of Neurons. Sensory (afferent) neurons carry signals to the central nervous system (CNS); interneurons are contained entirely within the CNS and carry signals from one neuron to another; and motor (efferent) neurons carry signals from the CNS to muscles and glands.

body and end in the CNS; the word *afferent* refers to signal conduction *toward* the CNS. Some receptors, such as those for pain and smell, are themselves neurons. In other cases, such as taste and hearing, the receptor is a separate cell that communicates directly with a sensory neuron.

- Interneurons⁶ (association neurons)** lie entirely within the CNS. They receive signals from many other neurons and carry out the integrative function of the nervous system—that is, they process, store, and retrieve information and “make decisions” that determine how the body responds to stimuli. About 90% of our neurons are interneurons. The word *interneuron* refers to the fact that they lie *between*, and interconnect, the incoming sensory pathways and the outgoing motor pathways of the CNS.
- Motor (efferent) neurons** send signals predominantly to muscle and gland cells, the effectors that carry out the body’s responses to stimuli. They are called *motor* neurons because most of them lead to muscle cells, and *efferent* neurons to signify signal conduction *away from* the CNS.

Structure of a Neuron

There are several varieties of neurons, as we shall see, but a good starting point for discussing their structure is a motor neuron of the spinal cord (fig. 12.4). The control center of the neuron is the **soma**,⁷ also called the **neuro-soma**, **cell body**, or **perikaryon**⁸ (PERR-ih-CARE-ee-on). It has a single, centrally located nucleus with a large nucleolus. The cytoplasm contains mitochondria, lysosomes, a Golgi complex, numerous inclusions, and an extensive rough endoplasmic reticulum and cytoskeleton. The cytoskeleton consists of a dense mesh of microtubules and **neurofibrils** (bundles of actin filaments), which compartmentalize the rough ER into dark-staining regions called **Nissl⁹ bodies** (fig. 12.4e). Nissl bodies are unique to neurons and a helpful clue to identifying them in tissue sections with mixed cell types. Mature neurons have no centrioles and apparently undergo no further mitosis after adolescence; however, they are unusually long-lived cells, capable of functioning for over a hundred years. Even into old age, however, there are unspecialized stem cells in the CNS that can divide and develop into new neurons.

The major cytoplasmic inclusions in a neuron are glycogen granules, lipid droplets, melanin, and a golden brown pigment called *lipofuscin*¹⁰ (LIP-oh-FEW-sin), produced when lysosomes digest worn-out organelles and other products. Lipofuscin accumulates with age and

⁶*inter* = between

⁹Franz Nissl (1860–1919), German neuropathologist

¹⁰*lipo* = fat, lipid + *fuscin* = dusky, brown

FIGURE 12.4 A Representative Neuron. The Schwann cells and myelin sheath are explained later in this chapter. (a) Structure of a multipolar neuron such as a spinal motor neuron. (b) Photograph of this neuron type. (c) Detail of the myelin sheath. (d) Neurofibrils of the soma. (e) Nissl bodies, stained masses of rough ER separated by the bundles of neurofibrils shown in part (d).

pushes the nucleus to one side of the cell. Lipofuscin granules are also called “wear-and-tear granules” because they are most abundant in old neurons.

The soma usually gives rise to a few thick processes that branch into a vast number of **dendrites**¹¹—named for their striking resemblance to the bare branches of a tree in winter. Dendrites are the primary site for receiving signals from other neurons. Some neurons have only one dendrite and some have thousands. The more dendrites a neuron has, the more information it can receive and incorporate into its decision making. As tangled as the dendrites may seem, they provide exquisitely precise pathways for the reception and processing of neural information.

On one side of the soma is a mound called the **axon hillock**, from which the **axon (nerve fiber)** originates. The axon is cylindrical and relatively unbranched for most of its length, although it may give rise to a few branches called *axon collaterals* along the way, and most axons branch extensively at their distal end. An axon is specialized for rapid conduction of nerve signals to points remote from the soma. Its cytoplasm is called the **axoplasm** and its membrane the **axolemma**.¹² A neuron never has more than one axon, and some neurons in the retina and brain have none. The Schwann cells and myelin sheath that enclose the axon in figure 12.4 are explained in the following section on neuroglia.

Somas range from 5 to 135 μm in diameter, while axons range from 1 to 20 μm in diameter and from a few millimeters to more than a meter long. Such dimensions are more impressive when we scale them up to the size of familiar objects. If the soma of a spinal motor neuron were the size of a tennis ball, its dendrites would form a huge bushy mass that could fill a 30-seat classroom from floor to ceiling. Its axon would be up to a mile long but a little narrower than a garden hose. This is quite a point to ponder. The neuron must assemble molecules and organelles in its “mile-long garden hose” to the end of the axon. How it achieves this remarkable feat is explained shortly.

At the distal end, an axon usually has a **terminal arborization**¹³—an extensive complex of fine branches. Each branch ends in a **synaptic knob (terminal button)**, a little swelling that forms a junction (**synapse**¹⁴) with the next cell. It contains **synaptic vesicles** full of neurotransmitter.

Not all neurons fit the preceding description. Neurons are classified structurally according to the number of processes extending from the soma (fig. 12.5):

- **Multipolar neurons** are those, like the preceding, that have one axon and multiple dendrites. This is the most common type and includes most neurons of the brain and spinal cord.

FIGURE 12.5 Variation in Neuron Structure. Top row, left to right: Two multipolar neurons of the brain—a pyramidal cell and a Purkinje cell. Second row, left to right: Two bipolar neurons—a bipolar cell of the retina and an olfactory neuron. Third row: A unipolar neuron of the type involved in the senses of touch and pain. Bottom row: An anaxonic neuron (amacrine cell) of the retina.

¹¹dendr = tree, branch + ite = little

¹²axo = axis, axon + lemma = husk, peel, sheath

¹³arbor = tree

¹⁴syn = together + aps = to touch, join

- **Bipolar neurons** have one axon and one dendrite. Examples include olfactory cells of the nasal cavity, certain neurons of the retina, and sensory neurons of the inner ear.
- **Unipolar neurons** have only a single process leading away from the soma. They are represented by the neurons that carry sensory signals to the spinal cord. They are also called *pseudounipolar* because they start out as bipolar neurons in the embryo, but their two processes fuse into one as the neuron matures. A short distance away from the soma, the process branches like a T, with a *peripheral fiber* bringing signals from the source of sensation and a *central fiber* continuing into the spinal cord. In most other neurons, a dendrite carries signals toward the soma and an axon carries them away. In unipolar neurons, however, there is one long fiber that bypasses the soma and carries nerve signals directly to the spinal cord. The dendrites are the branching receptive endings in the skin or other place of origin, while the rest of the fiber is considered to be the axon (defined in these neurons by the presence of myelin and the ability to generate action potentials—two concepts explained later in this chapter).
- **Anaxonic neurons** have multiple dendrites but no axon. They communicate through their dendrites and do not produce action potentials. Some anaxonic neurons are found in the brain, retina, and adrenal medulla. In the retina, they help in visual processes such as the perception of contrast.

Axonal Transport

All of the proteins needed by a neuron must be made in the soma, where the protein-synthesizing organelles such as the nucleus, ribosomes, and rough endoplasmic reticulum are located. Yet many of these proteins are needed in the axon, for example to repair and maintain the axolemma, to serve as ion gates in the membrane, or to act in the synaptic knob as enzymes and signaling molecules. Other substances are transported from the axon terminals back to the soma for disposal or recycling. The two-way passage of proteins, organelles, and other materials along an axon is called **axonal transport**. Movement away from the soma down the axon is called **anterograde**¹⁵ transport and movement up the axon toward the soma is called **retrograde**¹⁶ transport.

Materials travel along microtubules of the cytoskeleton, which act like monorail tracks to guide them to their destination. But what is the “motor” that drives them along the tracks? Anterograde transport employs a motor

protein called *kinesin*,¹⁷ while retrograde transport uses one called *dynein*¹⁸ (the same protein we encountered earlier in cilia and flagella; see chapter 3). These proteins carry materials “on their backs” while they reach out, like the myosin heads of muscle (see chapter 11), to bind repeatedly to the microtubules and crawl along them.

There are two types of axonal transport: fast and slow.

1. **Fast axonal transport** occurs at a rate of 20 to 400 mm/day and may be either anterograde or retrograde:
 - *Fast anterograde transport* moves mitochondria, synaptic vesicles, other organelles, components of the axolemma, calcium ions, enzymes such as acetylcholinesterase, and small molecules such as glucose, amino acids, and nucleotides, toward the distal end of the axon.
 - *Fast retrograde transport* returns used synaptic vesicles and other materials to the soma and informs the soma of conditions at the axon terminals. Some pathogens exploit this process to invade the nervous system. They enter the distal tips of an axon and travel to the soma by retrograde transport. Examples include tetanus toxin and the herpes simplex, rabies, and polio viruses. In such infections, the delay between infection and the onset of symptoms corresponds to the time needed for the pathogens to reach the somas.
2. **Slow axonal transport**, also called *axoplasmic flow*, occurs at a rate of 0.5 to 10 mm/day and is always anterograde. It moves enzymes and cytoskeletal components down the axon, renews worn-out axoplasmic components in mature neurons, and supplies new axoplasm for developing or regenerating neurons. Damaged nerve fibers regenerate at a speed governed by slow axonal transport.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

4. Sketch a multipolar neuron and label its soma, dendrites, axon, terminal arborization, synaptic knobs, myelin sheath, and nodes of Ranvier.
5. Explain the difference between a sensory neuron, motor neuron, and interneuron.
6. What is the functional difference between a dendrite and an axon?
7. How do proteins and other chemicals synthesized in the soma get to the synaptic knobs? By what process can a virus that invades a peripheral nerve fiber get to the soma of that neuron?

¹⁵antero = forward + grad = to walk, to step

¹⁶retro = back + grad = to walk, to step

¹⁷kines = motion + in = protein

¹⁸dyne = force + in = protein

12.3 Supportive Cells (Neuroglia)

Objectives

When you have completed this section, you should be able to

- name the six types of cells that aid neurons and state their respective functions;
- describe the myelin sheath that is found around certain nerve fibers and explain its importance;
- describe the relationship of unmyelinated nerve fibers to their supportive cells; and
- explain how damaged nerve fibers regenerate.

There are about a trillion (10^{12}) neurons in the nervous system—10 times as many neurons in your body as there are stars in our galaxy! Yet they are outnumbered as much as 50 to 1 by supportive cells called **neuroglia** (noo-ROG-lee-uh), or **glial** (GLEE-ul) **cells**. Glial cells protect the neurons and help them function. The word *glia*, which means “glue,” implies one of their roles—to bind neurons together and provide a supportive framework for the nervous tissue. In the fetus, glial cells form a scaffold that guides young migrating neurons to their destinations. Wherever a mature neuron is not in synaptic contact with another cell, it is covered with glial cells. This prevents neurons from contacting each other except at points specialized for signal transmission, and thus gives precision to their conduction pathways.

Types of Neuroglia

There are six kinds of neuroglia, each with a unique function (table 12.1). Four types occur only in the central nervous system (fig. 12.6):

1. **Oligodendrocytes**¹⁹ (OL-ih-go-DEN-dro-sites) somewhat resemble an octopus; they have a bulbous body with as many as 15 armlike processes. Each process reaches out to a nerve fiber and spirals around it like electrical tape wrapped repeatedly around a wire. This wrapping, called the *myelin sheath*, insulates the nerve fiber from the extracellular fluid. For reasons explained later, it speeds up signal conduction in the nerve fiber.
2. **Ependymal**²⁰ (ep-EN-dih-mul) **cells** resemble a cuboidal epithelium lining the internal cavities of the brain and spinal cord. Unlike true epithelial cells, however, they have no basement membrane and they exhibit rootlike processes that penetrate into the underlying tissue. Ependymal cells produce *cerebrospinal fluid (CSF)*, a clear liquid that bathes the CNS and fills its internal cavities. They have patches of cilia on their apical

TABLE 12.1 Types of Glial Cells

Types	Functions
Neuroglia of CNS	
Oligodendrocytes	Form myelin in brain and spinal cord
Ependymal cells	Line cavities of brain and spinal cord; secrete and circulate cerebrospinal fluid
Microglia	Phagocytize and destroy microorganisms, foreign matter, and dead nervous tissue
Astrocytes	Cover brain surface and nonsynaptic regions of neurons; form supportive framework in CNS; induce formation of blood-brain barrier; nourish neurons; produce growth factors that stimulate neurons; communicate electrically with neurons and may influence synaptic signaling; remove K^+ and some neurotransmitters from ECF of brain and spinal cord; help to regulate composition of ECF; form scar tissue to replace damaged nervous tissue
Neuroglia of PNS	
Schwann cells	Form neurilemma around all PNS nerve fibers and myelin around most of them; aid in regeneration of damaged nerve fibers
Satellite cells	Surround somas of neurons in the ganglia; provide electrical insulation and regulate chemical environment of neurons

surfaces that help to circulate the CSF. Ependymal cells and CSF are considered in more detail in chapter 14.

3. **Microglia** are small macrophages that develop from white blood cells called monocytes. They wander through the CNS, putting out fingerlike extensions to constantly probe the tissue for cellular debris or other problems. They are thought to perform a complete checkup on the brain tissue several times a day, phagocytizing dead tissue, microorganisms, and other foreign matter. They become concentrated in areas damaged by infection, trauma, or stroke. Pathologists look for clusters of microglia in brain tissue as a clue to sites of injury.
4. **Astrocytes**²¹ are the most abundant glial cells in the CNS and constitute over 90% of the tissue in some areas of the brain. They cover the entire brain surface and most nonsynaptic regions of the neurons in the gray matter of the CNS. They are named for their many-branched, somewhat starlike shape. They have the most diverse functions of any glia:
 - They form a supportive framework for the nervous tissue.
 - They have extensions called *perivascular feet*, which contact the blood capillaries and stimulate

¹⁹oligo = few + dendro = branches + cyte = cell

²⁰ependyma = upper garment

²¹astro = star + cyte = cell

FIGURE 12.6 Neuroglia of the Central Nervous System.

them to form a tight seal called the *blood–brain barrier*. This barrier isolates the blood from the brain tissue and limits what substances are able to get to the brain cells, thus protecting the neurons (see chapter 14).

- They convert blood glucose to lactate and supply this to the neurons for nourishment.
- They secrete proteins called *nerve growth factors* (see Insight 12.3) that promote neuron growth and synapse formation.
- They communicate electrically with neurons and may influence synaptic signaling between them.
- They regulate the chemical composition of the tissue fluid. When neurons transmit signals, they release neurotransmitters and potassium ions. Astrocytes absorb these substances and prevent them from reaching excessive levels in the tissue fluid.
- When neurons are damaged, astrocytes form hardened scar tissue and fill space formerly occupied by the neurons. This process is called *astrocytosis* or *sclerosis*.

The other two types of glial cells occur only in the peripheral nervous system:

5. **Schwann**²² (pronounced “shwon”) **cells** envelop nerve fibers of the PNS. In most cases, a Schwann cell winds repeatedly around a nerve fiber and

produces a myelin sheath similar to the one produced by oligodendrocytes in the CNS. There are some important differences between the CNS and PNS in the way myelin is produced, which we consider shortly. In addition to myelinating peripheral nerve fibers, Schwann cells assist in the regeneration of damaged fibers, which also is discussed later.

6. **Satellite cells** surround the neurosomas in ganglia of the PNS. They provide electrical insulation around the soma and regulate the chemical environment of the neurons.

INSIGHT 12.1

Clinical Application

Glial Cells and Brain Tumors

A tumor consists of a mass of rapidly dividing cells. Mature neurons, however, have little or no capacity for mitosis and seldom form tumors. Some brain tumors arise from the meninges (protective membranes of the CNS) or arise by metastasis from tumors elsewhere, such as malignant melanoma and colon cancer. Most adult brain tumors, however, are composed of glial cells, which are mitotically active throughout life. Such tumors are called *gliomas*.²³ Gliomas usually grow rapidly and are highly malignant. Because of the blood–brain barrier, brain tumors usually do not yield to chemotherapy and must be treated with radiation or surgery.

²²Theodor Schwann (1810–82), German histologist

²³*glia* = glial cells + *oma* = tumor

Myelin

The **myelin** (MY-eh-lin) **sheath** is an insulating layer around a nerve fiber, somewhat like the rubber insulation on a wire. It is formed by oligodendrocytes in the central nervous system and Schwann cells in the peripheral nervous system. Since it consists of the plasma membranes of these glial cells, its composition is like that of plasma membranes in general. It is about 20% protein and 80% lipid, the latter including phospholipids, glycolipids, and cholesterol.

Production of the myelin sheath is called **myelination**. It begins in the fourteenth week of fetal development, yet hardly any myelin exists in the brain at the time of birth. Myelination proceeds rapidly in infancy and isn't completed until late adolescence. Since myelin has such a high lipid content, dietary fat is important to early nervous system development. It is best not to give children under 2 years old the sort of low-fat diets (skimmed milk, etc.) that may be beneficial to an adult.

In the PNS, a Schwann cell spirals repeatedly around a single nerve fiber, laying down as many as a hundred compact layers of its own membrane with almost no cytoplasm between the membranes (fig. 12.7a). These layers constitute the myelin sheath. The Schwann cell spirals outward as it wraps the nerve fiber, finally ending with a thick outermost coil called the **neurilemma**²⁴ (noor-ih-LEM-ah). Here, the bulging body of the Schwann cell contains its nucleus and most of its cytoplasm. External to the neurilemma is a basal lamina and then a thin sleeve of fibrous connective tissue called the *endoneurium*. To visualize this myelination process, imagine that you wrap an almost-empty tube of toothpaste tightly around a pencil. The pencil represents the axon, and the spiral layers of toothpaste tube (with the toothpaste squeezed out) represent the myelin. The toothpaste would be forced to one end of the tube, which would form a bulge on the external surface of the wrapping, like the body of the Schwann cell.

In the CNS, each oligodendrocyte reaches out to myelinate several nerve fibers in its immediate vicinity (fig. 12.7b). Since it is anchored to multiple nerve fibers, it cannot migrate around any one of them like a Schwann cell does. It must push newer layers of myelin under the older ones, so myelination spirals inward toward the nerve fiber. Nerve fibers of the CNS have no neurilemma or endoneurium.

In both the PNS and CNS, a nerve fiber is much longer than the reach of a single glial cell, so it requires many Schwann cells or oligodendrocytes to cover one nerve fiber. Consequently, the myelin sheath is segmented. The gaps between the segments are called **nodes of Ranvier**²⁵ (RON-vee-AY), and the myelin-covered segments from one gap to the next are called **internodes** (see fig. 12.4). The

INSIGHT 12.2 Clinical Application

Diseases of the Myelin Sheath

Multiple sclerosis and Tay-Sachs disease are degenerative disorders of the myelin sheath. In *multiple sclerosis*²⁶ (MS), the oligodendrocytes and myelin sheaths of the CNS deteriorate and are replaced by hardened scar tissue, especially between the ages of 20 and 40. Nerve conduction is disrupted, with effects that depend on what part of the CNS is involved—double vision, blindness, speech defects, neurosis, tremors, or numbness, for example. Patients experience variable cycles of milder and worse symptoms until they eventually become bedridden. The cause of MS remains uncertain; most hypotheses suggest that it is an autoimmune disorder triggered by a virus in genetically susceptible individuals. There is no cure. There is conflicting evidence of how much it shortens a person's life expectancy, if at all. A few die within 1 year of diagnosis, but many people live with MS for 25 or 30 years.

*Tay-Sachs*²⁷ disease is a hereditary disorder seen mainly in infants of Eastern European Jewish ancestry. It results from the abnormal accumulation of a glycolipid called GM₂ (ganglioside) in the myelin sheath. GM₂ is normally decomposed by a lysosomal enzyme, but this enzyme is lacking from people who are homozygous recessive for the Tay-Sachs allele. As GM₂ accumulates, it disrupts the conduction of nerve signals and the victim typically suffers blindness, loss of coordination, and dementia. Signs begin to appear before the child is a year old, and most victims die by the age of 3 or 4 years. Asymptomatic adult carriers can be identified by a blood test and advised by genetic counselors on the risk of their children having the disease.

internodes are about 0.2 to 1.0 mm long. The short section of nerve fiber between the axon hillock and the first glial cell is called the **initial segment**. Since the axon hillock and initial segment play an important role in initiating a nerve signal, they are collectively called the **trigger zone**.

Unmyelinated Nerve Fibers

Many nerve fibers in the CNS and PNS are unmyelinated. In the PNS, however, even the unmyelinated fibers are enveloped in Schwann cells. In this case, one Schwann cell harbors from 1 to 12 small nerve fibers in grooves in its surface (fig. 12.8). The Schwann cell's plasma membrane does not spiral repeatedly around the fiber as it does in a myelin sheath, but folds once around each fiber and somewhat overlaps itself along the edges. This wrapping is the neurilemma (also called a *mesaxon* in unmyelinated nerve fibers). Most nerve fibers travel through individual channels in the Schwann cell, but small fibers are sometimes bundled together within a single channel. A basal lamina surrounds the entire Schwann cell along with its nerve fibers.

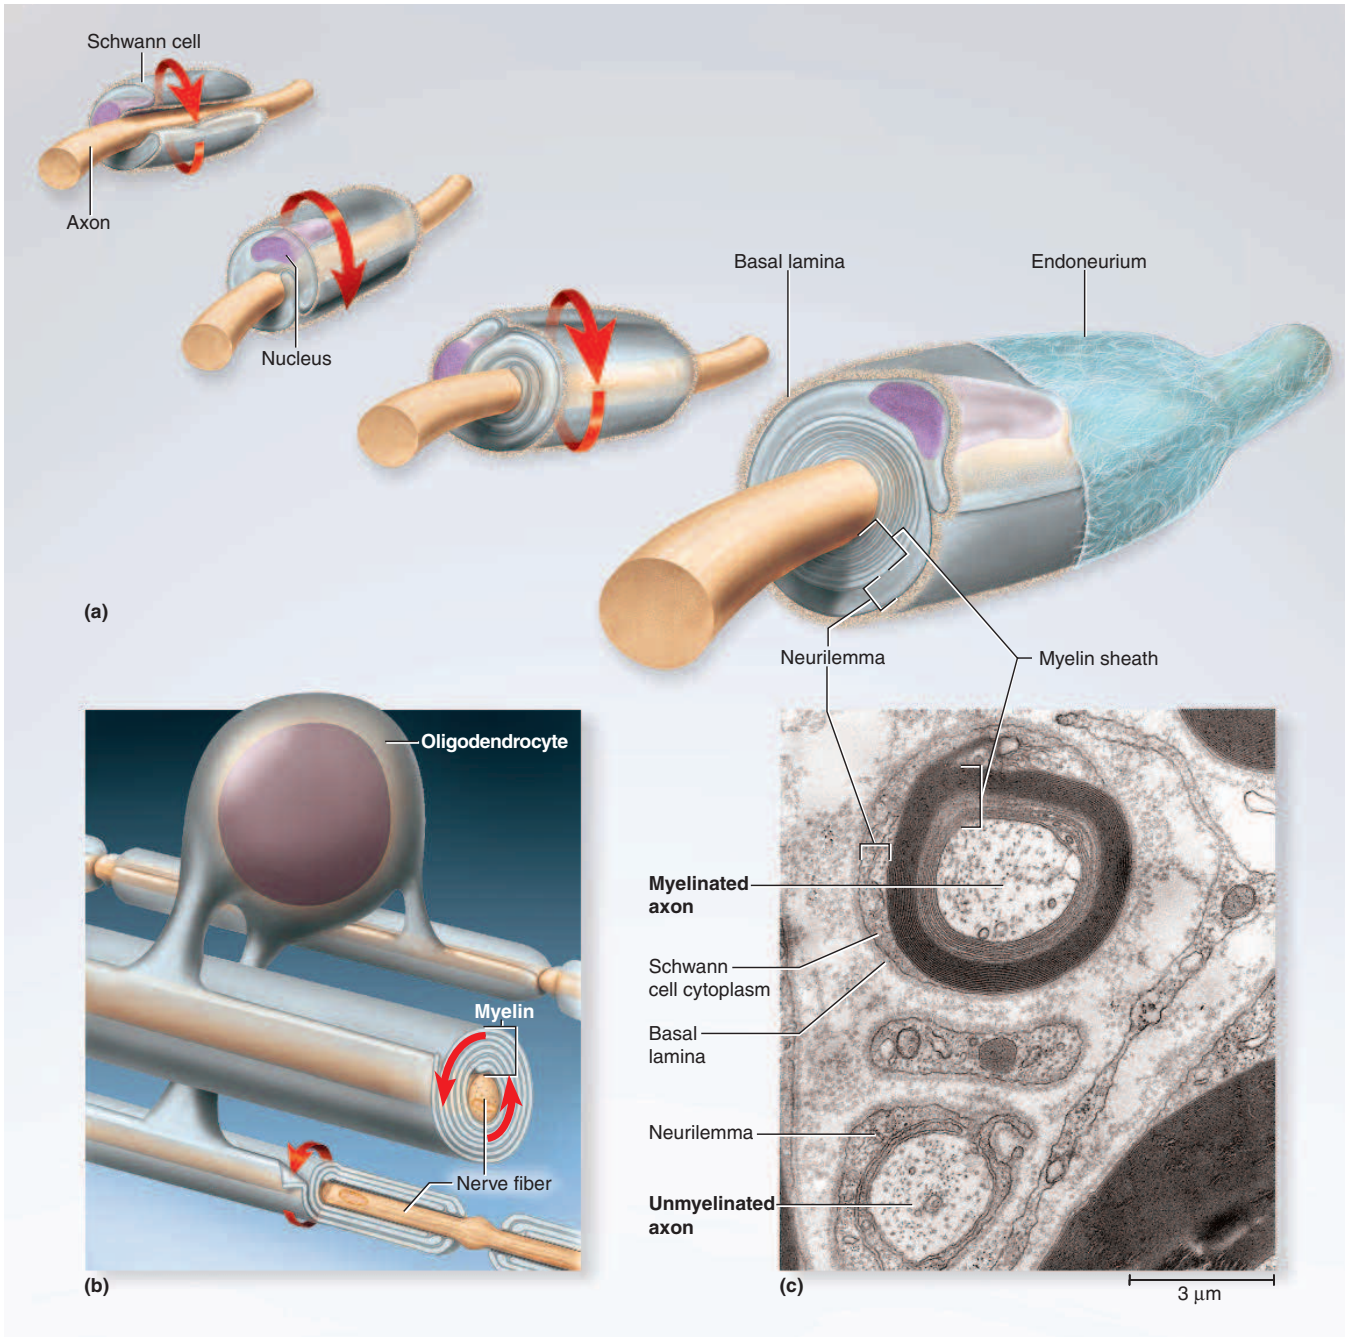

FIGURE 12.7 Myelination. (a) A Schwann cell of the PNS, wrapping repeatedly around an axon to form the multilayered myelin sheath. The myelin spirals outward away from the axon as it is laid down. The outermost coil of the Schwann cell constitutes the neurilemma. (b) An oligodendrocyte of the CNS wrapping around the axons of multiple neurons. Here, the myelin spirals inward toward the axon as it is laid down. These contrasting modes of myelination are called *centrifugal myelination* ("away from the center") in the PNS and *centripetal myelination* ("toward the center") in the CNS. (c) A myelinated axon (top) and unmyelinated axon (bottom) (TEM).

FIGURE 12.8 Unmyelinated Nerve Fibers. Multiple unmyelinated fibers are enclosed in channels in the surface of a single Schwann cell. In some cases, smaller nerve fibers may be bundled together within a single Schwann cell channel.

❖ What is the functional disadvantage of an unmyelinated nerve fiber? What is its anatomical advantage?

Conduction Speed of Nerve Fibers

The speed at which a nerve signal travels along a nerve fiber depends on two factors: the diameter of the fiber and the presence or absence of myelin. Signal conduction occurs along the surface of a fiber, not deep within its axoplasm. Large fibers have more surface area and conduct signals more rapidly than small fibers. Myelin further speeds signal conduction for reasons discussed later. Nerve signals travel about 0.5 to 2.0 m/sec in small unmyelinated fibers (2–4 μm in diameter) and 3 to 15 m/sec in myelinated fibers of the same size. In large myelinated fibers (up to 20 μm in diameter), they travel as fast as 120 m/sec. One might wonder why all of our nerve fibers are not large,

myelinated, and fast, but if this were so, our nervous system would be impossibly bulky or limited to far fewer fibers. Slow unmyelinated fibers are quite sufficient for processes in which quick responses are not particularly important, such as secreting stomach acid or dilating the pupil. Fast myelinated fibers are employed where speed is more important, as in motor commands to the skeletal muscles and sensory signals for vision and balance.

Regeneration of Nerve Fibers

Nerve fibers of the PNS are vulnerable to cuts, crushing injuries, and other trauma. A damaged peripheral nerve fiber may regenerate, however, if its soma is intact and at least some neurilemma remains. Figure 12.9 shows the process of regeneration, taking as its example a somatic motor neuron:

- 1 In the normal nerve fiber, note the size of the soma and the size of the muscle fibers for comparison to later stages.
- 2 When a nerve fiber is cut, the fiber distal to the injury cannot survive because it is incapable of protein synthesis. Protein-synthesizing organelles are limited to the soma. As the distal fiber degenerates, so do its Schwann cells, which depend on it for their maintenance. Macrophages clean up tissue debris at the point of injury and beyond.
- 3 The soma exhibits a number of abnormalities of its own, probably because it is cut off from the supply of nerve growth factors from the neuron's target cells (see Insight 12.3). The soma swells, the endoplasmic reticulum breaks up (so the Nissl bodies disperse), and the nucleus moves off center. Not all damaged neurons survive; some die at this stage. But often, the axon stump sprouts multiple growth processes as the severed distal end shows continued degeneration of its axon and Schwann cells. Muscle fibers deprived of their nerve supply exhibit a shrinkage called *denervation atrophy*.
- 4 Near the injury, Schwann cells, the basal lamina, and the neurilemma form a **regeneration tube**. The Schwann cells produce cell-adhesion molecules and nerve growth factors that enable a neuron to regrow to its original destination. When one growth process finds its way into the tube, it grows rapidly (3–5 mm/day), and the other growth processes are retracted.
- 5 The regeneration tube guides the growing sprout back to the original target cells, reestablishing synaptic contact.
- 6 When contact is established, the soma shrinks and returns to its original appearance, and the reinnervated muscle fibers regrow.

FIGURE 12.9 Regeneration of a Damaged Nerve Fiber. See text for explanation.

Regeneration is not perfect. Some nerve fibers connect to the wrong muscle fibers or never find a muscle fiber at all, and some damaged motor neurons simply die. Nerve injury is therefore often followed by some degree of functional deficit. Damaged nerve fibers in the CNS cannot regenerate at all, but since the CNS is enclosed in bone, it suffers less trauma than the PNS.

Think About It

What features necessary for regeneration, present in the PNS, are lacking from the CNS?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

8. How is a glial cell different from a neuron? List the six types of glial cells and discuss their functions.
9. How is myelin produced? How does myelin production in the CNS differ from that in the PNS?
10. How can a severed peripheral nerve fiber find its way back to the cells it originally innervated?

12.4 Electrophysiology of Neurons

Objectives

When you have completed this section, you should be able to

- explain why a cell has an electrical charge difference (voltage) across its membrane;
- explain how stimulation of a neuron causes a local electrical response in its membrane;
- explain how local responses generate a nerve signal; and
- explain how the nerve signal is conducted down an axon.

The nervous system has intrigued scientists and philosophers since ancient times. The Roman physician Galen thought that the brain pumped a vapor called *psychic pneuma* through hollow nerves and squirted it into the muscles to make them contract. The French philosopher René Descartes still argued for this theory in the seventeenth century. It finally fell out of favor in the eighteenth century, when Luigi Galvani discovered the role of electricity in muscle contraction (see p. 421). Further progress had to await improvements in microscope technology and histological staining methods. Italian histologist Camillo Golgi (1843–1926) developed an important method for staining neurons with silver. This enabled Spanish histologist Santiago Ramón y Cajal

INSIGHT 12.3 Medical History

Nerve Growth Factor—From Bedroom Laboratory to Nobel Prize

It is remarkable what odds can be overcome by intelligent self-confidence. Neurobiologist Rita Levi-Montalcini (1909–) (fig. 12.10) affords a striking example. Born of a cultured and accomplished Italian Jewish family, Rita and her twin sister Paola aspired to attend a college-preparatory high school. Their tradition-minded father, however, believed the only fitting roles for women were wife and mother; he sent them instead to a high school with no mathematics or science classes for girls. The girls decided to attend university anyway, and hired their own tutor to prepare them for the admissions exam. Rita entered medical school in 1930, graduated *summa cum laude* in medicine and surgery, and embarked on advanced study in psychiatry and neurology. Paola became a renowned artist.

But then arose the sinister specter of antisemitism, as fascist dictator Mussolini issued a 1936 decree barring Jews from academic or professional careers. Levi-Montalcini returned to live with her family, despairing of being able to pursue medical practice or research. A visiting college friend, however, reminded her of how much the neuroanatomist Ramón y Cajal had done under very primitive conditions. That inspired her to set up a little laboratory in her bedroom, where she studied nervous system development in chick embryos. She had read of work by Viktor Hamburger at Washington University in St. Louis, Missouri, showing that early removal of the limbs from chick embryos stopped the growth of motor nerves from the spinal cord. Hamburger believed the limb tissues must secrete a chemical that attracts nerves to grow into them. Levi-Montalcini, however, believed that nerves start to grow into the limb stumps, but soon die for lack of a substance needed to sustain them.

Fleeing first from Allied bombing and then from Hitler's invasion of Italy, Levi-Montalcini had to abandon her work and go into hiding with her family until the end of the war. At war's end, Hamburger invited her to join him at Washington University,

FIGURE 12.10 Rita Levi-Montalcini (1909–).

where they found her hypothesis to be correct. Levi-Montalcini and Stanley Cohen isolated the nerve-sustaining substance in the 1950s and named it *nerve growth factor* (NGF). NGF is a protein secreted by gland, muscle, and glial cells and picked up by the axon terminals of neurons. It prevents apoptosis in growing neurons and thus enables them to establish connections with their target cells. Levi-Montalcini and Cohen shared a 1986 Nobel Prize for their discovery. NGF was the first of many cell growth factors discovered, and launched what is today a vibrant field of research in the use of growth factors to stimulate tissue development and repair (see Insight 12.4, for example).

Levi-Montalcini followed this discovery with other pioneering work in apoptosis. She and her sister Paola also created the Levi-Montalcini Foundation to support the career development of young people and especially the scientific education of women in Africa.

(1852–1934), with tremendous skill and patience, to trace the course of nerve fibers through tissue sections. He demonstrated that the nervous pathway was not a continuous “wire” or tube, but a series of cells separated by the gaps we now call synapses. Golgi and Ramón y Cajal shared the 1906 Nobel Prize for Physiology or Medicine for these important discoveries.

Ramón y Cajal's theory, now called the *neuron doctrine*, suggested another direction for research—how do neurons communicate? Two key issues in neurophysiology are (1) How does a neuron generate an electrical signal, and (2) How does it transmit a meaningful message to the next cell? These are the questions to which this section and the next are addressed.

Electrical Potentials and Currents

Neural communication, like muscle excitation, is based on electrophysiology—cellular mechanisms for producing electrical potentials and currents. An **electrical potential** is a difference in the concentration of charged particles between one point and another. It is a form of potential energy that, under the right circumstances, can produce a current. An electrical **current** is a flow of charged particles from the one point to another. A new flashlight battery, for example, typically has a potential, or charge, of 1.5 volts (V). If the two poles of the battery are connected by a wire, electrons flow through the wire from one pole of the battery to the other, creating a current that lights the

bulb. As long as the battery has a potential (voltage), we say it is **polarized**.

Living cells are also polarized. As we saw in chapter 11, the charge difference across the plasma membrane is called the **resting membrane potential (RMP)**. It is much less than the potential of a flashlight battery—typically about -70 millivolts (mV) in an unstimulated, “resting” neuron. The negative value means there are more negatively charged particles on the inside of the membrane than on the outside.

We do not have free electrons in the body as we do in an electrical circuit. Electrical currents in the body are created, instead, by the flow of ions such as Na^+ and K^+ through gated channels in the plasma membrane. As we saw in chapters 3 and 11, gated channels can be opened and closed by various stimuli. This enables cells to turn electrical currents on and off.

The Resting Membrane Potential

The reason a cell has a resting membrane potential is that electrolytes are unequally distributed between the extracellular fluid (ECF) on the outside of the plasma membrane and the intracellular fluid (ICF) on the inside. The RMP results from the combined effect of three factors: (1) the diffusion of ions down their concentration gradients through the membrane; (2) selective permeability of the membrane, allowing some ions to pass more easily than others; and (3) the electrical attraction of cations and anions to each other.

Potassium ions (K^+) have the greatest influence on the RMP, because the plasma membrane is more permeable to K^+ than to any other ion. Imagine a hypothetical cell in which all the K^+ starts out in the ICF, with none in the ECF. Also in the ICF are a number of cytoplasmic anions that cannot escape from the cell because of their size or charge—phosphates, sulfates, small organic acids, proteins, ATP, and RNA. Assuming K^+ can diffuse freely through channels in the plasma membrane, it diffuses down its concentration gradient and out of the cell, leaving these cytoplasmic anions behind (fig. 12.11). As a result, the ICF grows more and more negatively charged. But as the ICF becomes more negative, it exerts a stronger attraction for the positive potassium ions and attracts some of them back into the cell. Eventually an *equilibrium* (balance) is reached in which K^+ is moving out of the cell (diffusion down its concentration gradient) and into the cell (by electrical attraction) at equal rates. The *net* diffusion of K^+ then stops. At the point of equilibrium, K^+ is about 40 times as concentrated in the ICF as in the ECF.

If K^+ were the only ion affecting the RMP, it would give the membrane a potential of about -90 mV. However, sodium ions (Na^+) also enter the picture. Sodium is about 12 times as concentrated in the ECF as in the ICF. The resting plasma membrane is much less permeable to Na^+ than to K^+ , but Na^+ does diffuse down its concentration gradient into the cell, attracted by the negative charge in

FIGURE 12.11 Ionic Basis of the Resting Membrane

Potential. Note that sodium ions are much more concentrated in the extracellular fluid (ECF) than in the intracellular fluid (ICF), while potassium ions are more concentrated in the ICF. Large anions unable to penetrate the plasma membrane give the cytoplasm a negative charge relative to the ECF.

❏ If we suddenly increased the concentration of Cl^- ions in the ICF, would the membrane potential become higher or lower?

the ICF. This sodium leak is only a trickle, but it is enough to neutralize some of the negative charge and reduce the voltage across the membrane.

Sodium leaks into the cell and potassium leaks out, but the sodium–potassium (Na^+/K^+) pump described in chapter 3 continually compensates for this leakage. It pumps 3 Na^+ out of the cell for every 2 K^+ it brings in, consuming 1 ATP for each exchange cycle. By removing more cations from the cell than it brings in, it contributes about -3 mV to the resting membrane potential. The net effect of all this— K^+ diffusion out of the cell, Na^+ diffusion inward, and the Na^+/K^+ pump—is the resting membrane potential of -70 mV.

The Na^+/K^+ pump accounts for about 70% of the energy (ATP) requirement of the nervous system. Every signal generated by a neuron slightly upsets the distribution of Na^+ and K^+ , so the pump must work continually to restore equilibrium. This is why nervous tissue has one of the highest rates of ATP consumption of any tissue in the body, and why it demands so much glucose and oxygen. Although a neuron is said to be resting when it is not producing signals, it is highly active maintaining its RMP and “waiting,” as it were, for something to happen.

Local Potentials

We now consider the disturbances in membrane potential that occur when a neuron is stimulated. Typically (but with exceptions), the response of a neuron begins at a dendrite, spreads through the soma, travels down the axon, and ends at the synaptic knobs. We consider the process in that order.

Various neurons can be stimulated by chemicals, light, heat, or mechanical distortion of the plasma membrane. We'll take as our example a neuron being chemically stimulated on its dendrite (fig. 12.12). The chemical—perhaps a pain signal from a damaged tissue or odor molecule in a breath of air—binds to receptors on the neuron. This leads to the opening of sodium gates that allow Na^+ to rush into the cell. The Na^+ inflow neutralizes some of the internal negative charge, so the voltage across the membrane drifts toward zero. Any such case in which membrane voltage shifts to a less negative value is called **depolarization**.

The incoming Na^+ diffuses for short distances along the inside of the plasma membrane and produces a current that travels from the point of stimulation toward the cell's trigger zone. This short-range change in voltage is called a **local potential**. There are four characteristics that distinguish local potentials from the action potentials we will study shortly (table 12.2). You will appreciate these distinctions more fully after you have studied action potentials.

1. Local potentials are **graded**, meaning that they vary in magnitude (voltage) according to the strength of the stimulus. An intense or prolonged stimulus opens more ion gates than a weaker stimulus. Thus, more Na^+ enters the cell and the voltage changes more than it does with a weaker stimulus.
2. Local potentials are **decremental**, meaning they get weaker as they spread from the point of stimulation. The decline in strength occurs because as Na^+ spreads out under the plasma membrane and depolarizes it, K^+ flows out and reverses the effect of the Na^+ inflow. Therefore, the voltage shift caused by Na^+ diminishes rapidly with distance. This prevents local potentials from having long-distance effects.
3. Local potentials are **reversible**, meaning that if stimulation ceases, K^+ diffusion out of the cell quickly returns the membrane voltage to its resting potential.
4. Local potentials can be either **excitatory** or **inhibitory**. So far, we have considered only

FIGURE 12.12 Excitation of a Neuron by a Chemical Stimulus. When the chemical (ligand) binds to a receptor on the neuron, the receptor acts as a ligand-regulated gate that opens and allows Na^+ to diffuse into the cell. This depolarizes the plasma membrane.

excitatory local potentials, which depolarize a cell and make a neuron more likely to produce an action potential. Acetylcholine usually has this effect. Other neurotransmitters, such as glycine, cause an opposite effect—they **hyperpolarize** a cell, or make the membrane more negative. The neuron is then less sensitive and less likely to produce an action potential. A balance between excitatory and inhibitory potentials is very important to information processing in the nervous system, and we explore this more fully later in the chapter.

TABLE 12.2

Comparison of Local Potentials and Action Potentials

Local Potential	Action Potential
Produced by gated channels on the dendrites and soma	Produced by voltage-regulated gates on the trigger zone and axon
May be a positive (depolarizing) or negative (hyperpolarizing) voltage change	Always begins with depolarization
Graded; proportional to stimulus strength	All or none; either does not occur at all or exhibits the same peak voltage regardless of stimulus strength
Reversible; returns to RMP if stimulation ceases before threshold is reached	Irreversible; goes to completion once it begins
Local; has effects for only a short distance from point of origin	Self-propagating; has effects a great distance from point of origin
Decremental; signal grows weaker with distance	Nondecremental; signal maintains same strength regardless of distance

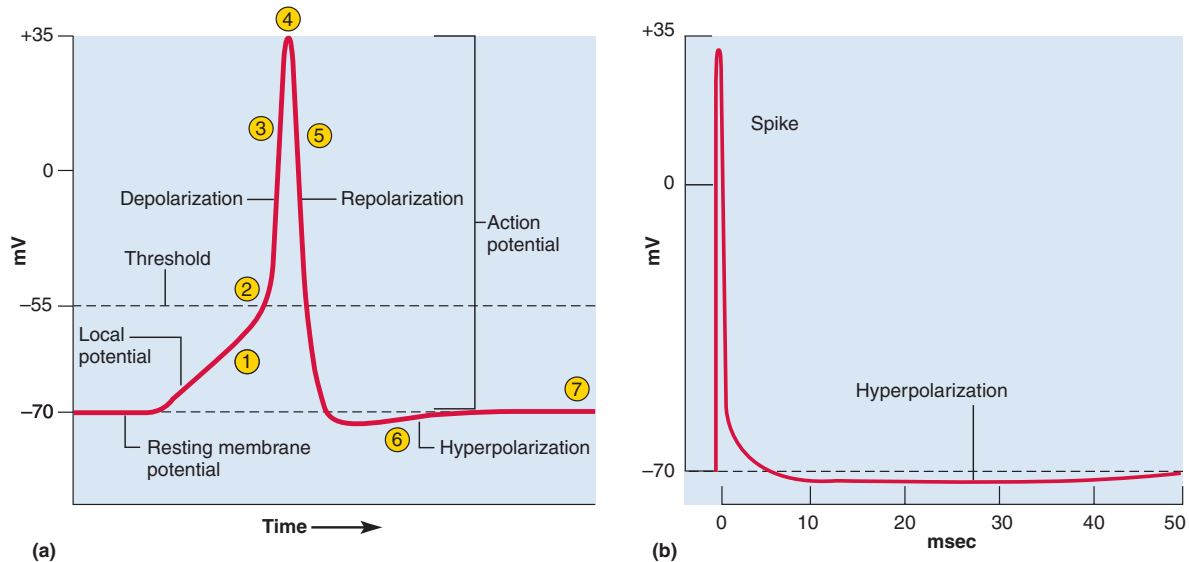

FIGURE 12.13 An Action Potential. (a) Diagrammed with a distorted timescale to make details of the action potential visible. Numbers correspond to stages discussed in the text. (b) On an accurate timescale, the local potential is so brief it is imperceptible, the action potential appears as a spike, and the hyperpolarization is very prolonged.

Action Potentials

An **action potential** is a more dramatic change produced by voltage-regulated ion gates in the plasma membrane. Action potentials occur only where there is a high enough density of voltage-regulated gates. Most of the soma has only 50 to 75 gates per square micrometer (μm^2) and cannot generate action potentials. The trigger zone, however, has 350 to 500 gates per μm^2 . If an excitatory local potential spreads all the way to the trigger zone and is still strong enough when it arrives, it can open these gates and generate an action potential.

The action potential is a rapid up-and-down shift in membrane voltage. Figure 12.13a shows an action potential numbered to correspond to the following description.

- 1 When sodium ions arrive at the axon hillock, they depolarize the membrane at that point. This appears as a steadily rising local potential.
- 2 For anything more to happen, this local potential must rise to a critical voltage called the **threshold** (typically about -55 mV). This is the minimum needed to open voltage-regulated gates.
- 3 The neuron now “fires,” or produces an action potential. At threshold, voltage-regulated Na^+ gates open quickly, while K^+ gates open more slowly. The initial effect on membrane potential is therefore due to Na^+ . Initially, only a few Na^+ gates open, but as Na^+ enters the cell, it further depolarizes the membrane. This stimulates still more voltage-regulated Na^+ gates to open and admit even more Na^+ . Thus,

a positive feedback cycle is created that makes the membrane voltage rise rapidly.

- 4 As the rising membrane potential passes 0 mV, Na^+ gates are *inactivated* and begin closing. By the time they all close and Na^+ inflow ceases, the voltage peaks at approximately $+35$ mV. (The peak is as low as 0 mV in some neurons and as high as 50 mV in others.) The membrane is now positive on the inside and negative on the outside—its polarity is reversed compared to the RMP.
- 5 By the time the voltage peaks, the slow K^+ gates are fully open. Potassium ions, repelled by the positive intracellular fluid, now exit the cell. Their outflow **repolarizes** the membrane—that is, it shifts the voltage back into the negative numbers. The action potential consists of the up-and-down voltage shifts that occur from the time the threshold is reached to the time the voltage returns to the RMP.
- 6 Potassium gates stay open longer than Na^+ gates, so slightly more K^+ leaves the cell than the amount of Na^+ that entered. Therefore, the membrane voltage drops to 1 or 2 mV more negative than the original RMP, producing a negative overshoot called **hyperpolarization** (or *afterpotential*).
- 7 As you can see, Na^+ and K^+ switch places across the membrane during an action potential. During hyperpolarization, Na^+ diffusion into the cell and (in the CNS) the removal of extracellular K^+ by astrocytes gradually restore the original RMP.

FIGURE 12.14 Actions of the Sodium and Potassium Gates During an Action Potential. The red part of each graph in the action potential where the events of steps 1 through 4 are occurring.

Figure 12.14 correlates these voltage changes with events in the plasma membrane. At the risk of being misleading, this figure is drawn as if most of the Na^+ and K^+ had traded places. In reality, only about one ion in a million crosses the membrane to produce an action potential, and an action potential affects ion distribution only in a thin layer close to the membrane. If the illustration tried to represent these points accurately, the difference would be so slight you could not see it; indeed, the changes in ion concentrations inside and outside the cell are so slight they cannot be measured in the laboratory

unless a neuron has been stimulated to produce numerous action potentials in quick succession. Even after thousands of action potentials, the cytosol still has a higher concentration of K^+ and a lower concentration of Na^+ than the ECF does.

Figure 12.13a also is deliberately distorted. In order to demonstrate the different phases of the local potential and action potential, the magnitudes of the local potential and hyperpolarization are exaggerated, the local potential is stretched out to make it seem longer, and the duration of hyperpolarization is shrunken so the graph will fit the page.

When these events are plotted on a more realistic timescale, they look like figure 12.13b. The local potential is so brief it is unnoticeable, and hyperpolarization is very long but only slightly more negative than the RMP. An action potential is often called a *spike*; it is easy to see why from this figure.

Earlier we saw that local potentials are graded, decremental, and reversible. We can now examine how action potentials compare on these points.

- Action potentials follow an **all-or-none law**. If a stimulus depolarizes the neuron to threshold, the neuron fires at its maximum voltage (such as +35 mV); if threshold is not reached, the neuron does not fire at all. Above threshold, stronger stimuli do not produce stronger action potentials. Thus, action potentials are not graded (proportional to stimulus strength).
- Action potentials are **nondcremental**. For reasons to be examined shortly, they do not get weaker with distance. The last action potential at the end of a nerve fiber is just as strong as the first action potential in the trigger zone up to a meter away.
- Action potentials are **irreversible**. If a neuron reaches threshold, the action potential goes to completion; it cannot be stopped once it begins.

In some respects, we can compare the firing of a neuron to the firing of a gun. As the trigger is squeezed, a gun either fires with maximum force or does not fire at all (analogous to the all-or-none law). You cannot fire a fast bullet by squeezing the trigger hard or a slow bullet by squeezing it gently—once the trigger is pulled to its “threshold,” the bullet always leaves the muzzle at the same velocity. And, like an action potential, the firing of a gun is irreversible once the threshold is reached. Table 12.2 further contrasts a local potential with an action potential, including some characteristics of action potentials explained in the following sections.

The Refractory Period

During an action potential and for a few milliseconds after, it is difficult or impossible to stimulate that region of a neuron to fire again. This period of resistance to restimulation is called the **refractory period**. It is divided into two phases: an *absolute refractory period* in which no stimulus of any strength will trigger a new action potential, followed by a *relative refractory period* in which it is possible to trigger a new action potential, but only with an unusually strong stimulus (fig. 12.15).

The absolute refractory period lasts from the start of the action potential until the membrane returns to the resting potential—that is, for as long as the Na⁺ gates are open and subsequently inactivated. The relative refractory period lasts until hyperpolarization ends. During this period, K⁺ gates are still open. A new stimulus tends to admit Na⁺ and depolarize the membrane, but K⁺ diffuses out through the open gates as Na⁺ comes in, and thus

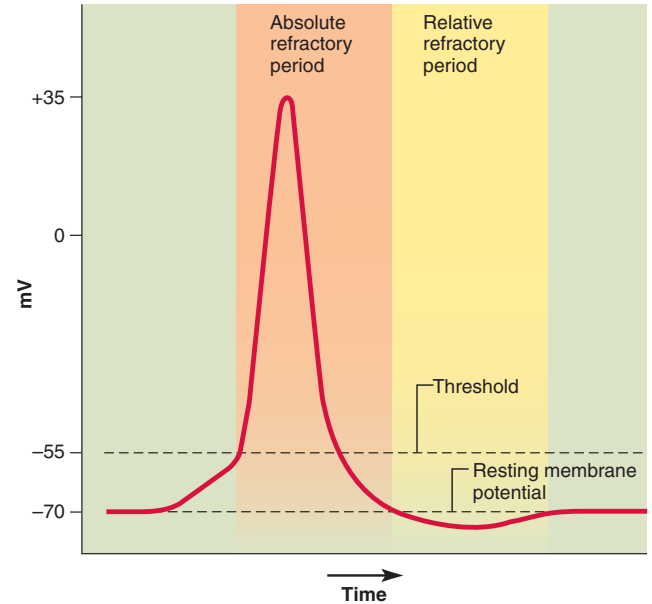

FIGURE 12.15 The Absolute and Relative Refractory Periods in Relation to the Action Potential.

opposes the effect of the stimulus. It requires an especially strong stimulus to override the K⁺ outflow and depolarize the cell enough to set off a new action potential. By the end of hyperpolarization, K⁺ gates are closed and the cell is as responsive as ever.

The refractory period refers only to a small patch of membrane where an action potential has already begun, not to the entire neuron. Other parts of the neuron can still be stimulated while a small area of it is refractory, and even this area quickly recovers once the nerve signal has passed on.

Signal Conduction in Nerve Fibers

If a neuron is to communicate with another cell, a signal has to travel to the end of the axon. We can now examine how this is achieved.

Unmyelinated Fibers

Unmyelinated fibers present a relatively simple case of signal conduction, easy to understand based on what we have already covered (fig. 12.16). An unmyelinated fiber has voltage-regulated ion gates along its entire length. When an action potential occurs at the trigger zone, Na⁺ enters the axon and diffuses to adjacent regions just beneath the plasma membrane. The resulting depolarization excites voltage-regulated gates immediately distal to the action potential. Sodium and potassium gates open and close just as they did at the trigger zone, and a new action potential is produced. By repetition, this excites the membrane immediately distal to that. This chain reaction continues until the traveling signal reaches the end of the axon.

460 PART THREE Integration and Control

FIGURE 12.16 Conduction of a Nerve Signal in an Unmyelinated Fiber. Note that the membrane polarity is reversed in the region of the action potential (red). A region of membrane in its refractory period (yellow) trails the action potential and prevents the nerve signal from going backward toward the soma. The other membrane areas (green) are fully polarized and ready to respond.

Note that an action potential itself does not travel along an axon; rather, it stimulates the production of a new action potential in the membrane just ahead of it. Thus, we can distinguish an *action potential* from a *nerve signal*. The nerve signal is a traveling wave of excitation produced by self-propagating action potentials. It is like a line of falling dominoes. No one domino travels to the end of the line, but each domino pushes over the next one and there is a transmission of energy from the first domino to the last. Similarly, no one action potential travels to the end of an axon; a nerve signal is a chain reaction of action potentials.

If one action potential stimulates the production of a new one next to it, you might think that the signal could also start traveling backward and return to the soma. This does not occur, however, because the membrane behind the nerve signal is still in its refractory period and cannot be restimulated. Only the membrane ahead is sensitive to stimulation. The refractory period thus ensures that nerve signals are conducted in the proper direction, from the soma to the synaptic knobs.

A traveling nerve signal is an electrical current, but it is not the same as a current traveling through a wire. A current in a wire travels millions of meters per second

and is decremental—it gets weaker with distance. A nerve signal is much slower (not more than 2 m/sec in unmyelinated fibers), but it is *nondecremental*. Even in the longest axons, the last action potential generated at a synaptic knob has the same voltage as the first one generated at the trigger zone. To clarify this concept, we can compare the nerve signal to a burning fuse. When a fuse is lit, the heat ignites powder immediately in front of this point, and this repeats itself in a self-propagating fashion until the end of the fuse is reached. At the end, the fuse burns just as hotly as it did at the beginning. In a fuse, the combustible powder is the source of potential energy that keeps the process going in a nondecremental fashion. In an axon, the potential energy comes from the ion gradient across the plasma membrane. Thus, the signal does not grow weaker with distance; it is self-propagating, like the burning of a fuse.

Myelinated Fibers

Matters are somewhat different in myelinated fibers. Voltage-regulated ion gates are scarce in the myelin-covered internodes—fewer than $25/\mu\text{m}^2$ in these regions compared with 2,000 to $12,000/\mu\text{m}^2$ at the nodes of Ranvier. There would be little point in having ion gates in the internodes—myelin insulates the fiber from the ECF at these points, and Na^+ from the ECF could not flow into the cell even if more gates were present.

The only way a nerve signal can travel along an internode is for Na^+ that enters at the previous node to diffuse down the fiber under the axolemma (fig. 12.17a). This is a very fast process, but the nerve fiber resists its flow (just as a wire resists a current) and the signal becomes weaker the farther it goes. Therefore, this aspect of conduction is decremental. The signal cannot travel much farther than 1 mm before it becomes too weak to open any voltage-regulated gates. But fortunately, there is another node of Ranvier every millimeter or less along the axon, where the axolemma is exposed to ECF and there is an abundance of voltage-regulated gates. When the diffusing ions reach this point, the signal is just strong enough to open these gates and create a new action potential. This action potential has the same strength as the one at the previous node, so each node of Ranvier boosts the signal back to its original strength (+35 mV). This mode of signal conduction is called **saltatory²⁸ conduction**—the propagation of a nerve signal that seems to jump from node to node (fig. 12.17b).

In the internodes, saltatory conduction is therefore based on a process that is very fast (diffusion of ions along the fiber) but decremental. In the nodes, conduction is slower but nondecremental. Since most of the axon is covered with myelin, conduction occurs mainly by the fast diffusion process. This is why myelinated fibers transmit signals much faster (up to 120 m/sec) than unmyelinated ones (up to 2 m/sec).

²⁸from *saltare* = to leap, to dance

FIGURE 12.17 Saltatory Conduction of a Nerve Signal in a Myelinated Fiber. (a) Ions can be exchanged with the ECF only at the nodes of Ranvier. In the internodes, the nerve signal travels by the rapid diffusion of ions along the inside of the plasma membrane. (b) Action potentials occur only at the nodes, and the nerve signal (red) therefore appears to jump from node to node.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

11. What causes K^+ to diffuse out of a resting cell? What attracts it into the cell?
12. What happens to Na^+ when a neuron is stimulated on its dendrite? Why does the movement of Na^+ raise the voltage on the plasma membrane?
13. What does it mean to say a local potential is graded, decremental, and reversible?
14. How does the plasma membrane at the trigger zone differ from that on the soma? How does it resemble the membrane at a node of Ranvier?
15. What makes an action potential rise to +35 mV? What makes it drop again after this peak?
16. List four ways in which an action potential is different from a local potential.
17. Explain why myelinated fibers conduct signals much faster than unmyelinated fibers.

12.5 Synapses

Objectives

When you have completed this section, you should be able to

- explain how messages are transmitted from one neuron to another;
- give examples of neurotransmitters and describe their actions; and
- explain how stimulation of a postsynaptic cell is stopped.

A nerve signal soon reaches the end of an axon and can go no farther. In most cases, it triggers the release of a neurotransmitter that stimulates a new wave of electrical activity in the next cell across the synapse. The most thoroughly studied type of synapse is the neuromuscular junction described in chapter 11, but here we consider synapses between two neurons. The first neuron in the signal path is the **presynaptic neuron**, which releases the neurotransmitter. The second is the **postsynaptic neuron**, which responds to it (fig. 12.18a).

The presynaptic neuron may synapse with a dendrite, the soma, or the axon of a postsynaptic neuron and form an *axodendritic*, *axosomatic*, or *axoaxonic synapse*, respectively (fig. 12.18b). A neuron can have an enormous number of synapses (fig. 12.19). For example, a spinal motor neuron is covered with about 10,000 synaptic

FIGURE 12.18 Synaptic Relationships Between Neurons. (a) Pre- and postsynaptic neurons. (b) Types of synapses defined by the site of contact on the postsynaptic neuron.

FIGURE 12.19 Synaptic Knobs on the Soma of a Neuron in a Marine Slug, *Aplysia* (SEM).

◀ Are these synapses axodendritic, axosomatic, or axoaxonic?

knobs from other neurons—8,000 ending on its dendrites and another 2,000 on the soma. In a part of the brain called the cerebellum, one neuron can have as many as 100,000 synapses.

The Discovery of Neurotransmitters

As the neuron doctrine became generally accepted, it raised the question of how neurons communicate with each other. In the early twentieth century, biologists assumed that synaptic communication was electrical—a logical hypothesis given that neurons seemed to touch each other and signals were transmitted so quickly from one to the next. Ramón y Cajal's careful histological examinations, however, revealed a 20 to 40 nm gap between neurons—the **synaptic cleft**—casting doubt on the possibility of electrical transmission.

In 1921, the German pharmacologist Otto Loewi (1873–1961) conclusively demonstrated that neurons communicate by releasing chemicals. The *vagus nerves* supply the heart, among other organs, and slow it down. Loewi opened two frogs and flooded the hearts with saline to keep them moist. He stimulated the vagus nerve of one frog, and its heart rate dropped as expected. He then removed some of the saline from that heart and squirted it onto the heart of the second frog. The solution alone reduced that frog's heart rate. Evidently it contained something released by the vagus nerve of the first frog. Loewi called it *Vagusstoffe* (“vagus substance”) and it was later renamed acetylcholine—the first known neurotransmitter.

Think About It

As described, does the previous experiment conclusively prove that the second frog's heart slowed as a result of something released by the vagus nerves? If you were Loewi, what control experiment would you do to rule out alternative explanations?

Following Loewi's work, the idea of electrical communication between cells fell into disrepute. Now, however, we realize that some neurons, neuroglia, and cardiac and single-unit smooth muscle (see chapter 11) do indeed have **electrical synapses**, where adjacent cells are joined by gap junctions and ions can diffuse directly from one cell into the next. These junctions have the advantage of quick transmission because there is no delay for the release and binding of neurotransmitter. Their disadvantage, however, is that they cannot integrate information and make decisions. The ability to do that is a property of **chemical synapses**, in which neurons communicate by neurotransmitters.

Structure of a Chemical Synapse

The synaptic knob (fig. 12.20) was described in chapter 11. It contains synaptic vesicles, many of which are “docked” at release sites on the plasma membrane, ready to release their neurotransmitter on demand. A reserve pool of synaptic vesicles is located a little farther away from the membrane, clustered near the release sites and tethered to the cytoskeleton by protein microfilaments.

The postsynaptic neuron does not show such conspicuous specializations. At this end, the neuron has

no synaptic vesicles and cannot release neurotransmitters. Its membrane does, however, contain proteins that function as receptors and ligand-regulated ion gates.

Neurotransmitters and Related Messengers

More than 100 confirmed or suspected neurotransmitters have been identified since Loewi's time. They fall into four major categories according to chemical composition (fig. 12.21). Some of the best-known ones are listed in table 12.3. Parts of the brain referred to in this table will become familiar to you as you study chapter 14, and you may wish to refer back to this table then to enhance your understanding of brain function.

1. **Acetylcholine** is in a class by itself. It is formed from acetic acid (acetate) and choline.
2. **Amino acid** neurotransmitters include glycine, glutamate, aspartate, and γ -aminobutyric acid (GABA).
3. **Monoamines (biogenic amines)** are synthesized from amino acids by removal of the $-\text{COOH}$ group. They retain the $-\text{NH}_2$ (amino group), hence their name. The major monoamines are epinephrine,

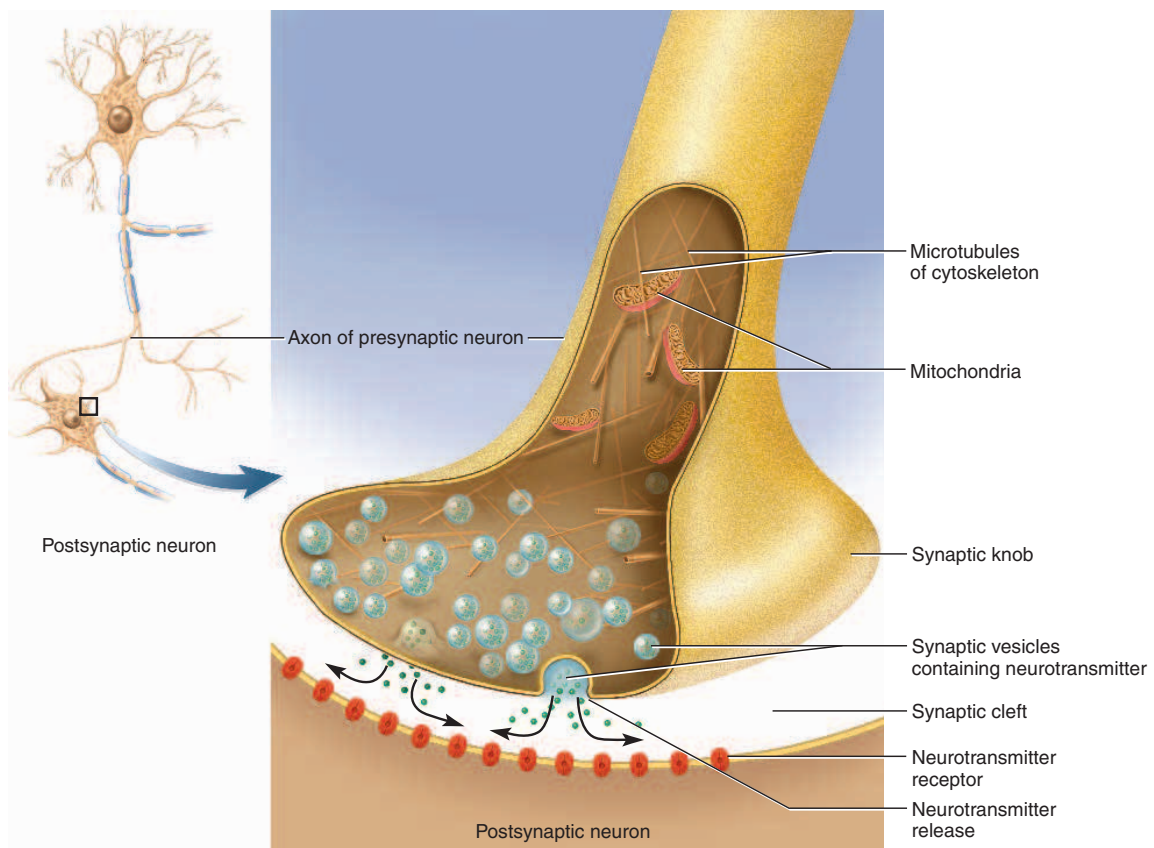

FIGURE 12.20 Structure of a Chemical Synapse.

FIGURE 12.21 Classification of Some Neurotransmitters. The neuropeptides are chains of amino acids, each identified by its three-letter code. Table 2.8 (p. 76) explains the codes.

norepinephrine, dopamine, histamine, and serotonin (5-hydroxytryptamine, or 5-HT). The first three of these are in a subclass of monoamines called **catecholamines** (CAT-eh-COAL-uh-meens).

- Neuropeptides** are chains of 2 to 40 amino acids. Some examples are β -endorphin and substance P. Neuropeptides typically act at lower concentrations and have longer lasting effects than other neurotransmitters, and they are stored in *secretory granules* (*dense-core vesicles*) that are about 100 nm in diameter, twice as large as typical synaptic vesicles. Some neuropeptides also function as hormones or as **neuromodulators**, whose action is discussed later in this chapter. Some neuropeptides are produced not only by neurons but also by the digestive tract; thus they are known as *gut-brain peptides*. Some of these cause cravings for specific nutrients such as fat or sugar and may be associated with certain eating disorders (see p. 1014).

Think About It

Neuropeptides can be synthesized only in the soma and must be transported to the synaptic knobs. Why is their synthesis limited to the soma?

The more we learn about neurotransmitters, hormones, and other chemical messengers, the harder it is to distinguish them from each other or even to rigorously define *neurotransmitter*. Traditionally, neurotransmitters have been conceived as small organic compounds that function at the synapse as follows: (1) they are synthesized by the presynaptic neuron, (2) they are released in response to stimulation, (3) they bind to specific receptors on the

postsynaptic cell, and (4) they alter the physiology of that cell. Neuropeptides are an exception to the small size of neurotransmitters, and neurons have additional means of communication, such as the gas nitric oxide, that fall outside the scope of this traditional concept.

We will see, especially in chapter 15, that a given neurotransmitter does not have the same effect everywhere in the body. There are multiple receptor types in the body for a particular neurotransmitter—over 14 receptor types for serotonin, for example—and it is the receptor that governs what effect a neurotransmitter has on its target cell.

Synaptic Transmission

Neurotransmitters are diverse in their action. Some are excitatory, some are inhibitory, and for some the effect depends on what kind of receptor the postsynaptic cell has. Some neurotransmitters open ligand-regulated ion gates while others act through second-messenger systems (see p. 94). Bearing this diversity in mind, we will here examine three kinds of synapses with different modes of action: an *excitatory cholinergic synapse*, an *inhibitory GABA-ergic synapse*, and an *excitatory adrenergic synapse*.

An Excitatory Cholinergic Synapse

A **cholinergic**²⁹ (CO-lin-UR-jic) synapse employs acetylcholine (ACh) as its neurotransmitter. ACh excites some postsynaptic cells (such as skeletal muscle; chapter 11)

²⁹cholin = acetylcholine + erg = work, action

TABLE 12.3

Neurotransmitters

Name	Locations and Actions
Acetylcholine (ACh)	Neuromuscular junctions, most synapses of autonomic nervous system, retina, and many parts of the brain; excites skeletal muscle, inhibits cardiac muscle, and has excitatory or inhibitory effects on smooth muscle and glands depending on location
Amino acids	
Glutamate (glutamic acid)	Cerebral cortex and brainstem; accounts for about 75% of all excitatory synaptic transmission in the brain; involved in learning and memory
Aspartate (aspartic acid)	Spinal cord; effects similar to those of glutamate
Glycine	Inhibitory neurons of the brain, spinal cord, and retina; most common inhibitory neurotransmitter in the spinal cord
GABA (γ -aminobutyric acid)	Thalamus, hypothalamus, cerebellum, occipital lobes of cerebrum, and retina; the most common inhibitory neurotransmitter in the brain
Monoamines (biogenic amines)	
Catecholamines	
Norepinephrine	Sympathetic nervous system, cerebral cortex, hypothalamus, brainstem, cerebellum, and spinal cord; involved in dreaming, waking, and mood; excites cardiac muscle; can excite or inhibit smooth muscle and glands depending on location
Epinephrine	Hypothalamus, thalamus, spinal cord, and adrenal medulla; effects similar to those of norepinephrine
Dopamine	Hypothalamus, limbic system, cerebral cortex, and retina; highly concentrated in substantia nigra of midbrain; involved in elevation of mood and control of skeletal muscles
Other monoamines	
Serotonin	Hypothalamus, limbic system, cerebellum, retina, and spinal cord; also secreted by blood platelets and intestinal cells; involved in sleepiness, alertness, thermoregulation, and mood
Histamine	Hypothalamus; also a potent vasodilator released by mast cells of connective tissue and basophils of the blood
Neuropeptides	
Substance P	Basal nuclei, midbrain, hypothalamus, cerebral cortex, small intestine, and pain-receptor neurons; mediates pain transmission
Enkephalins	Hypothalamus, limbic system, pituitary, pain pathways of spinal cord, and nerve endings of digestive tract; act as analgesics (pain relievers) by inhibiting substance P; inhibit intestinal motility; secretion increases sharply in women in labor
β -endorphin	Digestive tract, spinal cord, and many parts of the brain; also secreted as a hormone by the pituitary; suppresses pain; reduces perception of fatigue and may produce "runner's high" in athletes
Cholecystokinin (CCK)	Cerebral cortex and small intestine; suppresses appetite

and inhibits others, but this discussion will describe an excitatory action. The steps in transmission at such a synapse are as follows (fig. 12.22):

- 1 The arrival of a nerve signal at the synaptic knob opens voltage-regulated calcium gates.
- 2 Ca^{2+} enters the knob and triggers exocytosis of the synaptic vesicles, releasing ACh.
- 3 Empty vesicles drop back into the cytoplasm to be refilled with ACh, while synaptic vesicles in the reserve pool move to the active sites and release their ACh—a bit like a line of Revolutionary War soldiers firing their muskets and falling back to reload as another line moves to the fore.
- 4 Meanwhile, ACh diffuses across the synaptic cleft and binds to ligand-regulated gates on the postsynaptic neuron. These gates open, allowing Na^+ to enter the cell and K^+ to leave. Although illustrated separately, Na^+ and K^+ pass in opposite directions through the same gates.
- 5 As Na^+ enters the cell, it spreads out along the inside of the plasma membrane and depolarizes it, producing a local potential called the **postsynaptic potential**. Like other local potentials, if this is strong and persistent enough (that is, if enough Na^+ makes it to the axon hillock), it opens voltage-regulated ion gates in the trigger zone and causes the postsynaptic neuron to fire.

FIGURE 12.22 Transmission at a Cholinergic Synapse.

Acetylcholine directly opens ion gates in the plasma membrane of the postsynaptic neuron. Numbered steps correspond to the description in the text.

An Inhibitory GABA-ergic Synapse

A **GABA-ergic** synapse employs γ -aminobutyric acid (GABA) as its neurotransmitter. Amino acid neurotransmitters work by the same mechanism as ACh—binding to ion gates and causing immediate changes in membrane potential. The release of GABA and binding to its receptor are similar to the preceding case. The GABA receptor, however, is a chloride channel. When this channel opens, Cl^- enters the cell and makes the inside even more negative than the resting membrane potential. The neuron is therefore inhibited, or less likely to fire.

An Excitatory Adrenergic Synapse

An **adrenergic synapse** employs the neurotransmitter norepinephrine (NE), also called noradrenaline. NE, other monoamines, and neuropeptides act through second-messenger

FIGURE 12.23 Transmission at an Adrenergic Synapse.

The norepinephrine receptor is not an ion channel. It activates a second-messenger system with a variety of possible effects in the postsynaptic cell. Numbered steps correspond to the description in the text.

systems such as cyclic AMP (cAMP). The receptor is not an ion gate but a transmembrane protein associated with a G protein. Figure 12.23 shows some ways in which an adrenergic synapse can function, numbered to correspond to the following:

- 1 The unstimulated NE receptor is bound to a G protein.
- 2 Binding of NE to the receptor causes the G protein to dissociate from it.
- 3 The G protein binds to adenylate cyclase, activates this enzyme, and induces it to convert ATP to cyclic AMP.
- 4 Cyclic AMP can induce several alternative effects in the cell.
- 5 One effect is to produce an internal chemical that binds to a ligand-regulated ion gate from the inside of the membrane, opening the gate and depolarizing the cell.

- ⑥ Another is to activate preexisting cytoplasmic enzymes, which can lead to diverse metabolic changes (for example, inducing a liver cell to break down glycogen and release glucose into the blood).
- ⑦ Yet another is for cAMP to induce genetic transcription, so that the cell produces new cytoplasmic enzymes, again leading to diverse possible metabolic effects.

Although slower to respond than cholinergic and GABA-ergic synapses, adrenergic synapses do have an advantage—**enzyme amplification**. A single NE molecule binding to a receptor can induce the formation of many cAMPs, each of those can activate many enzyme molecules or induce the transcription of a gene to generate numerous mRNA molecules, and each of those can result in the production of a vast number of metabolic products such as glucose molecules.

As complex as synaptic events may seem, they typically require only 0.5 msec or so—an interval called **synaptic delay**. This is the time from the arrival of a signal at the axon terminal of a presynaptic cell to the beginning of an action potential in the postsynaptic cell.

Cessation of the Signal

It is important not only to stimulate a postsynaptic cell but also to turn off the stimulus in due time. Otherwise the postsynaptic neuron could continue firing indefinitely, causing a breakdown in physiological coordination. Here we examine some ways this is done.

A neurotransmitter molecule binds to its receptor for only 1 msec or so, then dissociates from it. If the presynaptic cell continues to release neurotransmitter, one molecule is quickly replaced by another and the postsynaptic cell is restimulated. This immediately suggests a way of stopping synaptic transmission—stop adding new neurotransmitter and get rid of that which is already there. The first step is achieved simply by the cessation of signals in the presynaptic nerve fiber. The second can be achieved in the following ways:

- **Diffusion.** Neurotransmitter escapes from the synapse into the nearby ECF. In the CNS, astrocytes absorb it and return it to the neurons.
- **Reuptake.** The synaptic knob reabsorbs amino acids and monoamines by endocytosis and breaks them down with an enzyme called **monoamine oxidase (MAO)**. Some antidepressant drugs work by inhibiting MAO (see Insight 15.2, p. 582).
- **Degradation in the synaptic cleft.** The enzyme acetylcholinesterase (AChE), located in the synaptic cleft and on the postsynaptic membrane, breaks ACh down into acetate and choline. These breakdown products have no stimulatory effect on the postsynaptic cell. The synaptic knob reabsorbs the choline and uses it to synthesize more ACh.

Neuromodulators

Neuromodulators are hormones, neuropeptides, and other messengers that modify synaptic transmission. They may stimulate a neuron to install more receptors in the postsynaptic membrane, thus adjusting its sensitivity to a neurotransmitter, or they may alter the rate of neurotransmitter synthesis, release, reuptake, or breakdown. One neuromodulator family is the **enkephalins**, small peptides that inhibit spinal interneurons from transmitting pain signals to the brain. Their role is further described in chapter 16. Another, much simpler, neuromodulator is nitric oxide (NO), a lightweight gas that is released by postsynaptic neurons in some areas of the brain concerned with learning and memory. NO diffuses into the presynaptic neuron and stimulates it to release more neurotransmitter—like one neuron’s way of telling the other, “Give me more.” Thus, there is at least some chemical communication that goes backward across a synapse.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

18. Concisely describe five steps that occur between the arrival of an action potential at the synaptic knob and the beginning of a new action potential in the postsynaptic neuron.
19. Contrast the actions of acetylcholine, GABA, and norepinephrine at their respective synapses.
20. Describe three mechanisms that stop synaptic transmission.
21. What is the function of neuromodulators?

12.6 Neural Integration

Objectives

When you have completed this section, you should be able to

- explain how a neuron “decides” whether or not to generate action potentials;
- explain how the nervous system translates complex information into a simple code;
- explain how neurons work together in groups to process information and produce effective output; and
- describe how memory works at a cellular and molecular level.

Synaptic delay slows the transmission of nerve signals; the more synapses there are in a neural pathway, the longer it takes information to get from its origin to its destination. You might wonder, therefore, why we have synapses—why

a nervous pathway is not, indeed, a continuous “wire” as biologists believed before the neuron doctrine was accepted. The presence of synapses is not due to limitations on the length of a neuron—after all, one nerve fiber can reach from your toes to your brainstem; imagine how long some nerve fibers may be in a giraffe or a whale! We also have seen that cells can communicate through gap junctions much more quickly than they can through chemical synapses. So why have chemical synapses at all?

What we value most about our nervous system is its ability to process information, store it, and make decisions—and chemical synapses are the decision-making devices of the system. The more synapses a neuron has, the greater its information-processing capability. At this moment, you are using certain *pyramidal cells* of the cerebral cortex (see fig. 12.5) to read and comprehend this passage. Each pyramidal cell has about 40,000 synaptic contacts with other neurons. The cerebral cortex alone (the main information-processing tissue of your brain) is estimated to have 100 trillion (10^{14}) synapses. To get some impression of this number, imagine trying to count them. Even if you could count two synapses per second, day and night without stopping, and you were immortal, it would take you 1.6 million years. The ability of your neurons to process information, store and recall it, and make decisions is called **neural integration**.

Postsynaptic Potentials

Neural integration is based on the postsynaptic potentials produced by neurotransmitters. Remember that a typical neuron has a resting membrane potential (RMP) of about -70 mV and a threshold of about -55 mV. A neuron has to be depolarized to this threshold in order to produce action potentials. Any voltage change in that direction makes a neuron more likely to fire and is therefore called an **excitatory postsynaptic potential (EPSP)** (fig. 12.24a). EPSPs usually result from Na^+ flowing into the cell and canceling some of the negative charge on the inside of the membrane.

In other cases, a neurotransmitter hyperpolarizes the postsynaptic cell and makes it more negative than the RMP. Since this makes the postsynaptic cell less likely to fire, it is called an **inhibitory postsynaptic potential (IPSP)** (fig. 12.24b). Some IPSPs are produced by a neurotransmitter opening ligand-regulated chloride gates, causing Cl^- to flow into the cell and make the cytosol more negative. A less common way is to open selective K^+ gates, increasing K^+ diffusion out of the cell.

We must recognize that because of ion leakage through their membranes, all neurons fire at a certain background rate even when they are not being stimulated. EPSPs and IPSPs do not determine whether or not a neuron fires, but only change the rate of firing by stimulating or inhibiting the production of more action potentials.

FIGURE 12.24 Postsynaptic Potentials. (a) An excitatory postsynaptic potential (EPSP), which shifts the membrane voltage closer to threshold and makes the cell more likely to fire. (b) An inhibitory postsynaptic potential (IPSP), which shifts the membrane voltage farther away from threshold and makes the cell less likely to fire. The sizes of these postsynaptic potentials are greatly exaggerated here for clarity; compare figure 12.26.

❖ Why is a single EPSP insufficient to make a neuron fire?

Glutamate and aspartate are excitatory brain neurotransmitters that produce EPSPs. Glycine and GABA produce IPSPs and are therefore inhibitory. Acetylcholine (ACh) and norepinephrine are excitatory to some cells and inhibitory to others, depending on the type of receptors present on the target cells. For example, ACh excites skeletal muscle but inhibits cardiac muscle because the two types of muscle have different types of ACh receptors. This is discussed more fully in chapter 15.

Summation, Facilitation, and Inhibition

One neuron may receive input from thousands of other neurons. Some incoming nerve fibers may produce EPSPs while others produce IPSPs. The neuron's response depends on whether the *net* input is excitatory or inhibitory. If the EPSPs override the IPSPs, threshold may be reached and the neuron will fire more rapidly; if the IPSPs prevail, the neuron will fire less rapidly. **Summation** is the

process of adding up postsynaptic potentials and responding to their net effect. It occurs in the trigger zone.

Suppose, for example, you are working in the kitchen and accidentally touch a hot cooking pot. EPSPs in your motor neurons might cause you to jerk your hand back quickly and avoid being burned. Yet a moment later, you might nonchalantly pick up a cup of tea that is even hotter than the pot. Since you are expecting the teacup to be hot, you do not jerk your hand away. You have learned that it will not injure you, so at some level of the nervous system, IPSPs prevail and inhibit the motor response.

It is fundamentally a balance between EPSPs and IPSPs that enables the nervous system to make decisions. A postsynaptic neuron is like a little cellular democracy acting on the “majority vote” of hundreds or thousands of presynaptic cells. In the teacup example, some presynaptic neurons are sending messages that signify “hot! danger!” in the form of EPSPs that may activate a hand-withdrawal reflex, while at the same time, others are producing IPSPs that signify “safe” and suppress the withdrawal reflex. Whether the postsynaptic neurons cause you to jerk your hand back depends on whether the EPSPs override the IPSPs or vice versa.

A single action potential in a synaptic knob does not produce enough activity to make a postsynaptic cell fire. An EPSP may be produced, but it fades before reaching threshold. A typical EPSP is a voltage change of only 0.5 mV and lasts only 15 to 20 msec. If a neuron has an RMP of -70 mV and a threshold of -55 mV, it needs at least 30 EPSPs to reach threshold and fire. There are two ways in which EPSPs can add up to do this, and both may occur simultaneously.

- 1. Temporal summation** (fig. 12.25a). This occurs when a single synapse generates EPSPs so quickly that each is generated before the previous one fades. This allows the EPSPs to add up over time to a threshold voltage that triggers an action potential (fig. 12.26). Temporal summation can occur if even one presynaptic neuron stimulates the postsynaptic neuron intensely enough.
- 2. Spatial summation** (fig. 12.25b). This occurs when EPSPs from several different synapses add up to threshold at the axon hillock. Any one synapse may admit only a moderate amount of Na^+ into the cell, but several synapses acting together admit enough Na^+ to reach threshold. The presynaptic neurons cooperate to induce the postsynaptic neuron to fire.

Neurons routinely work in groups to modify each other's actions. **Facilitation** is a process in which one neuron enhances the effect of another one. In spatial summation, for example, one neuron acting alone may be unable to induce a postsynaptic neuron to fire. But when they cooperate, their combined “effort” does induce firing in the postsynaptic cell. They each enhance one another's effect, or *facilitate* each other.

FIGURE 12.25 Temporal and Spatial Summation. Vertical lines on the nerve fibers indicate relative firing frequency. Arrows within the postsynaptic neuron indicate Na^+ diffusion. (a) In temporal summation, a single presynaptic neuron stimulates the postsynaptic neuron so intensely that its EPSPs add up to threshold and make it fire. (b) In spatial summation, multiple inputs to the postsynaptic cell each produce a moderate amount of stimulation, but collectively they produce enough EPSPs to add up to threshold at the trigger zone and make the cell fire.

Presynaptic inhibition is the opposite of facilitation, a mechanism in which one presynaptic neuron suppresses another one. This mechanism is used to reduce or halt unwanted synaptic transmission. In figure 12.27, we see three neurons, which we will call neuron *S* for the stimulator, neuron *I* for the inhibitor, and neuron *R* for the responder. Neuron *I* forms an axoaxonic synapse with *S* (synapses with the axon of *S*). When presynaptic inhibition is not occurring, neuron *S* releases its neurotransmitter and triggers a response in *R*. But when there is a need to block transmission across this pathway, neuron *I* releases the inhibitory neurotransmitter GABA. GABA prevents the voltage-regulated calcium gates of neuron *S* from opening. Consequently, neuron *S* releases less neurotransmitter or none, and fails to stimulate neuron *R*.

Neural Coding

The nervous system must interpret and pass along both quantitative and qualitative information about its environment—whether a light is dim or bright, red or green; whether a taste is mild or intense, salty or sour; whether a sound

470 PART THREE Integration and Control

FIGURE 12.26 Summation of EPSPs. Each stimulus (arrows) produces one EPSP. If enough EPSPs arrive at the trigger zone faster than they fade, they can build on each other to bring the neuron to threshold and trigger an action potential.

is loud or soft, high-pitched or low. Considering the complexity of information to be communicated about conditions in and around the body, it is a marvel that it can be done in the form of something as simple as action potentials—particularly since all the action potentials of a given neuron are identical. Yet when we considered the genetic code in chapter 4, we saw that complex messages can indeed be

expressed in simple codes. The way in which the nervous system converts information to a meaningful pattern of action potentials is called **neural coding** (or *sensory coding* when it occurs in the sense organs).

The most important mechanism for transmitting qualitative information is the **labeled line code**. This code is based on the fact that each nerve fiber to the brain leads from a receptor that specifically recognizes a particular stimulus type. Nerve fibers in the optic nerve, for example, carry signals only from light receptors in the eye; these fibers will never carry information about taste or sound. The brain therefore interprets any signals in those fibers in terms of light—even if the signals result from artificial stimulation of the nerve. This effect is seen when you rub your eyelids and see flashes of light as the pressure on the eyeball mechanically stimulates optic nerve fibers. Electrical stimulation of the auditory nerve can enable deaf people to hear sounds of different frequencies, even when receptors in the inner ear are nonfunctional. Thus, each nerve fiber to the brain is a line of communication “labeled,” or recognized by the brain, as representing a particular stimulus quality—the color of a light, the pitch of a sound, or the salty or sour quality of a taste, for example.

Quantitative information—information about the intensity of a stimulus—is encoded in two ways. One depends on the fact that different neurons have different thresholds of excitation. A weak stimulus excites neurons with the lowest thresholds, while a strong stimulus excites less sensitive high-threshold neurons. Bringing additional neurons into play as the stimulus becomes stronger is called **recruitment**. It enables the nervous system to judge stimulus strength by which neurons, and how many of them, are firing.

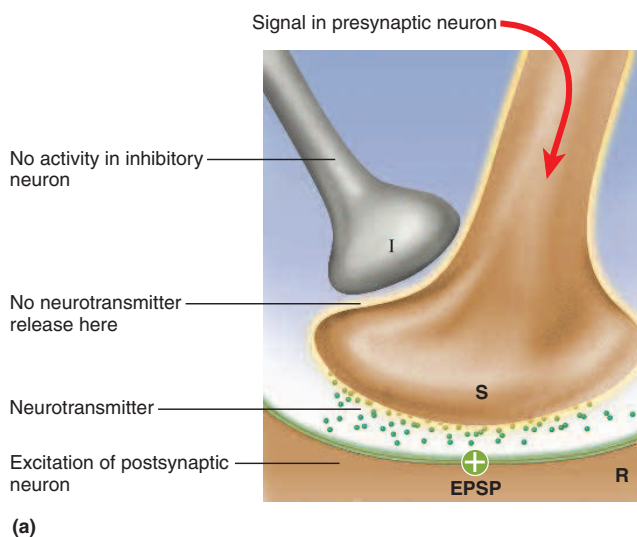

FIGURE 12.27 Presynaptic Inhibition. S, stimulating neuron. I, inhibitory neuron. R, responding postsynaptic neuron. +, excitation (EPSP). –, inhibition (IPSI). (a) In the absence of inhibition, neuron S releases neurotransmitter and stimulates neuron R. (b) In presynaptic inhibition, neuron I suppresses the release of neurotransmitter by S, and S cannot stimulate R.

FIGURE 12.28 An Example of Neural Coding. This figure is based on recordings made from a sensory fiber of the frog sciatic nerve as the gastrocnemius muscle was stretched by suspending weights from it. As the stimulus strength (weight) and stretch increase, the firing frequency of the neuron increases. Firing frequency is a coded message that informs the CNS of stimulus intensity.

■ In what other way is the CNS informed of stimulus intensity?

Another way of encoding stimulus strength depends on the fact that the more strongly a neuron is stimulated, the more frequently it fires. A weak stimulus may cause a neuron to generate 6 action potentials per second, and a strong stimulus, 600 per second. Thus, the central nervous system can judge stimulus strength from the firing frequency of afferent neurons (fig. 12.28).

There is a limit to how often a neuron can fire, set by its absolute refractory period. Think of an electronic camera flash by analogy. If you take a photograph and your flash unit takes 15 seconds to recharge, then you cannot take more than four photographs per minute. Similarly, if a nerve fiber takes 1 msec to repolarize after it has fired, then it cannot fire more than 1,000 times per second. Refractory periods may be as short as 0.5 msec, which sets a theoretical limit to firing frequency of 2,000 action potentials per second. The highest frequencies actually observed, however, are between 500 and 1,000 per second.

In summary, a mild stimulus excites sensitive, low-threshold nerve fibers. As the stimulus intensity rises, these fibers fire at a higher and higher frequency, up to a certain maximum. If the stimulus intensity exceeds the capacity of these low-threshold fibers, it may recruit less sensitive, high-threshold fibers to begin firing. Still further increases in intensity cause these high-threshold fibers to fire at a higher and higher frequency.

Think About It

How is neural recruitment related to the process of multiple motor unit summation described in chapter 11?

Neural Pools and Circuits

So far, we have dealt with interactions involving only two or three neurons at a time. Actually, neurons function in larger ensembles called **neural pools**, each of which consists of thousands to millions of interneurons concerned with a particular body function—one to control the rhythm of your breathing, one to move your limbs rhythmically as you walk, one to regulate your sense of hunger, and another to interpret smells, for example. At this point, we explore a few ways in which neural pools collectively process information.

Information arrives at a neural pool through one or more input neurons, which branch repeatedly and synapse with numerous interneurons in the pool. Some input neurons form multiple synapses with a single postsynaptic cell. They can produce EPSPs at all points of contact with that cell and, through spatial summation, make it fire more easily than if they synapsed with it at only one point. Within the **discharge zone** of an input neuron, that neuron acting alone can make the postsynaptic cells fire (fig. 12.29). But in a broader **facilitated zone**, it synapses with still other neurons in the pool, with fewer synapses on each of them. It can stimulate those neurons to fire only with the assistance of other input neurons; that is, it facilitates the others. It “has a vote” on what the postsynaptic cells in the facilitated zone will do, but it cannot determine the outcome alone. Such arrangements, repeated thousands of times throughout the central nervous system, give neural pools great flexibility in integrating

FIGURE 12.29 Facilitated and Discharge Zones in a Neural Pool. In the discharge zone, the presynaptic input neuron has so many synaptic contacts with each postsynaptic neuron that it alone can induce the postsynaptic cell to fire, employing spatial summation as in figure 12.25b. In a facilitated zone, the presynaptic neuron lacks enough synaptic contacts with a postsynaptic neuron to induce firing by itself. However, it can collaborate with other presynaptic neurons, facilitating each other in making the postsynaptic cell fire.

input from several sources and “deciding” on an appropriate output.

The functioning of a radio can be understood from a circuit diagram showing its components and their connections. Similarly, the functions of a neural pool are partly determined by its **neural circuit**—the pathways among its neurons. Just as a wide variety of electronic devices are constructed from a relatively limited number of circuit types, a wide variety of neural functions result from the operation of four principal kinds of neural circuits (fig. 12.30):

1. In a **diverging circuit**, one nerve fiber branches and synapses with several postsynaptic cells. Each of those may synapse with several more, so input from just one neuron may produce output through hundreds of neurons. Such a circuit allows one motor neuron of the brain, for example, to ultimately stimulate thousands of muscle fibers.
2. A **converging circuit** is the opposite of a diverging circuit—input from many different nerve fibers is funneled to one neuron or neural pool. Such an arrangement allows input from your eyes, inner ears, and stretch receptors in your neck to be channeled

to an area of the brain concerned with the sense of balance. Also through neural convergence, a respiratory center in your brainstem receives input from other parts of your brain, from receptors for blood chemistry in your arteries, and from stretch receptors in your lungs. The respiratory center can then produce an output that takes all of these factors into account and sets an appropriate pattern of breathing.

3. In a **reverberating circuit**, neurons stimulate each other in a linear sequence such as $A \rightarrow B \rightarrow C \rightarrow D$, but neuron C sends an axon collateral back to A. As a result, every time C fires it not only stimulates output neuron D, but also restimulates A and starts the process over. Such a circuit produces a prolonged or repetitive effect that lasts until one or more neurons in the circuit fail to fire, or until an inhibitory signal from another source stops one of them from firing. A reverberating circuit sends repetitious signals to your diaphragm and intercostal muscles, for example, to make you inhale. When the circuit stops firing, you exhale; the next time it fires, you inhale again. Reverberating circuits may also be involved in short-term memory, as discussed in the next section, and they may play a role in the uncontrolled “storms” of neural activity that occur in epilepsy.

4. In a **parallel after-discharge circuit**, an input neuron diverges to stimulate several chains of neurons. Each chain has a different number of synapses, but eventually they all reconverge on a single output neuron. Since the chains differ in total synaptic delay, their signals arrive at the output neuron at different times, and the output neuron may go on firing for some time after input has ceased. Unlike a reverberating circuit, this type has no feedback loop. Once all the neurons in the circuit have fired, the output ceases. Continued firing after the stimulus stops is called *after-discharge*. It explains why you can stare at a lamp, then close your eyes and continue to see an image of it for a while. Such a circuit is also important in withdrawal reflexes, in which a brief pain produces a longer-lasting output to the limb muscles and causes you to draw back your hand or foot from danger.

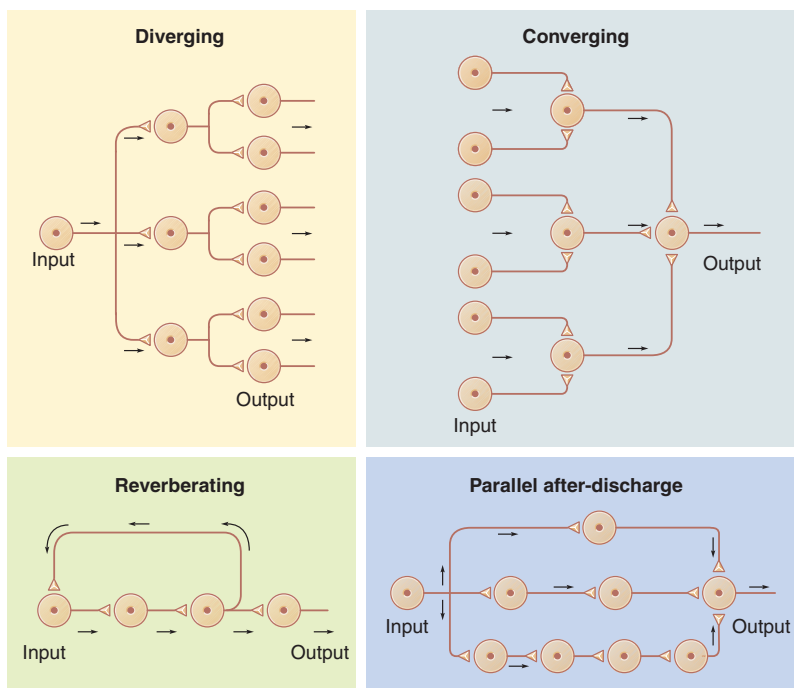

FIGURE 12.30 Four Types of Neural Circuits. Arrows indicate the direction of the nerve signal.

Which of these four circuits is likely to fire the longest after a stimulus ceases? Why?

Memory and Synaptic Plasticity

You may have wondered as you studied this chapter, How am I going to remember all of this? It seems fitting that we end with the subject of how memory works, for you now have

the information necessary to understand its cellular and chemical basis.

The things we learn and remember are not stored in individual “memory cells” in the brain. We do not have a neuron assigned to remember our phone number and another assigned to remember our grandmother’s face, for example. Instead, the physical basis of memory is a *pathway* through the brain called a **memory trace (engram)**³⁰, in which new synapses have formed or existing synapses have been modified to make transmission easier. In other words, synapses are not fixed for life; in response to experience, they can be added, taken away, or modified to make transmission easier or harder. Indeed, synapses can be formed or deleted in as little as 1 or 2 hours. This ability of synapses to change is called **synaptic plasticity**.

Think about when you learned as a child to tie your shoes. The procedure was very slow, confusing, and laborious at first, but eventually it became so easy you could do it with little thought—like a motor program playing out in your brain without requiring your conscious attention. It became easier to do because the synapses in a certain pathway were modified to allow signals to travel more easily across them than across “untrained” synapses. The process of making transmission easier is called **synaptic potentiation** (one form of synaptic plasticity).

Neuroscientists still argue about how to classify the various forms of memory, but three kinds often recognized are *immediate memory*, *short-term memory*, and *long-term memory*. We also know of different modes of synaptic potentiation that last from just a few seconds to a lifetime, and we can correlate these at least tentatively with different forms of memory.

Immediate Memory

Immediate memory is the ability to hold something in mind for just a few seconds. By remembering what just happened, we get a feeling for the flow of events and a sense of the present. Immediate memory is indispensable to the ability to read; you must remember the earliest words of a sentence until you get to its end in order to extract any meaning from the sentence. You could not make any sense of what you read if you forgot each word as soon as you moved on to the next one. Immediate memory might be based on reverberating circuits. Our impression of what just happened can thus reecho in our minds for a few seconds as we experience the present moment and anticipate the next one.

Short-Term Memory

Short-term memory (STM) lasts from a few seconds to a few hours. Information stored in STM may be quickly

forgotten if we stop mentally reciting it, we are distracted, or we have to remember something new. **Working memory** is a form of STM that allows us to hold an idea in mind long enough to carry out an action such as calling a telephone number we just looked up, working out the steps of a mathematics problem, or searching for a lost set of keys while remembering where we have already looked. It is limited to a few bits of information such as the digits of a telephone number. These short-term memory tasks may be carried out by reverberating circuits of neurons.

Somewhat longer-lasting memories, however, probably involve an effect called **synaptic facilitation** (different from the facilitation of one neuron by another that we studied earlier in the chapter). This form of facilitation is induced by *tetanic stimulation*, the rapid arrival of repetitive signals at a synapse. Each signal causes a certain amount of Ca^{2+} to enter the synaptic knob. If signals arrive very rapidly, the neuron cannot pump out all the Ca^{2+} admitted by one action potential before the next action potential occurs. More and more Ca^{2+} accumulates in the knob. Since Ca^{2+} is what triggers the release of neurotransmitter, each signal releases more neurotransmitter than the one before. With more neurotransmitter, the EPSPs in the postsynaptic cell become stronger and stronger, and that cell is more likely to fire. Thus, tetanic stimulation facilitates the synapse and makes it easier for the postsynaptic cell to fire.

Memories lasting for a few hours, such as remembering what someone said to you earlier in the day or remembering an upcoming appointment, may involve **posttetanic potentiation**. In this process, the Ca^{2+} level in the synaptic knob stays elevated for so long that another signal, coming well after the tetanic stimulation has ceased, releases an exceptionally large burst of neurotransmitter. That is, if a synapse has been heavily used in the recent past, a new stimulus can excite the postsynaptic cell more easily. Thus, your memory may need only a slight jog to recall something from several hours earlier.

Long-Term Memory

Long-term memory (LTM) lasts up to a lifetime and is less limited than STM in the amount of information it can store. LTM allows you to memorize the lines of a play, the words of a favorite song, or (one hopes!) textbook information for an exam. On a still longer timescale, it enables you to remember your name, the route to your home, and your childhood experiences.

There are two forms of long-term memory: declarative and procedural. **Declarative memory** is the retention of events and facts that you can put into words—numbers, names, dates, and so forth. **Procedural memory** is the retention of motor skills—how to tie your shoes, play a

³⁰*en* = inner + *gram* = mark, trace, record

musical instrument, or type on a keyboard. These forms of memory involve different regions of the brain but are probably similar at the cellular level.

Some LTM involves the physical remodeling of synapses or the formation of new ones through the growth and branching of axon terminals and dendrites. In the pyramidal cells of the brain, the dendrites are studded with knob-like *dendritic spines* that increase the area of synaptic contact. Studies on fish and other experimental animals have shown that social and sensory deprivation causes these spines to decline in number, while a richly stimulatory environment causes them to proliferate—an intriguing clue to the importance of a stimulating environment to infant and child development. In some cases of LTM, a new synapse grows beside the original one, giving the presynaptic cell twice as much input into the postsynaptic cell.

LTM can also be grounded in molecular changes called **long-term potentiation**. This involves *NMDA*³¹ receptors, which are glutamate-binding receptors found on the synaptic knobs of pyramidal cells. NMDA receptors are usually blocked by magnesium ions (Mg^{2+}), but when they bind glutamate and are simultaneously subjected to tetanic stimulation, they expel the Mg^{2+} and open to admit Ca^{2+} into the dendrite. When Ca^{2+} enters, it acts as a second messenger that leads to a variety of effects:

- The neuron produces even more NMDA receptors, which makes it more sensitive to glutamate in the future.

- It synthesizes proteins concerned with physically remodeling a synapse.
- It releases nitric oxide, which diffuses back to the presynaptic neuron and triggers still more glutamate release.

You can see that in all of these ways, long-term potentiation can increase transmission across “experienced” synapses. Remodeling a synapse or installing more neurotransmitter receptors has longer-lasting effects than facilitation or posttetanic potentiation.

The anatomical sites of memory are discussed in chapter 14 in connection with brain anatomy. Regardless of the sites, however, the cellular mechanisms are as described here.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

22. Contrast the two types of summation at a synapse.
23. Describe how the nervous system communicates quantitative and qualitative information about stimuli.
24. List the four types of neural circuits and describe their similarities and differences. Discuss the unity of form and function in these four types—that is, explain why each type would not perform as it does if its neurons were connected differently.
25. How does long-term potentiation enhance the transmission of nerve signals along certain pathways?

INSIGHT 12.4 Clinical Application

Alzheimer and Parkinson Diseases

Alzheimer and Parkinson diseases are the two most common degenerative disorders of the brain. Both are associated with neurotransmitter deficiencies.

*Alzheimer*³² disease (AD) may begin before the age of 50 with symptoms so slight and ambiguous that early diagnosis is difficult. One of its first symptoms is memory loss, especially for recent events. A person with AD may ask the same questions repeatedly, show a reduced attention span, and become disoriented and lost in previously familiar places. Family members often feel helpless and confused as they watch their loved one’s personality gradually deteriorate beyond recognition. The AD patient may become moody, confused, paranoid, combative, or hallucinatory—he or she may ask irrational questions such as, Why is the room full of snakes? The patient may even-

tually lose even the ability to read, write, talk, walk, and eat. Death ensues from pneumonia or other complications of confinement and immobility.

AD affects about 11% of the U.S. population over the age of 65; the incidence rises to 47% by age 85. It accounts for nearly half of all nursing home admissions and is a leading cause of death among the elderly. AD claims about 100,000 lives per year in the United States.

Diagnosis of AD can be confirmed by autopsy. There is atrophy of some of the gyri (folds) of the cerebral cortex and the hippocampus, an important center of memory. Nerve cells exhibit *neurofibrillary tangles*—dense masses of broken and twisted cytoskeleton (fig. 12.31). Alois Alzheimer first observed these in 1907 in the brain of a patient who had died of senile dementia. The more severe the signs of disease, the more neurofibrillary tangles are seen at autopsy. In the intercellular spaces, there are *senile plaques* consisting of aggregations of cells, altered nerve fibers, and a core of β -amyloid protein—the

³¹N-methyl-D-aspartate, a chemical similar to glutamate

³²Alois Alzheimer (1864–1915), German neurologist

breakdown product of a glycoprotein of plasma membranes. Amyloid protein is rarely seen in elderly people without AD. It is now widely believed to be the crucial factor that triggers all the other aspects of AD pathology.

Intense biomedical research efforts are currently geared toward identifying the causes of AD and developing treatment strategies. Three genes on chromosomes 1, 14, and 21 have been implicated in various forms of early- and late-onset AD. Interestingly, persons with Down syndrome (trisomy-21), who have three copies of chromosome 21 instead of the usual two, tend to show early-onset Alzheimer disease. Nongenetic (environmental) factors also seem to be involved.

As for treatment, considerable attention now focuses on trying to halt β -amyloid formation or stimulate the immune system to clear β -amyloid from the brain tissue, but clinical trials in both of these approaches have been suspended until certain serious side effects can be resolved. AD patients show deficiencies of acetylcholine (ACh) and nerve growth factor (NGF). Some patients show improvement when treated with NGF or cholinesterase inhibitors, but results so far have been modest.

*Parkinson*³³ disease (PD), also called *paralysis agitans* or *parkinsonism*, is a progressive loss of motor function beginning in a person's 50s or 60s. It is due to degeneration of dopamine-releasing neurons in a portion of the brain called the *substantia nigra*. A gene has recently been identified for a hereditary form of PD, but most cases are nonhereditary and of little-known cause; some authorities suspect environmental neurotoxins.

Dopamine (DA) is an inhibitory neurotransmitter that normally prevents excessive activity in motor centers of the brain called the *basal nuclei*. Degeneration of dopamine-releasing neurons leads to an excessive ratio of ACh to DA, causing hyperactivity of the basal nuclei. As a result, a person with PD suffers involuntary muscle contractions. These take such forms as shaking of the hands (tremor) and compulsive "pill-rolling" motions of the thumb and fingers. In addition, the facial muscles may become rigid and produce a staring, expressionless face with a slightly open mouth. The patient's range of motion diminishes. He or she takes smaller steps and develops a slow, shuffling gait with a forward-bent posture and a tendency to fall forward. Speech becomes slurred and handwriting becomes cramped and eventually illegible. Tasks such as buttoning clothes and preparing food become increasingly laborious.

Patients cannot be expected to recover from PD, but its effects can be alleviated with drugs and physical therapy. Treatment with dopamine is ineffective because it cannot cross the blood-brain barrier, but its precursor, levodopa (L-dopa), does cross the barrier and has been used to treat PD since the 1960s. L-dopa affords some relief from symptoms, but it does not slow progression of the disease and it has undesirable side effects on the liver and heart. It is effective for only 5 to 10 years of treatment. A newer drug,

deprenyl, is a monoamine oxidase (MAO) inhibitor that retards neural degeneration and delays the development of symptoms.

A surgical technique called *pallidotomy* has been used since the 1940s to quell severe tremors. It involves the destruction of a small portion of cerebral tissue in an area called the *globus pallidus*. Pallidotomy fell out of favor in the late 1960s when L-dopa came into common use. By the early 1990s, however, the limitations of L-dopa had become apparent, while MRI- and CT-guided methods had improved surgical precision and reduced the risks of brain surgery. Pallidotomy has thus made a comeback. Other surgical treatments for parkinsonism target brain areas called the *subthalamic nucleus* and the *ventral intermediate nucleus* of the thalamus, and involve either the destruction of tiny areas of tissue or the implantation of a stimulating electrode. Such procedures are generally used only in severe cases that are unresponsive to medication.

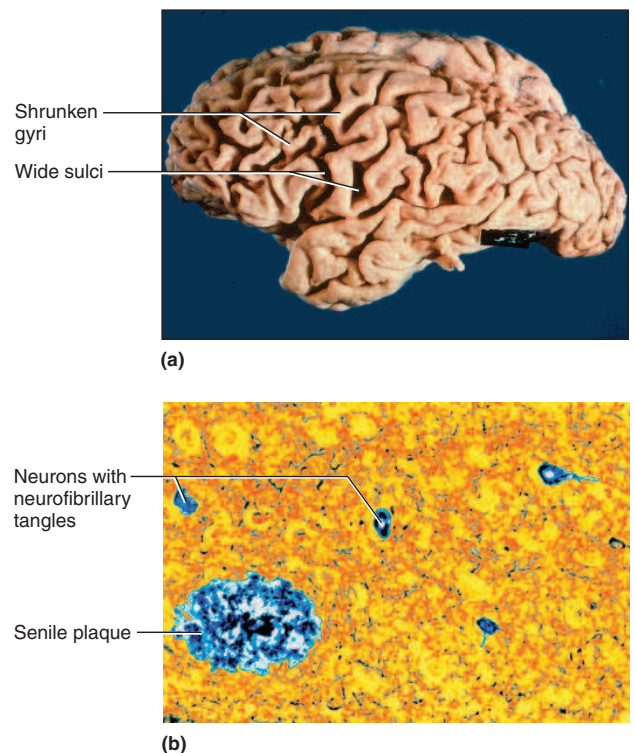

FIGURE 12.31 Alzheimer Disease. (a) Brain of a person who died of AD. Note the shrunken folds of cerebral tissue (gyri) and wide gaps (sulci) between them. (b) Cerebral tissue from a person with AD. Neurofibrillary tangles are present within the neurons, and a senile plaque is evident in the extracellular matrix.

³³James Parkinson (1755–1824), British physician

CONNECTIVE ISSUES

Interactions Between the NERVOUS SYSTEM and Other Organ Systems

← indicates ways in which this system affects other systems

→ indicates ways in which other systems affect this system

INTEGUMENTARY SYSTEM

Nervous system regulates piloerection and sweating; controls cutaneous blood flow to regulate heat loss

Provides sensations of heat, cold, pressure, pain, and vibration; protects peripheral nerves

SKELETAL SYSTEM

Nervous stimulation generates muscle tension essential for bone development and remodeling

Serves as reservoir for Ca^{2+} needed for neural function; protects CNS and some peripheral nerves

MUSCULAR SYSTEM

Somatic nervous system activates skeletal muscles and maintains muscle tone

Gives expression to thoughts, emotions, and motor commands that arise in the CNS

ENDOCRINE SYSTEM

Hypothalamus controls pituitary gland; sympathetic nervous system stimulates adrenal medulla

Many hormones affect neuron growth and metabolism; hormones control electrolyte balance essential for neural function

CIRCULATORY SYSTEM

Nervous system regulates heartbeat, blood vessel diameters, blood pressure, and routing of blood; influences blood clotting

Delivers O_2 and nutrients; carries away wastes; transports hormones to and from CNS; cerebrospinal fluid is produced from and returned to blood

LYMPHATIC AND IMMUNE SYSTEMS

Nerves innervate lymphatic organs and influence development and activity of immune cells; nervous system plays a role in regulating immune responses; emotional states influence susceptibility to infection

Immune cells (including microglia) provide protection and promote tissue repair

RESPIRATORY SYSTEM

Nervous system regulates rate and depth of respiration

Provides O_2 , removes CO_2 , and helps to maintain proper pH for neural function

URINARY SYSTEM

Nervous system regulates renal blood flow, thus affecting rate of urine formation; controls emptying of bladder; brain secretes antidiuretic hormone, which regulates urine volume

Disposes of wastes and maintains electrolyte and pH balance

DIGESTIVE SYSTEM

Nervous system regulates appetite, feeding behavior, digestive secretion and motility, and defecation

Provides nutrients; liver provides stable level of blood glucose for neural function during periods of fasting

REPRODUCTIVE SYSTEM

Nervous system regulates sex drive, arousal, and orgasm; secretes or stimulates pituitary release of many hormones involved in menstrual cycle, sperm production, pregnancy, childbirth, and lactation

Sex hormones influence CNS development and sexual behavior; hormones of the menstrual cycle stimulate or inhibit hypothalamus

CHAPTER REVIEW

Review of Key Concepts

12.1 Overview of the Nervous System (p. 442)

1. The nervous and endocrine systems are the body's two main systems of internal communication and physiological coordination.
2. The nervous system receives information from *receptors*, *integrates* information, and issues commands to *effectors*.
3. The nervous system is divided into the *central nervous system (CNS)* and *peripheral nervous system (PNS)*. The PNS has *sensory* and *motor* divisions, and each of these has *somatic* and *visceral* subdivisions.
4. The visceral motor division is also called the *autonomic nervous system*, which has *sympathetic* and *parasympathetic* divisions.

12.2 Properties of Neurons (p. 443)

1. Neurons have the properties of *excitability*, *conductivity*, and *secretion*.
2. Neurons are classified by their location and function into *sensory (afferent) neurons*, *interneurons (association neurons)*, and *motor (efferent) neurons*.
3. A neuron has a *soma* where its nucleus and most other organelles are located; usually multiple *dendrites* that receive signals and conduct them to the soma; and one *axon* (nerve fiber) that carries nerve signals away from the soma.
4. The axon branches at the distal end into a *terminal arborization*, and each branch ends in a *synaptic knob*. The synaptic knob contains *synaptic vesicles*, which contain neurotransmitters.
5. Neurons are described as *multipolar*, *bipolar*, or *unipolar* depending on the number of dendrites present, or *anaxonic* if they have no axon.
6. Neurons move material along the axon by *axonal transport*, which can be *fast* or *slow*, *anterograde* (away from the soma) or *retrograde* (toward the soma).

12.3 Supportive Cells (Neuroglia) (p. 448)

1. Supportive cells called *neuroglia* greatly outnumber neurons. There are six kinds of neuroglia: *oligodendrocytes*, *ependymal cells*, *microglia*, and *astrocytes* in the CNS, and *Schwann cells* and *satellite cells* in the PNS.
2. *Oligodendrocytes* produce the myelin sheath around CNS nerve fibers.
3. *Ependymal cells* line the inner cavities of the CNS and secrete and circulate cerebrospinal fluid.
4. *Microglia* are macrophages that destroy microorganisms, foreign matter, and dead tissue in the CNS.
5. *Astrocytes* play a wide variety of protective, nutritional, homeostatic, and communicative roles for the neurons, and form scar tissue when CNS tissue is damaged.
6. *Schwann cells* cover nerve fibers in the PNS and produce myelin around most of them.
7. *Satellite cells* surround somas of the PNS neurons; they insulate the neurons and regulate their chemical environment.
8. *Myelin* is a multilayered coating of oligodendrocyte or Schwann cell membrane around a nerve fiber, with periodic gaps called *nodes of Ranvier* between the glial cells.
9. Signal transmission is relatively slow in small nerve fibers, unmyelinated fibers, and at nodes of Ranvier. It is much faster in large nerve fibers and myelinated segments (*internodes*) of a fiber.
10. Damaged nerve fibers in the PNS sometimes regenerate if the soma is unharmed. Repair requires a *regeneration tube* composed of Schwann cells, *basal lamina*, and *neurilemma*, which are present only in the PNS. Damaged fibers in the CNS cannot regenerate.

12.4 Electrophysiology of Neurons (p. 453)

1. An *electrical potential* is a difference in electrical charge between two points. When a cell has a charge difference between the two sides of the

plasma membrane, it is *polarized*. In a resting neuron, the charge difference is called the *resting membrane potential (RMP)*. It is typically -70 mV (negative on the intracellular side).

2. A *current* is a flow of charge particles—in living cells, mainly Na^+ and K^+ . Resting cells have more K^+ inside than outside the cell, and more Na^+ outside than inside. A current occurs when gates in the plasma membrane open and allow these ions to diffuse across the membrane, down their concentration gradients.
3. When a neuron is stimulated on the dendrites or soma, Na^+ gates open and allow Na^+ to enter the cell. This slightly depolarizes the membrane, creating a *local potential*. Short-distance diffusion of Na^+ inside the cell allows local potentials to spread to nearby areas of membrane.
4. Local potentials are *graded*, *decremental*, *reversible*, and can be *excitatory* or *inhibitory*.
5. The trigger zone and unmyelinated regions of a nerve fiber have voltage-regulated Na^+ and K^+ gates that open in response to changes in membrane potential and allow these ions through.
6. If a local potential reaches *threshold* at the trigger zone, voltage-regulated gates open. The inward movement of Na^+ followed by the outward movement of K^+ creates a quick voltage change called an *action potential*. The cell *depolarizes* as the membrane potential becomes less negative, and *repolarizes* as it returns toward the RMP.
7. Unlike local potentials, action potentials follow an *all-or-none law* and are *nondecremental* and *irreversible*. Following an action potential, a patch of cell membrane has a temporary *refractory period* in which it cannot respond to another stimulus.
8. One action potential triggers another in the plasma membrane just distal to it. By repetition of this process, a chain of action potentials, or *nerve signal*, travels the entire length of an unmyelinated axon. The refractory

478 PART THREE Integration and Control

period of the recently active membrane prevents this signal from traveling backward toward the soma.

- In a myelinated fiber, only the initial segment and nodes of Ranvier have voltage-regulated gates. In the internodes, the signal travels rapidly by Na^+ diffusing along the intracellular side of the membrane. At each node, new action potentials occur, slowing the signal somewhat, but restoring signal strength. Myelinated nerve fibers are said to show *saltatory conduction* because the signal seems to jump from node to node.

12.5 Synapses (p. 462)

- At the distal end of a nerve fiber is a *synapse* where it meets the next cell (usually another neuron or a muscle or gland cell).
- The *presynaptic* neuron must release chemical signals called *neurotransmitters* to cross the synaptic cleft and stimulate the next (*postsynaptic*) cell.
- Neurotransmitters include acetylcholine (ACh), monoamines such as norepinephrine (NE) and serotonin, amino acids such as glutamate and GABA, and neuropeptides such as β -endorphin and substance P. A single neurotransmitter can affect different cells differently because of the variety of receptors for it that various cells possess.
- Some synapses are excitatory, as when ACh triggers the opening of $\text{Na}^+ - \text{K}^+$ gates and depolarizes the postsynaptic cell, or when NE triggers the synthesis of the second messenger cAMP.
- Some synapses are inhibitory, as when GABA opens a Cl^- gate and the inflow of Cl^- hyperpolarizes the postsynaptic cell.
- In some synapses, a neurotransmitter such as NE does not directly open an ion gate, but acts through second-messenger systems such as cAMP.
- Synaptic transmission ceases when the neurotransmitter diffuses away from the synaptic cleft, is reabsorbed by the presynaptic cell, or is degraded by an enzyme in the cleft such as acetylcholinesterase (AChE).
- Hormones, neuropeptides, nitric oxide (NO), and other chemicals can act as *neuromodulators*, which alter synaptic function by altering neurotransmitter synthesis, release, reuptake, or breakdown.

12.6 Neural Integration (p. 467)

- Synapses slow down communication in the nervous system, but their role in *neural integration* (information processing and decision making) overrides this drawback.
- Neural integration is based on the relative effects of small depolarizations called *excitatory postsynaptic potentials (EPSPs)* and small hyperpolarizations called *inhibitory postsynaptic potentials (IPSPs)* in the postsynaptic membrane. EPSPs make it easier for the postsynaptic neuron to fire, and IPSPs make it harder.
- Some combinations of neurotransmitter and receptor produce EPSPs and some produce IPSPs. The postsynaptic neuron can fire only if EPSPs override IPSPs enough for the membrane voltage to reach threshold.
- One neuron may receive input from thousands of others, some producing EPSPs and some producing IPSPs. *Summation*, the adding up of these potentials, occurs in the trigger zone. Two types of summation are *temporal* (based on how frequently a presynaptic neuron is stimulating the postsynaptic one) and *spatial* (based on how many presynaptic neurons are simultaneously stimulating the postsynaptic one).
- One presynaptic neuron can *facilitate* another, making it easier for the second to stimulate a postsynaptic cell, or it can produce *presynaptic inhibition*, making it harder for another neuron to stimulate the postsynaptic cell.
- Neurons encode qualitative and quantitative information by means of *neural coding*. Stimulus type (qualitative information) is represented by which nerve cells are firing (the *labeled line code*). Stimulus intensity (quantitative information) is represented both by which nerve cells are firing (sensitive low-threshold neurons or less sensitive high-threshold ones) and by their firing frequency.
- The refractory period sets an upper limit on how frequently a neuron can fire.
- Neurons work in groups called *neural pools*.
- A presynaptic neuron can, by itself, cause postsynaptic neurons in its *discharge zone* to fire. In its *facilitated zone*, it can only get a postsynaptic cell to fire by collaborating with other presynaptic neurons (facilitating each other).
- Signals can travel *diverging*, *converging*, *reverberating*, or *parallel after-discharge circuits* of neurons.
- Memories are formed by neural pathways of modified synapses. The ability of synapses to change with experience is called *synaptic plasticity*, and changes that make synaptic transmission easier are called *synaptic potentiation*.
- Immediate memory may be based on reverberating circuits. *Short-term memory (STM)* may employ these circuits as well as *synaptic facilitation*, which is thought to involve an accumulation of Ca^{2+} in the synaptic knob.
- Long-term memory (LTM)* involves the remodeling of synapses, or modification of existing synapses so that they release more neurotransmitter or have more receptors for a neurotransmitter. The two forms of LTM are *declarative* and *procedural memory*.

Testing Your Recall

- The integrative functions of the nervous system are performed mainly by
 - afferent neurons.
 - efferent neurons.
 - neuroglia.
 - sensory neurons.
 - interneurons.
- The highest density of voltage-regulated ion gates is found on the _____ of a neuron.
 - dendrites
 - soma
 - nodes of Ranvier
 - internodes
 - synaptic knobs
- The soma of a mature neuron lacks
 - a nucleus.
 - endoplasmic reticulum.
 - lipofuscin.
 - centrioles.
 - ribosomes.
- The glial cells that fight infections in the CNS are
 - microglia.
 - satellite cells.
 - ependymal cells.
 - oligodendrocytes.
 - astrocytes.
- Posttetanic potentiation of a synapse increases the amount of _____ in the synaptic knob.
 - neurotransmitter
 - neurotransmitter receptors
 - calcium
 - sodium
 - NMDA
- An IPSP is _____ of the postsynaptic neuron.
 - a refractory period
 - an action potential
 - a depolarization
 - a repolarization
 - a hyperpolarization
- Saltatory conduction occurs only
 - at chemical synapses.
 - in the initial segment of an axon.
 - in both the initial segment and axon hillock.
 - in myelinated nerve fibers.
 - in unmyelinated nerve fibers.
- Some neurotransmitters can have either excitatory or inhibitory effects depending on the type of
 - receptors on the postsynaptic cell.
 - synaptic vesicles in the axon.
 - synaptic potentiation that occurs.
 - postsynaptic potentials on the synaptic knob.
 - neuromodulator involved.
- Differences in the volume of a sound are likely to be encoded by differences in _____ in nerve fibers from the inner ear.
 - neurotransmitters
 - signal conduction velocity
 - types of postsynaptic potentials
 - firing frequency
 - voltage of the action potentials
- Motor effects that depend on repetitive output from a neural pool are most likely to use
 - parallel after-discharge circuits.
 - reverberating circuits.
 - facilitated circuits.
 - diverging circuits.
 - converging circuits.
- Neurons that convey information to the CNS are called sensory, or _____, neurons.
- To perform their role, neurons must have the properties of excitability, secretion, and _____.
- The _____ is a period of time in which a neuron is producing an action potential and cannot respond to another stimulus of any strength.
- Neurons receive incoming signals by way of specialized extensions of the cell called _____.
- In the CNS, myelin is produced by glial cells called _____.
- A myelinated nerve fiber can produce action potentials only in specialized regions called _____.
- The trigger zone of a neuron consists of its _____ and _____.
- The neurotransmitter secreted at an adrenergic synapse is _____.
- A presynaptic nerve fiber cannot cause other neurons in its _____ to fire, but it can make them more sensitive to stimulation from other presynaptic fibers.
- _____ are substances released along with a neurotransmitter that modify the neurotransmitter's effect.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- A neuron never has more than one axon.
- Oligodendrocytes perform the same function in the brain as Schwann cells do in the peripheral nerves.
- A resting neuron has a higher concentration of K^+ in its cytoplasm than in the extracellular fluid surrounding it.
- During an action potential, most of the Na^+ and K^+ exchange places across the plasma membrane.
- Excitatory postsynaptic potentials lower the threshold of a neuron and thus make it easier to stimulate.
- The absolute refractory period sets an upper limit on how often a neuron can fire.
- A given neurotransmitter has the same effect no matter where in the body it is secreted.
- Myelinated nerve fibers conduct signals more rapidly than unmyelinated ones because they have nodes of Ranvier.
- Learning occurs by increasing the number of neurons in the brain tissue.
- Mature neurons are incapable of mitosis.

Answers in appendix B

Testing Your Comprehension

- Schizophrenia is sometimes treated with drugs such as chlorpromazine that inhibit dopamine receptors. A side effect is that patients begin to develop muscle tremors, speech impairment, and other disorders similar to Parkinson disease. Explain.
- Hyperkalemia is an excess of potassium in the extracellular fluid. What effect would this have on the resting membrane potentials of the nervous system and on neural excitability?
- Suppose a poison were to slow down the $\text{Na}^+ - \text{K}^+$ pumps of nerve cells. How would this affect the resting membrane potentials of neurons? Would it make neurons more excitable than normal, or make them more difficult to stimulate? Explain.
- The unity of form and function is an important concept in understanding synapses. Give two structural reasons why nerve signals cannot travel backward across a chemical synapse.
- The local anesthetics tetracaine and procaine (Novocain) prevent voltage-regulated Na^+ gates from opening. Explain why this would block the conduction of pain signals in a sensory nerve.

What might be the consequences if signals did travel freely in both directions?

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Function of antagonistic muscles (p. 324)
- Basic neuron structure (p. 444)
- EPSPs and IPSPs (p. 468)
- Parallel after-discharge circuits (p. 472)

Every year in the United States, thousands of people become paralyzed by spinal cord injuries that result from automobile and motorcycle accidents, contact sports, and falls. Although the spinal cord is protected by the vertebral column, damage may occur as a result of vertebral fractures or viral infections. Because the spinal cord serves as a pathway for messages between the brain and the rest of the body, spinal cord injuries often have a devastating effect on one's quality of life. Their treatment is one of the most lively areas of medical research today.

As physical therapists are well aware, the consequences of spinal cord injury can vary greatly, but include paralysis of the lower limbs (*paraplegia*) or all four limbs (*quadriplegia*), respiratory paralysis, loss of sensation or motor control in more limited regions of the body, and disorders of bladder and bowel control and sexual function. Therapists who treat spinal patients must know spinal cord anatomy and function to understand their patients' functional deficits and prospects for improvement and to plan an appropriate regimen of treatment. Such anatomical knowledge is necessary, as well, for understanding *hemiplegia*—paralysis of one or both limbs on either the left or right side of the body—even though this usually results from strokes or other brain injuries rather than spinal cord injuries. The spinal cord is the “information highway” that connects the brain with the lower body; it contains the neural routes that explain why a lesion to a specific part of the brain results in a functional loss in a specific locality in the lower body.

In this chapter, we will study not only the spinal cord but also the spinal nerves that arise from it with ladderlike regularity at intervals along its length. Thus, we will examine components of both the central and peripheral nervous systems, but these components are so closely related, structurally and functionally, that it is appropriate to consider them together. Similarly, the brain and cranial nerves will be considered together in the following chapter. These two chapters therefore elevate our study of the nervous system from the cellular level (chapter 12) to the organ and system levels.

13.1 The Spinal Cord

Objectives

When you have completed this section, you should be able to

- state the three principal functions of the spinal cord;
- describe the gross and microscopic structure of the spinal cord; and
- trace the pathways (tracts) followed by nerve signals traveling up and down the spinal cord.

Functions

The spinal cord serves three principal functions:

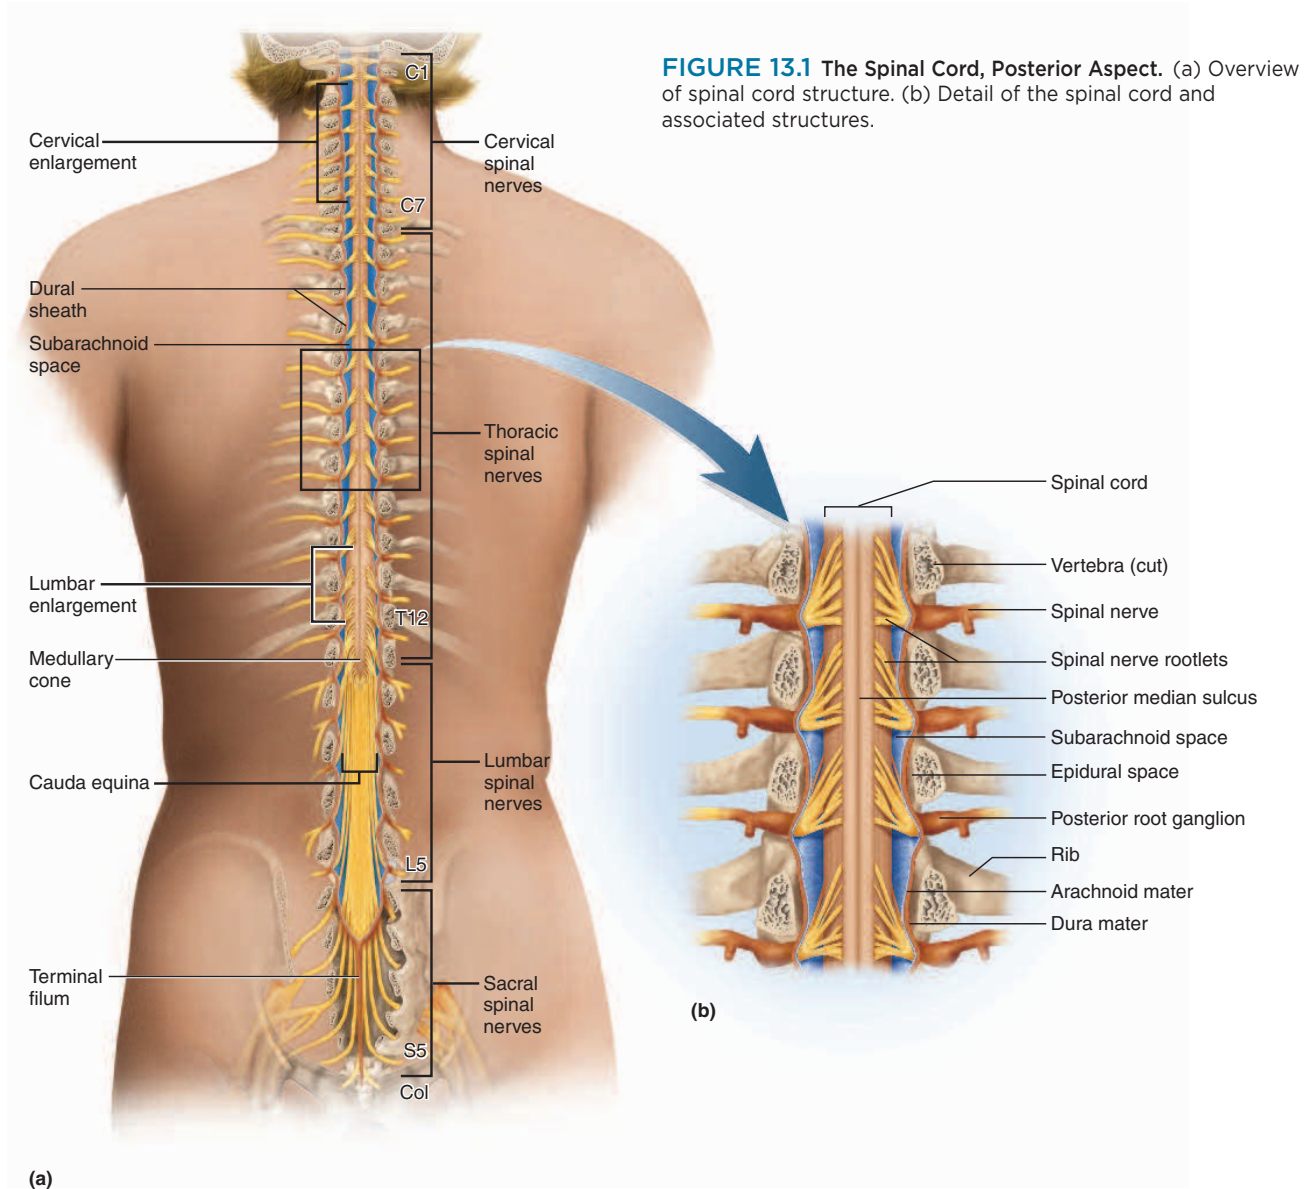

1. **Conduction.** It contains bundles of nerve fibers that conduct information up and down the cord, connecting different levels of the trunk with each other and with the brain. This enables sensory information to reach the brain, motor commands to reach the effectors, and input received at one level of the cord to affect output from another level.
2. **Locomotion.** Walking involves repetitive, coordinated contractions of several muscle groups in the limbs. Motor neurons in the brain initiate walking and determine its speed, distance, and direction, but the simple repetitive muscle contractions that put one foot in front of another, over and over, are coordinated by groups of neurons called **central pattern generators** in the cord. These neural circuits produce the sequence of outputs to the extensor and flexor muscles that cause alternating movements of the lower limbs.
3. **Reflexes.** Reflexes are involuntary stereotyped responses to stimuli, such as the withdrawal of a hand from pain. They involve the brain, spinal cord, and peripheral nerves.

Surface Anatomy

The **spinal cord** (fig. 13.1) is a cylinder of nervous tissue that arises from the brainstem at the foramen magnum of the skull. It passes through the vertebral canal as far as the inferior margin of the first lumbar vertebra (L1) or slightly beyond. In adults, it averages about 1.8 cm thick and 45 cm long. Early in fetal development, the spinal cord extends for the full length of the vertebral column. However, the vertebral column grows faster than the spinal cord, so the cord extends only to L3 by the time of birth and to L1 in an adult. Thus, it occupies only the upper two-thirds of the vertebral canal; the lower one-third is described shortly. The cord gives rise to 31 pairs of spinal nerves. The first pair passes between the skull and vertebra C1, and the rest pass through the intervertebral foramina. Although the spinal cord is not visibly segmented, the part supplied by each pair of spinal nerves is called a *segment*. The cord exhibits longitudinal grooves on its anterior and posterior sides—the *anterior median fissure* and *posterior median sulcus*, respectively (fig. 13.2b).

The spinal cord is divided into **cervical**, **thoracic**, **lumbar**, and **sacral regions**. It may seem odd that it has a sacral region when the cord itself ends well above the sacrum. These regions, however, are named for the level of the vertebral column from which the spinal nerves emerge, not for the vertebrae that contain the cord itself.

In two areas, the cord is a little thicker than elsewhere. In the inferior cervical region, a **cervical enlargement** of the cord gives rise to nerves of the upper limbs. In the lumbosacral region, there is a similar **lumbar enlargement**

where nerves to the pelvic region and lower limbs arise. Inferior to the lumbar enlargement, the cord tapers to a point called the **medullary cone (conus medullaris)**. The lumbar enlargement and medullary cone give rise to a bundle of nerve roots that occupy the vertebral canal from L2 to S5. This bundle, named the **cauda equina**¹ (CAW-duh ee-KWY-nah) for its resemblance to a horse's tail, innervates the pelvic organs and lower limbs.

Think About It

Spinal cord injuries commonly result from fractures of vertebrae C5 to C6, but never from fractures of L3 to L5. Explain both observations.

¹cauda = tail + equin = horse

Meninges of the Spinal Cord

The spinal cord and brain are enclosed in three fibrous connective tissue membranes called **meninges**² (meh-NIN-jeez)—singular, *meninx* (MEN-inks) (fig. 13.2). These membranes separate the soft tissue of the central nervous system from the bones of the vertebrae and skull. From superficial to deep, they are the **dura mater**, **arachnoid mater**, and **pia mater**.

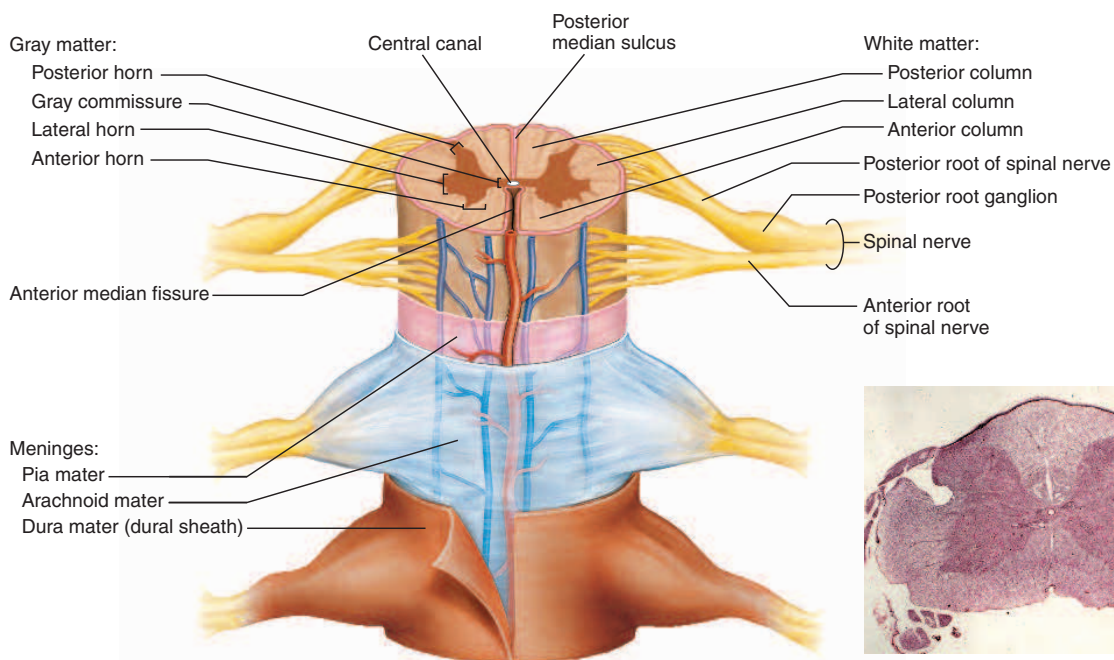

The **dura mater**³ (DOO-ruh MAH-tur) forms a loose-fitting sleeve called the **dural sheath** around the spinal cord. It is a tough collagenous membrane about as thick as a rubber kitchen glove. The space between the sheath and

²menin = membrane

³dura = tough + mater = mother, womb

(a) Spinal cord and vertebra (cervical)

(b) Spinal cord and meninges (thoracic)

(c) Lumbar spinal cord

FIGURE 13.2 Cross-Sectional Anatomy of the Spinal Cord. (a) Relationship to the vertebra, meninges, and spinal nerve. (b) Detail of the spinal cord, meninges, and spinal nerves. (c) Cross section of the lumbar spinal cord with spinal nerves.

vertebral bones, called the **epidural space**, is occupied by blood vessels, adipose tissue, and loose connective tissue. Anesthetics are sometimes introduced to this space to block pain signals during childbirth or surgery; this procedure is called *epidural anesthesia*.

The **arachnoid**⁴ (ah-RACK-noyd) **mater** consists of a simple squamous epithelium, the *arachnoid membrane*, adhering to the inside of the dura, and a loose mesh of

⁴arachn = spider, spider web + oid = resembling

collagenous and elastic fibers spanning the gap between the arachnoid membrane and the pia mater. This gap, called the **subarachnoid space**, is filled with cerebrospinal fluid (CSF), a clear liquid discussed in chapter 14. Inferior to the medullary cone, the subarachnoid space is called the **lumbar cistern** and is occupied by the cauda equina and CSF.

The **pia**⁵ (PEE-uh) **mater** is a delicate, translucent membrane that closely follows the contours of the spinal cord. It continues beyond the medullary cone as a fibrous strand, the **terminal filum**, within the lumbar cistern. At the level of vertebra S2, it exits the lower end of the cistern, fuses with the dura mater, and the two form a **coccygeal ligament** that anchors the cord and meninges to vertebra Co1. At regular intervals along the cord, extensions of the pia called **denticulate ligaments** extend through the arachnoid to the dura, anchoring the cord and limiting side-to-side movements.

Cross-Sectional Anatomy

Figure 13.2a shows the relationship of the spinal cord to a vertebra and spinal nerve, and figure 13.2b shows the cord itself in more detail. The spinal cord, like the brain, consists of two kinds of nervous tissue called gray and white matter. **Gray matter** has a relatively dull color because it contains little myelin. It contains the somas, dendrites, and proximal parts of the axons of neurons. It is the site of synaptic contact between neurons, and therefore the site of all synaptic integration (information processing) in the central nervous system. **White matter**, by contrast, has a bright, pearly white appearance, which it gets from an abundance of myelin. It is composed of bundles of axons, called **tracts**, that carry signals from one part of the CNS to another. Both gray and white matter also have an abundance of glial cells. In silver-stained nervous tissue, gray matter tends to have a brown or golden color and white matter a lighter tan to yellow color.

INSIGHT 13.1 Clinical Application

Spina Bifida

About one baby in 1,000 is born with *spina bifida* (SPY-nuh BIF-ih-duh), a congenital defect in which one or more vertebrae fail to form a complete vertebral arch for enclosure of the spinal cord. This is especially common in the lumbosacral region. One form, *spina bifida occulta*,⁶ involves only one to a few vertebrae and causes no functional problems. Its only external sign is a dimple or hairy pigmented spot. *Spina bifida cystica*⁷ is more serious. A sac protrudes from the spine and may contain meninges, cerebrospinal fluid, and parts of the spinal cord and nerve roots (fig. 13.3). In extreme cases, inferior spinal cord function is absent, causing lack of bowel control and paralysis of the lower limbs and urinary bladder. The last of these conditions can lead to chronic urinary infections and renal failure. Spina bifida cystica usually requires surgical closure within 72 hours of birth. The prognosis depends on the location and severity of the defect. It can range from a nearly normal, productive life, to a lifetime of treatment for the multisystem complications of the disorder, to infant death in extreme cases.

An ample dietary intake of folic acid (a B vitamin) reduces the risk of bearing a child with spina bifida. Unfortunately, the defect arises during the first 4 weeks of development, so by the time a woman knows she is pregnant, it is already too late for a

FIGURE 13.3 Spina Bifida Cystica. The sac in the lumbar region is called a myelomeningocele.

folic acid supplement to have this preventive effect. Ideally, folic acid supplementation must begin 3 months before conception. Thus, it should be part of the diet for all women who are attempting to conceive or who may do so. Good sources include green leafy vegetables, black beans, lentils, and enriched bread and pasta.

⁵*pia* = tender, soft

⁶*bifid* = divided, forked + *occult* = hidden

⁷*cyst* = sac, bladder

Gray Matter

The spinal cord has a central core of gray matter that looks somewhat butterfly- or H-shaped in cross sections. The core consists mainly of two **posterior (dorsal) horns**, which extend toward the posterolateral surfaces of the cord, and two thicker **anterior (ventral) horns**, which extend toward the anterolateral surfaces. The right and left sides are connected by a **gray commissure**. In the middle of the commissure is the **central canal**, which is collapsed in most areas of the adult spinal cord, but in some places (and in young children) remains open, lined with ependymal cells, and filled with CSF.

Near its attachment to the spinal cord, a spinal nerve branches into a **posterior (dorsal) root** and **anterior (ventral) root**. The posterior root carries sensory nerve fibers, which enter the posterior horn of the cord and sometimes synapse with an interneuron there. Such interneurons are especially numerous in the cervical and lumbar enlargements and are quite evident in histological sections at these levels. The anterior horns contain the large somas of the somatic motor neurons. Axons from these neurons exit by way of the anterior root of the spinal nerve and lead to the skeletal muscles. The spinal nerve roots are described more fully later in this chapter.

An additional **lateral horn** is visible on each side of the gray matter from the second thoracic through the first lumbar segments of the cord. It contains neurons of the sympathetic nervous system, which send their axons out of the cord by way of the anterior root along with the somatic efferent fibers.

White Matter

The white matter of the spinal cord surrounds the gray matter. It consists of bundles of axons that course up and down the cord and provide avenues of communication between different levels of the CNS. These bundles are arranged in three pairs called **columns**, or **funiculi**⁸ (few-NIC-you-lee)—a **posterior (dorsal)**, **lateral**, and **anterior (ventral) column** on each side. Each column consists of subdivisions called **tracts**, or **fasciculi**⁹ (fah-SIC-you-lye).

Spinal Tracts

Knowledge of the locations and functions of the spinal tracts is essential in diagnosing and managing spinal cord injuries. **Ascending tracts** carry sensory information up the cord, and **descending tracts** conduct motor impulses down. All nerve fibers in a given tract have a similar origin, destination, and function. Many of these fibers, as you will see, have their origin or destination in a region called the *brainstem*. Described more fully in chapter 14 (see fig. 14.1), this is a vertical stalk that supports the large *cerebellum* at the rear of the head and, even larger,

two globes called the *cerebral hemispheres* that dominate the brain. In the following discussion, you will find references to brainstem and other regions where spinal cord tracts begin and end. Spinal cord anatomy will grow in meaning as you study the brain.

Several of these tracts undergo **decussation**¹⁰ (DEE-cuh-SAY-shun) as they pass up or down the brainstem and spinal cord—meaning that they cross over from the left side of the body to the right, or vice versa. As a result, the left side of the brain receives sensory information from the right side of the body and sends motor commands to that side, while the right side of the brain senses and controls the left side of the body. A stroke that damages motor centers of the right side of the brain can thus cause paralysis of the left limbs, and vice versa.

When the origin and destination of a tract are on opposite sides of the body, we say they are **contralateral**¹¹ to each other. When a tract does not decussate, so the origin and destination of its fibers are on the same side of the body, we say they are **ipsilateral**.¹²

The major spinal cord tracts are summarized in table 13.1 and figure 13.4. Bear in mind that each tract is repeated on the right and left sides of the spinal cord.

Ascending Tracts

Ascending tracts carry sensory signals up the spinal cord. Sensory signals typically travel across three neurons from their origin in the receptors to their destination in the sensory areas of the brain: a **first-order neuron** that detects a stimulus and transmits a signal to the spinal cord or brainstem; a **second-order neuron** that continues as far as a “gateway” called the *thalamus* at the upper end of the brainstem; and a **third-order neuron** that carries the signal the rest of the way to the sensory region of the cerebral cortex. The axons of these neurons are called the *first- through third-order nerve fibers* (fig. 13.5). Deviations from the pathway described here will be noted for some of the sensory systems to follow.

The major ascending tracts are as follows. The names of most of them consist of the prefix *spino-* followed by a root denoting the destination of its fibers in the brain, although this naming system does not apply to the first two.

- The **gracile**¹³ **fasciculus** (GRAS-el fah-SIC-you-lus) (fig. 13.5a) carries signals from the midthoracic and lower parts of the body. Below vertebra T6, it composes the entire posterior column. At T6, it is joined by the cuneate fasciculus, discussed next. It consists of first-order nerve fibers that travel up the ipsilateral side of the spinal cord and terminate at the *gracile nucleus* in the medulla oblongata of the brainstem. These fibers carry signals for vibration,

¹⁰*decuss* = to cross, form an X

¹¹*contra* = opposite + *later* = side

¹²*ipsi* = the same + *later* = side

¹³*gracil* = thin, slender

⁸*funicul* = little rope, cord

⁹*fascicul* = little bundle

TABLE 13.1		Major Spinal Tracts	
Tract	Column	Decussation	Functions
Ascending (sensory) tracts			
Cuneate fasciculus	Posterior	In medulla	Sensations of limb and trunk position and movement, deep touch, visceral pain, and vibration, from level T6 up
Gracile fasciculus	Posterior	In medulla	Same as cuneate fasciculus, below level T6
Spinothalamic	Lateral and anterior	In spinal cord	Sensations of light touch, tickle, itch, temperature, pain, and pressure
Spinoreticular	Lateral and anterior	In spinal cord (some fibers)	Sensation of pain from tissue injury
Posterior spinocerebellar	Lateral	None	Feedback from muscles (proprioception)
Anterior spinocerebellar	Lateral	In spinal cord	Same as posterior spinocerebellar
Descending (motor) tracts			
Lateral corticospinal	Lateral	In medulla	Fine control of limbs
Anterior corticospinal	Anterior	None	Fine control of limbs
Tectospinal	Anterior	In midbrain	Reflexive head turning in response to visual and auditory stimuli
Lateral reticulospinal	Lateral	None	Balance and posture; regulation of awareness of pain
Medial reticulospinal	Anterior	None	Same as lateral reticulospinal
Lateral vestibulospinal	Anterior	None	Balance and posture
Medial vestibulospinal	Anterior	In medulla (some fibers)	Control of head position

FIGURE 13.4 Tracts of the Spinal Cord. All of the illustrated tracts occur on both sides of the cord, but only the ascending sensory tracts are shown on the left (red), and only the descending motor tracts on the right (green).

❖ If you were told that this cross section is either at level T4 or T10, how could you determine which is correct?

FIGURE 13.5 Some Ascending Pathways of the CNS. The spinal cord, medulla, and midbrain are shown in cross section and the cerebrum and thalamus (top) in frontal section. Nerve signals enter the spinal cord at the bottom of the figure and carry somatosensory information up to the cerebral cortex. (a) The cuneate fasciculus. (b) The spinothalamic tract.

visceral pain, deep and discriminative touch (touch whose location one can precisely identify), and especially *proprioception*¹⁴ from the lower limbs and lower trunk. (Proprioception is the nonvisual sense of the position and movements of the body.)

- The **cuneate**¹⁵ (CUE-nee-ate) **fasciculus** (fig. 13.5a) joins the gracile fasciculus at the T6 level. It occupies the lateral portion of the posterior column and forces the gracile fasciculus medially. It carries the same type of sensory signals, originating from

¹⁴*proprio* = one's own + *ception* = sensation

¹⁵*cune* = wedge

level T6 and up (from the upper limb and chest). Its fibers end in the *cuneate nucleus* on the ipsilateral side of the medulla oblongata. In the medulla, second-order fibers of the gracile and cuneate systems decussate and form the **medial lemniscus**¹⁶ (lem-NIS-cus), a tract of nerve fibers that leads the rest of the way up the brainstem to the thalamus. Third-order fibers go from the thalamus to the cerebral cortex. Because of decussation, the signals carried by the gracile and cuneate fasciculi ultimately go to the contralateral cerebral hemisphere.

- The **spinothalamic** (SPY-no-tha-LAM-ic) **tract** (fig. 13.5b) and some smaller tracts form the *anterolateral system*, which passes up the anterior and lateral columns of the spinal cord. The spinothalamic tract carries signals for pain, temperature, pressure, tickle, itch, and light or crude touch. Light touch is the sensation produced by stroking hairless skin with a feather or cotton wisp, without indenting the skin; crude touch is touch whose location one can only vaguely identify. In this pathway, first-order neurons end in the posterior horn of the spinal cord near the point of entry. Here they synapse with second-order neurons, which decussate to the opposite side of the spinal cord and form the ascending spinothalamic tract. These fibers lead all the way to the thalamus. Third-order neurons continue from there to the cerebral cortex. Because of its decussation, the spinothalamic tract ultimately sends its signals to the contralateral cerebral hemisphere.
- The **spinoreticular tract** also travels up the anterolateral system. It carries pain signals resulting from tissue injury. The first-order sensory neurons enter the posterior horn and immediately synapse with second-order neurons. These decussate to the opposite anterolateral system, ascend the cord, and end in a loosely organized core of gray matter called the *reticular formation* in the medulla and pons. Third-order neurons continue from the pons to the thalamus, and fourth-order neurons complete the path from there to the cerebral cortex. The reticular formation is further described in chapter 14, and the role of the spinoreticular tract in pain sensation is further discussed in chapter 16.
- The **posterior (dorsal) and anterior (ventral) spinocerebellar** (SPY-no-SERR-eh-BEL-ur) **tracts** travel through the lateral column and carry proprioceptive signals from the limbs and trunk to the cerebellum, a large motor control area at the rear of the brain. The first-order neurons of this system originate in the muscles and tendons and end in the posterior horn of the spinal cord. Second-order neurons send their fibers up the spinocerebellar tracts and end in the

cerebellum. Fibers of the posterior tract travel up the ipsilateral side of the spinal cord. Those of the anterior tract cross over and travel up the contralateral side but then cross back in the brainstem to enter the ipsilateral side of the cerebellum. Both tracts provide the cerebellum with feedback needed to coordinate muscle action, as discussed in chapter 14.

Descending Tracts

Descending tracts carry motor signals down the brainstem and spinal cord. A descending motor pathway typically involves two neurons called the upper and lower motor neurons. The **upper motor neuron** begins with a soma in the cerebral cortex or brainstem and has an axon that terminates on a **lower motor neuron** in the brainstem or spinal cord. The axon of the lower motor neuron then leads the rest of the way to the muscle or other target organ. The names of most descending tracts consist of a word root denoting the point of origin in the brain, followed by the suffix *-spinal*. The major descending tracts are described here.

- The **corticospinal** (COR-tih-co-SPY-nul) **tracts** carry motor signals from the cerebral cortex for precise, finely coordinated limb movements. The fibers of this system form ridges called *pyramids* on the anterior surface of the medulla oblongata, so these tracts were once called *pyramidal tracts*. Most corticospinal fibers decussate in the lower medulla and form the **lateral corticospinal tract** on the contralateral side of the spinal cord. A few fibers remain uncrossed and form the **anterior (ventral) corticospinal tract** on the ipsilateral side (fig. 13.6). Fibers of the anterior tract decussate lower in the spinal cord, however, so even they control contralateral muscles.
- The **tectospinal** (TEC-toe-SPY-nul) **tract** begins in a midbrain region called the *tectum*¹⁷ and crosses to the contralateral side of the midbrain. It descends through the brainstem to the upper spinal cord on that side, going only as far as the neck. It is involved in reflex turning of the head, especially in response to sights and sounds.
- The **lateral and medial reticulospinal** (reh-TIC-you-lo-SPY-nul) **tracts** originate in the reticular formation of the brainstem. They control muscles of the upper and lower limbs, especially to maintain posture and balance. They also contain *descending analgesic pathways* that reduce the transmission of pain signals to the brain (see chapter 16).
- The **lateral and medial vestibulospinal** (vess-TIB-you-lo-SPY-nul) **tracts** begin in the brainstem *vestibular nuclei*, which receive impulses for balance from the inner ear. The lateral vestibulospinal tract passes

¹⁶lemniscus = ribbon

¹⁷tectum = roof

FIGURE 13.6 Two Descending Pathways of the CNS. The lateral and anterior corticospinal tracts, which carry signals for voluntary muscle contraction. Nerve signals originate in the cerebral cortex at the top of the figure and carry motor commands down the spinal cord.

down the anterior column of the spinal cord and facilitates neurons that control the extensor muscles of the limbs, thus inducing the limbs to stiffen and straighten. This is an important reflex in responding to body tilt and keeping one's balance. The medial vestibulospinal tract splits into ipsilateral and contralateral fibers that descend through the anterior column on both sides of the spinal cord and terminate in the neck. It plays a role in the control of head position.

Rubrospinal tracts are prominent in other mammals, where they aid in muscle coordination. Although often pictured in illustrations of supposedly human anatomy, they are almost nonexistent in humans and have little functional importance.

Think About It

You are blindfolded and either a tennis ball or an iron ball is placed in your right hand. What spinal tract(s) would carry the signals that enable you to discriminate between these two objects?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. Name the four major regions and two enlargements of the spinal cord.
2. Describe the distal (inferior) end of the spinal cord and the contents of the vertebral canal from level L2 to S5.
3. Sketch a cross section of the spinal cord showing the anterior and posterior horns. Where are the gray and white matter? Where are the columns and tracts?
4. Give an anatomical explanation of why a stroke in the right cerebral hemisphere can paralyze the limbs on the left side of the body.

13.2 The Spinal Nerves

Objectives

When you have completed this section, you should be able to

- describe the attachment of a spinal nerve to the spinal cord;
- trace the branches of a spinal nerve distal to its attachment;
- name the five plexuses of spinal nerves and describe their general anatomy;
- name some major nerves that arise from each plexus; and
- explain the relationship of dermatomes to the spinal nerves.

General Anatomy of Nerves and Ganglia

The spinal cord communicates with the rest of the body by way of the spinal nerves. Before we discuss those specific nerves, however, it is necessary to be familiar with the structure of nerves and ganglia in general.

A **nerve** is a cordlike organ composed of numerous nerve fibers (axons) bound together by connective tissue (fig. 13.8). If we compare a *nerve fiber* to a wire carrying an electrical current in one direction, a *nerve* would be comparable to an electrical cable composed of thousands of wires carrying currents in opposite directions. A nerve contains anywhere from a few nerve fibers to more than a

million. Nerves usually have a pearly white color and resemble frayed string as they divide into smaller and smaller branches.

Nerve fibers of the peripheral nervous system are ensheathed in Schwann cells, which form a neurilemma and often a myelin sheath around the axon (see p. 450). External to the neurilemma, each fiber is surrounded by a basal lamina and then a thin sleeve of loose connective tissue called the **endoneurium**. In most nerves, the nerve fibers are gathered in bundles called **fascicles**, each wrapped in a sheath called the **perineurium**. The perineurium is composed of up to 20 layers of overlapping, squamous, epithelium-like cells. Several fascicles are then bundled together and wrapped in an outer perineurium to

INSIGHT 13.2 Clinical Application

Poliomyelitis and Amyotrophic Lateral Sclerosis

*Poliomyelitis*¹⁸ and *amyotrophic lateral sclerosis*¹⁹ (ALS) are two diseases that involve destruction of motor neurons. In both diseases, the skeletal muscles atrophy from lack of innervation.

Poliomyelitis is caused by the poliovirus, which destroys motor neurons in the brainstem and anterior horn of the spinal cord. Signs of polio include muscle pain, weakness, and loss of some reflexes, followed by paralysis, muscular atrophy, and sometimes respiratory arrest. The virus spreads by fecal contamination of water. Historically, polio afflicted many children who contracted the virus from swimming in contaminated pools. For a time, the polio vaccine nearly eliminated new cases, but the disease has lately begun to reemerge among children in some parts of the world.

ALS is also known as Lou Gehrig²⁰ disease after the baseball player who had to retire from the sport because of it. It is marked not only by the degeneration of motor neurons and atrophy of the muscles, but also sclerosis (scarring) of the lateral regions of the spinal cord—hence its name. Most cases occur when astrocytes fail to reabsorb the neurotransmitter glutamate from the tissue fluid, allowing it to accumulate to a neurotoxic level. The early signs of ALS include muscular weakness and difficulty in speaking, swallowing, and using the hands. Sensory and intellectual functions remain unaffected, as evidenced by the accomplishments of astrophysicist and best-selling author Stephen Hawking (Figure 13.7), who was stricken with ALS while he was in college. Despite near-total paralysis, he remains highly productive and communicates with the aid of a speech synthesizer and computer. Tragically, many people are

quick to assume that those who have lost most of their ability to communicate their ideas and feelings have few ideas and feelings to communicate. To a victim, this may be more unbearable than the loss of motor function itself.

compose the nerve as a whole. The epineurium is composed of dense irregular connective tissue and protects the nerve from stretching and injury. Nerves have a high metabolic rate and need a plentiful blood supply, which is furnished by blood vessels that penetrate these connective tissue coverings.

Think About It

How does the structure of a nerve compare to that of a skeletal muscle? Which of the descriptive terms for nerves have similar counterparts in muscle histology?

As we have seen in chapter 12, peripheral nerve fibers are of two kinds: sensory (afferent) fibers carry signals from sensory receptors to the CNS, and motor (efferent) fibers carry signals from the CNS to muscles and glands. Both sensory and motor fibers can also be described as *somatic* or *visceral* and as *general* or *special* depending on the organs they innervate (table 13.2).

TABLE 13.2

The Classification of Nerve Fibers

Class	Description
Afferent fibers	Carry sensory signals from receptors to the CNS
Efferent fibers	Carry motor signals from the CNS to effectors
Somatic fibers	Innervate skin, skeletal muscles, bones, and joints
Visceral fibers	Innervate blood vessels, glands, and viscera
General fibers	Innervate widespread organs such as muscles, skin, glands, viscera, and blood vessels
Special fibers	Innervate more localized organs in the head, including the eyes, ears, olfactory and taste receptors, and muscles of chewing, swallowing, and facial expression

Nerves can be classified as sensory, motor, or mixed. Purely **sensory nerves**, composed of afferent fibers, are rare; they include the olfactory and optic nerves described in chapter 14. **Motor nerves** carry only efferent fibers. Most nerves, however, are mixed. A **mixed nerve** consists of both afferent and efferent fibers and thus conducts signals in two directions, although any one nerve fiber within the nerve conducts signals one way only. Many nerves commonly described as motor are actually mixed because they carry sensory signals of proprioception from the muscle back to the CNS.

If a nerve resembles a thread, a **ganglion**²¹ resembles a knot in the thread. A ganglion is a cluster of neurosomas outside the CNS. It is enveloped in an epineurium continuous with that of the nerve. Among the neurosomas are bundles of nerve fibers leading into and out of

the ganglion. Figure 13.9 shows a type of ganglion called the *posterior root ganglion* associated with the spinal nerves.

Spinal Nerves

There are 31 pairs of **spinal nerves**: 8 cervical (C1–C8), 12 thoracic (T1–T12), 5 lumbar (L1–L5), 5 sacral (S1–S5), and 1 coccygeal (Co) (fig. 13.10). The first cervical nerve emerges between the skull and atlas, and the others emerge through intervertebral foramina, including the anterior and posterior foramina of the sacrum and the sacral hiatus. Thus, spinal nerves C1 through C7 emerge superior to the correspondingly numbered vertebrae (nerve C5 above vertebra C5, for example); nerve C8 emerges inferior to vertebra C7; and below this, the pattern changes, with all the remaining spinal nerves emerging inferior to the correspondingly numbered vertebrae (nerve L3 inferior to vertebra L3, for example).

²¹gangli = knot

FIGURE 13.9 Anatomy of a Ganglion (Longitudinal Section). The posterior root ganglion contains the somas of unipolar sensory neurons conducting signals from peripheral sense organs toward the spinal cord. Below this is the anterior root of the spinal nerve, which conducts motor signals away from the spinal cord, toward peripheral effectors. (The anterior root is not part of the ganglion.)

❖ Where are the somas of the motor neurons located?

FIGURE 13.10 The Spinal Nerve Roots and Plexuses, Posterior Aspect.

Proximal Branches

Each spinal nerve has two points of attachment to the spinal cord. As a spinal nerve passes through the intervertebral foramen, it divides into a branch called the **posterior (dorsal) root**, which passes posteriorly toward the back of the spinal cord, and a branch called the **anterior (ventral) root**, which passes anteriorly toward the front of the spinal cord (fig. 13.11).

Shortly after the branch point, the posterior root expands into a **posterior (dorsal) root ganglion**, which contains the somas of the sensory neurons carrying signals to the spinal cord (see fig. 13.9). The posterior root then divides into six to eight **rootlets** that enter the posterior horn of the cord (figs. 13.1b and 13.12). Anteriorly, another six to eight rootlets leave the spinal cord and converge to form the anterior root.

The anterior and posterior roots merge, penetrate the dural sac, enter the intervertebral foramen, and there form the spinal nerve proper. Thus, the spinal nerve is a mixed nerve, carrying sensory information to the spinal cord by way of the posterior root and motor commands away from the cord by way of the anterior root. The anterior and posterior roots are shortest in the cervical region and become longer inferiorly. The roots that arise from segments L2 to Co of the cord form the cauda equina. Some viruses invade the central nervous system by way of these roots (see Insight 13.3).

Distal Branches

Distal to the vertebrae, the branches of a spinal nerve are more complex (fig. 13.13). Immediately after emerging from the intervertebral foramen, the nerve divides into an

FIGURE 13.11 Branches of a Spinal Nerve in Relation to the Spinal Cord and Vertebra (Cross Section).

FIGURE 13.12 The Point of Entry of Two Spinal Nerves into the Spinal Cord. Posterior (dorsal) view with vertebrae cut away. Note that each posterior root divides into several rootlets that enter the spinal cord. A segment of the spinal cord is the portion receiving all the rootlets of one spinal nerve.

● In the labeled rootlets of spinal nerve C5, are the nerve fibers afferent or efferent? How do you know?

FIGURE 13.13 Rami of the Spinal Nerves. (a) Anterolateral view of the spinal nerves and their subdivisions in relation to the spinal cord and vertebrae. (b) Cross section of the thorax showing innervation of muscles and skin of the chest and back. This section is cut through the intercostal muscles between two ribs.

anterior ramus, a **posterior ramus**,²² and a small **meningeal branch**. Thus, each spinal nerve branches on both ends—into anterior and posterior *roots* approaching the spinal cord, and anterior and posterior *rami* leading away from the vertebral column.

The meningeal branch (see fig. 13.11) reenters the vertebral canal and innervates the meninges, vertebrae, and spinal ligaments. The posterior ramus innervates the muscles and joints in that region of the spine and the skin of the back. The larger anterior ramus innervates the anterior and lateral skin and muscles of the trunk, and gives rise to nerves of the limbs.

Think About It

Do you think the meningeal branch is sensory, motor, or mixed? Explain your reasoning.

The anterior ramus differs from one region of the trunk to another. In the thoracic region, it forms an **intercostal nerve**, which travels along the inferior margin of a rib and innervates the skin and intercostal muscles (thus contributing to breathing). It also innervates the internal

oblique, external oblique, and transverse abdominal muscles. All other anterior rami form the *nerve plexuses* described next.

As shown in figure 13.13, the anterior ramus also gives off a pair of *communicating rami*, which connect with a string of *sympathetic chain ganglia* alongside the vertebral column. These are seen only in spinal nerves T1 through L2. They are components of the sympathetic nervous system and are discussed more fully in chapter 15.

Nerve Plexuses

Except in the thoracic region, the anterior rami branch and anastomose (merge) repeatedly to form five weblike nerve plexuses: the small **cervical plexus** in the neck, the **brachial plexus** near the shoulder, the **lumbar plexus** of the lower back, the **sacral plexus** immediately inferior to this, and finally, the tiny **coccygeal plexus** adjacent to the lower sacrum and coccyx. A general view of these plexuses is shown in figure 13.10; they are illustrated and described in tables 13.3 through 13.6. The spinal nerve roots that give rise to each plexus are indicated in violet in each table. Some of these roots give rise to smaller branches called *trunks*, *anterior divisions*, *posterior*

²²ramus = branch

divisions, and *cords*, which are color-coded and explained in the individual tables.

The nerves tabulated here have somatosensory and motor functions. *Somatosensory* means that they carry sensory signals from bones, joints, muscles, and the skin, in contrast to sensory input from the viscera or from special sense organs such as the eyes and ears. These signals are for touch, heat, cold, stretch, pressure, pain, and other sensations. One of the most important sensory roles of these nerves is *proprioception*, in which the brain receives information about body position and movements from nerve endings in the muscles, tendons, and joints. The brain uses this information to adjust muscle actions and thereby maintain equilibrium (balance) and coordination.

The motor function of these nerves is primarily to stimulate the contraction of skeletal muscles. These nerves also carry autonomic fibers to the blood vessels of the skin, muscles, and other organs, thus adjusting blood flow to changing local needs.

The following tables identify the areas of skin innervated by the sensory fibers and the muscle groups innervated by the motor fibers of the individual nerves. The muscle tables in chapter 10 provide a more detailed breakdown of the muscles supplied by each nerve and the actions they perform. You may assume that for each muscle, these nerves also carry autonomic fibers to its blood vessels and sensory fibers from its proprioceptors. Throughout these tables, *nerve* is abbreviated *n.* and nerves as *nn.*

INSIGHT 13.3 Clinical Application

Shingles

Chickenpox (*varicella*), a common disease of early childhood, is caused by the *varicella-zoster*²³ virus. It produces an itchy rash that usually clears up without complications. The virus, however, remains for life in the posterior root ganglia, kept in check by the immune system. If the immune system is compromised, however, the virus can travel down the sensory nerves by fast axonal transport and cause *shingles* (*herpes*²⁴ *zoster*). This is particularly common after the age of 50. Shingles is characterized by a painful trail of skin discoloration and fluid-filled vesicles along the path of the nerve. These signs usually appear in the chest and waist, often on just one side of the body. There is no cure, and the vesicles generally heal spontaneously within 1 to 3 weeks. In the meantime, aspirin and steroidal ointments can help to relieve the pain and inflammation of the lesions. Antiviral drugs such as acyclovir can shorten the course of an episode of shingles, but only if taken within the first 2 to 3 days of outbreak. Even after the lesions disappear, however, some people suffer intense pain along the course of the nerve (*postherpetic neuralgia*, *PHN*), lasting for months or even years. PHN has proven very difficult to treat, but pain relievers and antidepressants are of some help. Childhood vaccination against varicella reduces the risk of shingles later in life.

²³*varicella* = little spot + *zoster* = girdle

²⁴*herpes* = creeping

TABLE 13.3 The Cervical Plexus

The cervical plexus (fig. 13.14) receives fibers from the anterior rami of nerves C1 to C5 and gives rise to the nerves listed below, in order from superior to inferior. The most important of these are the *phrenic*²⁵ (FREN-ic) nerves, which travel down each side of the mediastinum, innervate the diaphragm, and play an essential role in breathing (see fig. 15.3, p. 569). In addition to the major nerves listed here, there are several motor branches that innervate the geniohyoid, thyrohyoid, scalene, levator scapulae, trapezius, and sternocleidomastoid muscles.

Nerve	Composition	Cutaneous and Other Sensory Innervation	Muscular Innervation (Motor and Proprioceptive)
Lesser occipital n.	Somatosensory	Upper third of medial surface of external ear, skin posterior to ear, posterolateral neck	None
Great auricular n.	Somatosensory	Most of the external ear, mastoid region, region from parotid salivary gland (see fig. 10.5) to slightly inferior to angle of mandible	None
Transverse cervical n.	Somatosensory	Anterior and lateral neck, underside of chin	None
Ansa cervicalis	Mixed	None	Omohyoid, sternohyoid, and sternothyroid muscles
Supraclavicular nn.	Somatosensory	Lower anterior and lateral neck, shoulder, anterior chest	None
Phrenic n.	Mixed	Diaphragm, pleura, and pericardium	Diaphragm

**FIGURE 13.14** The Cervical Plexus.²⁵*phren* = diaphragm

TABLE 13.4 The Brachial Plexus

The brachial plexus (figs. 13.15 and 13.16) is formed predominantly by the anterior rami of nerves C5 to T1 (C4 and T2 make smaller contributions). It passes over the first rib into the axilla and innervates the upper limb and some muscles of the neck and shoulder. The subdivisions of this plexus are called *roots*, *trunks*, *divisions*, and *cords* (color-coded in fig. 13.15). The five **roots** are the anterior rami of C5 through T1. Roots C5 and C6 converge to form the **upper trunk**; C7 continues as the **middle trunk**; and C8 and T1 converge to form the **lower trunk**. Each trunk divides into an **anterior** and **posterior division**; as the body is dissected from the anterior surface of the shoulder inward, the posterior divisions are found behind the anterior ones. Finally, the six divisions merge to form three large fiber bundles—the **lateral**, **posterior**, and **medial cords**. From these cords arise the following major nerves, listed in order of the illustration from superior to inferior.

Nerve	Composition	Cord of Origin	Cutaneous and Joint Innervation (Sensory)	Muscular Innervation (Motor and Proprioceptive)
Musculocutaneous n.	Mixed	Lateral	Skin of anterolateral forearm; elbow joint	Brachialis, biceps brachii, and coracobrachialis muscles
Axillary n.	Mixed	Posterior	Skin of lateral shoulder and arm; shoulder joint	Deltoid and teres minor muscles
Radial n.	Mixed	Posterior	Skin of posterior arm; posterior and lateral forearm and wrist; joints of elbow, wrist, and hand	Mainly extensor muscles of posterior arm and forearm (see tables 10.10 and 10.11)
Median n.	Mixed	Lateral and medial	Skin of lateral two-thirds of hand; tips of digits I-IV; joints of hand	Mainly forearm flexors; thenar group and lumbricals I-II of hand (see tables 10.10 to 10.12)
Ulnar n.	Mixed	Medial	Skin of palmar and medial hand and digits III-V; joints of elbow and hand	Some forearm flexors; adductor pollicis; hypothenar group; interosseous muscles; lumbricals III-IV (see tables 10.11 and 10.12)

FIGURE 13.15 The Brachial Plexus. The labeled nerves innervate muscles tabulated in chapter 11, and those in boldface are further detailed in table 13.4.

INSIGHT 13.4 Clinical Application

Spinal Nerve Injuries

The radial and sciatic nerves are especially vulnerable to injury. The radial nerve, which passes through the axilla, may be compressed against the humerus by improperly adjusted crutches, causing *crutch paralysis*. A similar injury often resulted from the now-discredited practice of correcting a dislocated shoulder by putting a foot in a person's armpit and pulling on the arm. One consequence of radial nerve injury is *wrist drop*—the fingers, hand, and wrist are chronically flexed

because the extensor muscles supplied by the radial nerve are paralyzed.

Because of its position and length, the sciatic nerve of the hip and thigh is the most vulnerable nerve in the body. Trauma to this nerve produces *sciatica*, a sharp pain that travels from the gluteal region along the posterior side of the thigh and leg as far as the ankle. Ninety percent of cases result from a herniated intervertebral disc or osteoarthritis of the lower spine, but sciatica can also be caused by pressure from a pregnant uterus, dislocation of the hip, injections in the wrong area of the buttock, or sitting for a long time on the edge of a hard chair. Men sometimes suffer sciatica because of the habit of sitting on a wallet carried in the hip pocket.

TABLE 13.5 The Lumbar Plexus

The lumbar plexus (fig. 13.17) is formed from the anterior rami of nerves L1 to L4 and some fibers from T12. With only five roots and two divisions, it is less complex than the brachial plexus. It gives rise to the following nerves.

Nerve	Composition	Cutaneous and Joint Innervation (Sensory)	Muscular Innervation (Motor and Proprioceptive)
Iliohypogastric n.	Mixed	Skin of lower anterior abdominal and posterolateral gluteal regions	Internal and external abdominal oblique and transverse abdominal muscles
Ilioinguinal n.	Mixed	Skin of upper medial thigh; male scrotum and root of penis; female labia majora	Internal abdominal oblique
Genitofemoral n.	Mixed	Skin of middle anterior thigh; male scrotum; female labia majora	Male cremaster muscle (see p. 1055)
Lateral femoral cutaneous n.	Somatosensory	Skin of anterior and upper lateral thigh	None
Femoral n.	Mixed	Skin of anterior, medial, and lateral thigh and knee; skin of medial leg and foot; hip and knee joints	Iliacus, pectineus, quadriceps femoris, and sartorius muscles
Obturator n.	Mixed	Skin of medial thigh; hip and knee joints	Obturator externus; medial (adductor) thigh muscles (see table 10.13)

FIGURE 13.17 The Lumbar Plexus.

TABLE 13.6 The Sacral and Coccygeal Plexuses

The sacral plexus is formed from the anterior rami of nerves L4, L5, and S1 through S4. It has six roots and anterior and posterior divisions. Since it is connected to the lumbar plexus by fibers that run through the *lumbosacral trunk*, the two plexuses are sometimes referred to collectively as the *lumbosacral plexus*. The coccygeal plexus is a tiny plexus formed from the anterior rami of S4, S5, and Co (fig. 13.18).

The *tibial* and *common fibular nerves* travel together through a connective tissue sheath; they are referred to collectively as the **sciatic (sy-AT-ic) nerve**. The sciatic nerve passes through the greater sciatic notch of the pelvis, extends for the length of the thigh, and ends at the popliteal fossa. Here, the tibial and common fibular nerves diverge and follow their separate paths into the leg. The tibial nerve descends through the leg and then gives rise to the medial and plantar nerves in the foot. The common fibular nerve divides into deep and superficial fibular nerves. The sciatic nerve is a common focus of injury and pain (see Insight 13.4).

Nerve	Composition	Cutaneous and Joint Innervation (Sensory)	Muscular Innervation (Motor and Proprioceptive)
Superior gluteal n.	Mixed	None	Gluteus minimus, gluteus medius, and tensor fasciae latae muscles
Inferior gluteal n.	Mixed	None	Gluteus maximus muscle
Posterior cutaneous n.	Somatosensory	Skin of gluteal region, perineum, posterior and medial thigh, popliteal fossa, and upper posterior leg	None
Tibial n.	Mixed	Skin of posterior leg; plantar skin; knee and foot joints	Hamstring muscles; posterior muscles of leg (see tables 10.14 and 10.15); most intrinsic foot muscles (via plantar nerves) (see table 10.16)
Fibular (peroneal) n. (common, deep, and superficial)	Mixed	Skin of anterior distal third of leg, dorsum of foot, and toes I-II; knee joint	Biceps femoris muscle; anterior and lateral muscles of leg; extensor digitorum brevis muscle of foot (see tables 10.14 to 10.16)
Pudendal n.	Mixed	Skin of penis and scrotum of male; clitoris, labia majora and minora, and lower vagina of female	Muscles of perineum (see table 10.7)

**FIGURE 13.18** The Sacral and Coccygeal Plexuses.

Cutaneous Innervation and Dermatomes

Each spinal nerve except C1 receives sensory input from a specific area of skin called a **dermatome**.²⁶ A *dermatome map* (fig. 13.19) is a diagram of the cutaneous regions innervated by each spinal nerve. Such a map is oversimplified, however, because the dermatomes overlap at their edges by as much as 50%. Therefore, severance of one sensory nerve root does not entirely deaden sensation from a dermatome. It is necessary to sever or anesthetize three successive spinal nerves to produce a total loss of sensation from one dermatome. Spinal nerve damage is assessed by testing the dermatomes with pinpricks and noting areas in which the patient has no sensation.

²⁶derma = skin + tome = segment, part

FIGURE 13.19 A Dermatome Map of the Anterior Aspect of the Body. Each zone of the skin is innervated by sensory branches of the spinal nerves indicated by the labels. Nerve C1 does not innervate the skin.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. What is meant by the anterior and posterior roots of a spinal nerve? Which of these is sensory and which is motor?
2. Where are the neurosomas of the posterior root located? Where are the neurosomas of the anterior root?
3. List the five plexuses of spinal nerves and state where each one is located.
4. State which plexus gives rise to each of the following nerves: axillary, ilioinguinal, obturator, phrenic, pudendal, radial, and sciatic.

13.3 Somatic Reflexes

Objectives

When you have completed this section, you should be able to

- define *reflex* and explain how reflexes differ from other motor actions;
- describe the general components of a typical reflex arc; and
- explain how the basic types of somatic reflexes function.

Most of us have had our reflexes tested with a little rubber hammer; a tap near the knee produces an uncontrollable jerk of the leg, for example. In this section, we discuss what reflexes are and how they are produced by an assembly of receptors, neurons, and effectors. We also survey the different types of neuromuscular reflexes and how they are important to motor coordination.

The Nature of Reflexes

Reflexes are quick, involuntary, stereotyped reactions of glands or muscles to stimulation. This definition sums up four important properties of a reflex:

1. Reflexes *require stimulation*—they are not spontaneous actions but responses to sensory input.
2. Reflexes are *quick*—they generally involve few if any interneurons and minimum synaptic delay.
3. Reflexes are *involuntary*—they occur without intent, often without our awareness, and they are difficult to suppress. Given an adequate stimulus, the response is essentially automatic. You may become conscious of the stimulus that evoked a reflex, and this awareness may enable you to correct or avoid a potentially dangerous situation, but awareness is not

a part of the reflex itself. It may come after the reflex action has been completed, and somatic reflexes can occur even if the spinal cord has been severed so that no stimuli reach the brain.

4. Reflexes are *stereotyped*—they occur in essentially the same way every time; the response is very predictable.

Reflexes include glandular secretion and contractions of all three types of muscle. They also include some learned responses, such as the salivation of dogs in response to a sound they have come to associate with feeding time, first studied by Ivan Pavlov and named *conditioned reflexes*. In this section, however, we are concerned with unlearned skeletal muscle reflexes that are mediated by the brainstem and spinal cord. They result in the involuntary contraction of a muscle—for example, the quick withdrawal of your hand from a hot stove or the lifting of your foot when you step on something sharp. These are called **somatic reflexes**, since they involve the somatic nervous system. Chapter 15 concerns *visceral reflexes*. The somatic reflexes have traditionally been called *spinal reflexes*, although this is a misleading expression for two reasons: (1) Spinal reflexes are not exclusively somatic; the autonomic (visceral) reflexes also involve the spinal cord. (2) Some somatic reflexes are mediated more by the brain than by the spinal cord.

A somatic reflex employs a **reflex arc**, in which signals travel along the following pathway:

1. *somatic receptors* in the skin, a muscle, or a tendon;
2. *afferent nerve fibers*, which carry information from these receptors into the posterior horn of the spinal cord or to the brainstem;
3. an *integrating center*, a point of synaptic contact between neurons in the gray matter of the spinal cord or brainstem. In most reflex arcs, there are one or more interneurons in the integrating center. Synaptic events in the integrating center determine whether the efferent (output) neurons issue a signal to the muscle.
4. *efferent nerve fibers*, which carry motor impulses to the skeletal muscles; and
5. *skeletal muscles*, the somatic effectors that carry out the response.

The Muscle Spindle

Many somatic reflexes involve stretch receptors called **muscle spindles** embedded in the skeletal muscles. These are among the body's **proprioceptors**, sense organs specialized to monitor the position and movement of body parts. The function of muscle spindles is to inform the brain of muscle length and body movements. This enables the brain to send motor commands back to the muscles that control coordinated movement, corrective reflexes

(for example, to keep one's balance), muscle tone, and posture. Spindles are especially abundant in muscles that require fine control. Hand and foot muscles have 100 or more spindles per gram of muscle, whereas there are relatively few in large muscles with coarse movements, and none at all in the middle-ear muscles.

Muscle spindles are named for their fusiform shape (fig. 13.20). They are about 4 to 10 mm long, thick in the middle and tapered at the ends, and scattered through the perimysium of a muscle with their long axes parallel to the muscle fibers. Spindles are especially concentrated at the ends of a muscle, near the tendons. A spindle contains 3 to 12 modified muscle fibers and a few nerve fibers, all wrapped in a fibrous capsule that blends at each end into the perimysium. The muscle fibers within the spindle are called **intrafusal²⁷ fibers**, while those that make up the rest of the muscle and do its work are called **extrafusal fibers**.

Intrafusal fibers are modified muscle cells that have sarcomeres and contractile ability only at the two ends; the middle of the fiber lacks sarcomeres and cannot contract. There are two classes of intrafusal fibers:

1. typically about five **nuclear chain fibers**, which have a single file of nuclei in the noncontractile region; and
2. typically two or three **nuclear bag fibers**, which are fatter, about twice as long, and have nuclei clustered in the baglike middle region.

Muscle spindles have three principal classes of nerve fibers; the first two are sensory fibers that detect changes in muscle length, and the third is a motor fiber that adjusts the length of the muscle spindle itself:

1. One **primary afferent (group Ia) fiber**, which arises from springlike *anulospiral endings* that coil around the middle of both nuclear chain and nuclear bag fibers. This is a large, fast nerve fiber, very sensitive to small changes in muscle length and to sudden body movements.
2. Up to eight **secondary afferent (group II) fibers**, which wind primarily around the nuclear chain fibers adjacent to the region of the anulospiral endings. They are intermediate-size fibers with slower conduction speed than the primary afferents. These fibers inform the brain of muscle length but are less responsive to the *rate* of muscle shortening or lengthening.
3. **Gamma motor neurons**, which originate in the anterior horn of the spinal cord and lead to the contractile ends of the intrafusal fibers. These are relatively small-diameter, slow motor nerve fibers compared with the large, fast **alpha motor neurons**

²⁷intra = within + fus = spindle

FIGURE 13.20 A Muscle Spindle and Its Innervation.

that innervate the working part of the muscle (the extrafusal fibers). Gamma motor neurons stimulate shortening of the contractile ends of an intrafusal fiber. This stretches the middle part of the fiber and makes the sensory neurons fire, or makes them more likely to fire if the muscle is stretched. Thus, gamma motor neurons adjust the sensitivity of the muscle spindle.

A muscle spindle is a remarkably complex and sophisticated device, with functional subtypes of nuclear bag fibers and gamma motor neurons, but we will not delve into all these details. Fundamentally, a muscle spindle does this: When a muscle is at rest, relaxed, and stretched, the muscle spindle itself is stretched, and both types of sensory nerve fibers transmit a steady stream of

signals to the brain informing it of the length of the muscle. This is called a *steady-state* or *tonic* response (further explained in chapter 16). As a muscle contracts, the spindles shorten along with it. The secondary fiber fires at lower frequency and the primary fiber completely ceases firing; this is called a *dynamic* or *phasic* response. The primary fiber resumes firing, but at a slow rate, when the muscle is fully contracted and stable. Both fiber types inform the brain of muscle length, but the primary fiber also informs it of how fast muscle length is changing. These responses provide information on the speed of body movements and allow the brain to initiate quick corrective reflexes—for example when your body tilts a little bit and you adjust muscle tension to keep your balance.

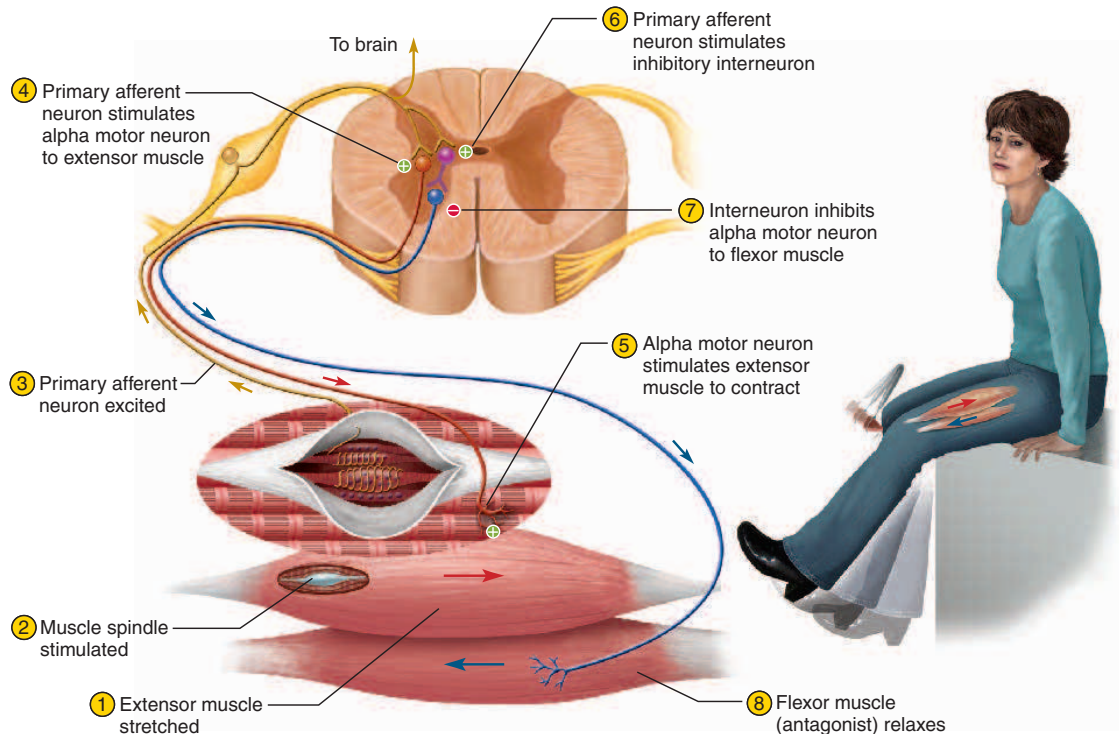

FIGURE 13.21 The Patellar Tendon Reflex Arc and Reciprocal Inhibition of the Antagonistic Muscle. Plus signs indicate excitation of a postsynaptic cell (EPSPs), and minus signs indicate inhibition (IPSPs). The tendon reflex occurs in the quadriceps femoris muscle (large red arrow), while the hamstring muscles exhibit reciprocal inhibition (large blue arrow) so they do not contract and oppose the quadriceps.

Why is no IPSP shown at point 8 if the contraction of this muscle is being inhibited?

The Stretch Reflex

When a muscle is stretched, it “fights back”—it contracts, maintains increased tonus, and feels stiffer than an unstretched muscle. This response, called the **stretch (myotatic)²⁸ reflex**, helps to maintain equilibrium and posture. For example, if your head starts to tip forward, it stretches muscles such as the semispinalis and splenius capitis of the back of your neck. This stimulates their muscle spindles, which send afferent signals to the cerebellum by way of the brainstem. The cerebellum integrates this information and relays it to the cerebral cortex, and the cortex sends signals back, via the brainstem, to the muscles. The muscles contract and raise your head.

Stretch reflexes often feed back not to a single muscle but to a set of synergists and antagonists. Since the contraction of a muscle on one side of a joint stretches the antagonist on the other side, the flexion of a joint creates a stretch reflex in the extensors, and extension creates a stretch reflex in the flexors. Consequently, stretch reflexes are valuable in stabilizing joints by balancing the tension

of the extensors and flexors. They also dampen (smooth out) muscle action. Without stretch reflexes, a person’s movements tend to be jerky. Stretch reflexes are especially important in coordinating vigorous and precise movements such as dance.

A stretch reflex is mediated primarily by the brain and is not, therefore, strictly a spinal reflex, but a weak component of it is spinal and occurs even if the spinal cord is severed from the brain. The spinal component can be more pronounced if a muscle is stretched very suddenly. This occurs in a **tendon reflex**—the reflexive contraction of a muscle when its tendon is tapped, as in the familiar knee-jerk (patellar) reflex. Tapping the patellar ligament with a reflex hammer suddenly stretches the quadriceps femoris muscle of the thigh (fig. 13.21). This stimulates numerous muscle spindles in the quadriceps and sends an intense volley of signals to the spinal cord, mainly by way of primary afferent fibers.

In the spinal cord, the primary afferent fibers synapse directly with the alpha motor neurons that return to the muscle, thus forming **monosynaptic reflex arcs**. That is, there is only one synapse between the afferent and efferent neuron, so there is little synaptic delay and a very prompt

²⁸myo = muscle + tat (from tasis) = stretch

FIGURE 13.22 The Flexor and Crossed Extension Reflexes. A pain stimulus triggers a withdrawal reflex, which results in contraction of flexor muscles of the injured limb. At the same time, a crossed extension reflex results in contraction of extensor muscles of the opposite limb. The latter reflex aids in balance when the injured limb is raised. Note that for each limb, while the agonist contracts, the alpha motor neuron to its antagonist is inhibited, as indicated by the red minus signs in the spinal cord.

❏ Would you expect this reflex arc to show more synaptic delay, or less, than the ones in figure 13.21? Why?

response. The alpha motor neurons excite the quadriceps muscle, making it contract and creating the knee jerk.

There are many other tendon reflexes. A tap on the calcaneal tendon causes plantar flexion of the foot, a tap on the triceps brachii tendon causes extension of the elbow, and a tap on the masseter causes clenching of the jaw. Testing somatic reflexes is valuable in diagnosing many diseases that cause exaggeration, inhibition, or absence of reflexes—for example, neurosyphilis, diabetes mellitus, multiple sclerosis, alcoholism, electrolyte imbalances, and lesions of the nervous system.

Stretch reflexes and other muscle contractions often depend on **reciprocal inhibition**, a reflex phenomenon that prevents muscles from working against each other by inhibiting antagonists. In the knee jerk, for example, the quadriceps femoris would not produce much joint movement if its antagonists, the hamstring muscles, contracted

at the same time. But reciprocal inhibition prevents that from happening. Some branches of the sensory fibers from the muscle spindles in the quadriceps stimulate spinal cord interneurons that, in turn, *inhibit* the alpha motor neurons of the hamstrings (fig. 13.21). The hamstring muscles remain relaxed and allow the quadriceps to extend the knee.

The Flexor (Withdrawal) Reflex

A **flexor reflex** is the quick contraction of flexor muscles resulting in the withdrawal of a limb from an injurious stimulus. For example, suppose you are wading in a lake and step on a broken bottle with your right foot (fig. 13.22). Even before you are consciously aware of the pain, you quickly pull your foot away before the glass penetrates any deeper. This action involves contraction

of the flexors and relaxation of the extensors in that limb; the latter is another case of reciprocal inhibition.

The protective function of this reflex requires more than a quick jerk like a tendon reflex, so it involves more complex neural pathways. Sustained contraction of the flexors is produced by a parallel after-discharge circuit in the spinal cord (see fig. 12.30, p. 472). This circuit is part of a **polysynaptic reflex arc**—a pathway in which signals travel over many synapses on their way back to the muscle. Some signals follow routes with only a few synapses and return to the flexor muscles quickly. Others follow routes with more synapses, and therefore more delay, so they reach the flexor muscles a little later. Consequently, the flexor muscles receive prolonged output from the spinal cord and not just one sudden stimulus as in a stretch reflex. By the time these efferent signals begin to die out, you will probably be consciously aware of the pain and begin taking voluntary action to prevent further harm.

The Crossed Extension Reflex

In the preceding situation, if *all* you did was to quickly lift the injured leg from the lake bottom, you would fall over. To prevent this and maintain your balance, other reflexes shift your center of gravity over the leg that is still on the ground. The **crossed extension reflex** is the contraction of extensor muscles in the limb opposite from the one that is withdrawn (fig. 13.22). It extends that limb and enables you to keep your balance. To produce this reflex, branches of the afferent nerve fibers cross from the stimulated side of the body to the contralateral side of the spinal cord. There, they synapse with interneurons, which, in turn, excite or inhibit alpha motor neurons to the muscles of the contralateral limb.

In the ipsilateral leg (the side that was hurt), you would contract your flexors and relax your extensors to lift the leg from the ground. On the contralateral side, you would relax your flexors and contract the extensors to stiffen that leg, since it must suddenly support your entire body. At the same time, signals travel up the spinal cord and cause contraction of contralateral muscles of the hip and abdomen to shift your center of gravity over the extended leg. To a large extent, the coordination of all these muscles and maintenance of equilibrium is mediated by the cerebellum and cerebral cortex.

The flexor reflex employs an **ipsilateral reflex arc**—one in which the sensory input and motor output are on the same sides of the spinal cord. The crossed extension reflex employs a **contralateral reflex arc**, in which the input and output are on opposite sides. An **intersegmental reflex arc** is one in which the input and output occur at different levels (segments) of the spinal cord—for example, when pain to the foot causes contractions of abdominal and hip muscles higher up the body. Note that all of these reflex arcs can function simultaneously to produce a coordinated protective response to pain.

FIGURE 13.23 A Tendon Organ.

The Tendon Reflex

Tendon organs are proprioceptors located in a tendon near its junction with a muscle (fig. 13.23). A tendon organ is about 1 mm long and consists of a tangle of knobby nerve endings entwined in the collagen fibers of the tendon. As long as the tendon is slack, its collagen fibers are slightly spread and they put little pressure on the nerve endings woven among them. When muscle contraction pulls on the tendon, the collagen fibers come together like the two sides of a stretched rubber band and squeeze the nerve endings between them. The nerve fiber sends signals to the spinal cord that provide the CNS with feedback on the degree of muscle tension at the joint.

The **tendon reflex** is a response to excessive tension on the tendon. It inhibits alpha motor neurons to the muscle so the muscle does not contract as strongly. This serves to moderate muscle contraction before it tears a tendon or pulls it loose from the muscle or bone. Nevertheless, strong muscles and quick movements sometimes damage a tendon before the reflex can occur, causing such athletic injuries as a ruptured calcaneal tendon.

The tendon reflex also functions when some parts of a muscle contract more than others. It inhibits the fibers connected with overstimulated tendon organs so that their contraction is more comparable to the contraction of the rest of the muscle. This reflex spreads the workload more evenly over the entire muscle, which is beneficial in such actions as maintaining a steady grip on a tool.

Table 13.7 and Insight 13.5 describe some injuries and other disorders of the spinal cord and spinal nerves.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

9. Name five structural components of a typical somatic reflex arc. Which of these is absent from a monosynaptic arc?
10. State the function of each of the following in a muscle spindle: *intrafusal fiber*, *anulospiral ending*, and *gamma motor neuron*.
11. Explain how nerve fibers in a tendon sense the degree of tension in a muscle.
12. Why must the withdrawal reflex, but not the stretch reflex, involve a polysynaptic reflex arc?
13. Explain why the crossed extension reflex must accompany a withdrawal reflex of the leg.

TABLE 13.7

Some Disorders of the Spinal Cord and Spinal Nerves

Guillain-Barré syndrome	An acute demyelinating nerve disorder often triggered by viral infection, resulting in muscle weakness, elevated heart rate, unstable blood pressure, shortness of breath, and sometimes death from respiratory paralysis	
Neuralgia	General term for nerve pain, often caused by pressure on spinal nerves from herniated intervertebral discs or other causes	
Paresthesia	Abnormal sensations of prickling, burning, numbness, or tingling; a symptom of nerve trauma or other peripheral nerve disorders	
Peripheral neuropathy	Any loss of sensory or motor function due to nerve injury; also called <i>nerve palsy</i>	
Rabies (hydrophobia)	A disease usually contracted from animal bites, involving viral infection that spreads via somatic motor nerve fibers to the CNS and then autonomic nerve fibers; leads to seizures, coma, and death; invariably fatal if not treated before CNS symptoms appear	
Spinal meningitis	Inflammation of the spinal meninges due to viral, bacterial, or other infection	
Disorders described elsewhere		
Amyotrophic lateral sclerosis p. 491	Leprosy p. 592	Sciatica p. 500
Carpal tunnel syndrome p. 363	Multiple sclerosis p. 450	Shingles p. 497
Crutch paralysis p. 500	Poliomyelitis p. 491	Spina bifida p. 485
Diabetic neuropathy pp. 592, 675	Paraplegia p. 510	Spinal cord trauma p. 510
Hemiplegia p. 510	Quadriplegia p. 510	

INSIGHT 13.5 Clinical Application

Spinal Cord Trauma

In the United States, 10,000 to 12,000 people become paralyzed annually by spinal cord trauma, usually as a result of vertebral fractures. The group at greatest risk is males from 16 to 30 years old, because of their high-risk behaviors. Fifty-five percent of their injuries are from automobile and motorcycle accidents, 18% from sports, and 15% from gunshot and stab wounds. Elderly people are also at above-average risk because of falls, and in times of war, battlefield injuries account for many cases.

Effects of Injury

Complete *transection* (severance) of the spinal cord causes immediate loss of motor control at and below the level of the injury. Transection superior to segment C4 presents a threat of respiratory failure. Victims also lose all sensation from the level of injury and below, although some patients temporarily feel burning pain within one or two dermatomes of the level of the lesion.

In the early stage, victims exhibit a syndrome (a suite of signs and symptoms) called *spinal shock*. The muscles below the level of injury exhibit flaccid paralysis (inability to contract) and an absence of reflexes because of the lack of stimulation from higher levels of the CNS. For 8 days to 8 weeks after the accident, the patient typically lacks bladder and bowel reflexes and thus retains urine and feces. Lacking sympathetic stimulation to the blood vessels, a patient may exhibit *neurogenic shock* in which the vessels dilate and blood pressure drops dangerously low. Fever may occur because the hypothalamus cannot induce sweating to cool the body. Spinal shock can last from a few days to several weeks (usually 7 to 20 days).

As spinal shock subsides, somatic reflexes begin to reappear, at first in the toes and progressing to the feet and legs. Autonomic reflexes also reappear. Contrary to the earlier urinary and fecal retention, a patient now has the opposite problem, incontinence, as the rectum and bladder empty reflexively in response to stretch. Both the somatic and autonomic nervous systems typically exhibit exaggerated reflexes, a state called *hyperreflexia* or the *mass reflex reaction*. Stimuli such as a full bladder or cutaneous touch can trigger an extreme cardiovascular reaction. The systolic blood pressure, normally about 120 mm Hg, jumps to as high as 300 mm Hg. This causes intense headaches and sometimes a stroke. Pressure receptors in the major arteries sense this rise in blood pressure and activate a reflex that slows the heart, sometimes to a rate as low as 30 or 40 beats/minute (*bradycardia*), compared with a normal rate of 70 to 80. The patient may also experience profuse sweating and blurred vision.

Men at first lose the capacity for erection and ejaculation. They may recover these functions later and become capable of ejaculating and fathering children, but without sexual sensation. In females, menstruation may become irregular or cease.

The most serious permanent effect of spinal cord trauma is paralysis. The flaccid paralysis of spinal shock later changes to spastic paralysis as spinal reflexes are regained, but lack inhibitory control from the brain. Spastic paralysis typically starts with chronic flexion of the hips and knees (flexor spasms) and progresses to a state in which the limbs become straight and rigid (extensor spasms). Three forms of muscle paralysis are *paraplegia*, a paralysis of both lower limbs resulting from spinal cord lesions at levels T1 to L1; *quadriplegia*, the paralysis of all four limbs resulting from lesions

above level C5; and *hemiplegia*, paralysis of one side of the body, usually resulting not from spinal cord injuries but from a stroke or other brain lesion. Spinal cord lesions from C5 to C7 can produce a state of partial quadriplegia—total paralysis of the lower limbs and partial paralysis (*paresis*, or weakness) of the upper limbs.

Pathogenesis

Spinal cord trauma produces two stages of tissue destruction. The first is instantaneous—the destruction of cells by the traumatic event itself. The second wave of destruction, involving tissue death by necrosis and apoptosis, begins in minutes and lasts for days. It is far more destructive than the initial injury, typically converting a lesion in one spinal cord segment to a lesion that spans four or five segments, two above and two below the original site.

Microscopic hemorrhages appear in the gray matter and pia mater within minutes and grow larger over the next 2 hours. The white matter becomes edematous (swollen). This hemorrhaging and edema spread to adjacent segments of the cord and can fatally affect respiration or brainstem function when it occurs in the cervical region. *Ischemia* (iss-KEE-me-uh), the lack of blood, quickly leads to tissue necrosis. The white matter regains circulation in about 24 hours, but the gray matter remains ischemic. Inflammatory cells (leukocytes and macrophages) infiltrate the lesion as the circulation recovers, and while they clean up necrotic tissue, they also contribute to the damage by releasing destructive free radicals and other toxic chemicals. The necrosis worsens, and is accompanied by another form of cell death, apoptosis (see chapter 5). Apoptosis of the spinal oligodendrocytes, the myelinating glial cells of the CNS, results in demyelination of spinal nerve fibers, followed by death of the neurons.

In as little as 4 hours, this second wave of destruction, called *posttraumatic infarction*, consumes about 40% of the cross-sectional area of the spinal cord; within 24 hours, it destroys 70%. As many as five segments of the cord become transformed into a fluid-filled cavity, which is replaced with collagenous scar tissue over the next 3 to 4 weeks. This scar is one of the obstacles to the regeneration of lost nerve fibers.

Treatment

The first priority in treating a spinal injury patient is to immobilize the spine to prevent further injury to the cord. Respiratory or other life support may also be required. Methylprednisolone, a steroid, dramatically improves recovery. Given within 3 hours of the trauma, it reduces injury to cell membranes and inhibits inflammation and apoptosis.

After these immediate requirements are met, reduction (repair) of the fracture is important. If a CT or MRI scan indicates spinal cord compression by the vertebral canal, a *decompression laminectomy* may be performed, in which the vertebral arch is removed from the affected region. CT and MRI have helped a great deal in recent decades for assessing vertebral and spinal cord damage, guiding surgical treatment, and improving recovery. Physical therapy is important for maintaining muscle and joint function as well as promoting the patient's psychological recovery.

Treatment strategies for spinal cord injuries are a lively area of medical research today. Some current interests are the use of antioxidants to reduce free radical damage, and the implantation of embryonic stem cells, which has produced significant (but not perfect) recovery from spinal cord lesions in rats. Public hopes have often been raised by promising studies reported in the scientific literature and news media, only to be dashed by the inability of other laboratories to repeat and confirm the results.

CHAPTER REVIEW

Review of Key Concepts

13.1 The Spinal Cord (p. 482)

1. The spinal cord conducts signals up and down the body, contains *central pattern generators* that control locomotion, and mediates many reflexes.
2. The spinal cord occupies the vertebral canal from vertebrae C1 to L1. A bundle of nerve roots called the *cauda equina* occupies the vertebral canal from L2 to S5.
3. The cord is divided into cervical, thoracic, lumbar, and sacral regions, named for the levels of the vertebral column through which the spinal nerves emerge. The portion served by each spinal nerve is called a *segment* of the cord.
4. *Cervical* and *lumbar enlargements* are wide points in the cord marking the emergence of nerves that control the limbs.
5. The spinal cord is enclosed in three fibrous *meninges*. From superficial to deep, these are the *dura mater*, *arachnoid mater*, and *pia mater*. An *epidural space* exists between the dura mater and vertebral bone, and a *subarachnoid space* between the arachnoid and pia mater.
6. The pia mater issues periodic *denticulate ligaments* that anchor it to the dura, and continues inferiorly, with the dura, as a *coccygeal ligament* that anchors the cord to vertebra Co1.
7. In cross section, the spinal cord exhibits a central H-shaped core of *gray matter* surrounded by *white matter*. The gray matter contains the neurosomas, dendrites, and synapses, and the white matter consists of nerve fibers (axons).
8. The *posterior horn* of the gray matter receives afferent (sensory) nerve fibers from the posterior root of the spinal nerve. The *anterior horn* contains the somas that give rise to the efferent (motor) nerve fibers of the anterior root of the nerve. A *lateral horn* in the thoracic and lumbar regions contains somas of the sympathetic neurons.

9. The white matter is divided into *posterior*, *lateral*, and *anterior columns* on each side of the cord. Each column consists of multiple *tracts*, or bundles of nerve fibers. The nerve fibers in a given tract are similar in origin, destination, and function.
10. *Ascending tracts* carry sensory information up the cord to the brain. Their names and functions are listed in table 13.1.
11. From receptor to cerebral cortex, sensory signals typically travel through three neurons (*first-* through *third-order*) and cross over (*decussate*) from one side of the body to the other in the spinal cord or brainstem. Thus, the right cerebral cortex receives sensory input from the left side of the body (from the neck down) and vice versa.
12. *Descending tracts* carry motor commands from the brain downward. Their names and functions are also listed in table 13.1.
13. Motor signals typically begin in an *upper motor neuron* in the cerebral cortex and travel to a *lower motor neuron* in the brainstem or spinal cord. The latter neuron's axon leaves the CNS in a cranial or spinal nerve leading to a muscle.

13.2 The Spinal Nerves (p. 490)

1. A nerve is a cordlike organ composed of nerve fibers (axons) and connective tissue.
2. Each nerve fiber is enclosed in its own fibrous sleeve called an *endoneurium*. Nerve fibers are bundled in groups called *fascicles* separated from each other by a *perineurium*. A fibrous *epineurium* covers the entire nerve.
3. Nerve fibers are classified as *afferent* or *efferent* depending on the direction of signal conduction; *somatic* or *visceral* depending on the types of organs they innervate; and *special* or *general* depending on the locations of the organs they innervate (table 13.2).

4. A *sensory nerve* is composed of afferent fibers only, a *motor nerve* of efferent fibers only, and a *mixed nerve* is composed of both. Most nerves are mixed.
5. A *ganglion* is a swelling along the course of a nerve containing the cell bodies of the peripheral neurons.
6. There are 31 pairs of *spinal nerves*, which enter and leave the spinal cord and emerge mainly through the intervertebral foramina. Within the vertebral canal, each branches into a *posterior root*, which carries sensory signals to the posterior horn of the spinal cord, and an *anterior root*, which receives motor signals from the anterior horn. The posterior root has a swelling, the *posterior root ganglion*, containing the somas of unipolar somatic sensory neurons.
7. Distal to the intervertebral foramen, each spinal nerve branches into an *anterior ramus*, *posterior ramus*, and *meningeal branch*.
8. The anterior ramus gives rise to *intercostal nerves* in the thoracic region and *nerve plexuses* in all other regions. The nerve plexuses are weblike networks adjacent to the vertebral column: the *cervical*, *brachial*, *lumbar*, *sacral*, and *coccygeal plexus*. The nerves arising from each are described in tables 13.3 through 13.6.
9. A *dermatome* is a zone of the skin innervated by the sensory fibers of one spinal nerve.

13.3 Somatic Reflexes (p. 503)

1. A reflex is a quick, involuntary, stereotyped reaction of a gland or muscle to a stimulus.
2. *Somatic (spinal) reflexes* are responses of skeletal muscles. The nerve signals in a somatic reflex travel by way of a *reflex arc* from a receptor via an afferent neuron to the spinal cord or brainstem, usually through interneurons in the CNS, then via an efferent neuron to a skeletal muscle.

3. Many somatic reflexes are initiated by *proprioceptors*, organs that monitor the position and movements of body parts.
4. *Muscle spindles* are proprioceptors embedded in the skeletal muscles that respond to stretching of the muscle. They are composed of modified *intrafusal muscle fibers*, *primary* and *secondary afferent nerve fibers*, and *gamma motor neurons*, all enclosed in a fibrous sheath.
5. The *stretch reflex* is the tendency of a muscle to contract when it is stretched, as in the patellar tendon (knee-jerk) reflex. Stretch reflexes smooth joint actions and maintain equilibrium and posture. Many stretch reflexes travel via *monosynaptic* pathways so there is minimal synaptic delay and a very quick response.
6. A stretch reflex is often accompanied by *reciprocal inhibition*, a reflex that prevents an antagonistic muscle from contracting and interfering with the stretch reflex.
7. The *flexor reflex* is the withdrawal of a limb from an injurious stimulus, as in pulling back from a sharp object. It employs a polysynaptic reflex arc that produces a sustained response in the muscle.
8. The *crossed extension reflex* is contraction of the extensors on one side of the body when the flexors are contracted on the other side. It shifts the body weight so that one does not fall over.
9. The *tendon reflex* is the inhibition of a muscle contraction that occurs when its tendon is excessively stretched. Stretching stimulates a receptor in the tendon called a *tendon organ*. The reflex prevents tendon injuries and helps to distribute workload across a muscle.

Testing Your Recall

1. Below L2, the vertebral canal is occupied by a bundle of spinal nerve roots called
 - a. the terminal filum.
 - b. the descending tracts.
 - c. the gracile fasciculus.
 - d. the medullary cone.
 - e. the cauda equina.
2. The brachial plexus gives rise to all of the following nerves *except*
 - a. the axillary nerve.
 - b. the radial nerve.
 - c. the obturator nerve.
 - d. the median nerve.
 - e. the ulnar nerve.
3. Nerve fibers that adjust the tension in a muscle spindle are called
 - a. intrafusal fibers.
 - b. extrafusal fibers.
 - c. alpha motor neurons.
 - d. gamma motor neurons.
 - e. anulospiral fibers.
4. A stretch reflex requires the action of _____ to prevent an antagonistic muscle from interfering with the agonist.
 - a. gamma motor neurons
 - b. a withdrawal reflex
 - c. a crossed extension reflex
 - d. reciprocal inhibition
 - e. a contralateral reflex
5. A patient has a gunshot wound that caused a bone fragment to nick the spinal cord. The patient now feels no pain or temperature sensations from that level of the body down. Most likely, the _____ was damaged.
 - a. gracile fasciculus
 - b. medial lemniscus
 - c. tectospinal tract
 - d. lateral corticospinal tract
 - e. spinothalamic tract
6. Which of these is *not* a region of the spinal cord?
 - a. cervical
 - b. thoracic
 - c. pelvic
 - d. lumbar
 - e. sacral
7. In the spinal cord, the somas of the lower motor neurons are found in
 - a. the cauda equina.
 - b. the posterior horns.
 - c. the anterior horns.
 - d. the posterior root ganglia.
 - e. the fasciculi.
8. The outermost connective tissue wrapping of a nerve is called the
 - a. epineurium.
 - b. perineurium.
 - c. endoneurium.
 - d. arachnoid mater.
 - e. dura mater.
9. The intercostal nerves between the ribs arise from which spinal nerve plexus?
 - a. cervical
 - b. brachial
 - c. lumbar
 - d. sacral
 - e. none of them
10. All somatic reflexes share all of the following properties *except*
 - a. they are quick.
 - b. they are monosynaptic.
 - c. they require stimulation.
 - d. they are involuntary.
 - e. they are stereotyped.
11. Outside the CNS, the somas of neurons are clustered in swellings called _____.
12. Distal to the intervertebral foramen, a spinal nerve branches into an anterior and posterior _____.
13. The cerebellum receives feedback from the muscles and joints by way of the _____ tracts of the spinal cord.
14. In the _____ reflex, contraction of flexor muscles in one limb is accompanied by the contraction of extensor muscles in the contralateral limb.
15. Modified muscle fibers serving primarily to detect stretch are called _____.
16. The _____ nerves arise from the cervical plexus and innervate the diaphragm.
17. The crossing of a nerve fiber or tract from the right side of the CNS to the left, or vice versa, is called _____.
18. The nonvisual awareness of the body's position and movements is called _____.
19. The _____ ganglion contains the somas of neurons that carry sensory signals to the spinal cord.
20. The sciatic nerve is a composite of two nerves, the _____ and _____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

1. The gracile fasciculus is a descending spinal tract.
2. At the inferior end, the adult spinal cord ends before the vertebral column does.
3. Each spinal cord segment has only one pair of spinal nerves.
4. Some spinal nerves are sensory and others are motor.
5. The dura mater adheres tightly to the bone of the vertebral canal.
6. The anterior and posterior horns of the spinal cord are composed of gray matter.
7. The corticospinal tracts carry motor signals down the spinal cord.
8. The dermatomes are nonoverlapping regions of skin innervated by different spinal nerves.
9. Somatic reflexes are those that do not involve the brain.
10. The tendon reflex acts to inhibit muscle contraction.

Answers in appendix B

Testing Your Comprehension

1. Jillian is thrown from a horse. She strikes the ground with her chin, causing severe hyperextension of the neck. Emergency medical technicians properly immobilize her neck and transport her to a hospital, but she dies 5 minutes after arrival. An autopsy shows multiple fractures of vertebrae C1, C6, and C7 and extensive damage to the spinal cord. Explain why she died rather than being left quadriplegic.
2. Wallace is the victim of a hunting accident. A bullet grazed his vertebral column and bone fragments severed the left half of his spinal cord at segments T8 through T10. Since the accident, Wallace has had a condition called *dissociated sensory loss*, in which he feels no sensations of deep touch or limb position on the *left* side of his body below the injury, and no sensations of pain or heat from the *right* side. Explain what spinal tract(s) the injury has affected and why these sensory losses are on opposite sides of the body.
3. Anthony gets into a fight between rival gangs. As an attacker comes at him with a knife, he turns to flee, but stumbles. The attacker stabs him on the medial side of the right gluteal fold and Anthony collapses. He loses all use of his right limb, being unable to extend his hip, flex his knee, or move his foot. He never fully recovers these lost functions. Explain what nerve injury Anthony has most likely suffered.
4. Stand with your right shoulder, hip, and foot firmly against a wall. Raise your left foot from the floor without losing contact with the wall at any point. What happens? Why? What principle of this chapter does this demonstrate?
5. When a patient needs a tendon graft, surgeons sometimes use the tendon of the palmaris longus, a relatively dispensable muscle of the forearm. The median nerve lies nearby and looks very similar to this tendon. There have been cases in which a surgeon mistakenly removed a section of this nerve instead of the tendon. What effects do you think such a mistake would have on the patient?

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Anatomy of the cranium (pp. 249–255)
- Glial cells and their functions (pp. 448–449)
- Tracts of the spinal cord (pp. 486–490)
- Structure of nerves and ganglia (pp. 491–493)

The human brain has a high opinion of itself, sometimes claiming to be the most complex object in the known universe. It would be hard to argue otherwise. It has a mystique that continues to intrigue modern biologists and psychologists even as it did the philosophers of antiquity. Aristotle thought it was just a radiator for cooling the blood, but generations earlier, Hippocrates had expressed a more accurate view. “Men ought to know,” he said, “that from the brain, and from the brain only, arise our pleasures, joy, laughter and jests, as well as our sorrows, pains, griefs and tears. Through it, in particular, we think, see, hear, and distinguish the ugly from the beautiful, the bad from the good, the pleasant from the unpleasant.”

Brain function is so strongly associated with what it means to be alive and human that the cessation of brain activity is taken as a clinical criterion of death even when other organs of the body are still functioning. With its hundreds of neural pools and trillions of synapses, the brain performs sophisticated tasks beyond our present understanding. Still, all of our mental functions, no matter how complex, are ultimately based on the cellular activities described in chapter 12. The relationship of the mind or personality to the cellular function of the brain is a question that will provide fertile ground for scientific study and philosophical debate long into the future.

This chapter is a study of the brain and the cranial nerves directly connected to it. Here we will plumb some of the mysteries of motor control, sensation, emotion, thought, language, personality, memory, dreams, and plans. Brain circuitry and function easily fill many books the size of this one, and we can barely scratch the surface of this complex subject here. This coverage will, however, provide some intriguing insights and lay a basic foundation for further study in other courses.

In the evolution of the central nervous system from the simplest vertebrate animals to humans, the spinal cord has changed very little while the brain has changed a great deal. In fishes and amphibians, the brain weighs about the same as the spinal cord, but in humans, it weighs 55 times as much. It averages about 1,600 g (3.5 lb) in men and 1,450 g in women. The difference between the sexes is proportional to body size, not intelligence. The Neanderthal people had larger brains than modern humans do.

Ours is the most sophisticated brain when compared to others in awareness of the environment, adaptability to environmental variation and change, quick execution of complex decisions, fine motor control and mobility of the body, and behavioral complexity. Over the course of human evolution, it has shown its greatest growth in areas concerned with vision, memory, and motor control of the prehensile hand.

Major Landmarks

We begin with a general overview of the major landmarks of the brain. These will provide important reference points as we progress through a more detailed study.

Two directional terms often used in descriptions of CNS anatomy are *rostral* and *caudal*. **Rostral**¹ means “toward the nose” and **caudal**² means “toward the tail.” These are apt descriptions for an animal such as a laboratory rat, on which so much brain research has been done. The terms are retained for human neuroanatomy as well, but in references to the human brain, *rostral* means “toward the forehead” and *caudal* means “toward the spinal cord.” In the spinal cord and brainstem, which are vertically oriented, *rostral* means “higher” and *caudal* means “lower.”

We can conceptually divide the brain into three major portions—the *cerebrum*, *cerebellum*, and *brainstem*. The **cerebrum** (seh-REE-brum or SER-eh-brum) is about 83% of its volume and consists of a pair of half globes called the **cerebral hemispheres** (fig. 14.1a). Each hemisphere is marked by thick folds called **gyri**³ (JY-rye; singular, *gyrus*) separated by shallow grooves called **sulci**⁴ (SUL-sye; singular, *sulcus*). A very deep groove, the **longitudinal fissure**, separates the right and left hemispheres from each other. At the bottom of this fissure, the hemispheres are connected by a thick bundle of nerve fibers called the **corpus callosum**⁵—a prominent landmark for anatomical description (fig. 14.2).

The **cerebellum**⁶ (SER-eh-BEL-um) occupies the posterior cranial fossa inferior to the cerebrum (fig. 14.1b, c). It is also marked by gyri, sulci, and fissures. The cerebellum is the second-largest region of the brain; it constitutes about 10% of its volume but contains over 50% of its neurons.

14.1 Overview of the Brain

Objectives

When you have completed this section, you should be able to

- describe the major subdivisions and anatomical landmarks of the brain;
- describe the locations of the gray and white matter of the brain; and
- describe the embryonic development of the CNS and relate this to adult brain anatomy.

¹*rostr* = nose

²*caud* = tail

³*gy* = turn, twist

⁴*sulc* = furrow, groove

⁵*corpus* = body + *call* = thick

⁶*cereb* = brain + *ellum* = little

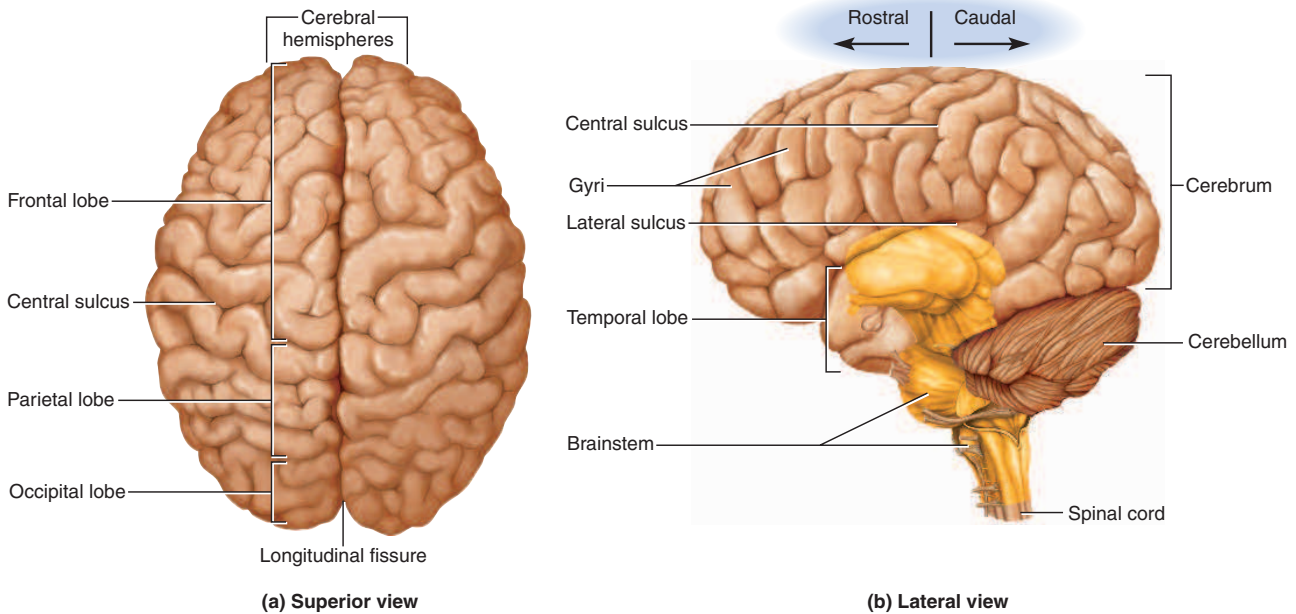

FIGURE 14.1 Surface Anatomy of the Brain. (a) Superior view of the cerebral hemispheres. (b) Left lateral view, with the brainstem in orange. The portion of the brainstem above the cerebellum is represented as showing through the cerebrum to convey its location. (c) The partially dissected brain of a cadaver. Part of the left hemisphere is cut away to expose the insula. The arachnoid mater is removed from the anterior (rostral) half of the brain to expose the gyri and sulci. The arachnoid with its blood vessels is seen in the posterior (caudal) half. Blood vessels of the brainstem are left in place.

FIGURE 14.2 Medial Aspect of the Brain. (a) Major anatomical landmarks of the medial surface. (b) Median section of the cadaver brain.

The **brainstem** is defined differently by various authorities. The original definition, adopted here, is that it is what remains of the brain if the cerebrum and cerebellum are removed. Its major components, from rostral to caudal, are the *diencephalon*, *midbrain*, *pons*, and *medulla oblongata* (fig. 14.2). Many authorities define it as the midbrain, pons, and medulla only, since the diencephalon belongs with the cerebrum in what is called the *forebrain*.

In a living person, the brainstem is oriented like a vertical stalk with the cerebrum perched on top like a mushroom cap. Postmortem changes give it a more oblique angle in the cadaver and, consequently, in many medical illustrations. Caudally, the brainstem ends at the foramen magnum of the skull, and the CNS continues below this as the spinal cord.

Gray and White Matter

The brain, like the spinal cord, is composed of gray and white matter (see figs. 14.5 and 14.6c). White matter has a bright, pearly white color stemming from the myelin around its nerve fibers. Gray matter, with very little myelin, has a duller white color in fresh tissue. Being the seat of the neuron cell bodies, dendrites, and synapses, gray matter forms a surface layer called the **cortex** over the cerebrum and cerebellum, and deeper masses called **nuclei** surrounded by white matter. White matter lies

deep to the cortical gray matter in most of the brain, opposite from the relationship of gray and white matter in the spinal cord. As in the spinal cord, white matter is composed of **tracts**, or bundles of axons, which here connect one part of the brain to another and to the spinal cord. These are described later in more detail.

Embryonic Development

Mature brain anatomy is often described in terms of *forebrain*, *midbrain*, and *hindbrain*—three terms that can be fully appreciated only with some awareness of the embryonic development of the CNS (fig. 14.3).

The nervous system develops from ectoderm, the outermost tissue layer of an embryo. Early in the third week of development, a dorsal streak called the *neuroectoderm* appears along the length of the embryo and thickens to form a **neural plate**. This is destined to give rise to most neurons and all glial cells except microglia, which come from mesoderm. As development progresses, the neural plate sinks and its edges thicken, forming a **neural groove** with a raised **neural fold** along each side. The neural folds then fuse along the midline, somewhat like a closing zipper, beginning in the cervical (neck) region and progressing both rostrally and caudally. By 4 weeks, this process creates a hollow channel called the **neural tube**. Following closure, the neural tube separates from the

FIGURE 14.3 Formation of the Embryonic Neural Tube. The left-hand figure in each case is a dorsal view of the embryo, and the right-hand figure is a three-dimensional representation of the tissues at the indicated level of the respective embryo.

FIGURE 14.4 Primary and Secondary Vesicles of the Embryonic Brain. (a) The primary vesicles at 4 weeks. (b) The secondary vesicles at 5 weeks. (c) The fully developed brain, color-coded to relate its structures to the secondary embryonic vesicles.

overlying ectoderm, sinks a little deeper, and grows lateral processes that later form motor nerve fibers. The lumen of the neural tube becomes a fluid-filled space that later constitutes the *central canal* of the spinal cord and *ventricles* of the brain.

As the neural tube develops, some ectodermal cells that originally lay along the margin of the groove separate from the rest and form a longitudinal column on each side called the **neural crest**. Neural crest cells give rise to the two inner meninges (arachnoid mater and pia mater); most of the peripheral nervous system, including the sensory and autonomic nerves and ganglia and Schwann cells; and some other structures of the skeletal, integumentary, and endocrine systems.

By the fourth week, the neural tube exhibits three anterior dilations, or *primary vesicles*, called the **forebrain** (*prosencephalon*⁷) (PROSS-en-SEF-uh-lon), **midbrain** (*mesencephalon*⁸) (MEZ-en-SEF-uh-lon), and **hindbrain** (*rhombencephalon*⁹) (ROM-ben-SEF-uh-lon) (fig. 14.4). By the fifth week, it subdivides into five *secondary vesicles*. The forebrain divides into two of them, the **telen-cephalon**¹⁰ (TEL-en-SEFF-uh-lon) and **diencephalon**¹¹

⁷pros = before, in front + encephal = brain

⁸mes = middle

⁹rhomb = rhombus

¹⁰tele = end, remote

¹¹di = through, between

(DY-en-SEF-uh-lon); the midbrain remains undivided and retains the name **mesencephalon**; and the hindbrain divides into two vesicles, the **metencephalon**¹² (MET-en-SEF-uh-lon) and **myelencephalon**¹³ (MY-el-en-SEF-uh-lon) (fig. 14.4b). The telencephalon has a pair of lateral outgrowths that later become the cerebral hemispheres, and the diencephalon exhibits a pair of small cuplike *optic vesicles* that become the retinas of the eyes. Figure 14.4 is color-coded to show which mature brain regions develop from each embryonic vesicle.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. List the three major parts of the brain and describe their locations.
2. Define gyrus and sulcus.
3. Contrast the composition and locations of gray and white matter in the brain.
4. Explain how the five secondary brain vesicles arise from the neural tube.

¹²met = behind, beyond, distal to

¹³myel = spinal cord

14.2 Meninges, Ventricles, Cerebrospinal Fluid, and Blood Supply

Objectives

When you have completed this section, you should be able to

- describe the meninges of the brain;
- describe the fluid-filled chambers within the brain;
- discuss the production, circulation, and function of the cerebrospinal fluid that fills these chambers; and
- explain the significance of the brain barrier system.

Meninges

The brain is enveloped in three connective tissue membranes, the meninges, which lie between the nervous tissue and bone. As in the spinal cord, these are the dura mater, arachnoid mater, and pia mater (fig. 14.5). They protect the brain and provide a structural framework for its arteries and veins. In the cranial cavity, the dura mater consists of two layers—an outer *periosteal layer* equivalent to the periosteum of the cranial bones, and an inner

FIGURE 14.5 The Meninges of the Brain. Frontal section of the head.

INSIGHT 14.1 Clinical Application

Meningitis

Meningitis—inflammation of the meninges—is one of the most serious diseases of infancy and childhood. It occurs especially between 3 months and 2 years of age. Meningitis is caused by a variety of bacteria and viruses that invade the CNS by way of the nose and throat, often following respiratory, throat, or ear infections. The pia mater and arachnoid are most often affected, and from here the infection can spread to the adjacent nervous tissue. In bacterial meningitis, the brain swells, the ventricles enlarge, and the brainstem may hemorrhage. Signs include a high fever, stiff neck, drowsiness, and intense headache and may progress to vomiting, loss of sensory and motor functions, and coma. Death can occur within hours of the onset. Infants and toddlers with a high fever should therefore receive immediate medical attention.

Meningitis is diagnosed partly by examining the cerebrospinal fluid (CSF) for bacteria and white blood cells. The CSF is obtained by making a *lumbar puncture (spinal tap)* between two lumbar vertebrae and drawing fluid from the subarachnoid space. This site is chosen because it has an abundance of CSF and there is no risk of injury to the spinal cord, which does not extend into the lower lumbar vertebrae.

meningeal layer. Only the meningeal layer continues into the vertebral canal, where it forms the dural sac around the spinal cord. The cranial dura mater is pressed closely against the cranial bone, with no intervening epidural space like the one around the spinal cord. It is not attached to the bone, however, except in limited places: around the foramen magnum, the sella turcica, the crista galli, and the sutures of the skull.

In some places, the two layers of the dura are separated by **dural sinuses**, spaces that collect blood that has circulated through the brain. Two major, superficial dural sinuses are the **superior sagittal sinus**, found just under the cranium along the median line, and the **transverse sinus**, which runs horizontally from the rear of the head toward each ear. These sinuses meet like an inverted T at the back of the brain and ultimately empty into the internal jugular veins of the neck. These and other sinuses of the brain are more fully described and pictured in chapter 20.

In certain places, the meningeal layer of the dura folds inward to separate major parts of the brain from each other: the *falx*¹⁴ *cerebri* (falks SER-eh-bry) extends into the longitudinal fissure as a tough, crescent-shaped wall between the right and left cerebral hemispheres; the *tentorium*¹⁵ (ten-TOE-ree-um) *cerebelli* stretches like a roof over the posterior cranial fossa and separates the cerebellum from the overlying cerebrum; and the *falx*

cerebelli partially separates the right and left halves of the cerebellum on the inferior side.

The arachnoid mater and pia mater are similar to those of the spinal cord. The arachnoid mater is a transparent membrane over the brain surface, visible in the caudal half of the cerebrum in figure 14.1c. A *subarachnoid space* separates it from the pia below, and in some places, a *subdural space* separates it from the dura above. The pia mater is a very thin, delicate membrane that closely follows all the contours of the brain, even dipping into the sulci. It is not usually visible without a microscope.

Ventricles and Cerebrospinal Fluid

The brain has four internal chambers called **ventricles** (fig. 14.6). The largest and most rostral ones are the **lateral ventricles**, which form an arc in each cerebral hemisphere. Through a tiny pore called the **interventricular foramen**, each lateral ventricle is connected to the **third ventricle**, a narrow median space inferior to the corpus callosum. From here, a canal called the **cerebral aqueduct** passes down the core of the midbrain and leads to the **fourth ventricle**, a small triangular chamber between the pons and cerebellum. Caudally, this space narrows and forms a **central canal** that extends through the medulla oblongata into the spinal cord.

On the floor or wall of each ventricle is a spongy mass of blood capillaries called a **choroid (CO-royd) plexus**, named for its histological resemblance to a fetal membrane called the chorion. Ependyma, a type of neuroglia that resembles a cuboidal epithelium, lines the ventricles and canals and covers the choroid plexuses. It produces cerebrospinal fluid.

Cerebrospinal fluid (CSF) is a clear, colorless liquid that fills the ventricles and canals of the CNS and bathes its external surface. The brain produces about 500 mL of CSF per day, but the fluid is constantly reabsorbed at the same rate and only 100 to 160 mL is normally present at one time (but see Insight 14.2). About 40% of it is formed in the subarachnoid space external to the brain, 30% by the general ependymal lining of the brain ventricles, and 30% by the choroid plexuses. CSF production begins with the filtration of blood plasma through the capillaries of the brain. Ependymal cells modify the filtrate as it passes through them, so the CSF has more sodium and chloride than blood plasma, but less potassium, calcium, and glucose and very little protein.

CSF is not a stationary fluid but continually flows through and around the CNS, driven partly by its own pressure, partly by the beating of ependymal cilia, and partly by rhythmic pulsations of the brain produced by each heartbeat. The CSF secreted in the lateral ventricles flows through the interventricular foramina into the third ventricle (fig. 14.7) and then down the cerebral aqueduct to the fourth ventricle. The third and fourth ventricles and their choroid plexuses add more CSF along the way.

¹⁴*falx* = sickle

¹⁵*tentorium* = tent

A small amount of CSF fills the central canal of the spinal cord, but ultimately, all of it escapes through three pores in the walls of the fourth ventricle—a *median aperture* and two *lateral apertures*. These lead into the subarachnoid

space on the brain and spinal cord surface. From this space, CSF is reabsorbed by **arachnoid villi**, cauliflower-shaped extensions of the arachnoid meninx that protrude through the dura mater into the superior sagittal sinus.

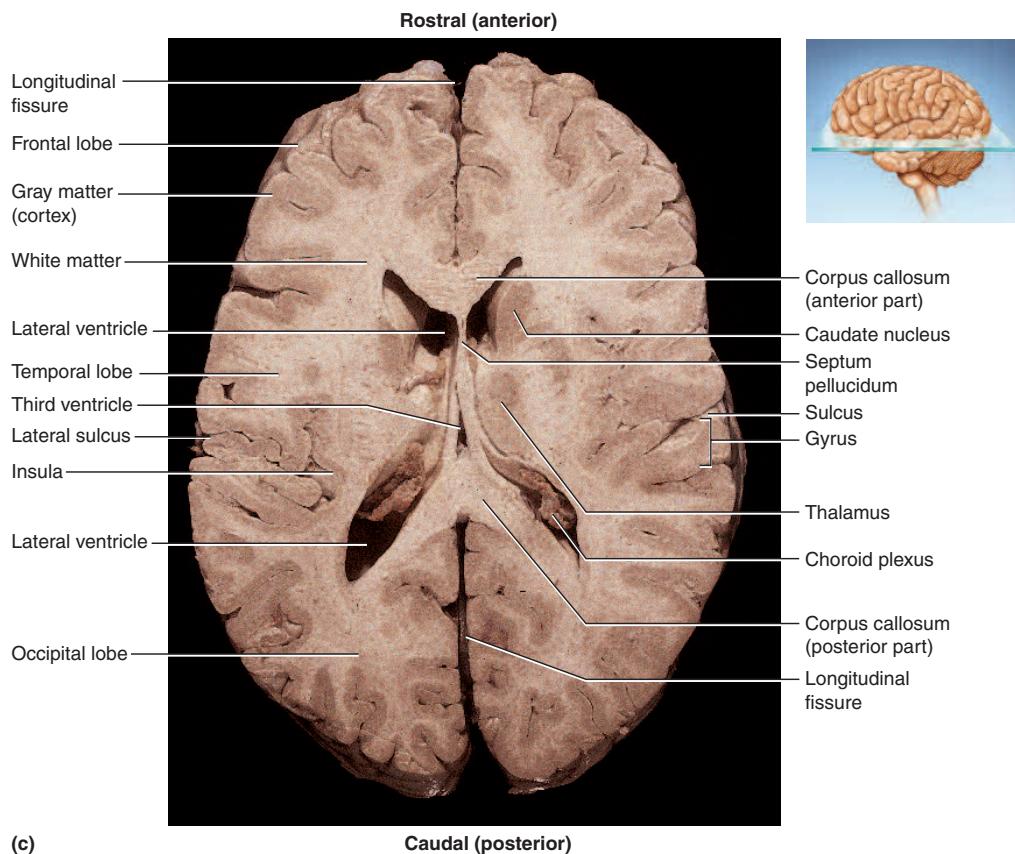

FIGURE 14.6 Ventricles of the Brain. (a) Right lateral aspect. (b) Anterior aspect. (c) Superior view of a horizontal section of the cadaver brain, showing the lateral ventricles and some other features of the cerebrum.

FIGURE 14.7 The Flow of Cerebrospinal Fluid.

Locate the sites of obstruction that cause hydrocephalus.

INSIGHT 14.2 Clinical Application

Hydrocephalus

*Hydrocephalus*¹⁶ is the abnormal accumulation of CSF in the brain, usually resulting from a blockage in its route of flow and reabsorption. Such obstructions occur most commonly in the interventricular foramen, cerebral aqueduct, and apertures of the fourth ventricle. The accumulated CSF expands the ventricles and compresses the nervous tissue, with potentially fatal consequences. In a fetus or infant, it can cause the entire head to enlarge because the cranial bones are not yet fused. Good recovery can be achieved if a tube (shunt) is inserted to drain fluid from the ventricles into a vein of the neck.

CSF penetrates the walls of the villi and mixes with the blood in the sinus.

Cerebrospinal fluid serves three purposes:

- 1. Buoyancy.** Because the brain and CSF are similar in density, the brain neither sinks nor floats in the CSF. It hangs from delicate specialized fibroblasts of the arachnoid meninx. A human brain removed from the body weighs about 1,500 g, but when suspended in CSF its effective weight is only about 50 g. By analogy, consider how much easier it is to lift another person when you are standing in a lake than it is on land. This buoyancy allows the brain to attain considerable size without being impaired by its own weight. If the brain rested heavily on the floor of the cranium, the pressure would kill the nervous tissue.
- 2. Protection.** CSF also protects the brain from striking the cranium when the head is jolted. If the jolt is severe, however, the brain still may strike the inside

¹⁶hydro = water + cephal = head

of the cranium or suffer shearing injury from contact with the angular surfaces of the cranial floor. This is one of the common findings in child abuse (shaken child syndrome) and in head injuries (concussions) from auto accidents, boxing, and the like.

3. **Chemical stability.** The flow of CSF rinses metabolic wastes from the nervous tissue and homeostatically regulates its chemical environment. Slight changes in CSF composition can cause malfunctions of the nervous system. For example, a high glycine concentration disrupts the control of body temperature and blood pressure, and a high pH causes dizziness and fainting.

Blood Supply and the Brain Barrier System

The blood vessels that supply and drain the brain are detailed in chapter 20. Although the brain is only 2% of the adult body weight, it receives 15% of the blood (about 750 mL/min) and consumes 20% of the oxygen and glucose. Because neurons have such a high demand for ATP, and therefore glucose and oxygen, the constancy of blood supply is especially critical to the nervous system. A mere 10-second interruption in blood flow can cause loss of consciousness; an interruption of 1 to 2 minutes can significantly impair neural function; and 4 minutes without blood causes irreversible brain damage.

Despite its critical importance to the brain, the blood is also a source of antibodies, macrophages, bacterial toxins, and other potentially harmful agents. Consequently, there is a **brain barrier system** that strictly regulates what substances can get from the bloodstream into the tissue fluid of the brain.

There are two potential points of entry that must be guarded: the blood capillaries throughout the brain tissue and the capillaries of the choroid plexuses. At the former site, the brain is well protected by the **blood-brain barrier (BBB)**, which consists of tight junctions between the endothelial cells that form the capillary walls. In the developing brain, astrocytes reach out and contact the capillaries with their perivascular feet, inducing the endothelial cells to form tight junctions that completely seal off the gaps between them. This ensures that anything leaving the blood must pass through the cells and not between them. The endothelial cells are more selective than gaps between them would be, and can exclude harmful substances from the brain tissue while allowing necessary ones to pass through. At the choroid plexuses, the brain is protected by a similar **blood-CSF barrier** formed by tight junctions between the ependymal cells. Tight junctions are absent from ependymal cells elsewhere, because it is important to allow exchanges between the brain tissue and CSF. That is, there is no brain-CSF barrier.

The brain barrier system (BBS) is highly permeable to water, glucose, and lipid-soluble substances such as

oxygen, carbon dioxide, alcohol, caffeine, nicotine, and anesthetics. It is slightly permeable to sodium, potassium, chloride, and the waste products urea and creatinine. While the BBS is an important protective device, it is an obstacle to the delivery of medications such as antibiotics and cancer drugs, and thus complicates the treatment of brain diseases.

Trauma and inflammation sometimes damage the BBS and allow pathogens to enter the brain tissue. Furthermore, there are places called **circumventricular organs (CVOs)** in the third and fourth ventricles where the barrier is absent and the blood has direct access to the brain. These enable the brain to monitor and respond to fluctuations in blood glucose, pH, osmolarity, and other variables. Unfortunately, CVOs also afford a route of invasion by the human immunodeficiency virus (HIV).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

5. Name the three meninges from superficial to deep. How does the dura mater of the brain differ from that of the spinal cord?
6. Describe three functions of the cerebrospinal fluid.
7. Where does the CSF originate and what route does it take through and around the CNS?
8. Name the two components of the brain barrier system and explain the importance of this system.

14.3 The Hindbrain and Midbrain

Objectives

When you have completed this section, you should be able to

- list the components of the hindbrain and midbrain and their functions; and
- describe the location and functions of the reticular formation.

The study of the brain in the following pages will be organized around the five secondary vesicles of the embryonic brain and their mature derivatives. We will proceed in a caudal to rostral direction, beginning with the hindbrain and its relatively simple functions and progressing to the forebrain, the seat of such complex functions as thought, memory, and emotion.

The Medulla Oblongata

As noted earlier, the embryonic hindbrain differentiates into two subdivisions: the myelencephalon and metencephalon (see fig. 14.4). The myelencephalon becomes

just one adult structure, the **medulla oblongata** (meh-DULL-uh OB-long-GAH-ta).

The medulla (figs. 14.2 and 14.8) begins at the foramen magnum of the skull and extends for about 3 cm rostrally, ending at a groove between the medulla and pons. It looks superficially like an extension of the spinal cord, but slightly wider. Significant differences are apparent, however, on closer inspection of its gross and microscopic anatomy. Externally, the anterior surface features a pair of ridges called the **pyramids**. Resembling side-by-side baseball bats, these are wider at the rostral end, taper caudally, and are separated by a groove, the *anterior median fissure* continuous with that of the spinal cord. Lateral to each pyramid is a prominent bulge called the **olive**. Posteriorly, the **gracile** and **cuneate fasciculi** of the spinal cord continue as two pairs of ridges on the medulla.

All nerve fibers connecting the brain to the spinal cord pass through the medulla. As we saw in the spinal cord, some of these are ascending (sensory) and some are descending (motor) fibers. The ascending fibers include first-order sensory fibers of the gracile and cuneate fasciculi, which end in the **gracile** and **cuneate nuclei** seen in figure 14.9c, a cross section of the medulla. Here, they synapse with second-order fibers that decussate and form the ribbonlike **medial lemniscus**¹⁷ on each side. The second-order fibers rise to the thalamus, synapsing there with third-order fibers that complete the path to the cerebral cortex (compare fig. 13.5a, p. 488). In the cross section near the cuneate nucleus, we also see a continuation of the spinal **posterior spinocerebellar tract**, which carries sensory signals to the cerebellum.

The largest group of descending fibers is the pair of **corticospinal tracts** filling the pyramids on the anterior surface. These carry motor signals from the cerebral cortex on the way to the spinal cord, ultimately to stimulate the skeletal muscles. Any time you think of and carry out a body movement below the neck, the signals en route to your muscles pass through here. About 90% of these fibers cross over at the *pyramidal decussation*, an externally visible point near the caudal end of the pyramids (fig. 14.8a). As a result, muscles below the neck are controlled by the contralateral side of the brain. A smaller bundle of descending fibers, the **tectospinal tract**, originates in the midbrain, passes through the medulla, and controls muscles of the neck.

The medulla contains neural networks involved in a multitude of fundamental sensory and motor functions. The former include the senses of touch, pressure, temperature, taste, and pain; the latter include chewing, salivation, swallowing, gagging, vomiting, respiration, speech, coughing, sneezing, sweating, cardiovascular and gastrointestinal control, and head, neck, and shoulder movements. Signals for these functions enter and leave the medulla not only by way of the spinal cord, but also by

four pairs of cranial nerves that begin or end here: the glossopharyngeal (cranial nerve IX), vagus (X), accessory (XI), and hypoglossal (XII) nerves. At the level of the section in figure 14.9c, we see the origins of two of them, the vagus and hypoglossal. (The trigeminal nerve, V, belongs to the pons but has parts that extend into the medulla and show in this cross section as well.) Functions of the individual nerves are detailed in table 14.1 (pp. 551–558).

Two other prominent features in the cross section are the inferior olivary nucleus and the reticular formation. The wavy **inferior olivary nucleus** is a major relay center for signals going from many levels of the brain and spinal cord to the cerebellum. The *reticular formation*, detailed later, is a loose network of nuclei extending throughout the medulla, pons, and midbrain. In the medulla, it includes a **cardiac center**, which regulates the rate and force of the heartbeat; a **vasomotor center**, which regulates blood pressure and flow by dilating and constricting blood vessels; two **respiratory centers**, which regulate the rhythm and depth of breathing; and other nuclei involved in the aforementioned motor functions.

The Pons

The metencephalon develops into two structures, the pons and cerebellum. We will return to the cerebellum after finishing the brainstem. The **pons**¹⁸ measures about 2.5 cm long. Most of it appears as a broad anterior bulge rostral to the medulla (figs. 14.2 and 14.8). Posteriorly, it consists mainly of two pairs of thick stalks called *cerebellar peduncles*, the cut edges in the upper half of figure 14.9b. They connect the cerebellum to the pons and midbrain (fig. 14.8b) and will be further described with the cerebellum.

In cross section, the pons exhibits continuations of the previously mentioned reticular formation, medial lemniscus, and tectospinal tract. We also see extensions of the spinal cord's **anterolateral system** and **anterior spinocerebellar tract** (see p. 487). The anterior half of the pons (lower half of fig. 14.9b) is dominated by tracts of white matter, including transverse fascicles that cross between left and right and connect the two hemispheres of the cerebellum, and longitudinal fascicles that carry sensory and motor signals up and down the brainstem.

Cranial nerves V to VIII begin or end in the pons, although we see only the trigeminal nerve (V) at the level of figure 14.9b. The other three emerge from the groove between the pons and medulla. The functions of these four nerves, detailed in table 14.1, include sensory roles in hearing, equilibrium, and taste, and in facial sensations such as touch and pain; as well as motor roles in eye movement, facial expressions, chewing, swallowing, urination, and the secretion of saliva and tears. The reticular formation in the pons contains additional nuclei concerned with sleep, respiration, and posture.

¹⁷lemn = ribbon + iscus = little

¹⁸pons = bridge

FIGURE 14.8 The Brainstem. (a) Anterior view. (b) Posterolateral view. Color-coded to match the embryonic origins in figure 14.4. The boundary between the middle and inferior cerebellar peduncles is indistinct. Authorities vary as to whether to include the diencephalon in the brainstem.

FIGURE 14.9 Cross Sections of the Brainstem. The level of each section is shown in the figure on the right. (a) The midbrain, cut obliquely to pass through the superior colliculi. (b) The pons. The straight edges indicate cut edges of the peduncles where the cerebellum was removed. (c) The medulla oblongata.

Trace the route taken through all three of these figures by fibers from the gracile and cuneate fasciculi described in chapter 13.

The Midbrain

The mesencephalon becomes just one mature brain structure, the **midbrain**—a short segment of brainstem that connects the hindbrain and forebrain (figs. 14.2 and 14.8). It contains the cerebral aqueduct, continuations of the medial lemniscus and reticular formation, and the motor nuclei for two cranial nerves that control eye movements: cranial nerve III (oculomotor) and IV (trochlear). Only the first of these is seen at the level of the cross section in figure 14.9a. (The *medial geniculate nucleus* seen in this figure is not part of the midbrain, but a part of the thalamus that happens to lie in the plane of this section.)

The part of the midbrain posterior to the cerebral aqueduct is a rooflike **tectum**.¹⁹ It exhibits four bulges, the **corpora quadrigemina**.²⁰ The upper pair, called the **superior colliculi**²¹ (col-LIC-you-lye), functions in visual attention, visually tracking moving objects, and such reflexes as blinking, focusing, pupillary dilation and constriction, and turning the eyes and head in response to a visual stimulus (for example, to look at something that you catch sight of in your peripheral vision). The lower pair, called the **inferior colliculi**, receives signals from the inner ear and relays them to other parts of the brain, especially the thalamus. Among other functions, they mediate the reflexive turning of the head in response to a sound, and one's tendency to jump when startled by a sudden noise.

Anterior to the cerebral aqueduct, the midbrain consists mainly of the **cerebral peduncles**—two stalks that anchor the cerebrum to the brainstem. Each peduncle has three main components: tegmentum, substantia nigra, and cerebral crus. The **tegmentum**²² is dominated by the **red nucleus**, named for a pink color imparted by its high density of blood vessels. Fibers from the red nucleus form the *rubrospinal tract* in most mammals, but in humans its connections go mainly to and from the cerebellum, with which it collaborates in fine motor control. The **substantia nigra**²³ (sub-STAN-she-uh NY-gruh) is a dark gray to black nucleus pigmented with melanin. It is a motor center that relays inhibitory signals to the thalamus and basal nuclei (both of which are discussed later), preventing unwanted body movement. Degeneration of the neurons in the substantia nigra leads to the muscle tremors of Parkinson disease (see Insight 12.4, p. 474). The **cerebral crus** (pronounced “cruss”; plural *crura*) is a bundle of nerve fibers that connect the cerebrum to the pons and carry the corticospinal nerve tracts.

Surrounding the cerebral aqueduct is an arrowhead-shaped body called the **central (periaqueductal) gray matter**. It is involved with the *reticulospinal tracts* in controlling awareness of pain, as further described in chapter 16.

Think About It

Why are the inferior colliculi shown in figure 14.8b but not in figure 14.9a? How are these two figures related?

The Reticular Formation

The **reticular**²⁴ **formation** is a loosely organized web of gray matter that runs vertically through all levels of the brainstem, appearing at all three levels of figure 14.9. It occupies much of the space between the white fiber tracts and the more anatomically distinct brainstem nuclei, and has connections with many areas of the cerebrum (fig. 14.10). It consists of more than 100 small neural networks without

²⁴ret = network + icul = little

FIGURE 14.10 The Reticular Formation. The formation consists of over 100 nuclei scattered throughout the brainstem. Red arrows indicate routes of input to the reticular formation; blue arrows indicate the radiating relay of signals from the thalamus to the cerebral cortex; and green arrows indicate output from the reticular formation to the spinal cord.

❶ Locate components of the reticular formation in all three parts of figure 14.9.

well-defined boundaries. The functions of these networks include the following:

- **Somatic motor control.** Some motor neurons of the cerebral cortex send their axons to reticular formation nuclei, which then give rise to the *reticulospinal tracts* of the spinal cord. These tracts adjust muscle tension to maintain tone, balance, and posture, especially during body movements. The reticular formation also relays signals from the eyes and ears to the cerebellum so the cerebellum can integrate visual, auditory, and vestibular (balance and motion) stimuli into its role in motor coordination. Other motor nuclei include *gaze centers*, which enable the eyes to track and fixate objects, and *central pattern generators*—neural pools that produce rhythmic signals to the muscles of breathing and swallowing.
- **Cardiovascular control.** The reticular formation includes the cardiac and vasomotor centers of the medulla oblongata.
- **Pain modulation.** The reticular formation is one route by which pain signals from the lower body reach the cerebral cortex. It is also the origin of the *descending analgesic pathways* mentioned in the description of the reticulospinal tracts on page 489. The nerve fibers in these pathways act in the spinal cord to block the transmission of pain signals to the brain (see chapter 16).
- **Sleep and consciousness.** The reticular formation has projections to the thalamus and cerebral cortex that allow it some control over what sensory signals reach the cerebrum and come to our conscious attention. It plays a central role in states of consciousness such as alertness and sleep. Injury to the reticular formation can result in irreversible coma.
- **Habituation.** This is a process in which the brain learns to ignore repetitive, inconsequential stimuli while remaining sensitive to others. In a noisy city, for example, a person can sleep through traffic sounds but wake promptly to the sound of an alarm clock or a crying baby. Reticular formation nuclei that modulate activity of the cerebral cortex are called the *reticular activating system* or *extrathalamic cortical modulatory system*.

The Cerebellum

The **cerebellum** is the largest part of the hindbrain and second-largest part of the brain as a whole (fig. 14.11). It consists of right and left **cerebellar hemispheres** connected by a narrow wormlike bridge called the **vermis**.²⁵ Each hemisphere exhibits slender, transverse, parallel

folds called **folia**²⁶ separated by shallow sulci. The cerebellum has a surface cortex of gray matter and a deeper layer of white matter. In a sagittal section, the white matter exhibits a branching, fernlike pattern called the **arbor vitae**.²⁷ Each hemisphere has four masses of gray matter called **deep nuclei** embedded in the white matter. All input to the cerebellum goes to the cortex and all of its output comes from the deep nuclei.

Although the cerebellum is only about 10% of the mass of the brain, it has about 60% as much surface area as the cerebral cortex and it contains more than half of all brain neurons—about 100 billion of them. Its tiny, densely spaced **granule cells** are the most abundant type of neuron in the entire brain. Its most distinctive neurons, however, are the unusually large, globose **Purkinje**²⁸ (pur-KIN-jee) **cells**. These have a tremendous profusion of dendrites compressed into a single plane like a flat tree (see fig. 12.5, p. 446, and the photograph on p. 441). The Purkinje cells are arranged in a single file, with these thick dendritic planes parallel to each other like books on a shelf. Their axons travel to the deep nuclei, where they synapse on output neurons that issue fibers to the brainstem.

The cerebellum is connected to the brainstem by three pairs of stalks called **cerebellar peduncles**²⁹ (peh-DUN-culs): a pair of *inferior peduncles* connected to the medulla oblongata, a pair of *middle peduncles* to the pons, and a pair of *superior peduncles* to the midbrain (see fig. 14.8b). These consist of thick bundles of nerve fibers that carry signals to and from the cerebellum. Connections between the cerebellum and brainstem regions are very complex, but overlooking some exceptions, we can draw a few generalizations. Most spinal input enters the cerebellum by way of the inferior peduncles; most input from the rest of the brain enters by way of the middle peduncles; and cerebellar output travels mainly by way of the superior peduncles.

The function of the cerebellum was unknown in the 1950s. By the 1970s, it had come to be regarded as a center for monitoring muscle contractions and aiding in motor coordination. People with cerebellar lesions exhibit serious deficits in coordination and locomotor ability; more will be said later in this chapter about the role of the cerebellum in movement. But cerebellar lesions also affect several sensory, linguistic, emotional, and other nonmotor functions. Recent studies by positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), and behavioral studies of people with cerebellar lesions, have created a much more expansive view of cerebellar function. It appears that its general role is the evaluation of certain kinds of sensory input, and monitoring muscle movement is only part of its broader function.

530 PART THREE Integration and Control

FIGURE 14.11 The Cerebellum. (a) Median section, showing relationship to the brainstem. (b) Superior aspect.

The cerebellum is highly active when a person explores objects with the fingertips, for example to compare the textures of two objects without looking at them. (Tactile nerve fibers from a rat's snout and a cat's forepaws also project strongly to the cerebellum.) Some spatial perception also resides here. The cerebellum is much more active when a person is required to solve a pegboard puzzle than when moving pegs randomly around the same puzzle board. People with cerebellar lesions also have difficulty identifying different views of a three-dimensional object as belonging to the same object.

The cerebellum is also a timekeeping center of the brain. PET scans show increased cerebellar activity when a person is required to judge the elapsed time between two stimuli. People with cerebellar lesions have difficulty with rhythmic finger-tapping tasks and other tests of temporal judgment. An important aspect of cerebellar timekeeping is the ability to predict where a moving object will be in the next second or so. You can imagine the

importance of this to a predator chasing its prey, to a tennis player, or in driving a car in heavy traffic. The cerebellum also helps to predict how much the eyes must move in order to compensate for head movements and remain fixed on an object.

Even hearing has some newly discovered and surprising cerebellar components. Cerebellar lesions impair a person's ability to judge differences in pitch between two tones and to distinguish between similar-sounding words such as *rabbit* and *rapid*. Language output also involves the cerebellum. If a person is given a noun such as *apple* and told to think of a related verb such as *eat*, the cerebellum shows higher PET activity than if the person is told merely to repeat the word *apple*.

People with cerebellar lesions also have difficulty planning and scheduling tasks. They tend to overreact emotionally and have difficulty with impulse control. Many children with attention-deficit/hyperactivity disorder (AD/HD) have abnormally small cerebellums.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- List several visceral functions controlled by nuclei of the medulla. What general function would be lost if the pyramids of the medulla were severed?
- List several sensory and motor functions of the pons.
- What functions are served by the superior and inferior colliculi? To what portion of the brainstem do they belong?
- Where is the reticular formation found? Define it in a single sentence.
- List several functions of the cerebellum.

14.4 The Forebrain

Objectives

When you have completed this section, you should be able to

- name the three major components of the diencephalon and describe their locations and functions;
- identify the five lobes of the cerebrum and their functions;
- describe the three types of tracts in the cerebral white matter;
- describe the distinctive cell types and histological arrangement of the cerebral cortex; and
- describe the location and functions of the basal nuclei and limbic system.

The forebrain consists of the diencephalon and telencephalon. The diencephalon encloses the third ventricle and is the most rostral part of the brainstem. The telencephalon develops chiefly into the cerebrum.

The Diencephalon

The embryonic diencephalon has three major derivatives: the *thalamus*, *hypothalamus*, and *epithalamus*.

The Thalamus

Each side of the brain has a **thalamus**,³⁰ an ovoid mass perched at the superior end of the brainstem beneath the cerebral hemisphere (see figs. 14.6c, 14.8, and 14.16). The thalami constitute about four-fifths of the diencephalon. They protrude medially into the third ventricle and laterally into the lateral ventricles. In about 70% of people, the two thalami are joined medially by a narrow *intermediate mass*.

The thalamus is composed of at least 23 nuclei, but we will consider only five major functional groups into which most of these are classified: the anterior, posterior, medial, lateral, and ventral groups. These regions and their functions are shown in figure 14.12a.

Generally speaking, the thalamus is the “gateway to the cerebral cortex.” Nearly all input to the cerebrum passes by way of synapses in the thalamic nuclei, including signals for taste, smell, hearing, equilibrium, vision, and such general senses as touch, pain, pressure, heat, and cold. (Some smell signals also get to the cerebrum by routes that bypass the thalamus.) The thalamic nuclei filter this information and relay only a small portion of it to the cerebral cortex.

The thalamus also plays a key role in motor control by relaying signals from the cerebellum to the cerebrum and providing feedback loops between the cerebral cortex and the *basal nuclei* (deep cerebral motor centers). Finally, the thalamus is involved in the memory and emotional functions of the *limbic system*, a complex of structures that include some cerebral cortex of the temporal and frontal lobes and some of the anterior thalamic nuclei. The role of the thalamus in motor and sensory circuits is further discussed later in this chapter and in chapter 16.

The Hypothalamus

The **hypothalamus** (see fig. 14.2) forms part of the walls and floor of the third ventricle. It extends anteriorly to the *optic chiasm* (ky-AZ-um), where the optic nerves meet, and posteriorly to a pair of humps called the **mammillary bodies** (see fig. 14.2a). Each mammillary body contains three to four *mammillary nuclei*. Their primary function is to relay signals from the limbic system to the thalamus. The pituitary gland is attached to the hypothalamus by a stalk (*infundibulum*) between the optic chiasm and mammillary bodies.

The hypothalamus is the major control center of the autonomic nervous system and endocrine system. It plays an essential role in the homeostatic regulation of nearly all organs of the body. Its nuclei include centers concerned with a wide variety of visceral functions (fig. 14.12b):

- Hormone secretion.** The hypothalamus secretes hormones that control the anterior pituitary gland. Acting through the pituitary, it regulates growth, metabolism, reproduction, and stress responses. The hypothalamus also produces two hormones that are stored in the posterior pituitary gland, concerned with labor contractions, lactation, and water conservation. These relationships are explored especially in chapter 17.
- Autonomic effects.** The hypothalamus is a major integrating center for the autonomic nervous system. It sends descending fibers to lower brainstem nuclei

³⁰*thalamus* = chamber, inner room

³¹*mammill* = nipple

FIGURE 14.12 The Diencephalon. Only some of the nuclei of the thalamus and hypothalamus are shown, and some of their functions are listed. These lists are by no means complete.

that influence heart rate, blood pressure, gastrointestinal secretion and motility, and pupillary diameter, among other functions.

- **Thermoregulation.** The *hypothalamic thermostat* consists of a collection of neurons, concentrated especially in the preoptic nucleus, that monitor body temperature. When the body temperature deviates

too much from its set point, this center activates either a heat-loss center in the anterior hypothalamus or a heat-promoting center in the posterior hypothalamus. Those centers activate mechanisms for lowering or raising the body temperature. The details of these mechanisms are described at the end of chapter 26.

- **Food and water intake.** Neurons of the *hunger* and *satiety centers* monitor blood glucose and amino acid levels and produce sensations of hunger and satiety (satisfaction of the appetite). Hypothalamic neurons called *osmoreceptors* monitor the osmolarity of the blood and stimulate water-seeking and drinking behavior when the body is dehydrated. Dehydration also stimulates the hypothalamus to produce *antidiuretic hormone*, which conserves water by reducing urine output.
- **Sleep and circadian rhythms.** The caudal part of the hypothalamus is part of the reticular formation. It contains nuclei that regulate the rhythm of sleep and waking. Superior to the optic chiasm, the hypothalamus contains a *suprachiasmatic nucleus* that controls our 24-hour (circadian) rhythm of activity.
- **Memory.** The mammillary nuclei lie in the pathway of signals traveling from the hippocampus, an important memory center of the brain, to the thalamus. Thus, they are important in memory, and lesions to the mammillary nuclei cause memory deficits. (Memory is discussed more fully on p. 541.)
- **Emotional behavior.** Hypothalamic centers are involved in a variety of emotional responses including anger, aggression, fear, pleasure, and contentment; and in sexual drive, copulation, and orgasm.

The Epithalamus

The **epithalamus** is a very small mass of tissue composed mainly of the **pineal gland** (an endocrine gland discussed in chapter 17), the **habenula**³² (a relay from the limbic system to the midbrain), and a thin roof over the third ventricle (see fig. 14.2a).

The Cerebrum

The embryonic telencephalon becomes the cerebrum, the largest and most conspicuous part of the human brain. Your cerebrum enables you to turn these pages, read and comprehend the words, remember ideas, talk about them with your peers, and take an examination. It is the seat of your sensory perception, memory, thought, judgment, and voluntary motor actions. It is the most complex and challenging frontier of neurobiology.

Gross Anatomy

The cerebrum so dwarfs and conceals the other structures that people often think of “cerebrum” and “brain” as synonymous. Its major anatomical landmarks were described on page 515 and should be reviewed if necessary (see figs. 14.1 and 14.2)—especially the two *cerebral hemispheres*, separated by the *longitudinal fissure* but connected by a prominent fiber tract, the *corpus cal-*

losum; and the conspicuous wrinkles, or *gyri*, of each hemisphere, separated by grooves called *sulci*. The folding of the cerebral surface into gyri allows a greater amount of cortex to fit in the cranial cavity. The gyri give the cerebrum a surface area of about 2,500 cm², comparable to 4½ pages of this book. If the cerebrum were smooth-surfaced, it would have only one-third as much area and proportionately less information-processing capability. This extensive folding is one of the greatest differences between the human brain and the relatively smooth-surfaced brains of most other mammals.

Some gyri have consistent and predictable anatomy, while others vary from brain to brain and from the right hemisphere to the left. Certain unusually prominent sulci divide each hemisphere into five anatomically and functionally distinct lobes, listed next. The first four are visible superficially and are named for the cranial bones overlying them (fig. 14.13); the fifth lobe is not visible from the surface.

1. The **frontal lobe** lies immediately behind the frontal bone, superior to the eyes. From the forehead, it extends caudally to a wavy vertical groove, the **central sulcus**. It is chiefly concerned with voluntary motor functions, motivation, foresight, planning, memory, mood, emotion, social judgment, and aggression.
2. The **parietal lobe** forms the uppermost part of the brain and underlies the parietal bone. Starting at the central sulcus, it extends caudally to the **parieto-occipital sulcus**, visible on the medial surface of each hemisphere (see fig. 14.2). It is the primary site for receiving and interpreting signals of the *general senses* described later in this chapter; for taste (one of the *special senses*); and for some visual processing.
3. The **occipital lobe** is at the rear of the head, caudal to the parieto-occipital sulcus and underlying the occipital bone. It is the principal visual center of the brain.
4. The **temporal lobe** is a lateral, horizontal lobe deep to the temporal bone, separated from the parietal lobe above it by a deep **lateral sulcus**. It is concerned with hearing, smell, learning, memory, and some aspects of vision and emotion.
5. The **insula**³³ is a small mass of cortex deep to the lateral sulcus, made visible only by retracting or cutting away some of the overlying cerebrum (see figs. 14.1c, 14.6c, and 14.13). It is less understood than the other lobes because it is less accessible to testing in living subjects, but it apparently plays roles in understanding spoken language, in the sense of taste, and in integrating sensory information from visceral receptors.

³²haben = strap, rein + ula = little

³³insula = island

FIGURE 14.13 Lobes of the Cerebrum. The frontal and temporal lobes are retracted slightly to reveal the insula.

The Cerebral White Matter

Most of the volume of the cerebrum is white matter. This is composed of glia and myelinated nerve fibers that transmit signals from one region of the cerebrum to another and between the cerebrum and lower brain centers. These fibers form bundles, or *tracts*, of three kinds (fig. 14.14):

1. **Projection tracts** extend vertically between higher and lower brain and spinal cord centers, and carry information between the cerebrum and the rest of the body. The corticospinal tracts, for example, carry motor signals from the cerebrum to the brainstem and spinal cord. Other projection tracts carry signals upward to the cerebral cortex. Superior to the brainstem, such tracts form a broad, dense sheet called the *internal capsule* between the thalamus and basal nuclei (described shortly), then radiate in a diverging, fanlike array (the *corona radiata*³⁴) to specific areas of the cortex.
2. **Commissural tracts** cross from one cerebral hemisphere to the other through bridges called **commissures** (COM-ih-shurs). The great majority of commissural tracts pass through the large C-shaped corpus callosum (see fig. 14.2), which forms the floor of the longitudinal fissure. A few tracts pass through the much smaller **anterior** and **posterior commissures**. Commissural tracts enable the two sides of the cerebrum to communicate with each other.

3. **Association tracts** connect different regions within the same cerebral hemisphere. *Long association fibers* connect different lobes of a hemisphere to each other, whereas *short association fibers* connect different gyri within a single lobe. Among their roles, association tracts link perceptual and memory centers of the brain; for example, they enable you to smell a rose, name it, and picture what it looks like.

The Cerebral Cortex

Neural integration is carried out in the gray matter of the cerebrum, which is found in three places: the cerebral cortex, basal nuclei, and limbic system. We begin with the **cerebral cortex**,³⁵ a layer covering the surface of the hemispheres (see fig. 14.6c). Even though it is only 2 to 3 mm thick, the cortex constitutes about 40% of the mass of the brain and contains 14 to 16 billion neurons. It possesses two principal types of neurons (fig. 14.15) called *stellate cells* and *pyramidal cells*. **Stellate cells** have spheroidal somas with dendrites projecting for short distances in all directions. They are concerned largely with receiving sensory input and processing information on a local level. **Pyramidal cells** are tall and conical (triangular in tissue sections). Their apex points toward the brain surface and has a thick dendrite with many branches and small, knobby *dendritic spines*.

³⁴corona = crown + radiata = radiating

³⁵cortex = bark, rind

FIGURE 14.14 Tracts of Cerebral White Matter. (a) Left lateral aspect, showing association and projection tracts. (b) Frontal section, showing commissural and projection tracts.

What route can commissural tracts take other than the one shown here?

The base gives rise to horizontally oriented dendrites and an axon that passes into the white matter. Pyramidal cells include the output neurons of the cerebrum—the only cerebral neurons whose fibers leave the cortex and connect with other parts of the CNS. Pyramidal cell axons have collaterals that synapse with other neurons in the cortex or in deeper regions of the brain.

About 90% of the human cerebral cortex is a six-layered tissue called **neocortex**³⁶ because of its relatively recent evolutionary origin. Although vertebrate animals have existed for about 600 million years, the neocortex did not develop significantly until about 60 million years ago, when there was a sharp increase in the diversity of mammals. It attained its highest development by far in the

primates. The six layers of neocortex, numbered in figure 14.15, vary from one part of the cerebrum to another in relative thickness, cellular composition, synaptic connections, size of the neurons, and destination of their axons. Layer IV is thickest in sensory regions and layer V in motor regions, for example. All axons that leave the cortex and enter the white matter arise from layers III, V, and VI.

Some regions of cerebral cortex have fewer than six layers. The earliest type of cortex to appear in vertebrate evolution was a one- to five-layered tissue called *paleocortex* (PALE-ee-oh-COR-tex), limited in humans to part of the insula and certain areas of the temporal lobe concerned with smell. The next to evolve was a three-layered *archicortex* (AR-kee-COR-tex), found in the human hippocampus, a memory-forming center in the temporal lobe. The neocortex was the last to evolve.

³⁶neo = new

FIGURE 14.15 Histology of the Neocortex. Neurons are arranged in six layers.

Are the long processes leading upward from each pyramidal cell body dendrites or axons?

Cortical surface

The Basal Nuclei

The basal nuclei are masses of cerebral gray matter buried deep in the white matter, lateral to the thalamus (fig. 14.16). They are often called *basal ganglia*, but the word *ganglion* is best restricted to clusters of neurons outside the CNS. Neuroanatomists disagree on how many brain centers to classify as basal nuclei, but agree on at least three: the **caudate³⁷ nucleus**, **putamen³⁸** (pyu-TAY-men), and **globus pallidus³⁹**. The putamen and globus pallidus are also collectively called the **lentiform⁴⁰ nucleus**, because together they form a lens-shaped body. The putamen and caudate nucleus are also collectively called the **corpus striatum⁴¹** after their striped appearance. The basal nuclei receive input from the substantia nigra of the midbrain and motor areas of the cerebral cortex, and send signals back to both of these locations. They are involved in motor control and are further discussed in a later section on that topic.

The Limbic System

The **limbic⁴² system** is an important center of emotion and learning. It was originally described in the 1850s as a ring of structures on the medial side of the cerebral hemisphere, encircling the corpus callosum and thalamus. Its most anatomically prominent components are

³⁷caudate = tailed, tail-like

³⁸putam = pod, husk

³⁹glob = globe, ball + pall = pale

⁴⁰lenti = lens + form = shape

⁴¹corpus = body + striat = stripe

⁴²limbus = border

FIGURE 14.16 The Basal Nuclei. Frontal section of the brain.

FIGURE 14.17 The Limbic System. This ring of structures (shown in violet) includes important centers of learning and emotion. In the frontal lobe, there is no sharp rostral boundary to limbic system components.

the **cingulate**⁴³ (SING-you-let) **gyrus** that arches over the top of the corpus callosum in the frontal and parietal lobes, the **hippocampus**⁴⁴ in the medial temporal lobe (fig. 14.17), and the **amygdala**⁴⁵ (ah-MIG-da-luh) immediately rostral to the hippocampus, also in the temporal lobe. There are still differences of opinion on what structures to consider as parts of the limbic system, but these three are agreed upon; other components include the mammillary nuclei and other hypothalamic nuclei, some thalamic nuclei, parts of the basal nuclei, and parts of the frontal cortex. Limbic system components are interconnected through a complex loop of fiber tracts allowing for somewhat circular patterns of feedback among its nuclei and cortical neurons. All of these structures are bilaterally paired; there is a limbic system in each cerebral hemisphere.

The limbic system was long thought to be associated with smell because of its close association with olfactory pathways, but beginning in the early 1900s and continuing even now, experiments have abundantly demonstrated more significant roles in emotion and memory. Most limbic system structures have centers for both gratification and aversion. Stimulation of a gratification center produces a sense of pleasure or reward; stimulation of an aversion center produces unpleasant sensations such as

fear or sorrow. Gratification centers dominate some limbic structures, such as the *nucleus accumbens* (not illustrated), while aversion centers dominate others such as the amygdala. The roles of the amygdala in emotion and the hippocampus in memory are described in the next section, on integrative brain functions.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

14. What are the three major components of the diencephalon? Which ventricle does the diencephalon enclose?
15. What is the role of the thalamus in sensory function?
16. List at least six functions of the hypothalamus.
17. Name the five lobes of the cerebrum and describe their locations, boundaries, and principal functions.
18. Distinguish between commissural, association, and projection tracts of the cerebrum.
19. Where are the basal nuclei located? What is their general function?
20. Where is the limbic system located? What component of it is involved in emotion? What component is involved in memory?

⁴³cingul = girdle

⁴⁴hippocampus = sea horse, named for its shape

⁴⁵amygdala = almond

14.5 Integrative Functions of the Brain

Objectives

When you have completed this section, you should be able to

- list the types of brain waves and discuss their relationship to mental states;
- describe the stages of sleep, their relationship to the brain waves, and the neural mechanisms of sleep;
- identify the brain regions concerned with consciousness and thought, memory, emotion, sensation, motor control, and language; and
- discuss the functional differences between the right and left cerebral hemispheres.

This section concerns such “higher” brain functions as sleep, memory, cognition, emotion, sensation, motor control, and language. These are associated especially with the cerebral cortex, but not exclusively; they involve interactions between the cerebral cortex and such areas as the basal nuclei, brainstem, and cerebellum. It is impossible in many cases to assign these functions to one specific brain region; functions of the brain do not have such easily defined anatomical boundaries. Some functions overlap anatomically; some cross anatomical boundaries from one region to another, often remote region; and some functions such as consciousness and memory are widely distributed through the cerebrum. Thus, we will consider these as *integrative* functions of the brain, focusing especially on the cerebrum but in many cases involving the combined action of multiple levels of the brain. Some of these present the most difficult challenges for neurobiology, but they are the most intriguing functions of the brain and involve its largest areas.

The Electroencephalogram

For research and clinical purposes, it is common to monitor surface electrical activity called **brain waves**. Recorded with electrodes on the scalp (fig. 14.18a), these are rhythmic voltage changes resulting predominantly from synchronized postsynaptic potentials in the superficial layers of the cerebral cortex. The recording, called an **electroencephalogram**⁴⁶ (EEG), is useful in studying normal brain functions such as sleep and consciousness, and in diagnosing degenerative brain diseases, metabolic abnormalities, brain tumors, trauma, and so forth. States of consciousness ranging from high alertness to deep sleep are correlated with changes in the EEG. The complete and

(a)

(b)

FIGURE 14.18 The Electroencephalogram (EEG). (a) An EEG is recorded from electrodes on the forehead and scalp. (b) Four classes of brain waves are seen in EEGs.

persistent absence of brain waves is a common clinical and legal criterion of brain death.

There are four types of brain waves, distinguished by differences in amplitude (mV) and frequency. Frequency is expressed in hertz (Hz), or cycles per second (fig. 14.18b):

1. **Alpha (α) waves** have a frequency of 8 to 13 Hz and are recorded especially in the parieto-occipital area. They dominate the EEG when a person is awake and resting, with the eyes closed and the mind wandering. They are suppressed when a person opens the eyes, receives specific sensory stimulation, or engages in a mental task such as performing mathematical calculations. They are absent during deep sleep.
2. **Beta (β) waves** have a frequency of 14 to 30 Hz and occur in the frontal to parietal region. They are accentuated during mental activity and sensory stimulation.
3. **Theta (θ) waves** have a frequency of 4 to 7 Hz. They are normal in children and in drowsy or sleeping

⁴⁶electro = electricity + encephalo = brain + gram = record

adults, but a predominance of theta waves in awake adults suggests emotional stress or brain disorders.

4. **Delta (δ) waves** are high-amplitude “slow waves” with a frequency of less than 3.5 Hz. Infants exhibit delta waves when awake, and adults exhibit them in deep sleep. A predominance of delta waves in awake adults indicates serious brain damage.

Sleep

Sleep is probably the human function most commonly studied with the aid of EEGs, both for scientific understanding and for diagnosis of sleep disorders. It is one of many bodily functions that occur in cycles called **circadian**⁴⁷ (sur-CAY-dee-an) **rhythms**, so named because they are marked by events that reoccur at intervals of about 24 hours. **Sleep** can be defined as a temporary state of unconsciousness from which one can awaken when stimulated. It is characterized by a stereotyped posture (usually lying down with the eyes closed) and inhibition of muscular activity (*sleep paralysis*). It superficially resembles other states of prolonged unconsciousness such as coma and animal hibernation, except that individuals cannot be aroused from those states by sensory stimulation.

Sleep occurs in distinct stages recognizable from changes in the EEG. In the first 30 to 45 minutes of sleep, the EEG waves drop in frequency but increase in amplitude as one passes through four sleep stages (fig. 14.19a):

- **Stage 1.** We feel drowsy, close our eyes, and begin to relax. Thoughts come and go, and we often feel a drifting sensation. We awaken easily if stimulated. The EEG is dominated by alpha waves.
- **Stage 2.** We pass into light sleep. The EEG declines in frequency but increases in amplitude. Occasionally it exhibits 1 or 2 seconds of *sleep spindles*, high spikes resulting from interactions between neurons of the thalamus and cerebral cortex.
- **Stage 3.** This is moderate to deep sleep, typically beginning about 20 minutes after stage 1. Sleep spindles occur less often, and theta and delta waves appear. The muscles relax, and the *vital signs* (body temperature, blood pressure, and heart and respiratory rates) fall.
- **Stage 4.** This is also called *slow-wave sleep (SWS)*, because the EEG is dominated by low-frequency, high-amplitude delta waves. The muscles are now very relaxed, vital signs are at their lowest levels, and we become difficult to awaken.

About five times a night, a sleeper backtracks from stage 3 or 4 to stage 2 and exhibits bouts of **rapid eye movement (REM) sleep** (fig. 14.19b). This is so named because the

eyes oscillate back and forth as if watching a movie. It is also called *paradoxical sleep* because the EEG resembles the waking state, yet the sleeper is harder to arouse than in any other stage. The vital signs increase and the brain consumes even more oxygen than when awake. Sleep paralysis, other than in the muscles of eye movement, is especially strong during REM sleep. Paralysis may serve to prevent the sleeper from acting out his or her dreams and may have prevented our tree-dwelling ancestors from falling during their sleep.

Dreams occur in both REM and non-REM sleep, but REM dreams tend to be longer, more vivid, and more emotional than non-REM dreams. The parasympathetic nervous system is very active during REM sleep, causing constriction of the pupils and erection of the penis or clitoris. In men, penile erection accompanies about 80% to 95% of REM sleep, but it is seldom associated with sexual dream content; only about 12% of men's dreams are sexual.

Young adults typically spend about 5% of their sleep time in stage 1, 50% to 60% in stage 2, 15% to 20% in stages 3 and 4, and 20% to 25% in REM sleep. These proportions are significantly different in children and elderly people.

The rhythm of sleep is well known, but its neurological mechanisms are still more of a mystery to science. The cycle of sleep and waking is controlled by a complex interaction between the cerebral cortex, thalamus, hypothalamus, and reticular formation. Nuclei in the upper reticular formation, near the junction of the pons and midbrain, induce arousal, whereas nuclei below the pons induce sleep. Sleep is also induced by a *ventrolateral preoptic nucleus* in the hypothalamus, which inhibits the arousal neurons of the upper reticular formation. These centers apparently work by regulating communication between the thalamus and cerebral cortex.

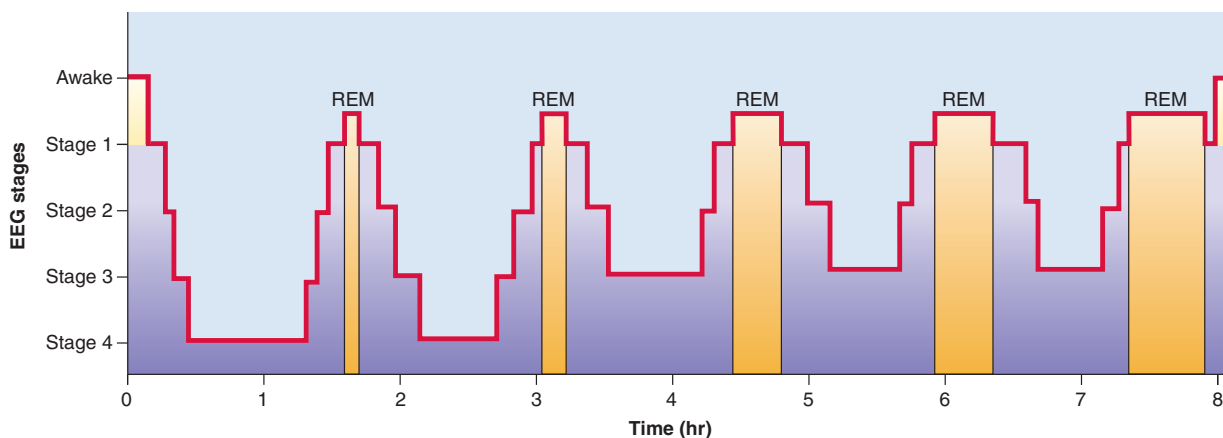

Another important control center for sleep is the **suprachiasmatic (SOO-pra-KY-az-MAT-ic) nucleus (SCN)**, located just above the optic chiasm in the anterior hypothalamus (see fig. 14.12b). Some nerve fibers from the eyes go to the SCN instead of to the visual cortex of the cerebrum. The SCN uses this input to synchronize multiple body rhythms with the external rhythm of night and day—including not just sleep but also body temperature, urine production, hormone secretion, and other functions. It does not in itself induce sleep or waking, but regulates the time of day that a person or animal sleeps. Destruction of the SCN produces an animal that sleeps the same number of hours per day, but at random times with no relationship to night or day.

We still know little about the purposes of sleep and dreaming. Non-REM sleep seems to have a restorative effect on the body, and prolonged sleep deprivation is fatal to experimental animals. Yet it is unclear why quiet bed rest alone cannot serve the restorative purpose for humans—that is, why we must lose consciousness. One

⁴⁷ *circa* = approximately + *dia* = a day, 24 hours

(a) One sleep cycle

(b) Typical 8-hour sleep period

FIGURE 14.19 Sleep Stages and Brain Activity. (a) A single sleep cycle, from waking to deep sleep, followed by 10 minutes of REM sleep. (b) Stages of sleep over an 8-hour night in a typical young adult. Stage 4 is attained only in the first two cycles. Periods of REM sleep increase from about 10 minutes in the first cycle to as long as 50 minutes in the last hour of sleep. Most dreaming occurs during REM sleep.

hypothesis is that sleep is a time to replenish such energy sources as glycogen and ATP. During waking hours, brain glycogen levels go down, while ATP consumption generates a sleep-inducing metabolite, adenosine (see p. 582). During sleep, ATP and glycogen levels rebound and the adenosine level goes down. Yet this is at best an incomplete explanation, because some animals with extraordinarily high metabolic rates (rapid ATP and glycogen consumption) sleep very little, and some with much lower metabolic rates (bats) sleep a great deal. From comparative zoology and evolutionary theory, there is evidence that sleep may have evolved to motivate animals to find a safe place and remain inactive during the most dangerous times of day, when such risks as predation may outweigh such benefits as food finding. Consistent with

this, humans sleep more in infancy (when at their most vulnerable), as well as when they are sick or injured and must recover in safety.

Some researchers have suggested that REM sleep is a period in which the brain either “consolidates” and strengthens memories by reinforcing synaptic connections, or purges superfluous information from memory by weakening or eliminating other synapses. There is some experimental evidence for associating sleep with memory: When people are given a new motor task to learn, then go to sleep while their brain activity is monitored, stage 4 sleep is seen in the regions involved in learning the task, not uniformly throughout the brain. But while intriguing hypotheses for the purposes of sleep and dreaming abound, the evidence for any of them is still scanty.

Cognition

Cognition⁴⁸ is the range of mental processes by which we acquire and use knowledge—sensory perception, thought, reasoning, judgment, memory, imagination, and intuition. Such functions are widely distributed over regions of cerebral cortex called **association areas**, which constitute about 75% of all brain tissue. This is the most difficult area of brain research and the most incompletely understood aspect of cerebral function. Much of what we know about it has come from studies of patients with brain lesions—areas of tissue destruction resulting from cancer, stroke, and trauma. The many brain injuries incurred in World Wars I and II yielded an abundance of insights into regional brain functions. More recently, imaging methods such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), described on page 24, have yielded much more sophisticated insights into brain function. These methods allow a researcher to scan a person's brain while that person performs various cognitive or motor tasks and to see which brain regions are most active in different mental and task states (see Insight 14.5).

A few examples of the effects of cerebral lesions reveal some functions of the association areas:

- Parietal lobe lesions can cause people to become unaware of objects, or even their own limbs, on the other side of the body—a condition called *contralateral neglect syndrome*. In typical cases, men shave only one-half of the face, women apply makeup to only one side, patients dress only half of the body, and some people deny that one arm or leg belongs to them. Such patients are unable to find their way around—say, to describe the route from home to work or navigate within a familiar building.
- Temporal lobe lesions often result in *agnosia*⁴⁹ (ag-NO-zee-ah), the inability to recognize, identify, and name familiar objects. In *prosopagnosia*,⁵⁰ a person cannot remember familiar faces, even his or her own reflection in a mirror.
- Frontal lobe lesions are especially devastating to the qualities we think of as personality. The **prefrontal cortex (frontal association area)**, the most rostral part of the frontal lobe, is well developed only in primates, especially humans. It integrates information from sensory and motor regions of the cortex and from other association areas. It gives us a sense of our relationship to the rest of the world, enabling us to think about it and to plan and execute appropriate behavior. It is responsible for giving appropriate expression to our emotions. Lesions here may produce profound personality disorders and socially inappropriate behaviors (see Insight 14.3).

As a broad generalization, we can conclude that the parietal association area is responsible for perceiving and attending to stimuli, the temporal association area for identifying them, and the frontal association area for planning our responses.

Memory

Memory is one of the cognitive functions, but warrants special attention. We studied its forms and its neural and molecular mechanisms in chapter 12 (pp. 472–474). Now that you have been introduced to the gross anatomy of the brain, we can consider where those processes occur anatomically.

Our subject is really a little broader than memory per se. Information management by the brain entails learning (acquiring new information), memory proper (information storage and retrieval), and forgetting (eliminating trivial information). Forgetting is as important as remembering. People with a pathological inability to forget trivial information have great difficulty in reading comprehension and other functions that require us to separate what is important from what is not. More often, though, brain-injured people are either unable to store new information (**anterograde amnesia**) or to recall things they knew before the injury (**retrograde amnesia**). *Amnesia* refers to defects in *declarative* memory (such as the ability to describe past events), not *procedural* memory (such as the ability to tie your shoes) (see definitions on p. 473).

The **hippocampus** of the limbic system is an important memory-forming center (see fig. 14.17). It does not store memories, but organizes sensory and cognitive experiences into a unified long-term memory. The hippocampus learns from sensory input while an experience is happening, but it has a short memory. Later, perhaps when one is sleeping, it plays this memory repeatedly to the cerebral cortex, which is a “slow learner” but forms longer-lasting memories through the processes described in chapter 12. This process of “teaching the cerebral cortex” until a long-term memory is established is called **memory consolidation**. Long-term memories are stored in various areas of cortex. One's vocabulary and memory of faces and familiar objects, for example, are stored in the superior temporal lobe, and memories of one's plans and social roles are stored in the prefrontal cortex.

Lesions of the hippocampus can cause profound anterograde amnesia. For example, in 1953, a famous patient known as H. M. underwent surgical removal of a large portion of both temporal lobes, including both hippocampi, in an effort to treat severe epilepsy. The operation had no adverse effect on his intelligence, procedural memory, or declarative memory for things that had happened early in his life, but it left him with an inability to establish new memories. He could hold a conversation with his psychologist, but a few minutes later deny that it had taken place. He worked with the same psychologist

INSIGHT 14.3 Medical History**The Seat of Personality—A Lesson from an Accidental Lobotomy**

Accidental but nonfatal destruction of parts of the brain has afforded many clues to the function of various regions. One of the most famous incidents occurred in 1848 to Phineas Gage, a laborer on a railroad construction project in Vermont. Gage was packing blasting powder into a hole with a 3½ ft tamping iron when the powder prematurely exploded. The tamping rod was blown out of the hole and passed through Gage's maxilla, orbit, and the frontal lobes of his brain before emerging from his skull near the hairline and landing 50 feet away (fig. 14.20). Gage went into convulsions, but later sat up and conversed with his crewmates as they drove him to a physician in an oxcart. On arrival, he stepped out on his own and told the physician, "Doctor, here is business enough for you." His doctor, John Harlow, reported that he could insert his index finger all the way into Gage's wound. Yet 2 months later, Gage was walking around town carrying on his normal business.

He was not, however, the Phineas Gage people had known. Before the accident, he had been a competent, responsible, financially prudent man, well liked by his associates. In an 1868 publication on the incident, Harlow said that following the accident, Gage was "fitful, irreverent, indulging at times in the grossest profanity." He became irresponsible, lost his job, worked for a while as a circus sideshow attraction, and died a vagrant 12 years later.

A 1994 computer analysis of Gage's skull indicated that the brain injury was primarily to the ventromedial region of both frontal lobes. In Gage's time, scientists were reluctant to attribute social behavior and moral judgment to any region of the brain. These functions were strongly tied to issues of religion and ethics and were considered inaccessible to scientific

analysis. Based partly on Phineas Gage and other brain-injury patients like him, neuroscientists today recognize that planning, moral judgment, and emotional control are among the functions of the prefrontal cortex.

FIGURE 14.20 Phineas Gage's 1848 Accident. The tamping bar flew upward, entered Gage's maxilla, passed through the orbit, destroyed brain tissue in the medial regions of each frontal lobe, and passed out of his skull near the hairline. The accident resulted in permanent personality changes that helped define some functions of the frontal lobes.

for more than 40 years after his operation, yet had no idea who she was from day to day.

Other parts of the brain involved in memory include the cerebellum, with a role in learning motor skills, and the amygdala, with a role in emotional memory—both of which are examined shortly.

Emotion

Emotional feelings and memories are not exclusively cerebral functions, but result from an interaction between areas of the prefrontal cortex and diencephalon. Emotional control centers of the brain have been identified by studying people with brain lesions and by such techniques as surgical removal, ablation (destruction) of small regions with electrodes, and stimulation with electrodes and chemical implants, especially in experimental animals. Changes in behavior following such procedures give clues to the functions that a region performs. However, interpretation of the results is difficult and controversial

because of the complex connections between the emotional brain and other regions.

The prefrontal cortex is the seat of judgment, intent, and control over the expression of our emotions. However we may feel, it is here that we decide the appropriate way to show those feelings. But the feelings themselves, and emotional memories, arise from deeper regions of the brain, especially the hypothalamus and amygdala. Here are the nuclei that stimulate us to recoil in fear from a rattlesnake or yearn for a lost love.

The amygdala is a major component of the limbic system described earlier (see fig. 14.17). It receives processed information from the general senses and from vision, hearing, taste, and smell. Such input enables it to mediate emotional responses to such stimuli as a disgusting odor, a foul taste, a beautiful sight, pleasant music, or a stomach-ache. It is especially important in the sense of fear, but also plays roles in food intake, sexual behavior, and drawing our attention to novel stimuli. Output from the amygdala goes in two directions of special interest: (1) Some goes to

the hypothalamus and lower brainstem and influences somatic and visceral motor systems. An emotional response to a stimulus may, through these connections, make one's heart race, raise the blood pressure, make the hair stand on end, or induce vomiting. (2) Other output goes to areas of the prefrontal cortex that mediate conscious control and expression of the emotions, such as the ability to express love, control anger, or overcome fear.

Many important aspects of personality depend on an intact, functional amygdala and hypothalamus. When specific regions are destroyed or artificially stimulated, humans and other animals exhibit blunted or exaggerated expressions of anger, fear, aggression, self-defense, pleasure, pain, love, sexuality, and parental affection, as well as abnormalities in learning, memory, and motivation. Lesions of the amygdala, for example, can completely abolish the sense of fear.

Much of our behavior is shaped by learned associations between stimuli, our responses to them, and the rewards or punishments that result. Nuclei involved in feelings of reward and punishment have been identified in the hypothalamus of cats, rats, monkeys, and other animals. In a representative experiment, an electrode is implanted in an area of an animal's hypothalamus called the *median forebrain bundle (MFB)*. The animal is placed in a chamber with a foot pedal wired to that electrode. When the animal steps on the pedal, it receives a mild electrical stimulus to the MFB. Apparently the sensation is strongly rewarding, because the animal soon starts to press the pedal over and over and may spend most of its time doing so—even to the point of neglecting food and water. Rats have been known to bar-press 5,000 to 12,000 times an hour, and monkeys up to 17,000 times an hour, to stimulate their MFBs.

These animals cannot tell us what they are feeling, but electrode implants have also been used to treat people who suffer otherwise incurable schizophrenia, pain, or epilepsy. These patients also repeatedly press a button to stimulate the MFB, but they do not report feelings of joy or ecstasy. Some are unable to explain why they enjoy the stimulus, and others report “relief from tension” or “a quiet, relaxed feeling.” With electrodes misplaced in other areas of the hypothalamus, subjects report feelings of fear or terror when stimulated.

Sensation

A great deal of the cerebrum is concerned with the senses—most cortex of the insula and of the parietal, occipital, and temporal lobes. Regions called **primary sensory cortex** are the sites where sensory input is first received and one becomes conscious of a stimulus. Adjacent to these are association areas where this sensory information is interpreted. For example, the primary visual cortex, which receives input from the eyes, is bordered by the visual association area, which interprets and makes cognitive sense of

the visual stimuli, so we know what we are looking at. Some association areas are *multimodal*—instead of processing information from a single sensory source, they receive input from multiple senses and integrate this into our overall perception of our surroundings. For example, in the frontal lobe just above the eyes, there is a patch of multimodal cortex called the *orbitofrontal cortex*, which receives taste, smell, and visual input to form our overall impression of the desirability of a particular food.

The sense organs and their signaling pathways in the CNS are the subject of chapter 16. Here we will examine only the areas of cerebral cortex involved in sensory perception.

The Special Senses

The **special senses** are limited to the head and employ relatively complex sense organs. They are the senses of vision, hearing, equilibrium, taste, and smell. Their primary cortices and association areas are located as follows (fig. 14.21).

- **Vision.** Visual signals are received by the **primary visual cortex** in the far posterior region of the occipital lobe. This is bordered anteriorly by the **visual association area**, which includes all the remainder of the occipital lobe, some of the posterior parietal lobe (concerned with spatial perception), and much of the inferior temporal lobe, where we recognize faces and other familiar objects.
- **Hearing.** Auditory signals are received by the **primary auditory cortex** in the superior region of the temporal lobe and in the nearby insula. The **auditory association area** occupies areas of temporal lobe inferior to the primary auditory cortex and deep within the lateral sulcus. This is where we become capable of recognizing spoken words, a familiar piece of music, or a voice on the telephone.
- **Equilibrium.** Signals from the inner ear for equilibrium (balance and the sense of motion) project mainly to the cerebellum and several brainstem nuclei concerned with head and eye movements and visceral functions. Some fibers of this system, however, are routed through the thalamus to areas of association cortex in the roof of the lateral sulcus and near the lower end of the central sulcus. This is the seat of consciousness of our body movements and orientation in space.
- **Taste and smell.** Gustatory (taste) signals are received by the **primary gustatory cortex** in the inferior end of the postcentral gyrus of the parietal lobe (discussed shortly) and an anterior region of the insula. Olfactory (smell) signals are received by the **primary olfactory cortex** in the medial surface of the temporal lobe and inferior surface of the frontal lobe. The *orbitofrontal cortex* mentioned earlier serves as a multimodal association area for both of these senses.

FIGURE 14.21 Some Functional Regions of the Cerebral Cortex. The Broca and Wernicke areas for language abilities are found in only one hemisphere, usually the left. The other regions shown here are mirrored in both hemispheres.

The General Senses

The **general (somesthetic,⁵¹ somatosensory, or somatic) senses** are distributed over the entire body and employ relatively simple receptors. They include such senses as touch, pressure, stretch, movement, heat, cold, and pain. Coming from the head, such signals reach the brain by way of certain cranial nerves, especially the trigeminal nerve; from the rest of the body, they ascend sensory tracts of the spinal cord such as the spinothalamic tract. In both routes, they decussate to the contralateral thalamus.

The thalamus processes the input and selectively relays signals to the **postcentral gyrus**. This is a fold of the cerebrum that lies immediately caudal to the central sulcus and thus forms the rostral border of the parietal lobe (fig. 14.22a). We can trace it from just above the lateral sulcus, ascending to the crown of the head and then passing downward into the longitudinal fissure. Its cerebral cortex is called the **primary somesthetic cortex**. Adjacent to it is a **somesthetic association area**, caudal to the gyrus and in the roof of the lateral sulcus (fig. 14.21). As we have seen elsewhere, awareness of stimulation occurs in the primary somesthetic cortex, but making cognitive sense of it is a function of the somesthetic association area.

Because of the aforementioned decussation in the sensory pathways, the right postcentral gyrus receives input from the left side of the body and vice versa. The primary somesthetic cortex is like an upside-down sensory map of the contralateral side of the body, traditionally diagrammed as a *sensory homunculus*⁵² (fig. 14.22b).

As the diagram shows, receptors in the lower limb project to superior and medial parts of the gyrus, and receptors in the face project to the inferior and lateral parts. Such point-for-point correspondence between an area of the body and an area of the CNS is called **somatotopy**.⁵³ The reason for the bizarre, distorted appearance of the homunculus is that the amount of cerebral tissue devoted to a given body region is proportional to how richly innervated and sensitive that region is, not to its size. Thus, the hands and face are represented by a much larger region of somesthetic cortex than the trunk is.

Motor Control

The intention to contract a skeletal muscle begins in the **motor association (premotor) area** of the frontal lobes (fig. 14.21). This is where we plan our behavior—where neurons compile a program for the degree and sequence of muscle contractions required for an action such as dancing, typing, or speaking. The program is then transmitted to neurons of the **precentral gyrus (primary motor area)**, which is the most posterior gyrus of the frontal lobe, immediately anterior to the central sulcus (fig. 14.23a). Neurons here send signals to the brainstem and spinal cord, which ultimately results in muscle contractions.

The precentral gyrus, like the postcentral one, exhibits somatotopy. The neurons for toe movements, for example, are deep in the longitudinal fissure on the medial side of the gyrus. The summit of the gyrus controls the trunk, shoulder, and arm, and the inferolateral region controls the facial muscles. This map is diagrammed as a *motor homunculus*

⁵¹som = body + esthet = feeling

⁵²hom = man + unculus = little

⁵³somato = body + topy = place

FIGURE 14.22 The Primary Somesthetic Cortex (Postcentral Gyrus). (a) Superior view of the brain showing the location of the postcentral gyrus (violet). (b) The sensory homunculus, drawn so that body parts are in proportion to the amount of cortex dedicated to their sensation. This gyrus also includes centers for visceral sensation from the intra-abdominal organs (the viscerosensory area).

FIGURE 14.23 The Primary Motor Cortex (Precentral Gyrus). (a) Superior view of the brain showing the location of the precentral gyrus (blue). (b) Motor homunculus, drawn so that body parts are in proportion to the amount of primary motor cortex dedicated to their control.

Which body regions are controlled by the largest areas of motor cortex—regions with a few large muscles or regions with numerous small muscles?

(fig. 14.23b). Like the sensory homunculus, it has a distorted look because the amount of cortex devoted to a given body region is proportional to the number of muscles and motor units in that region, not to the size of the region. Areas of fine control, such as the hands, have more muscles than such areas as the trunk and thigh, more motor units per muscle, and larger areas of motor cortex to control them.

The pyramidal cells of the precentral gyrus are called **upper motor neurons**. Their fibers project caudally, with about 19 million fibers ending in nuclei of the brainstem and 1 million forming the corticospinal tracts. Most of these fibers decussate in the lower medulla oblongata (at the pyramidal decussation) and form the *lateral corticospinal tract* on each side of the spinal cord. A smaller number of fibers pass through the medulla without decussation and form the anterior corticospinal tracts, which cross over lower in the spinal cord. Each precentral gyrus thus controls muscles on the contralateral side of the body. In the brainstem or spinal cord, the fibers from the upper motor neurons synapse with **lower motor neurons** whose axons innervate the skeletal muscles (see fig. 13.6, p. 490).

Other areas of the brain important in muscle control are the basal nuclei (see fig. 14.16) and cerebellum. Among the roles of the basal nuclei are determining the onset and cessation of intentional movements; the repetitive hip and shoulder movements that occur in walking; and highly practiced, learned behaviors that one carries out with little thought—for example, writing, typing, driving a car, using scissors, and tying one's shoes. The basal nuclei lie in a feedback circuit from the cerebrum to the basal nuclei to the thalamus and back to the cerebrum. Nearly all areas of cerebral cortex, except for the primary visual and auditory cortices, send signals to the basal nuclei. The basal nuclei process these and issue their output to the thalamus, which relays these signals back to the cerebral cortex—especially to the prefrontal cortex, motor association area, and precentral gyrus.

Lesions of the basal nuclei cause movement disorders called **dyskinesias**.⁵⁴ These are sometimes characterized by abnormal difficulty initiating movement, such as rising from a chair or beginning to walk, and by a slow shuffling walk. Such motor dysfunctions are seen in Parkinson disease (see p. 474). Smooth, easy movements require the excitation of agonistic muscles and inhibition of their antagonists. In Parkinson disease, the antagonists are not inhibited. Therefore, opposing muscles at a joint fight each other, making it a struggle to move as one wishes. Other dyskinesias are characterized by exaggerated or unwanted movements, such as flailing of the limbs (*ballismus*) in Huntington disease.

The cerebellum is highly important in motor coordination. In addition to its cognitive functions described on page 530, it aids in learning motor skills, maintains muscle tone and posture, smooths muscle contractions, coordinates eye

and body movements, and coordinates the motions of different joints with each other (such as the shoulder and elbow in pitching a baseball). The cerebellum acts as a comparator in motor control. Through the middle peduncles, it receives information from the upper motor neurons of the cerebrum about what movements one intended to make, and information about body movement from the eyes and inner ears. Through the inferior peduncles, it receives information from proprioceptors in the muscles and joints about the actual performance of the movement (fig. 14.24, left). The Purkinje cells of the cerebellum compare the two. If there is a discrepancy between the intent and the performance, they signal the deep cerebellar nuclei. These, in turn, issue signals to the thalamus and lower brainstem, ultimately ascending to the motor association area of the cerebrum and the reticulospinal and vestibulospinal tracts of the spinal cord (fig. 14.24, right). Output from these areas corrects the muscle performance to match the intent. Lesions of the cerebellum can result in a clumsy, awkward gait (*ataxia*) and make some tasks such as climbing stairs virtually impossible.

Language

Language includes several abilities—reading, writing, speaking, and understanding words—assigned to different regions of cerebral cortex (fig. 14.25). The **Wernicke**⁵⁵ (WUR-ni-keh) **area** is responsible for the recognition of spoken and written language. It lies just posterior to the lateral sulcus, usually in the left hemisphere, at the crossroad between visual, auditory, and somesthetic areas of cortex. It is a multimodal association area that receives input from all these neighboring regions. The *angular gyrus*, part of the parietal lobe just caudal and superior to the Wernicke area, is important in the ability to read and write.

When we intend to speak, the Wernicke area formulates phrases according to learned rules of grammar and transmits a plan of speech to the **Broca**⁵⁶ **area**, located in the inferior prefrontal cortex in the same hemisphere. PET scans show a rise in the metabolic activity of the Broca area as we prepare to speak (see fig. 14.40). This area generates a motor program for the muscles of the larynx, tongue, cheeks, and lips to produce speech. It transmits this program to the primary motor cortex, which executes it—that is, it issues commands to the lower motor neurons that supply the relevant muscles.

The emotional aspect of language is controlled by regions in the opposite hemisphere that mirror the Wernicke and Broca areas. Opposite the Broca area is the *affective language area*. Lesions to this area result in *aprosody*—flat, emotionless speech. The cortex opposite Wernicke's area is concerned with recognizing the emotional content of another person's speech. Lesions here can result in such problems as the inability to understand a joke.

⁵⁴dys = bad, abnormal, difficult + kines = movement

⁵⁵Karl Wernicke (1848–1905), German neurologist

⁵⁶Pierre Paul Broca (1824–80), French surgeon and anthropologist

FIGURE 14.24 Motor Pathways Involving the Cerebellum. The cerebellum receives its input from the afferent pathways (red) on the left and sends its output through the efferent pathways (green) on the right.

FIGURE 14.25 Language Centers of the Left Hemisphere.

Aphasia⁵⁷ (ah-FAY-zee-uh) is any language deficit resulting from lesions in the hemisphere (usually the left) containing the Wernicke and Broca areas. The many forms of aphasia are difficult to classify. *Nonfluent (Broca) aphasia*, due to a lesion in the Broca area, results in slow speech, difficulty in choosing words, or use of words that only approximate the correct word. For example, a person may say “tssair” when asked to identify a picture of a chair. In extreme cases, the person’s entire vocabulary consists of two or three words, sometimes those that were being spoken when a stroke occurred. Such patients feel very frustrated with themselves and often maintain a tight-lipped reluctance to talk. A lesion to the Wernicke area may cause *fluent (Wernicke) aphasia*, in which a person speaks normally and sometimes excessively, but uses jargon and invented words that make little sense (for example, “choss” for chair). Such a person also cannot comprehend written and spoken words. In *anomic aphasia*, a person can speak normally and understand speech, but cannot identify written words or pictures. Shown a picture of a chair, the person may say, “I know what it is. . . . I have a lot of them,” but be unable to name the object.

This represents only a small sample of the complex and puzzling linguistic effects of brain lesions. Other lesions to small areas of cortex can cause impaired mathematical ability, a tendency to write only consonants, or difficulty understanding the second half of each word a person reads.

Cerebral Lateralization

The two cerebral hemispheres look identical at a glance, but close examination reveals a number of differences.

For example, in women the left temporal lobe is longer than the right. In left-handed people, the left frontal, parietal, and occipital lobes are usually wider than those on the right. The two hemispheres also differ in some of their functions (fig. 14.26). Neither hemisphere is “dominant,” but each is specialized for certain tasks. This difference in function is called **cerebral lateralization**.

One hemisphere, usually the left, is called the *categorical hemisphere*. It is specialized for spoken and written language and for the sequential and analytical reasoning employed in such fields as science and mathematics. This hemisphere seems to break information into fragments and analyze it in a linear way. The other hemisphere, usually the right, is called the *representational hemisphere*. It perceives information in a more integrated, holistic way. It is the seat of imagination and insight, musical and artistic skill, perception of patterns and spatial relationships, and comparison of sights, sounds, smells, and tastes.

Cerebral lateralization is highly correlated with handedness. The left hemisphere is the categorical one in 96% of right-handed people, and the right hemisphere in 4%. Among left-handed people, the right hemisphere is categorical in 15% and the left in 70%, whereas in the remaining 15%, neither hemisphere is distinctly specialized.

Lateralization develops with age. In young children, if one cerebral hemisphere is damaged or removed (for example, because of brain cancer), the other hemisphere can often take over its functions. Adult males exhibit more lateralization than females and suffer more functional loss when one hemisphere is damaged. When the left hemisphere is damaged, men are three times as likely as women to become aphasic. The reason for this difference is not yet clear.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Suppose you are reading a novel and gradually fall asleep and begin to dream. How would your brain waves change during this sequence of events?
- Describe the locations and functions of the somesthetic, visual, auditory, and frontal association areas.
- Describe the somatotopy of the primary motor area and primary sensory area.
- What are the roles of the Wernicke area, Broca area, and precentral gyrus in language?

⁵⁷a = without + phas = speech

FIGURE 14.26 Lateralization of Cerebral Functions. The two cerebral hemispheres are not functionally identical.

14.6 The Cranial Nerves

Objectives

When you have completed this section, you should be able to

- list the 12 cranial nerves by name and number;
- identify where each cranial nerve originates and terminates; and
- state the functions of each cranial nerve.

To be functional, the brain must communicate with the rest of the body. Most of its input and output travels by way of the spinal cord, but it also communicates by way of 12 pairs of **cranial nerves**. These arise from the base of the brain, exit the cranium through its foramina, and lead to muscles and sense organs located mainly in the head and neck. The cranial nerves are numbered I to XII starting with the most rostral pair (fig. 14.27). Each nerve also has a descriptive name such as *optic nerve* and *vagus nerve*.

Cranial Nerve Pathways

Most motor fibers of the cranial nerves begin in nuclei of the brainstem and lead to glands and muscles. The sensory fibers begin in receptors located mainly in the head and neck and lead mainly to the brainstem. These include the special senses such as vision and hearing, as well as general senses such as touch and proprioception. Pathways for the special senses are described in chapter 16. Sensory fibers for proprioception begin in the muscles innervated by motor fibers of the cranial nerves, but they often travel to the brain in a different nerve than the one that supplies the motor innervation.

Most cranial nerves carry fibers between the brainstem and ipsilateral receptors and effectors. Thus, a lesion in one side of the brainstem causes a sensory or motor deficit on the same side of the head. This contrasts with lesions of the motor and somesthetic cortex of the cerebrum, which, as we saw earlier, cause sensory and motor deficits on the *contralateral* side of the body. The exceptions are the optic nerve (II), where half the fibers decussate to the opposite side of the brain (see chapter 16), and the trochlear nerve (IV), in which all efferent fibers lead to a muscle of the contralateral eye.

FIGURE 14.27 The Cranial Nerves. (a) Base of the brain, showing the 12 cranial nerves. (b) Photograph of the cranial nerves.

Cranial Nerve Classification

Cranial nerves are traditionally classified as sensory (I, II, and VIII), motor (III, IV, VI, XI, and XII), or mixed (V, VII, IX, and X). In reality, only cranial nerves I and II (for smell and vision) are purely sensory, whereas all of the rest contain both afferent and efferent fibers and are therefore mixed nerves. Those traditionally classified as motor not only stimulate muscle contractions but also contain afferent fibers of proprioception, which provide the brain with feedback for controlling muscle action and make one consciously aware of such things as the position of the tongue and orientation of the head. Cranial nerve VIII, concerned with hearing and equilibrium, is traditionally classified as sensory, but it also has motor fibers that return signals to the inner ear and “tune” it to sharpen the sense of hearing. The nerves traditionally classified as mixed have sensory

functions quite unrelated to their motor functions. For example, the facial nerve (VII) has a sensory role in taste and a motor role in controlling facial expressions.

Cranial Nerve Table

Table 14.1 describes and illustrates the 12 pairs of cranial nerves. For each nerve, it describes the composition (sensory, motor, or mixed); its functions; its course from origin to termination and its path through the cranium; signs and symptoms of nerve damage; and some clinical tests used to evaluate its function. In order to teach the traditional classification (which is relevant for such purposes as board examinations and comparison to other books), yet remind you that all but two of these nerves are mixed, the table describes many of the nerves as *predominantly* sensory or motor.

TABLE 14.1 The Cranial Nerves

Origins of proprioceptive fibers are not tabulated. Nerves listed as mixed or sensory are agreed by all authorities to be either mixed or purely sensory nerves. Nerves classified as *predominantly* motor or sensory are traditionally classified that way but contain some fibers of the other type.

I. Olfactory Nerve

This is the nerve for the sense of smell. It consists of several separate fascicles that pass independently through the cribriform plate in the roof of the nasal cavity. It is not visible on brains removed from the skull because these fascicles are severed by removal of the brain.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Sensory	Smell	Olfactory mucosa in nasal cavity	Olfactory bulbs	Cribriform foramina of ethmoid bone	Impaired sense of smell	Determine whether subject can smell (not necessarily identify) aromatic substances such as coffee, vanilla, clove oil, or soap

FIGURE 14.28 The Olfactory Nerve (I).

II. Optic Nerve

This is the nerve for vision.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Sensory	Vision	Retina	Thalamus and midbrain	Optic foramen	Blindness in part or all of visual field	Inspect retina with ophthalmoscope; test peripheral vision and visual acuity

FIGURE 14.29 The Optic Nerve (II).

TABLE 14.1 The Cranial Nerves (*cont.*)**III. Oculomotor⁵⁸ Nerve (OC-you-lo-MO-tur)**

This nerve controls muscles that turn the eyeball up, down, and medially, as well as controlling the iris, lens, and upper eyelid.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Predominantly motor	Eye movements, opening of eyelid, pupillary constriction, focusing	Midbrain	Somatic fibers to levator palpebrae superioris; superior, medial, and inferior rectus muscles; and inferior oblique muscle of eye. Autonomic fibers enter eyeball and lead to constrictor of iris and ciliary muscle of lens.	Superior orbital fissure	Drooping eyelid; dilated pupil; inability to move eye in some directions; tendency of eye to rotate laterally at rest; double vision; difficulty focusing	Look for differences in size and shape of right and left pupils; test pupillary response to light; test ability to track moving objects

**FIGURE 14.30** The Oculomotor Nerve (III).**IV. Trochlear⁵⁹ Nerve (TROCK-lee-ur)**

This nerve controls a muscle that rotates the eyeball medially and slightly depresses the eyeball when the head turns.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Predominantly motor	Eye movements	Midbrain	Superior oblique muscle of eye	Superior orbital fissure	Double vision and inability to rotate eye inferolaterally; eye points superolaterally and subject tends to tilt head toward affected side	Test ability of eye to rotate inferolaterally

**FIGURE 14.31** The Trochlear Nerve (IV).

⁵⁸*oculo* = eye + *motor* = mover

⁵⁹*trochlea* = pulley (for a loop through which the muscle's tendon passes)

TABLE 14.1 The Cranial Nerves (*cont.*)

V. Trigeminal⁶⁰ Nerve (tri-JEM-ih-nul)

This is the largest of the cranial nerves and the most important sensory nerve of the face. It forks into three divisions: *ophthalmic* (V_1), *maxillary* (V_2), and *mandibular* (V_3).

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Ophthalmic division (V_1) Sensory	Touch, temperature, and pain sensations from upper face	Superior region of face as illustrated; surface of eyeball; lacrimal (tear) gland; superior nasal mucosa; frontal and ethmoid sinuses	Pons	Superior orbital fissure	Loss of sensation from upper face	Test corneal reflex (blinking in response to light touch to eyeball)
Maxillary division (V_2) Sensory	Same as V_1 , lower on face	Middle region of face as illustrated; nasal mucosa; maxillary sinus; palate; upper teeth and gums	Pons	Foramen rotundum and infraorbital foramen	Loss of sensation from middle face	Test sense of touch, pain, and temperature with light touch, pinpricks, and hot and cold objects
Mandibular division (V_3) Mixed	<i>Sensory:</i> Same as V_1 and V_2 , lower on face <i>Motor:</i> mastication	<i>Sensory:</i> Inferior region of face as illustrated; anterior two-thirds of tongue (but not taste buds); lower teeth and gums; floor of mouth; dura mater <i>Motor:</i> Pons	<i>Sensory:</i> Pons <i>Motor:</i> Anterior belly of digastric; masseter, temporalis, mylohyoid, and pterygoid muscles; tensor tympani muscle of middle ear	Foramen ovale	Loss of sensation; impaired chewing	Assess motor functions by palpating masseter and temporalis while subject clenches teeth; test ability to move mandible from side to side and to open mouth against resistance

An Aid to Memory

Generations of biology and medical students have relied on mnemonic (memory-aiding) phrases and ditties, ranging from the sublimely silly to the unprintably ribald, to help them remember the cranial nerves and other anatomy. An old classic began, “On old Olympus’ towering tops...,” with the first letter of each word matching the first letter of each cranial nerve (olfactory, optic, oculomotor, etc.). Some cranial nerves have changed names, however, since that passage was devised. A substitute used by some students, using the first letter of each nerve’s name, is “Oh, once one takes the anatomy final, very good vacation ahead.” The first two letters of *ahead* represent nerves XI and XII. One of the author’s former students devised a mnemonic that can remind you of the first two to four letters of most cranial nerves:

**Old
Opie
occasionally
tries
trigonometry
and
feels
very
gloomy,
vague,
and
hypoactive.**

**olfactory (I)
optic (II)
oculomotor (III)
trochlear (IV)
trigeminal (V)
abducens (VI)
facial (VII)
vestibulocochlear (VIII)
glossopharyngeal (IX)
vagus (X)
accessory (XI)
hypoglossal (XII)**

⁶⁰*tri* = three + *gem* = born (*trigem* = triplets)

TABLE 14.1 The Cranial Nerves (*cont.*)**FIGURE 14.32** The Trigeminal Nerve (V).**VI. Abducens⁶¹ Nerve (ab-DOO-senz)**

This nerve controls a muscle that turns the eyeball laterally.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Predominantly motor	Lateral eye movement	Inferior pons	Lateral rectus muscle of eye	Superior orbital fissure	Inability to turn eye laterally; at rest, eye turns medially because of action of antagonistic muscles	Test lateral eye movement

**FIGURE 14.33** The Abducens Nerve (VI).

⁶¹ab = away + duc = to lead or turn

TABLE 14.1 The Cranial Nerves (*cont.*)

VII. Facial Nerve

This is the major motor nerve of the facial muscles. It divides into five prominent branches: *temporal*, *zygomatic*, *buccal*, *mandibular*, and *cervical*.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Mixed	<i>Sensory:</i> Taste <i>Motor:</i> Facial expression; secretion of tears, saliva, nasal and oral mucus	<i>Sensory:</i> Taste buds of anterior two-thirds of tongue <i>Motor:</i> Pons	<i>Sensory:</i> Thalamus <i>Motor:</i> Somatic fibers to digastric muscle, stapedius muscle of middle ear, stylohyoid muscle, muscles of facial expression. Autonomic fibers to submandibular and sublingual salivary glands, tear glands, nasal and palatine glands.	Internal acoustic meatus and stylomastoid foramen	Inability to control facial muscles; sagging due to loss of muscle tone; distorted sense of taste, especially for sweets	Test anterior two-thirds of tongue with substances such as sugar, salt, vinegar, and quinine; test response of tear glands to ammonia fumes; test subject's ability to smile, frown, whistle, raise eyebrows, close eyes, etc.

FIGURE 14.34 The Facial Nerve (VII). (a) The facial nerve and associated organs. (b) The five major branches of the facial nerve. (c) A way to remember the distribution of the five major branches.

TABLE 14.1 The Cranial Nerves (*cont.*)**VIII. Vestibulocochlear⁶² Nerve (vess-TIB-you-lo-COC-lee-ur)**

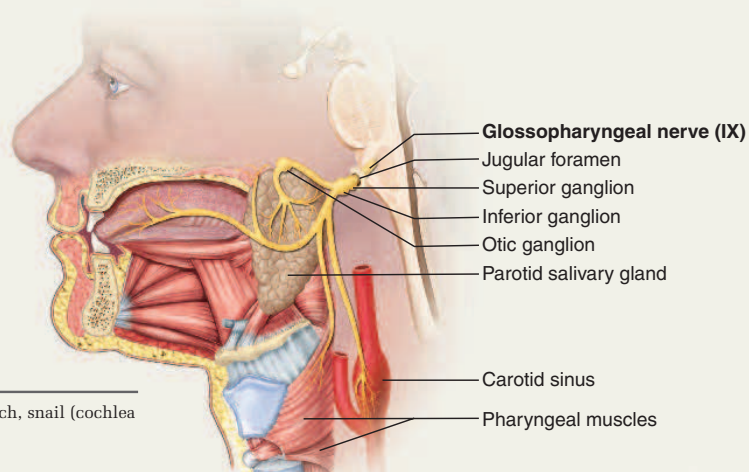

This is the nerve of hearing and equilibrium, but it also has motor fibers that lead to cells of the cochlea that tune the sense of hearing (see chapter 16).

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Predominantly sensory	Hearing and equilibrium	<i>Sensory:</i> Cochlea, vestibule, and semicircular ducts of inner ear <i>Motor:</i> Pons	<i>Sensory:</i> Fibers for hearing end in medulla; fibers for equilibrium end at junction of medulla and pons <i>Motor:</i> Outer hair cells of cochlea of inner ear	Internal acoustic meatus	Nerve deafness, dizziness, nausea, loss of balance, and nystagmus (involuntary rhythmic oscillation of eyes from side to side)	Look for nystagmus; test hearing, balance, and ability to walk a straight line

**FIGURE 14.35** The Vestibulocochlear Nerve (VIII).**IX. Glossopharyngeal⁶³ Nerve (GLOSS-oh-fah-RIN-jee-ul)**

This is a complex, mixed nerve with numerous sensory and motor functions in the head, neck, and thoracic regions including sensation from the tongue, throat, and outer ear; control of food ingestion; and some aspects of cardiovascular and respiratory function.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Mixed	<i>Sensory:</i> Taste; touch, pressure, pain, and temperature sensations from tongue and outer ear; regulation of blood pressure and respiration <i>Motor:</i> Salivation, swallowing, gagging	<i>Sensory:</i> Pharynx; middle and outer ear; posterior one-third of tongue (including taste buds); internal carotid artery <i>Motor:</i> Medulla oblongata	<i>Sensory:</i> Medulla oblongata <i>Motor:</i> Parotid salivary gland; glands of posterior tongue; stylopharyngeal muscle (which dilates pharynx during swallowing)	Jugular foramen	Loss of bitter and sour taste; impaired swallowing	Test gag reflex, swallowing, and coughing; note any speech impediments; test posterior one-third of tongue with bitter and sour substances

FIGURE 14.36 The Glossopharyngeal Nerve (IX).

⁶³*glosso* = tongue + *pharyng* = throat

TABLE 14.1 The Cranial Nerves (*cont.*)

X. Vagus⁶⁴ Nerve (VAY-gus)

The vagus has the most extensive distribution of any cranial nerve, supplying not only organs in the head and neck but also most viscera of the thoracic and abdominopelvic cavities. It plays major roles in the control of cardiac, pulmonary, digestive, and urinary functions.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Mixed	<i>Sensory:</i> Taste; sensations of hunger, fullness, and gastrointestinal discomfort <i>Motor:</i> Swallowing, speech, deceleration of heart, bronchoconstriction, gastrointestinal secretion and motility	<i>Sensory:</i> Thoracic and abdominopelvic viscera, root of tongue, pharynx, larynx, epiglottis, outer ear, dura mater <i>Motor:</i> Medulla oblongata	<i>Sensory:</i> Medulla oblongata <i>Motor:</i> Tongue, palate, pharynx, larynx, lungs, heart, liver, spleen, digestive tract, kidney, ureter	Jugular foramen	Hoarseness or loss of voice; impaired swallowing and gastrointestinal motility; fatal if both vagus nerves are damaged	Examine palatal movements during speech; check for abnormalities of swallowing, absence of gag reflex, weak hoarse voice, inability to cough forcefully

FIGURE 14.37 The Vagus Nerve (X).

⁶⁴vag = wandering.

TABLE 14.1 The Cranial Nerves (*cont.*)**XI. Accessory Nerve**

This nerve takes an unusual path. Unlike any other cranial nerve, it does not arise entirely from the brain. A small root does arise from the medulla oblongata, but a larger root arises from the cervical spinal cord. The latter root ascends alongside the spinal cord and enters the cranial cavity through the foramen magnum. It then joins the smaller root for a short distance and they exit the cranium together through the jugular foramen, bundled with the vagus and glossopharyngeal nerves. The accessory nerve controls mainly swallowing and neck and shoulder muscles.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Predominantly motor	Swallowing; head, neck, and shoulder movements	Medulla oblongata and spinal cord segments C1 to C6	Palate, pharynx, trapezius and sternocleidomastoid muscles	Jugular foramen	Impaired movement of head, neck, and shoulders; difficulty shrugging shoulder on damaged side; paralysis of sternocleidomastoid, causing head to turn toward injured side	Test ability to rotate head and shrug shoulders against resistance

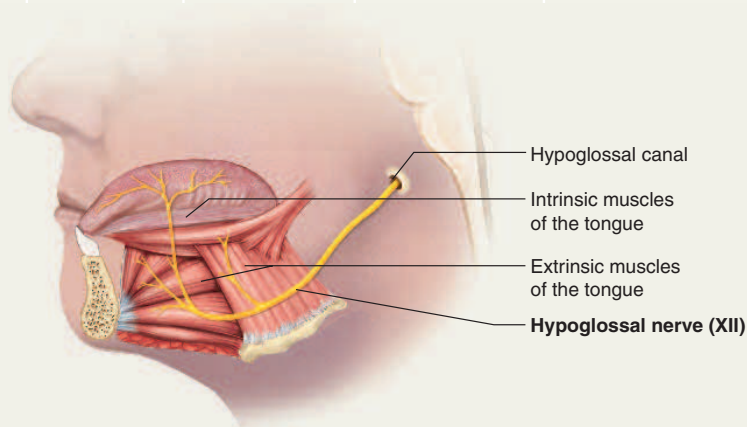

**FIGURE 14.38**
The Accessory Nerve (XI).

Posterior view

XII. Hypoglossal⁶⁵ Nerve (Hy-po-GLOSS-ul)

This nerve controls tongue movements.

Composition	Function	Origin	Termination	Cranial Passage	Effect of Damage	Clinical Test
Predominantly motor	Tongue movements of speech, food manipulation, and swallowing	Medulla oblongata	Intrinsic and extrinsic muscles of tongue	Hypoglossal canal	Impaired speech and swallowing; inability to protrude tongue if both right and left nerves are damaged; deviation of tongue toward injured side, and atrophy on that side, if only one nerve is damaged	Note deviations of tongue as subject protrudes and retracts it; test ability to protrude tongue against resistance

**FIGURE 14.39**
The Hypoglossal Nerve (XII).⁶⁵hypo = below + gloss = tongue

Like a machine with a great number of moving parts, the nervous system is highly subject to malfunctions. Table 14.2 lists a few well-known brain and cranial nerve dysfunctions. The effects of aging on the CNS are described on page 1142.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

25. List the purely sensory cranial nerves and state the function of each.
26. What is the only cranial nerve to extend beyond the head-neck region?
27. If the oculomotor, trochlear, or abducens nerve was damaged, the effect would be similar in all three cases. What would that effect be?
28. Which cranial nerve carries sensory signals from the greatest area of the face?
29. Name two cranial nerves involved in the sense of taste and describe where their sensory fibers originate.

TABLE 14.2 Some Disorders Associated with the Brain and Cranial Nerves

Cerebral palsy	Muscular incoordination resulting from damage to the motor areas of the brain during fetal development, birth, or infancy; causes include prenatal rubella infection, drugs, or radiation exposure; oxygen deficiency during birth; and hydrocephalus
Concussion	Damage to the brain typically resulting from a blow, often with loss of consciousness, disturbances of vision or equilibrium, and short-term amnesia
Encephalitis	Inflammation of the brain, accompanied by fever, usually caused by mosquito-borne viruses or herpes simplex virus; causes neuronal degeneration and necrosis; can lead to delirium, seizures, and death
Epilepsy	Disorder causing sudden, massive discharge of neurons (seizures) resulting in motor convulsions, sensory and psychic disturbances, and often impaired consciousness; may result from birth trauma, tumors, infections, drug or alcohol abuse, or congenital brain malformation
Migraine headache	Recurring headaches often accompanied by nausea, vomiting, dizziness, and aversion to light, often triggered by such factors as weather changes, stress, hunger, red wine, or noise; more common in women and sometimes running in families
Schizophrenia	A thought disorder involving delusions, hallucinations, inappropriate emotional responses to situations, incoherent speech, and withdrawal from society, resulting from hereditary or developmental abnormalities in neural networks

INSIGHT 14.4 Clinical Application

Some Cranial Nerve Disorders

*Trigeminal neuralgia*⁶⁶ (*tic douloureux*⁶⁷) is a syndrome characterized by recurring episodes of intense stabbing pain in the trigeminal nerve. The cause is unknown; there is no visible change in the nerve. It usually occurs after the age of 50 and mostly in women. The pain lasts only a few seconds to a minute or 2, but it strikes at unpredictable intervals and sometimes up to 100 times a day. The pain usually occurs in a specific zone of the face, such as around the mouth and nose. It may be trig-

gered by touch, drinking, tooth brushing, or washing the face. Analgesics (pain relievers) give only limited relief. Severe cases are treated by cutting the nerve, but this also deadens most other sensation in that side of the face.

*Bell*⁶⁸ *palsy* is a degenerative disorder of the facial nerve, probably due to a virus. It is characterized by paralysis of the facial muscles on one side with resulting distortion of the facial features, such as sagging of the mouth or lower eyelid. The paralysis may interfere with speech, prevent closure of the eye, or sometimes inhibit tear secretion. There may also be a partial loss of the sense of taste. Bell palsy may appear abruptly, sometimes overnight, and often disappears spontaneously within 3 to 5 weeks.

⁶⁶neur = nerve + algia = pain

⁶⁷douloureux = painful

⁶⁸Sir Charles Bell (1774–1842), Scottish physician

INSIGHT 14.5 Clinical Application

Images of the Mind

Enclosed as it is in the cranium, there is no easy way to observe a living brain directly. This has long frustrated neurobiologists, who once had to content themselves with glimpses of brain function afforded by electroencephalograms, patients with brain lesions, and patients who remained awake and conversant during brain surgery and consented to experimentation while the brain was exposed. New imaging methods, however, are yielding dramatic perspectives on brain function. Two of these—positron emission tomography (PET) and magnetic resonance imaging (MRI)—were explained in Insight 1.5 at the end of chapter 1. Both techniques rely on transient increases in blood flow to parts of the brain called into action to perform specific tasks. By monitoring these changes, neuroscientists can identify which parts of the brain are involved in specific tasks.

To produce a PET scan of the brain, the subject is given an injection of radioactively labeled glucose and a scan is made in a *control state* before any specific mental task is begun. Then the subject is given a task. For example, the subject may be instructed to read the word *car* and speak a verb related to it, such as *drive*. New PET scans are made in the *task state* while the subject performs this task. Neither control- nor task-state images are very revealing by themselves, but the computer subtracts the control-state data from the task-state data and presents a color-coded image of the difference. To compensate for chance events and individual variation, the computer also produces an image that is either averaged from several trials with one person or from trials with several different people.

In such averaged images, the busiest areas of the brain seem to “light up” from moment to moment as the task is performed (fig. 14.40). This identifies the regions used for various stages of the task, such as reading the word, thinking of a verb to go with it, planning to say *drive*, and actually saying it. Among other things, such experiments demonstrate that the Broca and Wernicke areas are not involved in simply repeating

words; they are active, however, when a subject must evaluate a word and choose an appropriate response—that is, they function in formulating the new word the subject is going to say. PET scans also show that different neural pools take over a task as we practice and become more proficient at it.

Functional magnetic resonance imaging (fMRI) depends on the role of astrocytes in brain metabolism. The main excitatory neurotransmitter secreted by cerebral neurons is glutamate. After a neuron releases glutamate and glutamate stimulates the next neuron, astrocytes quickly remove it from the synapse and convert it to glutamine. Astrocytes acquire the energy for this from the anaerobic fermentation of glucose. High activity in an area of cortex thus requires an increased blood flow to supply this glucose, but it does not elevate oxygen consumption from that blood. Thus, the oxygen supply exceeds demand in that part of the brain, and blood leaving the region contains more oxygen than the blood leaving less active regions. Since the magnetic properties of hemoglobin depend on how much oxygen is bound to it, fMRI can detect changes in brain circulation.

fMRI is more precise than PET and pinpoints regions of brain activity with a precision of 1 to 2 mm. It also has the advantages of requiring no injected substances and no exposure to radioisotopes. While it takes about 1 minute to produce a PET scan, fMRI produces images much more quickly, which makes it more useful for determining how the brain responds immediately to sensory input or mental tasks.

PET and fMRI scanning have enhanced our knowledge of neurobiology by identifying shifting patterns of brain activity associated with attention and consciousness, sensory perception, memory, emotion, motor control, reading, speaking, musical judgment, planning a chess strategy, and so forth. In addition to their contribution to basic neuroscience, these techniques have proven very valuable to neurosurgery and psychopharmacology. They also are enhancing our understanding of brain dysfunctions such as depression, schizophrenia, and attention-deficit/hyperactivity disorder (AD/HD). We have entered an exciting era in the safe visualization of normal brain function, producing pictures of the mind at work.

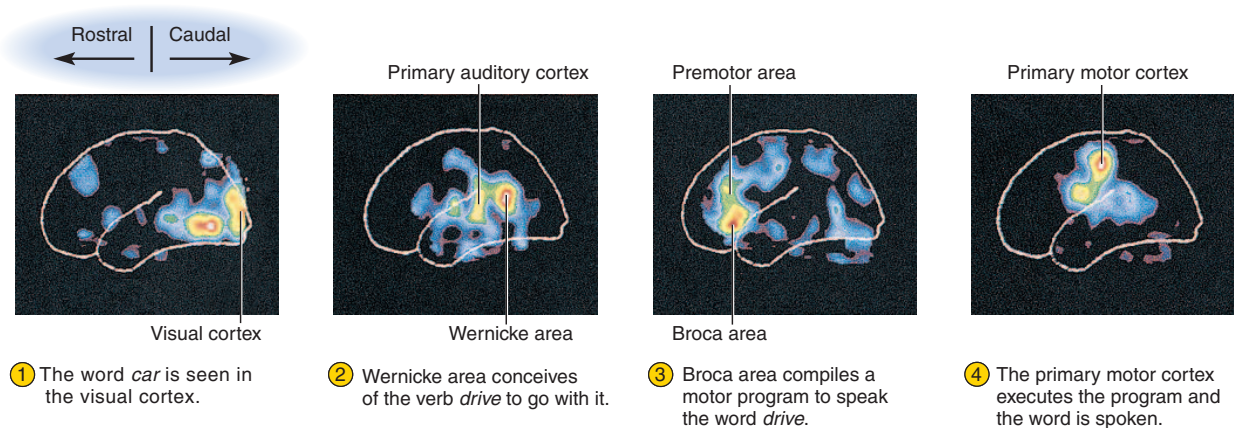

FIGURE 14.40 PET Scans of the Brain Made During the Performance of a Language Task. These images show the cortical regions that are active when a person reads words and then speaks them. The most active areas are shown in red and less active areas in blue.

CHAPTER REVIEW

Review of Key Concepts

14.1 Overview of the Brain (p. 515)

1. The adult brain weighs 1,450 to 1,600 g. It is divided into the *cerebrum*, *cerebellum*, and *brainstem*.
2. The cerebrum and cerebellum exhibit folds called *gyri* (or *folia* in the cerebellum) separated by grooves called *sulci*. The groove between the cerebral hemispheres is the *longitudinal fissure*.
3. The cerebrum and cerebellum have gray matter in their surface *cortex* and deeper *nuclei*, and white matter deep to the cortex.
4. Embryonic development of the brain progresses through *neural plate* and *neural tube* stages in the first 4 weeks. The anterior neural tube then begins to bulge and differentiate into forebrain, midbrain, and hindbrain. By the fifth week, the forebrain and hindbrain show further subdivision into two secondary vesicles each.
5. The five embryonic vesicles, in order from rostral to caudal, then differentiate into the mature cerebrum; diencephalon; midbrain; pons and cerebellum; and medulla oblongata.

14.2 Meninges, Ventricles, Cerebrospinal Fluid, and Blood Supply (p. 520)

1. Like the spinal cord, the brain is surrounded by a *dura mater*, *arachnoid mater*, and *pia mater*. The *dura mater* is divided into two layers, *periosteal* and *meningeal*, which in some places are separated by blood-filled *dural sinuses*. A *subarachnoid space* separates the arachnoid from the pia, and in some places, a *subdural space* separates the dura from the arachnoid.
2. The brain has four internal, interconnected cavities: two *lateral ventricles* in the cerebral hemispheres, a *third ventricle* between the hemispheres, and a *fourth ventricle* between the pons and cerebellum.
3. The ventricles and canals of the CNS are lined with *ependymal cells*, and each ventricle contains a *choroid plexus* of blood capillaries.
4. These spaces are filled with cerebrospinal fluid (CSF), which is produced

by the *ependyma* and *choroid plexuses* and in the *subarachnoid space* around the brain. The CSF of the ventricles flows from the lateral to the third and then fourth ventricle, out through *foramina* in the fourth, into the *subarachnoid space* around the brain and spinal cord, and finally returns to the blood by way of *arachnoid villi*.

5. CSF provides buoyancy, physical protection, and chemical stability for the CNS.
6. The brain has a high demand for glucose and oxygen and thus receives a copious blood supply.
7. The *blood-brain barrier* and *blood-CSF barrier* tightly regulate what substances can escape the blood and reach the nervous tissue.

14.3 The Hindbrain and Midbrain (p. 524)

1. The *medulla oblongata* is the most caudal part of the brain, just inside the *foramen magnum*. It conducts signals up and down the brainstem and between the brainstem and cerebellum, and contains nuclei involved in vasomotion, respiration, coughing, sneezing, salivation, swallowing, gagging, vomiting, gastrointestinal secretion, sweating, and control of tongue and head movements. Cranial nerves IX through XII arise from the medulla.
2. The *pons* is immediately rostral to the medulla. It conducts signals up and down the brainstem and contains nuclei involved in sleep, hearing, equilibrium, taste, eye movements, facial expression and sensation, respiration, swallowing, bladder control, and posture. Cranial nerve V arises from the pons, and nerves VI through VIII arise between the pons and medulla.
3. The *midbrain* is rostral to the pons. It conducts signals up and down the brainstem and contains nuclei involved in motor control, pain, visual attention, and auditory reflexes. It gives rise to cranial nerves III and IV.

4. The *reticular formation* is an elongated body of gray matter extending from the medulla to the caudal hypothalamus. It includes some of the nuclei already mentioned and is involved in the control of skeletal muscles, the visual gaze, breathing, swallowing, cardiac and vasomotor control, pain, sleep, consciousness, and sensory awareness.
5. The *cerebellum* is the largest part of the hindbrain. It is composed of two hemispheres joined by a *vermis*, and has three pairs of *cerebellar peduncles* that attach it to the medulla, pons, and midbrain and carry signals between the brainstem and cerebellum.
6. Histologically, the cerebellum exhibits a fernlike pattern of white matter called the *arbor vitae*, *deep nuclei* of gray matter embedded in the white matter, a great abundance of *granule cells*, and unusually large neurons called *Purkinje cells*.
7. The cerebellum is concerned largely with evaluation of sensory information. It performs roles in equilibrium, motor coordination, tactile sensation, spatial perception, timekeeping, language abilities, planning, and impulse control.

14.4 The Forebrain (p. 531)

1. The forebrain consists of the diencephalon and cerebrum.
2. The *diencephalon* is composed of the thalamus, hypothalamus, and epithalamus.
3. The *thalamus* constitutes four-fifths of the diencephalon. It processes sensory information of all kinds and relays signals to specific regions of the cerebral cortex. It also lies within the feedback loops between the cerebrum and cerebellum, and between the cerebral cortex and basal nuclei, and participates in the memory and emotional functions of the limbic system.
4. The *hypothalamus* is inferior to the thalamus and forms the walls and floor of the third ventricle.

It is a major homeostatic control center. It synthesizes some pituitary hormones and controls the timing of pituitary secretion, and is concerned with heart rate, blood pressure, gastrointestinal secretion and motility, pupillary diameter, thermoregulation, hunger and thirst, sleep and circadian rhythms, memory, sexual function, and emotion.

5. The *epithalamus* lies above the thalamus and includes the *pineal gland* (an endocrine gland) and *habenula* (a relay from limbic system to mid-brain).
 6. The cerebrum is the largest part of the brain. It is divided into two hemispheres, and each hemisphere into five lobes: *frontal*, *parietal*, *occipital*, and *temporal lobes* and the *insula*.
 7. Nerve fibers of the cerebral white matter are bundled in tracts of three kinds: *projection tracts* that extend between higher and lower brain centers; *commissural tracts* that cross between the right and left cerebral hemispheres through the *corpus callosum* and the *anterior* and *posterior commissures*; and *association tracts* that connect different lobes and gyri within a single hemisphere.
 8. The cerebral cortex is gray matter with two types of neurons: *stellate cells* and *pyramidal cells*. All output from the cortex travels by way of axons of the pyramidal cells. Most of the cortex is *neocortex*, in which there are six layers of nervous tissue. Evolutionarily older parts of the cerebrum have one- to five-layered *paleocortex* and *archicortex*.
 9. The *basal nuclei* are masses of cerebral gray matter lateral to the thalamus, concerned with motor control. They include the *caudate nucleus*, *putamen*, and *globus pallidus*.
 10. The *limbic system* is a loop of specialized cerebral cortex on the medial border of the temporal lobe and parts of the thalamus, hypothalamus, and frontal lobe. Some of its major parts are the *hippocampus*, *amygdala*, and *cingulate gyrus*. It is important in smell, emotion, and memory.
- beta*, *theta*, *delta*) predominate in various states of consciousness and certain brain disorders.
2. The cycle of sleep and waking is one of the body's many *circadian rhythms*. Sleep progresses from stage 1 to stage 4 with characteristic changes in the EEG and other physiological values. Most dreaming occurs during a fifth type of sleep called *rapid eye movement (REM) sleep*. Nuclei of the hypothalamus and reticular formation induce sleep and waking. The *suprachiasmatic nucleus* of the hypothalamus synchronizes sleep and waking with the day–night cycle.
 3. *Cognition* (consciousness, thought, etc.) involves several *association areas* of the cerebral cortex, especially in the parietal, temporal, and frontal lobes.
 4. Memories are stored in widely distributed areas of the cerebral cortex but are created especially by the hippocampus, amygdala, and cerebellum. The hippocampus processes information and organizes it into long-term memories (*memory consolidation*). These memories are then stored in regions including the prefrontal cortex and the temporal lobe. The cerebellum is also involved in procedural memory (learning motor skills) and the amygdala in emotional memory.
 5. The amygdala, hippocampus, and hypothalamus are important emotional centers of the brain, involved in such feelings as love, fear, anger, pleasure, and pain, and in learning to associate behaviors with reward and punishment.
 6. Sensory awareness resides in various regions of *primary sensory cortex*; interpretation of sensory input occurs in adjacent *association areas*. Vision resides primarily in the occipital lobe; hearing in the temporal lobe and insula; equilibrium in the cerebellum, brainstem, and around the junction of the lateral sulcus and central sulcus; and taste and smell in the lower parietal lobe, medial temporal lobe, and inferior frontal lobe.
 7. The general senses register in the postcentral gyrus of the parietal lobe, where there is a point-for-point correspondence (*somatotopy*) with specific regions on the contralateral side of the body.
 8. Motor control resides in the *motor association area* and *precentral gyrus* of the frontal lobe. The precentral gyrus shows a somatotopic correspondence with muscles on the contralateral side of the body.
 9. The basal nuclei and cerebellum play important roles in motor coordination and the conduct of learned motor skills.
 10. Language is coordinated largely by the *Wernicke* and *Broca areas*. The Wernicke area recognizes spoken and written language and formulates what one is going to say or write; the Broca area compiles a motor program for speech; and the precentral gyrus carries out this program, controlling the muscles of speech.
 11. The brain exhibits *cerebral lateralization*; some functions are coordinated mainly by the left hemisphere and others by the right. The *categorical hemisphere* (in most people, the left) is responsible for verbal and mathematical skills and logical, linear thinking. The *representational hemisphere* (usually the right) is a seat of imagination, insight, spatial perception, musical skill, and other “holistic” functions.

14.5 Integrative Functions of the Brain (p. 538)

1. The cerebral cortex generates *brain waves* that can be recorded as an *electroencephalogram (EEG)*. Different types of brain waves (*alpha*,

14.6 The Cranial Nerves (p. 549)

1. Twelve pairs of *cranial nerves* arise from the floor of the brain, pass through foramina of the skull, and lead primarily to structures in the head and neck.
2. Cranial nerves I and II are purely sensory. All the rest are mixed, although the sensory components of some are only proprioceptive and aid in motor control, so they are often classified as motor nerves (III, IV, VI, XI, and XII).
3. The olfactory nerve (I) carries the sensory signals for smell.
4. The optic nerve (II) carries the sensory signals for vision.
5. The oculomotor nerve (III) carries motor signals that control eye movements, opening of the eyelids, pupillary constriction, and focusing of the lens.
6. The trochlear nerve (IV) carries motor signals for eye movement.
7. The trigeminal nerve (V) is a large nerve with three branches (ophthalmic, maxillary, and mandibular). It is the main sensory nerve of the face and it carries motor signals for mastication.

8. The abducens nerve (VI) carries motor signals for eye movement. Cranial nerves III, IV, and VI control different muscles of the eye.
9. The facial nerve (VII) carries sensory signals for taste and motor signals that control facial expression and the secretion of saliva, tears, and nasal and oral mucus.
10. The vestibulocochlear nerve (VIII) carries sensory signals of hearing and equilibrium and carries motor signals to the inner ear for tuning the sense of hearing.
11. The glossopharyngeal nerve (IX) carries sensory signals for taste, touch, pressure, pain, and temperature sensations from the tongue; for touch, pain, and temperature sensations from the outer ear; and for regulation of blood pressure and respiration. It also carries motor signals for salivation, swallowing, and gagging.
12. The vagus nerve (X) has the most extensive distribution of all cranial nerves, with branches leading not only to organs in the head and neck but also to most viscera of the thoracic and abdominal cavities. It carries sensory signals for taste, hunger, fullness, and gastrointestinal discomfort, and motor signals for swallowing, speech, and regulation of pulmonary, cardiovascular, and gastrointestinal functions.
13. The accessory nerve (XI) carries motor signals for swallowing and for head, neck, and shoulder movements.
14. The hypoglossal nerve (XII) carries motor signals for the tongue movements of speech, food manipulation, and swallowing.

Testing Your Recall

1. Which of these is caudal to the hypothalamus?
 - a. the thalamus
 - b. the optic chiasm
 - c. the cerebral aqueduct
 - d. the pituitary gland
 - e. the corpus callosum
2. If the telencephalon was removed from a 5-week-old embryo, which of the following structures would fail to develop in the fetus?
 - a. cerebral hemispheres
 - b. the thalamus
 - c. the midbrain
 - d. the medulla oblongata
 - e. the spinal cord
3. The blood–CSF barrier is formed by
 - a. blood capillaries.
 - b. endothelial cells.
 - c. protoplasmic astrocytes.
 - d. oligodendrocytes.
 - e. ependymal cells.
4. The pyramids of the medulla oblongata contain
 - a. descending corticospinal fibers.
 - b. commissural fibers.
 - c. ascending spinocerebellar fibers.
 - d. fibers going to and from the cerebellum.
 - e. ascending spinothalamic fibers.
5. Which of the following does *not* receive any input from the eyes?
 - a. the hypothalamus
 - b. the frontal lobe
 - c. the thalamus
 - d. the occipital lobe
 - e. the midbrain
6. While studying in a noisy cafeteria, you get sleepy and doze off for a few minutes. You awaken with a start and realize that all the cafeteria sounds have just “come back.” While you were dozing, this auditory input was blocked from reaching your auditory cortex by
 - a. the temporal lobe.
 - b. the thalamus.
 - c. the reticular activating system.
 - d. the medulla oblongata.
 - e. the vestibulocochlear nerve.
7. Because of a brain lesion, a certain patient never feels full, but eats so excessively that she now weighs nearly 270 kg (600 lb). The lesion is most likely in her
 - a. hypothalamus.
 - b. amygdala.
 - c. hippocampus.
 - d. basal nuclei.
 - e. pons.
8. The _____ is most closely associated with the cerebellum in embryonic development and remains its primary source of input fibers throughout life.
 - a. telencephalon
 - b. thalamus
 - c. midbrain
 - d. pons
 - e. medulla
9. Damage to the _____ nerve could result in defects of eye movement.
 - a. optic
 - b. vagus
 - c. trigeminal
 - d. facial
 - e. abducens
10. All of the following *except* the _____ nerve begin or end in the orbit.
 - a. optic
 - b. oculomotor
 - c. trochlear
 - d. abducens
 - e. accessory
11. The right and left cerebral hemispheres are connected to each other by a thick C-shaped bundle of fibers called the _____.
12. The brain has four chambers called _____ filled with _____ fluid.
13. On a sagittal plane, the cerebellar white matter exhibits a branching pattern called the _____.
14. Abnormal accumulation of cerebrospinal fluid in the ventricles can cause a condition called _____.
15. Cerebrospinal fluid is secreted partly by a mass of blood capillaries called the _____ in each ventricle.
16. The primary motor area of the cerebrum is the _____ gyrus of the frontal lobe.
17. A lesion in which lobe of the cerebrum is most likely to cause a radical alteration of the personality?
18. Areas of cerebral cortex that identify or interpret sensory information are called _____.

19. Linear, analytical, and verbal thinking occurs in the _____ hemisphere of the cerebrum, which is on the left in most people.
20. The motor pattern for speech is generated in an area of cortex called the _____ and then transmitted to the primary motor cortex to be carried out.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- The two hemispheres of the cerebellum are separated by the longitudinal fissure.
- The cerebral hemispheres would fail to develop if the neural crests of the embryo were destroyed.
- The midbrain is caudal to the thalamus.
- The Broca area is ipsilateral to the Wernicke area.
- Most of the cerebrospinal fluid is produced by the choroid plexuses.
- Hearing is a function of the occipital lobe.
- Respiration is controlled by nuclei in both the pons and medulla oblongata.
- The trigeminal nerve carries sensory signals from a larger area of the face than the facial nerve does.
- Unlike other cranial nerves, the vagus nerve extends far beyond the head-neck region.
- Most of the brain's neurons are found in the cerebral cortex.

Answers in appendix B

Testing Your Comprehension

- Which cranial nerve conveys pain signals to the brain in each of the following situations: (a) sand blows into your eye; (b) you bite the rear of your tongue; and (c) your stomach hurts from eating too much?
- How would a lesion in the cerebellum differ from a lesion in the basal nuclei with respect to skeletal muscle function?
- Suppose that a neuroanatomist performed two experiments on an animal with the same basic spinal brainstem structure as a human's: In experiment 1, he selectively transected (cut across) the pyramids on the ventral side of the medulla oblongata, and in experiment 2, he selectively transected the gracile and cuneate fasciculi on the dorsal side. How would the outcomes of the two experiments differ?
- A person can survive destruction of an entire cerebral hemisphere but cannot survive destruction of the hypothalamus, which is a much smaller mass of brain tissue. Explain this difference and describe some ways that destruction of a cerebral hemisphere would affect one's quality of life.
- What would be the most obvious effects of lesions that destroyed each of the following: (a) the hippocampus, (b) the amygdala, (c) the Broca area, (d) the occipital lobe, and (e) the hypoglossal nerve?

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Innervation of smooth muscle (p. 432)
- Neurotransmitters and synaptic transmission (pp. 463–467)
- Spinal nerves (pp. 493–496)
- The hypothalamus (p. 531)
- The limbic system (p. 536)
- Cranial nerves (p. 549)

We are consciously aware of many of the activities of our nervous system discussed in the preceding chapters—the general and special senses, our cognitive processes and emotions, and our voluntary movements. But there is another branch of the nervous system that operates in comparative secrecy, usually without our willing it, thinking about it, or even being able to consciously modify or suppress it.

This secretive agent is called the *autonomic nervous system (ANS)*. Its name means “self-governed,” as it is almost fully independent of our will. Its job is to regulate such fundamental states and life processes as heart rate, blood pressure, body temperature, respiratory airflow, pupillary diameter, digestion, energy metabolism, defecation, and urination. In short, the ANS quietly manages a multitude of unconscious processes responsible for the body’s homeostasis.

Walter Cannon (1871–1945), the American physiologist who coined such expressions as *homeostasis* and the *fight or flight reaction*, dedicated his career to the study of the autonomic nervous system. He found that an animal can live without a functional sympathetic nervous system (one of the two divisions of the ANS), but it must be kept warm and free of stress. It cannot regulate its body temperature, tolerate any strenuous exertion, or survive on its own. Indeed, the ANS is more necessary for survival than are many functions of the somatic nervous system; an absence of autonomic function is fatal because the body cannot maintain homeostasis without it. Thus, for an understanding of bodily function, the mode of action of many drugs, and other aspects of health care, we must be especially aware of how the ANS works.

15.1 General Properties of the Autonomic Nervous System

Objectives

When you have completed this section, you should be able to

- explain how the autonomic and somatic nervous systems differ in form and function; and
- explain how the two divisions of the autonomic nervous system differ in general function.

The **autonomic¹ nervous system (ANS)** can be defined as a motor nervous system that controls glands, cardiac muscle, and smooth muscle. It is also called the **visceral motor system** to distinguish it from the somatic motor system that controls the skeletal muscles. The primary target organs of the ANS are the viscera of the thoracic and abdominopelvic cavities and some structures of the body wall, including cutaneous blood vessels, sweat glands, and piloerector muscles.

The ANS usually carries out its actions involuntarily, without our conscious intent or awareness, in contrast to the voluntary nature of the somatic motor system. This voluntary–involuntary distinction is not, however, as clear-cut as it once seemed. Some skeletal muscle responses are quite involuntary, such as the somatic reflexes, and some skeletal muscles are difficult or impossible to control, such as the middle-ear muscles. On the other hand, therapeutic uses of biofeedback have shown that some people can learn to voluntarily control such visceral functions as blood pressure.

Visceral effectors do not depend on the autonomic nervous system to function, but only to adjust their activity to the body’s changing needs. The heart, for example, goes on beating even if all autonomic nerves to it are severed, but the ANS modulates the heart rate in conditions of rest or exercise. If the somatic nerves to a skeletal muscle are severed, the muscle exhibits flaccid paralysis—it no longer functions. But if the autonomic nerves to cardiac or smooth muscle are severed, the muscle exhibits exaggerated responses (*denervation hypersensitivity*).

Visceral Reflexes

The ANS is responsible for the body’s **visceral reflexes**—unconscious, automatic, stereotyped responses to stimulation, much like the somatic reflexes discussed in chapter 13, but involving visceral receptors and effectors and somewhat slower responses. Some authorities regard the visceral afferent (sensory) pathways as part of the ANS, while most prefer to limit the term *ANS* to the efferent (motor) pathways. Regardless of this preference, however, autonomic activity involves a visceral reflex arc that includes receptors (nerve endings that detect stretch, tissue damage, blood chemicals, body temperature, and other internal stimuli), afferent neurons leading to the CNS, interneurons in the CNS, efferent neurons carrying motor signals away from the CNS, and finally effectors.

For example, high blood pressure activates a visceral *baroreflex*.² It stimulates stretch receptors called *baroreceptors* in the carotid arteries and aorta, and they transmit signals via the glossopharyngeal nerves to the medulla oblongata (fig. 15.1). The medulla integrates this input with other information and transmits efferent signals back to the

¹*auto* = self + *nom* = rule (self-governed)

²*baro* = pressure

FIGURE 15.1 An Autonomic Reflex Arc. A rise in blood pressure is detected by baroreceptors in the carotid artery. The glossopharyngeal nerve transmits signals to the medulla oblongata, resulting in parasympathetic output from the vagus nerve that reduces the heart rate and lowers blood pressure. Both right and left carotid arteries contain baroreceptors; only the right one is shown here.

heart by way of the vagus nerves. The vagus nerves slow down the heart and reduce blood pressure, thus completing a homeostatic negative feedback loop. A separate autonomic reflex arc accelerates the heart when blood pressure drops below normal—for example, when we move from a reclining to a standing position and gravity draws blood away from the upper body (see fig. 1.11, p. 18).

Divisions of the Autonomic Nervous System

The ANS has two subsystems: the sympathetic and parasympathetic divisions. These differ in anatomy and function, but they often innervate the same target organs and may have cooperative or contrasting effects on them.

The **sympathetic division** adapts the body in many ways for physical activity—it increases alertness, heart rate, blood pressure, pulmonary airflow, blood glucose concentration, and blood flow to cardiac and skeletal muscle, but at the same time, it reduces blood flow to the skin and digestive tract. Cannon referred to extreme sympathetic responses as the “fight or flight” reaction because they come into play when an animal must attack, defend itself, or flee from danger. In our own lives, this reaction occurs in many situations involving arousal, exercise, competition, stress, danger, trauma, anger, or fear. Ordinarily, however, the sympathetic division has more subtle effects that we notice barely, if at all. The **parasympathetic division**, by comparison, has a calming effect on many body functions. It is associated with reduced energy expenditure and normal bodily maintenance, including such functions as digestion and waste elimination. This can be thought of as the “resting and digesting” state.

This does not mean that the body alternates between states where one system or the other is active. Normally both systems are active simultaneously. They exhibit a background rate of activity called **autonomic tone**, and the balance between *sympathetic tone* and *parasympathetic tone* shifts in accordance with the body’s changing needs. Parasympathetic tone, for example, maintains smooth muscle tone in the intestines and holds the resting heart rate down to about 70 to 80 beats/minute. If the parasympathetic vagus nerves to the heart are cut, the heart beats at its own intrinsic rate of about 100 beats/min. Sympathetic tone keeps most blood vessels partially constricted and thus maintains blood pressure. A loss of sympathetic tone can cause such a rapid drop in blood pressure that a person goes into shock.

Neither division has universally excitatory or calming effects. The sympathetic division, for example, excites the heart but inhibits digestive and urinary functions, while the parasympathetic division has the opposite effects. We will later examine how differences in neurotransmitters and their receptors account for these differences of effect.

Neural Pathways

The ANS has components in both the central and peripheral nervous systems. It includes control nuclei in the hypothalamus and other regions of the brainstem, motor neurons in the spinal cord and peripheral ganglia, and nerve fibers that travel through the cranial and spinal nerves you have already studied.

The autonomic motor pathway to a target organ differs significantly from somatic motor pathways. In somatic pathways, a motor neuron in the brainstem or spinal cord issues a myelinated axon that reaches all the way to a skeletal muscle. In autonomic pathways, the signal must travel across two neurons to get to the target organ, and it must cross a synapse where these two neurons meet in an

FIGURE 15.2 Comparison of Somatic and Autonomic Efferent Pathways. The entire distance from CNS to effector is spanned by one neuron in the somatic system and two neurons in the autonomic system. Only acetylcholine (ACh) is employed as a neurotransmitter by the somatic neuron and the autonomic preganglionic neuron, but autonomic postganglionic neurons can employ either ACh or norepinephrine (NE).

autonomic ganglion (fig. 15.2). The first neuron, called the **preganglionic neuron**, has a soma in the brainstem or spinal cord; its axon terminates in the ganglion. It synapses there with a **postganglionic neuron** whose axon extends the rest of the way to the target cells. (Some call this cell the *ganglionic neuron* since its soma is in the ganglion and only its axon is truly postganglionic.) The axons of these neurons are called the *pre-* and *postganglionic fibers*.

In summary, the autonomic nervous system is a division of the nervous system responsible for homeostasis, acting through the mostly unconscious and involuntary

control of glands, smooth muscle, and cardiac muscle. Its target organs are mostly the thoracic and abdominopelvic viscera, but also include some cutaneous and other effectors. It acts through motor pathways that involve two neurons, preganglionic and postganglionic, reaching from CNS to effector. The ANS has two divisions, sympathetic and parasympathetic, that often have cooperative or contrasting effects on the same target organ. Both divisions have excitatory effects on some target cells and inhibitory effects on others. These and other differences between the somatic and autonomic nervous systems are summarized in table 15.1.

TABLE 15.1	Comparison of the Somatic and Autonomic Nervous Systems	
Feature	Somatic	Autonomic
Effectors	Skeletal muscle	Glands, smooth muscle, cardiac muscle
Control	Usually voluntary	Usually involuntary
Efferent pathways	One nerve fiber from CNS to effector; no ganglia	Two nerve fibers from CNS to effector; synapse at a ganglion
Neurotransmitters	Acetylcholine (ACh)	ACh and norepinephrine (NE)
Effect on target cells	Always excitatory	Excitatory or inhibitory
Effect of denervation	Flaccid paralysis	Denervation hypersensitivity

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

1. How does the autonomic nervous system differ functionally and anatomically from the somatic motor system?
2. How do the general effects of the sympathetic division differ from those of the parasympathetic division?

15.2 Anatomy of the Autonomic Nervous System

Objectives

When you have completed this section, you should be able to

- identify the anatomical components and nerve pathways of the sympathetic and parasympathetic divisions;
- discuss the relationship of the adrenal glands to the sympathetic nervous system; and
- describe the enteric nervous system of the digestive tract and explain its significance.

The Sympathetic Division

The sympathetic division is also called the *thoracolumbar division* because it arises from the thoracic and lumbar regions of the spinal cord. It has relatively short

preganglionic and long postganglionic fibers. The preganglionic neurosomata are in the lateral horns and nearby regions of the gray matter of the spinal cord. Their fibers exit by way of spinal nerves T1 to L2 and lead to the nearby **sympathetic chain** of ganglia (**paravertebral³ ganglia**). This is a longitudinal series of ganglia that lie adjacent to both sides of the vertebral column from the cervical to the coccygeal level. They are interconnected by longitudinal nerve cords (figs. 15.3 and 15.4). The number of ganglia varies from person to person, but usually there are 3 cervical (*superior*, *middle*, and *inferior*), 11 thoracic, 4 lumbar, 4 sacral, and 1 coccygeal ganglion in each chain.

It may seem odd that sympathetic ganglia exist in the cervical, sacral, and coccygeal regions considering that sympathetic fibers arise only from the thoracic and lumbar regions of the spinal cord (levels T1 to L2). But as shown in figure 15.4, nerve cords from the thoracic region ascend to the ganglia in the neck, and cords from the lumbar region descend to the sacral and coccygeal ganglia. Consequently, sympathetic nerve fibers are distributed to every level of the body. As a general rule, the head receives sympathetic output arising from spinal cord segment T1, the neck from T2, the thorax and upper limbs from T3 to T6, the abdomen from T7 to T11, and the lower limbs from T12 to L2. There is considerable overlap and individual variation in this pattern, however.

In the thoracolumbar region, each paravertebral ganglion is connected to a spinal nerve by two branches

³para = next to + vertebr = vertebral column

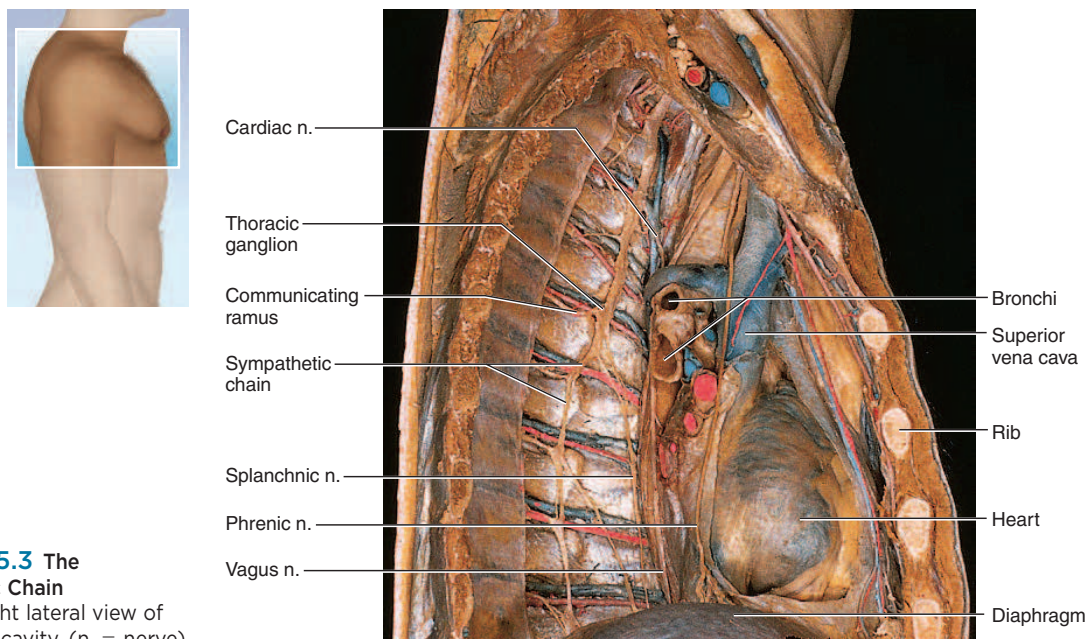

FIGURE 15.3 The Sympathetic Chain Ganglia. Right lateral view of the thoracic cavity. (n. = nerve)

FIGURE 15.4 Schematic of the Sympathetic Nervous System.

● Does the sympathetic innervation of the lungs make a person inhale and exhale?

called *communicating rami* (fig. 15.5). The preganglionic fibers are small myelinated fibers that travel from the spinal nerve to the ganglion by way of the **white communicating ramus**,⁴ which gets its color and name from the myelin. Unmyelinated postganglionic fibers leave the ganglion by way of the **gray communicating ramus**, named for its lack of myelin and duller color, and by other routes. This ramus forms a bridge back to the spinal nerve. Postganglionic fibers extend the rest of the way to the target organ.

Think About It

Would autonomic postganglionic fibers have faster or slower conduction speeds than somatic motor fibers? Why? (See hints in chapter 12.)

After entering the sympathetic chain, preganglionic fibers may follow any of three courses:

- Some end in the ganglion that they enter and synapse immediately with a postganglionic neuron.
- Some travel up or down the chain and synapse in ganglia at other levels. It is these fibers that link the paravertebral ganglia into a chain. They are the only route by which ganglia at the cervical, sacral, and coccygeal levels receive input.
- Some pass through the chain without synapsing and continue as *splanchnic* (SPLANK-nic) nerves, to be considered shortly.

Nerve fibers leave the sympathetic chain by three routes: spinal, sympathetic, and splanchnic nerves. These

⁴ramus = branch

FIGURE 15.5 Neural Pathways Through the Sympathetic Chain Ganglia. Sympathetic fibers can follow any of the three numbered routes: (1) the spinal nerve route, (2) the sympathetic nerve route, or (3) the splanchnic nerve route. The somatic efferent pathway is shown on the left for comparison.

• Name the parts of the spinal cord where the somas of the sympathetic and somatic efferent neurons are located.

are numbered in figure 15.5 to correspond to the following descriptions:

- ① **The spinal nerve route.** Some postganglionic fibers exit a ganglion by way of the gray ramus, return to the spinal nerve or its subdivisions, and travel the rest of the way to the target organ. This is the route to most sweat glands, piloerector muscles, and blood vessels of the skin and skeletal muscles.
- ② **The sympathetic nerve route.** Other postganglionic fibers leave by way of sympathetic nerves that extend to the heart, lungs, esophagus, and thoracic blood vessels. These nerves form a **carotid plexus** around each carotid artery of the neck and issue fibers from there to effectors in the head—including sweat, salivary, and nasal glands; piloerector muscles; blood vessels; and dilators of the iris. Some fibers from the superior and middle cervical ganglia form the *cardiac nerves* to the heart. (The cardiac nerves also contain parasympathetic fibers.)
- ③ **The splanchnic⁵ nerve route.** Some of the fibers that arise from spinal nerves T5 to T12 pass through the sympathetic ganglia without synapsing. Beyond the ganglia, they continue as **splanchnic nerves**, which lead to a second set of ganglia called **collateral (pre-vertebral) ganglia**. Here the preganglionic fibers synapse with the postganglionics.

The collateral ganglia contribute to a network called the **abdominal aortic plexus** wrapped around the aorta (fig. 15.6). There are three major collateral ganglia in this plexus—the **celiac**, **superior mesenteric**, and **inferior mesenteric ganglia**—located at points where arteries of the same names branch off the aorta. The postganglionic fibers accompany these arteries and their branches to the target organs. Table 15.2 summarizes the innervation to and from the three major collateral ganglia.

The term *solar plexus* is used by some authorities as a collective name for the celiac and superior mesenteric ganglia, and by others as a synonym for the celiac ganglion only. The term comes from the nerves radiating from the ganglion like rays of the sun.

In summary, effectors in the muscles and body wall are innervated mainly by sympathetic fibers in the spinal

nerves; effectors in the head and thoracic cavity by sympathetic nerves; and effectors in the abdominopelvic cavity by splanchnic nerves.

There is no simple one-to-one relationship between preganglionic and postganglionic neurons in the sympathetic division. For one thing, each postganglionic cell may receive synapses from multiple preganglionic cells, thus exhibiting the principle of *neural convergence* discussed in chapter 12. Furthermore, each preganglionic fiber branches and synapses with multiple postganglionic fibers, thus showing *neural divergence*. Most sympathetic preganglionic neurons synapse with 10 to 20 postganglionic neurons. This means that when one preganglionic neuron fires, it can excite multiple postganglionic fibers leading to different target organs. The sympathetic division thus tends to have relatively widespread effects—as suggested by the name *sympathetic*.⁶

The Adrenal Glands

The paired **adrenal⁷ (suprarenal) glands** rest like hats on the superior poles of the kidneys (fig. 15.6). Each adrenal is actually two glands with different functions and embryonic origins. The outer rind, the **adrenal cortex**, secretes steroid hormones discussed in chapter 17. The inner core, the **adrenal medulla**, is essentially a sympathetic ganglion. It consists of modified postganglionic neurons without dendrites or axons. Sympathetic preganglionic fibers penetrate through the cortex and terminate on these cells. The sympathetic nervous system and adrenal medulla are so closely related in development and function that they are referred to collectively as the *sympathoadrenal system*.

When stimulated, the adrenal medulla secretes a mixture of hormones into the bloodstream—about 85% epinephrine (adrenaline), 15% norepinephrine (noradrenaline), and a trace of dopamine. These hormones, the *catecholamines*, were briefly considered in chapter 12 because they also function as neurotransmitters.

The Parasympathetic Division

The parasympathetic division is also called the *craniosacral division* because it arises from the brain and sacral region of the spinal cord; its fibers travel in certain cranial

⁵splanchn = viscera

⁶sym = together + path = feeling

⁷ad = near + ren = kidney

TABLE 15.2 Innervation to and from the Collateral Ganglia

Sympathetic Ganglia	→	Collateral Ganglia	→	Postganglionic Target Organs
Thoracic ganglion 5 to 9 or 10	→	Celiac ganglion	→	Stomach, spleen, liver, small intestine, and kidneys
Thoracic ganglia 9 to 12	→	Celiac and superior mesenteric ganglia	→	Small intestine, colon, and kidneys
Lumbar ganglia	→	Inferior mesenteric ganglion	→	Rectum, urinary bladder, and reproductive organs

FIGURE 15.6 Abdominopelvic Components of the Sympathetic Nervous System. (a) Collateral ganglia, abdominal aortic plexus, and adrenal glands. (b) The adrenal gland, frontal section. Only the adrenal medulla plays a role in the sympathetic nervous system; the adrenal cortex has unrelated roles described in chapter 17.

and sacral nerves. Somas of the preganglionic neurons are located in the midbrain, pons, medulla oblongata, and segments S2 to S4 of the spinal cord (fig. 15.7). They issue long preganglionic fibers that end in **terminal ganglia** in or near the target organ (see fig. 15.1). (If a terminal ganglion is embedded within the wall of a target organ, it is also called an *intramural*⁸ *ganglion*.) Thus, the parasympathetic division has long preganglionic fibers, reaching almost all the way to the target cells, and short postganglionic fibers that cover the rest of the distance.

There is some neural divergence in the parasympathetic division, but much less than in the sympathetic. The parasympathetic division has a ratio of fewer than

five postganglionic fibers to every preganglionic fiber. Furthermore, the preganglionic fiber reaches the target organ before even this slight divergence occurs. The parasympathetic division is therefore relatively selective in its stimulation of target organs.

Parasympathetic fibers leave the brainstem by way of the following four cranial nerves. The first three supply all parasympathetic innervation to the head, and the last one supplies viscera of the thoracic and abdominopelvic cavities.

1. **Oculomotor nerve (III).** The oculomotor nerve carries parasympathetic fibers that control the lens and pupil of the eye. The preganglionic fibers enter the orbit and terminate in the *ciliary ganglion* behind the

⁸*intra* = within + *mur* = wall

FIGURE 15.7 Schematic of the Parasympathetic Nervous System.

• Which nerve carries the most parasympathetic nerve fibers?

eyeball. Postganglionic fibers enter the eyeball and innervate the *ciliary muscle*, which thickens the lens, and the *pupillary constrictor*, which narrows the pupil.

2. **Facial nerve (VII).** The facial nerve carries parasympathetic fibers that regulate the tear glands, salivary glands, and nasal glands. Soon after the facial nerve emerges from the pons, its parasympathetic fibers split away and form two smaller branches. The upper branch ends at the *pterygopalatine ganglion* near the junction of the maxilla and palatine bone. Postganglionic fibers then continue to the tear glands and glands of the nasal cavity, palate, and other areas of the oral cavity. The lower branch crosses the middle-ear cavity and ends at the *submandibular ganglion* near the angle of the mandible. Postganglionic fibers from here supply salivary glands in the floor of the mouth.
3. **Glossopharyngeal nerve (IX).** The glossopharyngeal nerve carries parasympathetic fibers concerned with salivation. The preganglionic fibers leave this nerve soon after its origin and form the *tympanic nerve*. A continuation of this nerve crosses the middle-ear cavity and ends in the *otic⁹ ganglion* near the foramen ovale. The postganglionic fibers then follow the trigeminal nerve to the *parotid salivary gland* just in front of the earlobe.
4. **Vagus nerve (X).** The vagus nerve carries about 90% of all parasympathetic preganglionic fibers. It travels down the neck and forms three networks in the mediastinum of the chest—the **cardiac plexus**, which supplies fibers to the heart; the **pulmonary plexus**, whose fibers accompany the bronchi and blood vessels into the lungs; and the **esophageal plexus**, whose fibers regulate swallowing.

At the lower end of the esophagus, these plexuses give off anterior and posterior **vagal trunks**, each of which contains fibers from both the right and left vagus nerves. These trunks penetrate the diaphragm, enter the abdominal cavity, and contribute to the extensive *abdominal*

aortic plexus mentioned earlier. As we have seen, sympathetic fibers synapse here. The parasympathetic fibers, however, pass through the plexus without synapsing. They synapse farther along, in terminal ganglia in or near the liver, pancreas, stomach, small intestine, kidney, ureter, and proximal half of the colon.

The remaining parasympathetic fibers arise from levels S2 to S4 of the spinal cord. They travel a short distance in the anterior rami of the spinal nerves and then form **pelvic splanchnic nerves** that lead to the **inferior hypogastric plexus**. Some parasympathetic fibers synapse here, but most pass through this plexus and travel by way of **pelvic nerves** to the terminal ganglia in their target organs: the distal half of the colon, the rectum, urinary bladder, and reproductive organs. With few exceptions, the parasympathetic system does not innervate body wall structures (sweat glands, piloerector muscles, or cutaneous blood vessels).

The sympathetic and parasympathetic divisions of the ANS are compared in table 15.3.

Think About It

Would autonomic functions be affected if the anterior roots of the cervical spinal nerves were damaged? Why or why not?

The Enteric Nervous System

The digestive tract has a nervous system of its own called the **enteric¹⁰ nervous system**. Unlike the ANS proper, it does not arise from the brainstem or spinal cord, but like the ANS, it innervates smooth muscle and glands. Thus, opinions differ on whether it should be considered part of the ANS. It consists of about 100 million neurons embedded in the wall of the digestive tract (see photograph on p. 565)—perhaps more neurons than there are in the spinal cord—and it has its own reflex arcs. The enteric nervous system regulates the motility of the esophagus, stomach, and intestines and the secretion of digestive enzymes and acid. To function normally, however, these digestive activities also require regulation by the sympathetic and parasympathetic systems. The enteric

TABLE 15.3 Comparison of the Sympathetic and Parasympathetic Divisions

Feature	Sympathetic	Parasympathetic
Origin in CNS	Thoracolumbar	Craniosacral
Location of ganglia	Paravertebral ganglia adjacent to spinal column and prevertebral ganglia anterior to it	Terminal ganglia near or within target organs
Fiber lengths	Short preganglionic Long postganglionic	Long preganglionic Short postganglionic
Neural divergence	Extensive	Minimal
Effects of system	Often widespread and general	More specific and local

INSIGHT 15.1 Clinical Application

Megacolon

The importance of the enteric nervous system becomes vividly clear when it is absent. Such is the case in a hereditary defect called *Hirschsprung disease*.¹¹ During normal embryonic development, neural crest cells migrate to the large intestine and establish the enteric nervous system. In Hirschsprung disease, however, they fail to supply the distal parts of the large intestine, leaving the sigmoid colon and rectum (see fig. 25.31, p. 1003) without enteric ganglia. In the absence of these ganglia, the sigmoidorectal region lacks motility, constricts permanently, and will not allow feces to pass. Feces accumulate and become impacted above the constriction, resulting in *megacolon*—a massive dilation of the bowel accompanied by abdominal distension and chronic constipation. The most life-threatening complications are colonic gangrene, perforation of the bowel, and bacterial infection of the peritoneum (*peritonitis*). The treatment of choice is surgical removal of the affected segment and attachment of the healthy colon directly to the anal canal.

Hirschsprung disease is usually evident even in the newborn, which fails to have its first bowel movement. It affects four times as many infant boys as girls, and although its incidence in the general population is about 1 in 5,000 live births, it occurs in about 1 out of 10 infants with Down syndrome.

Hirschsprung disease is not the only cause of megacolon. In Central and South America, biting insects called *kissing bugs* transmit parasites called *trypanosomes* to humans. These parasites, similar to the ones that cause African sleeping sickness, cause *Chagas*¹² disease. Among other effects, they destroy the autonomic ganglia of the enteric nervous system, leading to a massively enlarged and often gangrenous colon.

nervous system is discussed in more detail in chapter 25. Its importance in intestinal motility becomes dramatically apparent when the system is absent (see Insight 15.1).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

3. Explain why the sympathetic division is also called the thoracolumbar division even though its paravertebral ganglia extend all the way from the cervical to the sacral region.
4. Describe or diagram the structural relationships among the following: preganglionic fiber, postganglionic fiber, gray ramus, white ramus, and sympathetic ganglion.
5. Explain in anatomical terms why the parasympathetic division affects target organs more selectively than the sympathetic division does.
6. Trace the pathway of a parasympathetic fiber of the vagus nerve from the medulla oblongata to the small intestine.

¹²Carlos Chagas (1879–1934), Brazilian physician

15.3 Autonomic Effects on Target Organs

Objectives

When you have completed this section, you should be able to

- name the neurotransmitters employed at different synapses of the ANS;
- name the receptors for these neurotransmitters and explain how they relate to autonomic effects;
- explain how the ANS controls many target organs through dual innervation; and
- explain how control is exerted in the absence of dual innervation.

Neurotransmitters and Their Receptors

As noted earlier, the divisions of the ANS often have contrasting effects on an organ. The sympathetic division accelerates the heartbeat and the parasympathetic division slows it down, for example. But each division of the ANS also can have contrasting effects on different organs. For example, the parasympathetic division contracts the wall of the urinary bladder but relaxes the internal urethral sphincter; both actions are necessary for the expulsion of urine. It employs acetylcholine for both purposes. Similarly, the sympathetic division constricts most blood vessels but dilates the coronary arteries, and it achieves both effects with norepinephrine.

How can different autonomic neurons have such contrasting effects? There are two fundamental reasons: (1) sympathetic and parasympathetic fibers secrete different neurotransmitters, and (2) target cells respond in different ways even to the same neurotransmitter depending on what type of receptors they have for it. All autonomic nerve fibers secrete either acetylcholine or norepinephrine, and each of these neurotransmitters has two major classes of receptors (fig. 15.8).

- **Acetylcholine (ACh).** ACh is secreted by the preganglionic neurons in both divisions and the postganglionic neurons of the parasympathetic division (table 15.4). A few sympathetic postganglionics also secrete ACh—those that innervate sweat glands and some blood vessels. Any nerve fiber that secretes ACh is called a **cholinergic** (CO-li-NUR-jic) **fiber**, and any receptor that binds it is called a **cholinergic receptor**. There are two categories of cholinergic receptors:
 - **Muscarinic** (MUSS-cuh-RIN-ic) **receptors**. These are named for muscarine, a mushroom toxin

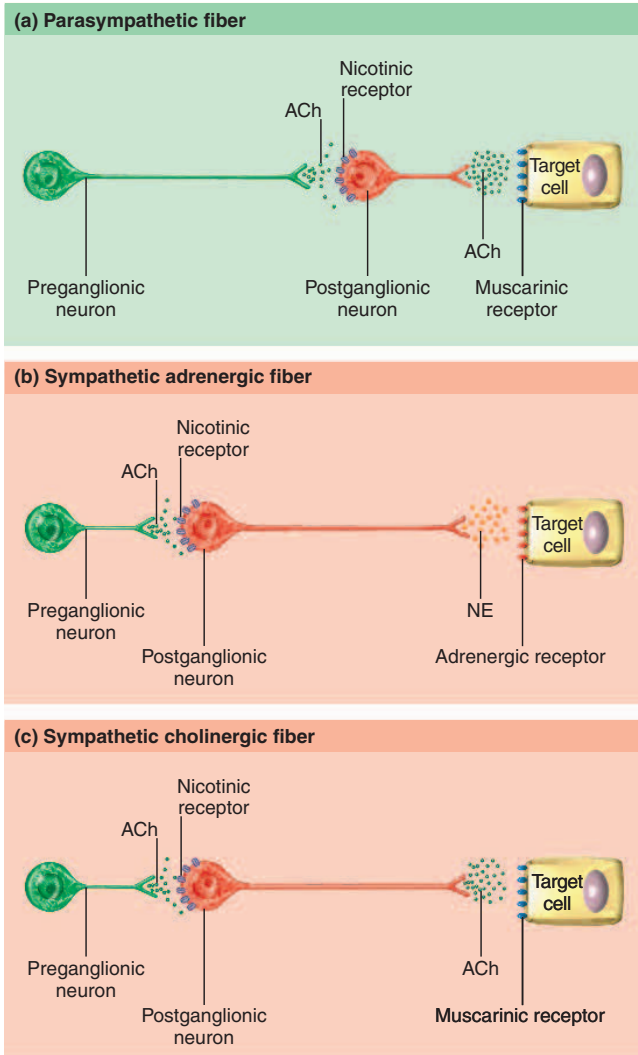

FIGURE 15.8 Neurotransmitters and Receptors of the Autonomic Nervous System. (a) All parasympathetic fibers are cholinergic. (b) Most sympathetic postganglionic fibers are adrenergic; they secrete norepinephrine (NE), and the target cell bears adrenergic receptors. (c) A few sympathetic postganglionic fibers are cholinergic; they secrete acetylcholine (ACh), and the target cell has cholinergic receptors of the muscarinic class.

TABLE 15.4		Locations of Cholinergic and Adrenergic Fibers in the ANS	
Division	Preganglionic Fibers	Postganglionic Fibers	
Sympathetic	Always cholinergic	Mostly adrenergic; a few cholinergic	
Parasympathetic	Always cholinergic	Always cholinergic	

used in their discovery. All cardiac muscle, smooth muscle, and gland cells that receive cholinergic innervation have muscarinic receptors. There are different subclasses of muscarinic receptors with different effects; thus ACh excites intestinal smooth muscle by binding to one type of muscarinic receptor, and inhibits cardiac muscle by binding to a different type. Muscarinic receptors work through a variety of second-messenger systems.

- Nicotinic (NIC-oh-TIN-ic) receptors.** These are named for another botanical toxin helpful to their discovery—nicotine. They occur at all synapses in the autonomic ganglia, where the preganglionic neurons stimulate the postganglionic cells; on cells of the adrenal medulla; and at the neuromuscular junctions of skeletal muscle fibers. The binding of ACh to a nicotinic receptor is always excitatory. Nicotinic receptors work by opening ligand-gated ion channels and producing an excitatory postsynaptic potential in the target cell.
- Norepinephrine (NE).** This neurotransmitter is secreted by nearly all sympathetic postganglionic neurons (table 15.4). Nerve fibers that secrete it are called **adrenergic fibers**, and the receptors for it are called **adrenergic receptors**. (NE is also called noradrenaline, the origin of the term *adrenergic*.) There are two principal categories of NE receptors:
 - α -adrenergic receptors.** These usually have excitatory effects. For example, the binding of NE to α -adrenergic receptors promotes labor contractions, stimulates piloerection, and constricts dermal blood vessels, yet it inhibits intestinal motility. These contrasting effects result from the different actions of two subclasses of α -adrenergic receptors— α_1 and α_2 . Receptors of the α_1 type act by suppressing the synthesis of cyclic AMP (cAMP), whereas α_2 receptors employ calcium ions as a second messenger.
 - β -adrenergic receptors.** These are usually inhibitory. For example, NE relaxes and dilates the bronchioles (thus enhancing respiratory airflow) when it binds to β -adrenergic receptors of the smooth muscle. Yet when it binds to the β -adrenergic receptors of cardiac muscle, it has an excitatory effect. Such contrasting effects—increased pulmonary airflow and a stronger, faster heartbeat—are obviously appropriate to a state of exercise. Here again there are two receptor subclasses, β_1 and β_2 , which mediate different effects. Both types, however, act through cAMP as a second messenger.

Table 15.5 summarizes the effects of sympathetic and parasympathetic stimulation on different target organs

TABLE 15.5 Effects of the Sympathetic and Parasympathetic Nervous Systems

Target	Sympathetic Effect and Receptor Type	Parasympathetic Effect (all muscarinic)
Eye		
Iris	Pupillary dilation (α)	Pupillary constriction
Ciliary muscle and lens	Relaxation for far vision (β)	Contraction for near vision
Lacrimal (tear) gland	None	Secretion
Integumentary system		
Merocrine sweat glands (cooling)	Secretion (muscarinic)	No effect
Apocrine sweat glands (scent)	Secretion (α)	No effect
Piloerector muscles	Hair erection (α)	No effect
Adipose tissue		
	Decreased fat breakdown (α)	No effect
	Increased fat breakdown (α , β)	
Adrenal medulla		
	Hormone secretion (nicotinic)	No effect
Circulatory system		
Heart rate and force	Increased (β)	Decreased
Deep coronary arteries	Vasodilation (β) Vasoconstriction (α)	Slight vasodilation
Blood vessels of most viscera	Vasoconstriction (α)	Vasodilation
Blood vessels of skeletal muscles	Vasodilation (β)	No effect
Blood vessels of skin	Vasoconstriction (α)	Vasodilation, blushing
Platelets (blood clotting)	Increased clotting (α)	No effect
Respiratory system		
Bronchi and bronchioles	Bronchodilation (β)	Bronchoconstriction
Mucous glands	Decreased secretion (α) Increased secretion (β)	No effect
Urinary system		
Kidneys	Reduced urine output (α)	No effect
Bladder wall	No effect	Contraction
Internal urinary sphincter	Contraction, urine retention (α)	Relaxation, urine release
Digestive system		
Salivary glands	Thick mucous secretion (α)	Thin serous secretion
Gastrointestinal motility	Decreased (α , β)	Increased
Gastrointestinal secretion	Decreased (α)	Increased
Liver	Glycogen breakdown (α , β)	Glycogen synthesis
Pancreatic enzyme secretion	Decreased (α)	Increased
Pancreatic insulin secretion	Decreased (α) Increased (β)	No effect
Reproductive system		
Penile or clitoral erection	No effect	Stimulation
Glandular secretion	No effect	Stimulation
Orgasm, smooth muscle roles	Stimulation (α)	No effect
Uterus	Relaxation (β) Labor contractions (α)	No effect

and shows how some of these effects hinge on the receptor type. Knowledge of these receptor types is also vital to the field of neuropharmacology (see Insight 15.2). Many naturally occurring drugs bind selectively to one or another class or subclass of receptor. Atropine binds only to muscarinic receptors and curare only to nicotinic receptors, for example. Many synthetic drugs are designed to be similarly selective.

The autonomic effects on glandular secretion are often an indirect result of their effect on the blood vessels. Many glandular secretions begin as a filtrate of the blood, which is then modified by the gland cells. Increasing the blood flow through a gland (such as a salivary or sweat gland) tends to increase secretion, and reducing the blood flow reduces secretion.

Sympathetic effects tend to last longer than parasympathetic effects. After a parasympathetic fiber secretes ACh into a synapse, it is quickly broken down by acetylcholinesterase (AChE) and its effect lasts only a few seconds. The NE released by a sympathetic fiber, however, has various fates: (1) Some is reabsorbed by the nerve fiber, where it is either reused or broken down by an enzyme called *monoamine oxidase (MAO)*. (2) Some diffuses into the adjacent tissues, where it is degraded by another enzyme, *catechol-O-methyltransferase (COMT)*. (3) Much of it passes into the bloodstream, where MAO and COMT are absent. This NE, along with epinephrine from the adrenal gland, circulates throughout the body and has a prolonged effect.

ACh and NE are not the only neurotransmitters employed by the ANS. Although all autonomic fibers secrete one of these, many of them also secrete neuropeptides that modulate ACh or NE function. Sympathetic fibers may also secrete enkephalin, substance P, neuropeptide Y, somatostatin, neurotensin, or gonadotropin-releasing hormone. Some parasympathetic fibers relax blood vessels by stimulating the endothelial cells to release the gas nitric oxide (NO). NO inhibits smooth muscle tone in the vessel wall, thus allowing the vessel to dilate. This increases the blood flow through the vessel. Among other functions, this mechanism is crucial to penile erection (see Insight 27.4, p. 1070).

Think About It

Table 15.5 notes that the sympathetic nervous system has an α -adrenergic effect on blood platelets and promotes clotting. How can the sympathetic nervous system stimulate platelets, considering that platelets are drifting cell fragments in the bloodstream with no nerve fibers leading to them?

Dual Innervation

Most of the viscera receive nerve fibers from both the sympathetic and parasympathetic divisions and thus are said to have **dual innervation**. In such cases, the two

divisions may have either *antagonistic* or *cooperative* effects on the same organ.

Antagonistic effects oppose each other. For example, the sympathetic division speeds up the heart and the parasympathetic division slows it down; the sympathetic division inhibits digestion and the parasympathetic division stimulates it; the sympathetic division dilates the pupil and the parasympathetic division constricts it. In some cases, these effects are exerted through dual innervation of the same effector cells, as in the heart, where nerve fibers of both divisions terminate on the same muscle cells. In other cases, antagonistic effects arise because each division innervates different effector cells with opposite effects on organ function. In the iris of the eye, for example, sympathetic fibers innervate the pupillary dilator and parasympathetic fibers innervate the constrictor (fig. 15.9).

FIGURE 15.9 Dual Innervation of the Iris. Shows antagonistic effects of the sympathetic (yellow) and parasympathetic (blue) divisions on the iris.

❖ If a person is in a state of fear, would you expect the pupils to be dilated or constricted? Why?

Cooperative effects are seen when the two divisions act on different effectors to produce a unified overall effect. Salivation is a good example. The parasympathetic division stimulates serous cells of the salivary glands to secrete a watery, enzyme-rich secretion, while the sympathetic division stimulates mucous cells of the same glands to secrete mucus. The enzymes and mucus are both necessary components of the saliva.

Even when both divisions innervate a single organ, they do not always innervate it equally or exert equal influence. For example, the parasympathetic division forms an extensive plexus in the wall of the digestive tract and exerts much more influence over it than the sympathetic division does. In the ventricles of the heart, by contrast, there is much less parasympathetic than sympathetic innervation.

Control Without Dual Innervation

Dual innervation is not always necessary for the ANS to produce opposite effects on an organ. The adrenal medulla, piloerector muscles, sweat glands, and many blood vessels receive only sympathetic fibers. The most significant example of control without dual innervation is regulation of blood pressure and routes of blood flow. The sympathetic fibers to a blood vessel have a baseline sympathetic tone, which keeps the vessels in a state of partial constriction called **vasomotor tone** (fig. 15.10). An increase in firing rate constricts a vessel by increasing smooth muscle contraction. A drop in firing frequency dilates a vessel by allowing the smooth muscle to relax. The blood pressure in the vessel, pushing outward on its wall, then dilates the vessel. Thus, the sympathetic division alone exerts opposite effects on the vessels.

Sympathetic control of vasomotor tone can shift blood flow from one organ to another according to the changing needs of the body. In times of emergency, stress, or exercise, the skeletal muscles and heart receive a high priority and the sympathetic division dilates the arteries that supply them. Such processes as digestion, nutrient absorption, and urine formation can wait; thus the sympathetic division constricts arteries to the gastrointestinal tract and kidneys. It also reduces blood flow through the skin, which may help to minimize bleeding in the event that the stress-producing situation leads to injury. Furthermore, since there is not enough blood in the body to supply all the organ systems equally, it is necessary to temporarily divert blood away from some organs in order to supply an adequate amount to the muscular system.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. What neurotransmitters are secreted by adrenergic and cholinergic fibers?

(a) Vasoconstriction

(b) Vasodilation

FIGURE 15.10 Sympathetic and Vasomotor Tone. (a) Vasoconstriction in response to a high rate of sympathetic nerve firing. (b) Vasodilation in response to a low rate of sympathetic nerve firing. Smooth muscle relaxation allows blood pressure within the vessel to push the vessel wall outward. Black lines crossing each nerve fiber represent action potentials, with a high firing frequency in part (a) and a lower frequency in part (b).

8. Why do sympathetic effects last longer than parasympathetic effects?
9. How can the sympathetic division cause smooth muscle to relax in some organs but contract in others?
10. What are the two ways in which the sympathetic and parasympathetic systems can affect each other when they both innervate the same target organ? Give examples.
11. How can the sympathetic nervous system have contrasting effects in a target organ without dual innervation?

15.4 Central Control of Autonomic Function

Objective

When you have completed this section, you should be able to

- describe how the autonomic nervous system is regulated by the brain and somatic nervous system.

In spite of its name, the ANS is not an independent nervous system. All of its output originates in the CNS, and it receives input from the cerebral cortex, hypothalamus, medulla oblongata, and somatic branch of the peripheral nervous system. In this section we briefly consider how the ANS is influenced by these other levels of the nervous system.

The Cerebral Cortex

Even if we usually cannot consciously control the ANS, it is clear that the mind does influence it. Anger raises the blood pressure, fear makes the heart race, thoughts of good food make the stomach rumble, sexual thoughts or images increase blood flow to the genitals, and anxiety inhibits sexual function. The limbic system (p. 536), an ancient part of the cerebral cortex, is involved in many emotional responses and has extensive connections with the hypothalamus, a site of several nuclei of autonomic control. Thus, the limbic system provides a pathway connecting sensory and mental experiences with the autonomic nervous system.

The Hypothalamus

Although the major site of CNS control over the somatic motor system is the primary motor cortex, the major control center of the visceral motor system is the hypothalamus. This small but vital region in the floor of the brain contains many nuclei for primitive functions, including hunger, thirst, thermoregulation, emotions, and sexuality. Artificial stimulation of different regions of the hypothalamus can activate the fight or flight response typical

of the sympathetic nervous system or have the calming effects typical of the parasympathetic. Output from the hypothalamus travels largely to nuclei in more caudal regions of the brainstem, and from there to the cranial nerves and the sympathetic neurons in the spinal cord.

The Midbrain, Pons, and Medulla Oblongata

These regions of the brainstem house numerous autonomic nuclei described in chapter 14: centers for cardiac and vaso-motor control, salivation, swallowing, sweating, gastrointestinal secretion, bladder control, pupillary constriction and dilation, and other primitive functions. Many of these nuclei belong to the reticular formation, which extends from the medulla to the hypothalamus. Autonomic output from these nuclei travels by way of the spinal cord and the oculomotor, facial, glossopharyngeal, and vagus nerves.

The Spinal Cord

Such autonomic reflexes as micturition (urination), defecation, erection, and ejaculation are integrated in the spinal cord (see details in chapters 23, 25, and 27). Fortunately, the brain is able to inhibit defecation and urination consciously, but when injuries sever the spinal cord from the brain, the autonomic spinal reflexes alone control the elimination of urine and feces.

Table 15.6 describes some dysfunctions of the autonomic nervous system.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- What system in the brain connects our conscious thoughts and feelings with the autonomic control centers of the hypothalamus?
- List some autonomic responses that are controlled by nuclei in the hypothalamus.
- What is the role of the midbrain, pons, and medulla in autonomic control?
- Name some visceral reflexes controlled by the spinal cord.

TABLE 15.6

Some Disorders of the Autonomic Nervous System

Horner syndrome	Chronic unilateral pupillary constriction, sagging of the eyelid, withdrawal of the eye into the orbit, flushing of the skin, and lack of facial perspiration, resulting from lesions in the cervical ganglia, upper thoracic spinal cord, or brainstem that interrupt sympathetic innervation of the head.
Raynaud disease	Intermittent attacks of paleness, cyanosis, and pain in the fingers and toes, caused when cold or emotional stress triggers excessive vasoconstriction in the digits; most common in young women. In extreme cases, causes gangrene and may require amputation. Sometimes treated by severing sympathetic nerves to the affected regions.

Disorders described elsewhere

Autonomic effects of cranial nerve injuries pp. 551–558
 Mass reflex reaction p. 510
 Orthostatic hypotension p. 806

INSIGHT 15.2 Clinical Application

Drugs and the Nervous System

Neuropharmacology is a branch of medicine that deals with the effects of drugs on the nervous system, especially drugs that mimic, enhance, or inhibit the action of neurotransmitters. A few examples will illustrate the clinical relevance of neurotransmitter and receptor functions.

A number of drugs work by stimulating adrenergic and cholinergic neurons or receptors. *Sympathomimetics*¹³ are drugs that enhance sympathetic action. They stimulate adrenergic receptors or promote norepinephrine release. For example, phenylephrine, found in such cold medicines as Chlor-Trimeton and Dimetapp, aids breathing by stimulating alpha receptors, dilating the bronchioles, and constricting nasal blood vessels, thus reducing swelling in the nasal mucosa. *Sympatholytics*¹⁴ are drugs that suppress sympathetic action by inhibiting norepinephrine release or by binding to adrenergic receptors without stimulating them. Propranolol, for example, is a *beta-blocker*. It reduces hypertension partly by blocking β -adrenergic receptors. This interferes with the effects of epinephrine and norepinephrine on the heart and blood vessels. (It also reduces the production of *angiotensin II*, a hormone that stimulates vasoconstriction and raises blood pressure.)

Parasympathomimetics enhance parasympathetic effects. Pilocarpine, for example, relieves glaucoma (excessive pressure in the eyeball) by dilating a vessel that drains fluid from the eye. *Parasympatholytics* inhibit ACh release or block its receptors. Atropine, for example, blocks muscarinic receptors. It is sometimes used to dilate the pupils for eye examinations and to dry the mucous membranes of the respiratory tract before inhalation anesthesia. It is an extract of the deadly nightshade plant, *Atropa belladonna*.¹⁵ Women of the Middle Ages used nightshade to dilate their pupils, which was regarded as a beauty enhancement.

The drugs we have mentioned so far act on the peripheral nervous system and its effectors. Many others act on the central nervous system. Strychnine, for example, blocks the inhibitory action of glycine on spinal motor neurons. The neurons then overstimulate the muscles, causing spastic paralysis and sometimes death by suffocation.

Sigmund Freud predicted that psychiatry would eventually draw upon biology and chemistry to deal with emotional problems once treated only by counseling and psychoanalysis. A branch of neuropharmacology called *psychopharmacology* has fulfilled his prediction. This field dates to the 1950s when chlorpromazine, an antihistamine, was accidentally found to relieve the symptoms of schizophrenia.

The management of clinical depression is one example of how contemporary psychopharmacology has supplemented counseling approaches. Some forms of depression result from deficiencies of the monoamine neurotransmitters. Thus, they yield to drugs that prolong the effects of the monoamines already present at the synapses. One of the earliest discovered antidepressants was imipramine, which blocks the synaptic reuptake of serotonin and norepinephrine. However, it produces undesirable side effects such as dry mouth and irregular cardiac rhythms. It has been largely replaced by Prozac (fluoxetine), which blocks serotonin reuptake and prolongs its mood-elevating effect; thus Prozac is called a *selective serotonin reuptake inhibitor (SSRI)*. It is also used to treat

fear of rejection, excess sensitivity to criticism, lack of self-esteem, and inability to experience pleasure, all of which were long handled only through counseling, group therapy, or psychoanalysis. After monoamines are taken up from the synapse, they are degraded by monoamine oxidase (MAO). Drugs called *MAO inhibitors* interfere with the breakdown of monoamine neurotransmitters and provide another pharmacological approach to depression.

Our growing understanding of neurochemistry also gives us deeper insight into the action of addictive drugs of abuse such as amphetamines and cocaine. Amphetamines ("speed") chemically resemble norepinephrine and dopamine, two neurotransmitters associated with elevated mood. Dopamine is especially important in sensations of pleasure. Cocaine blocks dopamine reuptake and thus produces a brief rush of good feelings. But when dopamine is not reabsorbed by the neurons, it diffuses out of the synaptic cleft and is degraded elsewhere. Cocaine thus depletes the neurons of dopamine faster than they can synthesize it, so that finally there is no longer an adequate supply to maintain normal mood. The postsynaptic neurons make new dopamine receptors as if "searching" for the neurotransmitter—all of which leads ultimately to anxiety, depression, and the inability to experience pleasure without the drug.

Caffeine exerts its stimulatory effect by competing with adenosine. Adenosine, which you know as a component of DNA, RNA, and ATP, also functions as a neuromodulator in the brain, inhibiting ACh release by cholinergic neurons. One theory of sleepiness is that it results when prolonged metabolic activity breaks down so much ATP that the accumulated adenosine has a noticeably inhibitory effect. Caffeine has enough structural similarity to adenosine (fig. 15.11) to bind to its receptors, but it does not produce the inhibitory effect. Thus, it prevents adenosine from exerting its effect, more ACh is secreted, and a person feels more alert.

FIGURE 15.11 Adenosine and Caffeine. Adenosine is an inhibitory neuromodulator that inhibits ACh release and produces a sense of sleepiness. Caffeine is similar enough in structure to bind to adenosine receptors and block the action of adenosine. This results in increased ACh release and heightened arousal.

¹³mimet = imitate, mimic

¹⁴lyt = break down, destroy

¹⁵bella = beautiful, fine + donna = woman

CHAPTER REVIEW

Review of Key Concepts

15.1 General Properties of the Autonomic Nervous System (p. 566)

- The autonomic nervous system (ANS) carries out many visceral reflexes that are crucial to homeostasis. It is a visceral motor system that acts on cardiac muscle, smooth muscle, and glands.
- Functions of the ANS are largely, but not entirely, unconscious and involuntary.
- The *sympathetic division* of the ANS prepares the body for physical activity and is especially active in stressful “fight or flight” situations.
- The *parasympathetic division* has a calming effect on many body functions, but stimulates digestion; it is especially active in “resting and digesting” states.
- Although the balance of activity may shift from one division to the other, both divisions are normally active simultaneously. Each maintains a background level of activity called *autonomic tone*.
- The ANS is composed of nuclei in the brainstem, motor neurons in the spinal cord and ganglia, and nerve fibers in the cranial and spinal nerves.
- Most autonomic efferent pathways, unlike somatic motor pathways, involve two neurons. A *preganglionic neuron* issues an axon to a peripheral ganglion; it synapses there with a *postganglionic neuron*, whose axon leads the rest of the way to the target cells.
- Sympathetic pathways show substantial neural divergence, with the average preganglionic neuron synapsing with 10 to 20 postganglionic neurons. Sympathetic stimulation therefore tends to have widespread effects on multiple target organs.
- Postganglionic fibers leave the sympathetic chain by way of either the spinal nerve route or the sympathetic nerve route. Preganglionic fibers that pass through the chain without synapsing travel by way of *splanchnic nerves* to various *collateral ganglia*, and synapse there with postganglionic neurons.
- The *adrenal medulla* is a modified sympathetic ganglion composed of anaxonic neurons. These cells secrete mainly epinephrine and norepinephrine into the blood when stimulated.
- The parasympathetic division issues relatively long preganglionic fibers through cranial nerves III, VII, IX, and X, and spinal nerves S2 through S4, to their target organs. The vagus nerve carries about 90% of all parasympathetic preganglionic fibers.
- Parasympathetic preganglionic fibers end in *terminal ganglia* in or near the target organ. Relatively short postganglionic fibers complete the route to specific target cells.
- The wall of the digestive tract contains an *enteric nervous system*, sometimes considered part of the ANS because it innervates smooth muscle and glands of the tract.
- ACh binds to two classes of receptors called *nicotinic* and *muscarinic* receptors. The binding of ACh to a nicotinic receptor always excites a target cell, but binding to a muscarinic receptor can have excitatory effects on some cells and inhibitory effects on others, owing to different subclasses of muscarinic receptors.
- NE binds to two major classes of receptors called alpha and beta receptors. Binding to an α -adrenergic receptor is usually excitatory, and binding to a β -adrenergic receptor is usually inhibitory, but there are exceptions to both owing to subclasses of each receptor type.
- ACh breaks down quickly, and parasympathetic effects are therefore usually short-lived. NE persists longer, and sympathetic effects tend to be longer-lasting.
- Autonomic neurons also employ a broad range of other neurotransmitters and neuromodulators ranging from the peptide enkephalin to the inorganic gas nitric oxide.
- Many organs receive *dual innervation* by both sympathetic and parasympathetic fibers. In such cases, the two divisions may have either antagonistic or cooperative effects on the organ.
- The sympathetic division can have contrasting effects on an organ even without dual innervation, by increasing or decreasing the firing rate of the sympathetic neuron.

15.2 Anatomy of the Autonomic Nervous System (p. 569)

- Sympathetic preganglionic neurons arise from thoracic and lumbar segments of the spinal cord and travel through spinal nerves T1 through L2 to a *sympathetic chain* of ganglia adjacent to the vertebral column.
- Most preganglionic fibers synapse with postganglionic neurons in one of the ganglia of this chain, sometimes at a higher or lower level than the ganglion at which they enter. Some fibers pass through the chain without synapsing.

15.3 Autonomic Effects on Target Organs (p. 576)

- The autonomic effect on a target cell depends on the neurotransmitter released and the type of receptors that the target cell has.
- Cholinergic* fibers secrete acetylcholine (ACh) and include all preganglionic fibers, all parasympathetic postganglionic fibers, and some sympathetic postganglionic fibers. Most sympathetic postganglionic fibers are *adrenergic* and secrete norepinephrine (NE).

15.4 Central Control of Autonomic Function (p. 581)

- All autonomic output originates in the CNS and is subject to control by multiple levels of the CNS.
- The hypothalamus is an especially important center of autonomic control, but the cerebral cortex, midbrain, pons, and medulla oblongata are also involved.
- Some autonomic reflexes such as defecation and micturition are regulated by the spinal cord.

Testing Your Recall

- The autonomic nervous system innervates all of these *except*
 - cardiac muscle.
 - skeletal muscle.
 - smooth muscle.
 - salivary glands.
 - blood vessels.
- Muscarinic receptors bind
 - epinephrine.
 - norepinephrine.
 - acetylcholine.
 - cholinesterase.
 - neuropeptides.
- All of the following cranial nerves except the ____ carry parasympathetic fibers.
 - vagus
 - facial
 - oculomotor
 - glossopharyngeal
 - hypoglossal
- Which of the following cranial nerves carries sympathetic fibers?
 - oculomotor
 - facial
 - trigeminal
 - vagus
 - none of them
- Which of these ganglia is *not* involved in the sympathetic division?
 - intramural
 - superior cervical
 - paravertebral
 - inferior mesenteric
 - celiac
- Epinephrine is secreted by
 - sympathetic preganglionic fibers.
 - sympathetic postganglionic fibers.
 - parasympathetic preganglionic fibers.
 - parasympathetic postganglionic fibers.
 - the adrenal medulla.
- The most significant autonomic control center within the CNS is
 - the cerebral cortex.
 - the limbic system.
 - the midbrain.
 - the hypothalamus.
 - the sympathetic chain ganglia.
- The gray communicating ramus contains
 - visceral sensory fibers.
 - parasympathetic motor fibers.
 - sympathetic preganglionic fibers.
 - sympathetic postganglionic fibers.
 - somatic motor fibers.
- Throughout the autonomic nervous system, the neurotransmitter released by the preganglionic neuron binds to ____ receptors on the postganglionic neuron.
 - nicotinic
 - muscarinic
 - adrenergic
 - alpha
 - beta
- Which of these does not result from sympathetic stimulation?
 - dilation of the pupil
 - acceleration of the heart
 - digestive secretion
 - enhanced blood clotting
 - piloerection
- Certain nerve fibers are called ____ fibers because they secrete norepinephrine.
- ____ is a state in which a target organ receives both sympathetic and parasympathetic fibers.
- ____ is a state of continual background activity of the sympathetic and parasympathetic divisions.
- Most parasympathetic preganglionic fibers are found in the ____ nerve.
- The digestive tract has a semi-independent nervous system called the ____ nervous system.
- MAO and COMT are enzymes that break down ____ at certain ANS synapses.
- The adrenal medulla consists of modified postganglionic neurons of the ____ nervous system.
- The sympathetic nervous system has short ____ and long ____ nerve fibers.
- Adrenergic receptors classified as α_1 , β_1 , and β_2 act by changing the level of ____ in the target cell.
- Sympathetic fibers to blood vessels maintain a state of partial vasoconstriction called ____.

Answers in appendix B

True or False

Determine which five of the following statements are false, and briefly explain why.

- The parasympathetic nervous system shuts down when the sympathetic nervous system is active, and vice versa.
- Blood vessels of the skin receive no parasympathetic innervation.
- Voluntary control of the ANS is not possible.
- The sympathetic nervous system stimulates digestion.
- Some sympathetic postganglionic fibers are cholinergic.
- Urination and defecation cannot occur without signals from the brain to the bladder and rectum.
- Some parasympathetic nerve fibers are adrenergic.
- Parasympathetic effects are more localized and specific than sympathetic effects.
- The parasympathetic division shows less neural divergence than the sympathetic division does.
- The two divisions of the ANS have antagonistic effects on the iris.

Answers in appendix B

Testing Your Comprehension

1. You are dicing raw onions while preparing dinner, and the vapor makes your eyes water. Describe the afferent and efferent pathways involved in this response.
2. Suppose you are walking alone at night when you hear a dog growling close behind you. Describe the ways your sympathetic nervous system would prepare you to deal with this situation.
3. Suppose that the cardiac nerves were destroyed. How would this affect the heart and the body's ability to react to a stressful situation?
4. What would be the advantage to a wolf in having its sympathetic nervous system stimulate the piloerector muscles? What happens in a human when the sympathetic system stimulates these muscles?
5. Pediatric literature has reported many cases of poisoning in children with Lomotil, an antidiarrheic medicine. Lomotil works primarily by means of the morphinelike effects of its chief ingredient, diphenoxylate, but it also contains atropine. Considering the mode of action described for atropine in Insight 15.2, why might atropine

contribute to the antidiarrheic effect of Lomotil? In atropine poisoning, would you expect the pupils to be dilated or constricted? The skin to be moist or dry? The heart rate to be elevated or depressed? The bladder to retain urine or void uncontrollably? Explain each answer. Atropine poisoning is treated with physostigmine, a cholinesterase inhibitor. Explain the rationale of this treatment.

Brushing Up...

To understand this chapter, it is important that you understand or brush up on the following concepts:

- Excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) (p. 468)
- Spatial summation (p. 469)
- Neural coding (p. 469)
- Converging circuits of neurons (p. 472)
- Spinal cord tracts (p. 486)
- Decussation (p. 486)

Anyone who enjoys music, art, fine food, or a good conversation appreciates the human senses. Yet their importance extends beyond deriving pleasure from the environment. In the 1950s, behavioral scientists at Princeton University studied the methods used by Soviet Communists to extract confessions from political prisoners, including solitary confinement and sensory deprivation. Student volunteers were immobilized in dark soundproof rooms or suspended in dark chambers of water. In a short time, they experienced visual, auditory, and tactile hallucinations, incoherent thought patterns, deterioration of intellectual performance, and sometimes morbid fear or panic. Similar effects have been seen in burn patients who are immobilized and extensively bandaged (including the eyes) and thus suffer prolonged lack of sensory input. Patients connected to life-support equipment and confined under oxygen tents sometimes become delirious. Sensory input is vital to the integrity of personality and intellectual function.

Furthermore, much of the information communicated by the sense organs never comes to our conscious attention—blood pressure, body temperature, and muscle tension, for example. By monitoring such conditions, however, the sense organs initiate somatic and visceral reflexes that are indispensable to homeostasis and to our very survival in a ceaselessly changing and challenging environment.

The accessory tissues may include epithelial, muscular, or connective tissue. Sense organs can be as complex as the eye and ear or as microscopic and simple as a dendrite wrapped in a little bit of connective tissue.

General Properties of Receptors

The fundamental purpose of any sensory receptor is **transduction**, the conversion of one form of energy to another—light, sound, heat, touch, vibration, or other forms of stimulus energy into nerve signals. (Any device that converts one energy form to another is a *transducer*—whether a sense organ, gasoline engine, or lightbulb).

The initial effect of a stimulus on a sensory cell is a small local electrical change called a **receptor potential**. In many cases, such as the senses of touch and smell, the sensory cell is a neuron. If the receptor potential is strong enough, the neuron fires off a volley of action potentials, thus generating a nerve signal to the CNS. In other cases, such as taste and hearing, the sensory cell is not a neuron but an epithelial cell. Nevertheless, it has synaptic vesicles at its base; it releases a neurotransmitter in response to a stimulus; and it stimulates an adjacent neuron. That neuron then generates signals to the CNS.

Not all sensory signals go to the brain, but when they do, we may experience a **sensation**—a subjective awareness of the stimulus. Yet most sensory signals delivered to the CNS produce no conscious sensation at all. Most of them are filtered out in the brainstem before reaching the cerebral cortex, a valuable function that keeps us from being distracted by innumerable unimportant stimuli detected by the sense organs. Other nerve signals concern functions that do not require conscious awareness, such as monitoring blood pH and body temperature.

Sensory receptors transmit four kinds of information—*modality, location, intensity, and duration*:

1. **Modality** refers to the type of stimulus or the sensation it produces. Vision, hearing, and taste are examples of sensory modalities. The action potentials for vision are identical to the action potentials for taste or any other modality—so how can the brain tell a visual signal from a taste signal? It does this partly by “assuming” that if a signal comes from the retina, it must be a visual signal; if it comes from a taste bud, it must be a taste; and so on. It’s as if each nerve pathway from sensory cells to the brain is “labeled” to identify its origin, and the brain employs these labels to interpret what modality the nerve signal represents—pain or tickle, sweet or bitter, green or red. This theory of sensory interpretation is called the **labeled line code**.
2. **Location** is also encoded by which nerve fibers are issuing signals to the brain. Any sensory neuron detects stimuli within an area called its **receptive field**. In the sense of touch, for example, a single

16.1 Properties and Types of Sensory Receptors

Objectives

When you have completed this section, you should be able to

- define *receptor* and *sense organ*;
- list the four kinds of information obtained from sensory receptors, and describe how the nervous system encodes each type; and
- outline three ways of classifying receptors.

A sensory **receptor** is any structure specialized to detect a stimulus. Some receptors are simple, bare nerve endings, such as the receptors for heat and pain, whereas others are true sense organs. A **sense organ** is a structure composed of nervous tissue along with other tissues that enhance its response to a certain type of stimulus.

FIGURE 16.1 Receptive Fields. (a) A neuron with a large receptive field, as found in the skin of the back. If the skin is touched in two close-together places within this receptive field, the brain will sense it as only one point of contact. (b) Neurons with small receptive fields, as found in the fingertips. Two close-together points of contact here are likely to stimulate two different neurons and to be felt as separate touches.

• If the receptive field in part (a) is 7 cm in diameter, is it possible for two touches 1 cm apart to be felt separately?

sensory neuron may cover an area of skin as large as 7 cm in diameter. No matter where the skin is touched within that receptive field, it stimulates the same neuron. The brain cannot determine whether the skin was touched at “point A” or at some other point 4 or 5 cm away. If the skin is simultaneously touched at two places in the same receptive field, it feels like a single touch (fig. 16.1a). In some areas of the body such as the back, however, it isn’t necessary to make finer distinctions. On the other hand, we must be able to localize touch sensations much more precisely with the fingertips. Here, each sensory neuron may cover a receptive field 1 mm or less in diameter—there is a much higher density of tactile nerve fibers. Two points of contact just 2 mm apart will be felt as separate touches (fig. 16.1b). That is, the fingertips have finer *two-point touch discrimination* than the skin of the back. You can imagine the importance of this in reading Braille, appreciating the texture of a fine fabric, or manipulating an object as small as a sesame seed. The receptive field concept is relevant not only to touch, but also to other senses such as vision.

Sensory projection is the ability of the brain to identify the site of stimulation, including very small and specific areas within a receptor such as the retina. The pathways followed by sensory signals to their ultimate destinations in the CNS are called **projection pathways**.

- Intensity** refers to whether a sound is loud or soft, a light is bright or dim, a pain is mild or excruciating, and so forth. It is encoded in three ways: (a) as stimulus intensity rises, the firing frequencies of sensory nerve fibers rise (see fig. 12.28, p. 471); (b) intense stimuli recruit greater numbers of nerve fibers to fire; and (c) weak stimuli activate only the most sensitive nerve fibers, whereas strong stimuli can activate a less sensitive group of fibers with higher thresholds. Thus, the brain can distinguish intensities based on which fibers are sending it signals, how many fibers are doing so, and how fast those fibers are firing (see *neural coding*, p. 469).
- Duration**, or how long a stimulus lasts, is encoded by changes in the firing frequency of a nerve fiber with the passage of time. All receptors exhibit the

property of **sensory adaptation**—if the stimulus is prolonged, the firing of the neuron gets slower over time, and with it, we become less aware of the stimulus. Adapting to hot bath water is an example of this. Receptors are classified according to how quickly they adapt. **Phasic receptors** generate a burst of action potentials when first stimulated, then quickly adapt and sharply reduce or stop signaling even if the stimulus continues. Some of them fire again when the stimulus ceases. Phasic receptors are found in the senses of smell, hair movement, and cutaneous pressure. Their phasic nature explains why we may notice a suspicious odor such as a gas leak for several seconds, and then the sensation fades in intensity even if the stimulus is still there. If we don't find the gas leak quickly, it becomes difficult to find it at all. **Tonic receptors** adapt more slowly and generate nerve signals more steadily. Proprioceptors are among the most slowly adapting tonic receptors because the brain must always be aware of body position, muscle tension, and joint motion.

Think About It

Although you may find it difficult to immerse yourself in a tub of hot water or a cold lake, you soon adapt and become more comfortable. In light of this, do you think cold and warm receptors are phasic or tonic? Explain.

Classification of Receptors

Receptors can be classified by several overlapping systems, some of which have been introduced in earlier chapters:

- By stimulus modality:
 - Thermoreceptors** respond to heat and cold.
 - Photoreceptors**, the eyes, respond to light.
 - Nociceptors**¹ (NO-sih-SEP-turs) are pain receptors; they respond to tissue injury or situations that threaten to damage a tissue.
 - Chemoreceptors** respond to chemicals, including odors, tastes, and body fluid composition.
 - Mechanoreceptors** respond to physical deformation of a cell or tissue caused by vibration, touch, pressure, stretch, or tension. They include the organs of hearing and balance and many receptors of the skin, viscera, and joints.
 - By the origin of the stimulus:
 - Exteroceptors** sense stimuli external to the body. They include the receptors for vision, hearing, taste, smell, and cutaneous sensations such as touch, heat, cold, and pain.
 - Interoceptors** detect stimuli in the internal organs such as the stomach, intestines, and bladder, and produce feelings of stretch, pressure, visceral pain, and nausea.
 - Proprioceptors** sense the position and movements of the body or its parts. They occur in muscles, tendons, and joint capsules.
3. By the distribution of receptors in the body. There are two broad classes of senses:
- General (somesthetic) senses** employ receptors that are widely distributed in the skin, muscles, tendons, joint capsules, and viscera. These include the senses of touch, pressure, stretch, heat, cold, and pain, as well as many stimuli that we do not perceive consciously, such as blood pressure and composition. Their receptors are relatively simple in structure—sometimes nothing more than a bare dendrite.
 - Special senses** are limited to the head, are innervated by the cranial nerves, and employ relatively complex sense organs. The special senses are vision, hearing, equilibrium, taste, and smell.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

- Not every sensory receptor is a sense organ. Explain.
- What does it mean to say sense organs are transducers? What form of energy do all receptors have as their output?
- Not every sensory signal results in conscious awareness of a stimulus. Explain.
- What is meant by the modality of a stimulus? Give some examples.
- Three schemes of receptor classification were presented in this section. In each scheme, how would you classify the receptors for a full bladder? How would you classify taste receptors?
- Nociceptors are tonic rather than phasic receptors. Speculate on why this is beneficial to homeostasis.

16.2 The General Senses

Objectives

When you have completed this section, you should be able to

- list several types of somesthetic receptors;
- describe the projection pathways for the general senses; and
- explain the mechanisms of pain and the spinal blocking of pain signals.

¹noc*i* = pain

Receptors for the general senses are relatively simple in structure and physiology. They consist of one or a few sensory nerve fibers and, usually, a sparse amount of connective tissue. These receptors are shown in figure 16.2 and described in table 16.1.

Unencapsulated Nerve Endings

Unencapsulated nerve endings are sensory dendrites that are not wrapped in connective tissue. They include the following:

- **Free nerve endings** include *warm receptors*, which respond to rising temperature; *cold receptors*, which respond to falling temperature; and *nociceptors* for pain. They are bare dendrites that have no special association with specific accessory cells or tissues. They are most abundant in the skin and mucous membranes. You can locate some of your cold receptors by gently touching your skin with the point of a graphite pencil. In spots where these receptors are located, this produces a sensation of cold.

- **Tactile (Merkel)² discs** are tonic receptors for light touch, thought to sense textures, edges, and shapes. They are flattened nerve endings that terminate adjacent to specialized *tactile (Merkel) cells* in the basal layer of the epidermis.
- **Hair receptors (peritrichial³ endings)** monitor the movements of hairs. They consist of a few dendrites entwined around the base of a hair follicle. They respond to any light touch that bends a hair. Because they adapt quickly, we are not constantly annoyed by our clothing bending the body hairs. However, when an ant crawls across our skin, bending one hair after another, we are very aware of it.

Encapsulated Nerve Endings

Encapsulated nerve endings are nerve fibers wrapped in glial cells or connective tissue. Most of them are mechanoreceptors for touch, pressure, and stretch. The connective tissue either enhances the sensitivity of the nerve fiber or makes it more selective with respect to which

FIGURE 16.2 Receptors of the General (Somesthetic) Senses. See table 16.1 for functions.

modality it responds to. We have already considered some encapsulated nerve endings in chapter 13—muscle spindles and tendon organs. Others are as follows:

- **Tactile (Meissner⁴) corpuscles** are phasic receptors for light touch and texture. They are tall, ovoid to pear-shaped, and consist of two or three nerve fibers meandering upward through a mass of flattened Schwann cells. They occur in the dermal papillae of the skin and are especially concentrated in sensitive hairless areas such as the fingertips, palms, eyelids, lips, nipples, and parts of the genitals. Scrape your fingernail lightly across the back of your hand, and then across the palm. The difference in sensation you feel is due to the high concentration of tactile corpuscles in the palmar skin. Tactile corpuscles enable you to tell the difference between silk and sandpaper, for example, by light strokes of your fingertips.
- **End bulbs (Krause⁵ end bulbs, Krause corpuscles)** are ovoid bodies composed of a connective tissue sheath around a sensory nerve fiber. They occur in the mucous membranes of the lips and tongue, in the conjunctiva on the anterior surface of the eye, and in the epineurium of large nerves.
- **Lamellar (pacinian⁶) corpuscles** are phasic receptors for deep pressure, stretch, tickle, and vibration. They are large receptors, up to 1 or 2 mm long, and look like a sliced onion in cross section. A single sensory dendrite travels through the center of the corpuscle. The innermost onionlike layers around it are flattened Schwann cells, but the greater bulk of the corpuscle consists of concentric layers of fibroblasts

with narrow fluid-filled spaces between them. These receptors occur in the periosteum of bone; in joint capsules; in the pancreas and some other viscera; and deep in the dermis, especially on the hands, feet, breasts, and genitals.

- **Bulbous (Ruffini⁷) corpuscles** are tonic receptors for heavy touch, pressure, stretching of the skin, and joint movements. They are flattened, elongated capsules containing a few nerve fibers and are located in the dermis, subcutaneous tissue, and joint capsules.

Somesthetic Projection Pathways

From the receptor to the final destination in the brain, most somesthetic signals travel by way of three neurons called the **first-, second-, and third-order neurons**. Their axons are called first- through third-order nerve fibers. The first-order fibers for touch, pressure, and proprioception are large, myelinated, and fast; those for heat and cold are small, unmyelinated or lightly myelinated, and slower.

Somesthetic signals from the head, such as facial sensations, travel by way of several cranial nerves (especially V, the trigeminal nerve) to the pons and medulla oblongata. In the brainstem, the first-order fibers of these neurons synapse with second-order neurons that decussate and end in the contralateral thalamus. Third-order neurons then complete the route to the cerebrum. Proprioceptive signals from the head are an exception, as the second-order fibers carry these signals to the cerebellum.

Below the head, the first-order fibers enter the posterior horn of the spinal cord. Signals ascend the spinal cord in the spinothalamic and other pathways detailed in

⁴Georg Meissner (1829–1905), German histologist

⁵Wilhelm J. F. Krause (1833–1910), German anatomist

⁶Filippo Pacini (1812–83), Italian anatomist

⁷Angelo Ruffini (1864–1929), Italian anatomist

TABLE 16.1 Receptors of the General Senses

Receptor Type	Locations	Modality
<i>Unencapsulated endings</i>		
Free nerve endings	Widespread, especially in epithelia and connective tissues	Pain, heat, cold
Tactile discs	Stratum basale of epidermis	Light touch, pressure
Hair receptors	Around hair follicle	Light touch, movement of hairs
<i>Encapsulated nerve endings</i>		
Tactile corpuscles	Dermal papillae of fingertips, palms, eyelids, lips, tongue, nipples, and genitals	Light touch, texture
End bulbs	Mucous membranes	Similar to tactile corpuscles
Bulbous corpuscles	Dermis, subcutaneous tissue, and joint capsules	Heavy continuous touch or pressure; joint movements
Lamellar corpuscles	Dermis, joint capsules, periosteum, breasts, genitals, and some viscera	Deep pressure, stretch, tickle, vibration
Muscle spindles	Skeletal muscles near tendon	Muscle stretch (proprioception)
Tendon organs	Tendons	Tension on tendons (proprioception)

chapter 13 (see table 13.1 and figure 13.5, p. 488). These pathways decussate either at or near the point of entry into the spinal cord, or in the brainstem, so the primary somesthetic cortex in each cerebral hemisphere receives signals from the contralateral side of the body.

Signals for proprioception below the head travel up the spinocerebellar tracts to the cerebellum. Signals from the thoracic and abdominal viscera travel to the medulla oblongata by way of sensory fibers in the vagus nerve (X). Recent research has shown that visceral pain signals also ascend the spinal cord in the gracile fasciculus.

Pain

Pain is a discomfort caused by tissue injury or noxious stimulation, and typically leading to evasive action. Few of us enjoy pain and we may wish that no such thing existed, but it is one of our most important senses and we would be far worse off without it. We see evidence of its value in such diseases as leprosy and diabetes mellitus, where the sense of pain is lost because of nerve damage (*neuropathy*). The absence of pain makes people unaware of minor injuries. They neglect them, so the injuries often become infected and worsen to the point that the victim may lose fingers, toes, or entire limbs.

In short, pain is an adaptive and necessary sensation. It is not simply an effect of the overstimulation of nerve fibers meant for other functions, but is mediated by its own specialized nerve fibers, the nociceptors. These are especially dense in the skin and mucous membranes, and occur in virtually all organs, although not in the brain. In some brain surgery, the patient must remain conscious and able to talk with the surgeon; such patients need only a local anesthetic. Nociceptors do occur in the meninges of the brain and play an important role in headaches.

There are two types of nociceptors corresponding to different pain sensations. Myelinated pain fibers conduct at speeds of 12 to 30 m/sec and produce the sensation of **fast (first) pain**—a feeling of sharp, localized, stabbing pain perceived at the time of injury. Unmyelinated pain fibers conduct at speeds of 0.5 to 2.0 m/sec and produce the **slow (second) pain** that follows—a longer-lasting, dull, diffuse feeling. Pain from the skin, muscles, and joints is called **somatic pain**, and pain from the viscera is called **visceral pain**. The latter often results from stretch, chemical irritants, or ischemia, and is often accompanied by nausea.

Injured tissues release several chemicals that stimulate the nociceptors and trigger pain. **Bradykinin** is the most potent pain stimulus known; it hurts intensely when injected under the skin. It not only makes us aware of injuries but also activates a cascade of reactions that promote healing. Serotonin, prostaglandins, and histamine also stimulate nociceptors, as do potassium ions and ATP released from ruptured cells.

Projection Pathways for Pain

It is notoriously difficult for clinicians to locate the origin of a patient's pain because pain travels by such diverse and complex routes and the sensation can originate anywhere along any of the routes. Pain signals reach the brain by two main pathways, but there are multiple subroutes within each of them:

1. Pain signals from the head travel to the brainstem by way of four cranial nerves: mainly the trigeminal (V), but also the facial (VII), glossopharyngeal (IX), and vagus (X) nerves. Trigeminal fibers enter the pons and descend to synapses in the medulla. Pain fibers of the other three cranial nerves also end here. Second-order neurons arise in the medulla and ascend to the thalamus, which relays the message to the cerebral cortex. We will consider the relay from thalamus to cortex shortly.
2. Pain signals from the neck down travel by way of three of the ascending spinal cord tracts: the spinothalamic tract, spinoreticular tract, and gracile fasciculus. These pathways are described in chapter 13 and need not be repeated here (see table 13.1 and fig. 13.5). The spinothalamic tract is the most significant pain pathway and carries most of the somatic pain signals that ultimately reach the cerebral cortex, making us conscious of pain. The spinoreticular tract carries pain signals to the reticular formation of the brainstem, and these are ultimately relayed to the hypothalamus and limbic system. These pain signals activate visceral, emotional, and behavioral reactions to pain, such as nausea, fear, and some reflex responses. The gracile fasciculus has not been recognized as a pain pathway until recently. It carries signals to the thalamus for visceral pain, such as the pain of a stomachache or from passing a kidney stone. Figure 16.3 shows the spinothalamic and spinoreticular pain pathways.

When the thalamus receives pain signals from the foregoing sources, it relays most of them through third-order neurons to their final destination in the postcentral gyrus of the cerebrum. Exactly what part of this gyrus receives the signals depends on where the pain originated; recall the concept of somatotopy and the sensory homunculus in chapter 14 (p. 545). Most of this gyrus is somesthetic—that is, it receives signals for somatic pain and other senses. A region of the gyrus deep within the lateral sulcus of the brain, however, is a viscerosensory area, which receives the signals of visceral pain conveyed by the gracile fasciculus.

Pain in the viscera is often mistakenly thought to come from the skin or other superficial sites—for example, when the pain of a heart attack is felt “radiating” along the left shoulder and medial side of the arm. This phenomenon, called **referred pain**, results from the convergence of neural pathways in the CNS. In the case of cardiac pain,

FIGURE 16.3 Projection Pathways for Pain. A first-order neuron conducts a pain signal to the posterior horn of the spinal cord, a second-order neuron conducts it to the thalamus, and a third-order neuron conducts it to the cerebral cortex. Signals from the spinothalamic tract pass through the thalamus. Signals from the spinoreticular tract bypass the thalamus on the way to the sensory cortex.

for example, spinal cord segments T1 to T5 receive input from the heart as well as from the chest and arm. Pain fibers from the heart and skin in this region converge on the same spinal interneurons, then follow the same pathway from there to the thalamus and cerebral cortex. The brain cannot distinguish which source the arriving signals are coming from. It acts as if it assumes that they are most likely from the skin, since skin has more pain receptors than the heart and suffers injury more often. Knowledge of the origins of referred pain is essential to the skillful diagnosis of organ dysfunctions (fig. 16.4).

CNS Modulation of Pain

A person's physical and mental state can greatly affect his or her perception of pain. Many mortally wounded soldiers, for example, report little or no pain. The central nervous system (CNS) has **analgesic**⁸ (pain-relieving)

FIGURE 16.4 Referred Pain. Pain from the viscera is often felt in specific areas of the skin. The pattern for women differs in some details from the one for men.

mechanisms that are just beginning to be understood. Their discovery is tied to the long-known analgesic effects of opium, morphine, and heroin. In 1974, neurophysiologists discovered receptor sites in the brain for these drugs. Since these opiates do not occur naturally in the body, physiologists wondered what normally binds to these receptors. They soon found two analgesic oligopeptides with 200 times the potency of morphine, and named them **enkephalins**.⁹ Larger analgesic neuropeptides, the **endorphins**¹⁰ and **dynorphins**,¹¹ were discovered later. All three of these are known as **endogenous opioids** (which means “internally produced opium-like substances”).

These opioids are secreted by the CNS, pituitary gland, digestive tract, and other organs in states of stress or exercise. In the CNS, they are found especially in the central (periaqueductal) gray matter of the midbrain (see fig. 14.9a, p. 527) and the posterior horn of the spinal cord. They are **neuromodulators** (see p. 467) that can block the transmission of pain signals and produce feelings of pleasure and euphoria. They may be responsible for the “second wind” (“runner’s high”) experienced by athletes and for the aforementioned battlefield reports. Their secretion rises sharply in women giving birth. Efforts to employ them in pain therapy have been disappointing, but exercise is an effective part of therapy for chronic pain and may help because it stimulates opioid secretion.

How do these opioids block pain? For pain to be perceived, signals from the nociceptors must get beyond the posterior horn of the spinal cord and travel to the brain. Through mechanisms called **spinal gating**, pain signals can be stopped at the posterior horn. Two of these mechanisms are described here.

⁹en = within + kephal = head

¹⁰acronym from endogenous morphinelike substance

¹¹dyn = pain

⁸an = without + alges = pain

FIGURE 16.5 Spinal Gating of Pain Signals.

One mechanism involves **descending analgesic fibers**—nerve fibers that arise in the brainstem, travel down the spinal cord in the reticulospinal tract, and block pain signals from traveling up the cord to the brain. Figure 16.5 depicts one relatively simple mechanism of pain modulation in the posterior horn. The normal route of pain transmission is indicated by the red arrows and steps 1 through 3:

- ① A nociceptor stimulates a second-order nerve fiber. The neurotransmitter at this synapse is called **substance P** (think *P* for “pain”¹²).
- ② The second-order nerve fiber transmits signals up the spinothalamic tract to the thalamus.
- ③ The thalamus relays the signals through a third-order neuron to the cerebral cortex, where one becomes conscious of pain.

The pathway for pain blocking, or modulation, is indicated by descending green arrows and steps 4 through 8:

- ④ Signals from the hypothalamus and cerebral cortex feed into the central gray matter of midbrain, allowing both autonomic and conscious influences on pain perception.

- ⑤ The midbrain relays signals to certain nuclei in the reticular formation of the medulla oblongata.
- ⑥ The medulla issues descending, serotonin-secreting analgesic fibers to the spinal cord. These fibers travel the reticulospinal tract and terminate in the posterior horn at all levels of the cord.
- ⑦ In the posterior horn, some of the descending analgesic fibers synapse on short spinal interneurons, which in turn synapse on the second-order pain fiber. These interneurons secrete enkephalins to inhibit the second-order neuron. This is an example of postsynaptic inhibition, working on the downstream side of the synapse between the first- and second-order pain neurons.
- ⑧ Some fibers from the medulla also exert presynaptic inhibition, synapsing on the axons of the nociceptors and blocking the release of substance P.

Another mechanism of spinal gating is one you may often have consciously employed without knowing why it worked. Have you ever banged your elbow on the edge of a table or pinched your finger in a door, and found that you could ease the pain by rubbing or massaging the injured area? This works because pain-inhibiting interneurons of the posterior horn, like the one at step 7 in

¹²Named *substance P* because it was first discovered in a powdered extract of brain and intestine

figure 16.5, also receive input from mechanoreceptors in the skin and deeper tissues. When you rub an injured area, you stimulate those mechanoreceptors; they stimulate the spinal interneurons; the interneurons secrete enkephalins; and enkephalins inhibit the second-order pain neurons.

The clinical control of pain has had a particularly interesting history, some of which is retold in Insight 16.5 (p. 632).

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

7. What stimulus modalities are detected by free nerve endings?
8. Name any four encapsulated nerve endings and identify their stimulus modalities.
9. Where do most second-order somesthetic neurons synapse with third-order neurons?
10. Explain the phenomenon of referred pain in terms of the neural pathways involved.
11. Explain the roles of bradykinin, substance P, and enkephalins in the perception of pain.

16.3 The Chemical Senses

Objectives

When you have completed this section, you should be able to

- explain how taste and smell receptors are stimulated; and
- describe the receptors and projection pathways for these two senses.

Taste and smell are the chemical senses. In both cases, environmental chemicals stimulate sensory cells.

Taste

Gustation (taste) is a sensation that results from the action of chemicals on the **taste buds**. There are about 4,000 taste buds, mainly on the tongue but also inside the cheeks and on the soft palate, pharynx, and epiglottis.

Anatomy

The tongue exhibits four types of surface protrusions called **lingual papillae** (fig. 16.6a):

1. **Filiform**¹³ **papillae** are tiny spikes without taste buds. They are responsible for the rough feel of a

cat's tongue and are important to many mammals for grooming the fur. They are the most abundant papillae on the human tongue, but they are small and play no gustatory role. They serve, however, in one's sense of the texture of food.

2. **Foliate**¹⁴ **papillae** are also weakly developed in humans. They form parallel ridges on the sides of the tongue about two-thirds of the way back from the tip. Most of their taste buds degenerate by the age of 2 or 3 years.
3. **Fungiform**¹⁵ (FUN-jih-form) **papillae** are shaped somewhat like mushrooms. Each has about three taste buds, located mainly on the apex. These papillae are widely distributed but especially concentrated at the tip and sides of the tongue.
4. **Vallate**¹⁶ (**circumvallate**) **papillae** are large papillae arranged in a V at the rear of the tongue. Each is surrounded by a deep circular trench. There are only 7 to 12 of them, but they contain up to half of all taste buds—around 250 each, located on the wall of the papilla facing the trench (fig. 16.6b).

Regardless of location and sensory specialization, all taste buds look alike (fig. 16.6c, d). They are lemon-shaped groups of 40 to 60 *taste cells*, *supporting cells*, and *basal cells*. **Taste (gustatory) cells** are more or less banana-shaped and have a tuft of apical microvilli called **taste hairs**, which serve as receptor surfaces for taste molecules. The hairs project into a pit called a **taste pore** on the epithelial surface of the tongue. Taste cells are epithelial cells, not neurons, but they synapse with sensory nerve fibers at their base and have synaptic vesicles for the release of stimulatory neurotransmitters. A taste cell lives for only 7 to 10 days. **Basal cells** are stem cells that multiply and replace taste cells that have died. **Supporting cells** resemble taste cells but have no taste hairs, synaptic vesicles, or sensory role.

Physiology

To be tasted, molecules must dissolve in the saliva and flood the taste pore. On a dry tongue, sugar or salt has as little taste as a sprinkle of sand. Physiologists currently recognize five primary taste sensations:

1. **Salty**, produced by metal ions such as sodium and potassium. Since these are vital electrolytes, there is obvious value in our ability to taste them and in having an appetite for salt. Electrolyte deficiencies can cause a craving for salt; many animals such as deer, elephants, and parrots seek salt deposits when necessary. Pregnancy can lower a woman's electrolyte concentrations and create a craving for salty food.

¹⁴*foli* = leaf + *ate* = like

¹⁵*fungi* = mushroom + *form* = shaped

¹⁶*vall* = wall + *ate* = like, possessing

¹³*fili* = thread + *form* = shaped

FIGURE 16.6 Gustatory (Taste) Receptors. (a) Superior aspect of the tongue and locations of its papillae. (b) Detail of the vallate papillae (compare p. 586). (c) Taste buds on the walls of two adjacent foliate papillae. (d) Structure of a taste bud.

- Sweet**, produced by many organic compounds, especially sugars. Sweetness is associated with carbohydrates and other foods of high caloric value. Many flowering plants have evolved sweet nectar and fruits that entice animals to eat them and disperse their pollen and seeds. Our fondness for fruit has coevolved with plant reproductive strategies.
- Sour**, usually associated with acids in such foods as citrus fruits.
- Bitter**, associated with spoiled foods and alkaloids such as nicotine, caffeine, quinine, and morphine. Alkaloids are often poisonous, and the bitter taste sensation usually induces a human or animal to reject a food. While flowering plants make their fruits temptingly sweet, they often load their leaves

with bitter, toxic alkaloids to deter animals from eating them.

- Umami** is a “meaty” taste produced by amino acids such as aspartic and glutamic acids—the savory taste of beef or chicken broth. Pronounced “ooh-mommy,” the word is Japanese slang for “delicious” or “yummy.”

The many flavors we perceive are not simply a mixture of these five primary tastes, but are also influenced by food texture, aroma, temperature, appearance, and one’s state of mind, among other things. Many flavors depend on smell; without its aroma, cinnamon merely has a faintly sweet taste, and coffee and peppermint are bitter. Some flavors such as pepper are due to stimulation of free endings of the trigeminal nerve rather than taste

buds. Food technologists refer to the texture of food as *mouthfeel*. Filiform and fungiform papillae of the tongue are innervated by the *lingual nerve* (a branch of the trigeminal) and are sensitive to texture.

All of the primary tastes can be detected throughout the tongue, but certain regions are more sensitive to one category than to others. The tip of the tongue is most sensitive to sweet tastes, which trigger such responses as licking, salivation, and swallowing. The lateral margins of the tongue are the most sensitive areas for salty and sour tastes. Taste buds in the vallate papillae at the rear of the tongue are especially sensitive to bitter compounds, which tend to trigger rejection responses such as gagging to protect against the ingestion of toxins. The threshold for the bitter taste is the lowest of all—that is, we can taste lower concentrations of alkaloids than of acids, salts, and sugars. The senses of sweet and salty are the least sensitive.

Sugars, alkaloids, and glutamate stimulate taste cells by binding to receptors on the membrane surface, which then activate G proteins and second-messenger systems within the cell. Sodium and acids penetrate into the cell and depolarize it directly. By either mechanism, taste cells then release neurotransmitters that stimulate the sensory dendrites at their base.

Projection Pathways

The facial nerve (cranial nerve VII) collects sensory information from taste buds of the anterior two-thirds of the tongue, the glossopharyngeal nerve (IX) from the posterior one-third, and the vagus nerve (X) from taste buds of the palate, pharynx, and epiglottis. All taste fibers project to a site in the medulla oblongata called the *solitary nucleus*. Second-order neurons arise here and relay the signals to two destinations: (1) nuclei in the hypothalamus and amygdala that activate autonomic reflexes such as salivation, gagging, and vomiting; and (2) the thalamus, which relays signals to the insula and postcentral gyrus of the cerebrum, where we become conscious of the taste. Processed signals are further relayed to the orbitofrontal cortex (see fig. 14.17, p. 537), where they are integrated with signals from the nose and eyes and we form an overall impression of the flavor and palatability of food.

Smell

The receptor cells for **olfaction (smell)** form a patch of epithelium, the **olfactory mucosa**, in the roof of the nasal cavity (fig. 16.7). This location places the olfactory cells close to the brain, but it is poorly ventilated; forcible sniffing is often needed to identify an odor or locate its source.

Anatomy

The olfactory mucosa covers about 5 cm² of the superior concha, cribriform plate, and nasal septum of each nasal

fossa. It consists of 10 to 20 million **olfactory cells** as well as epithelial supporting cells and basal stem cells. The rest of the nasal cavity is lined by a nonsensory *respiratory mucosa*.

Unlike taste cells, which are epithelial, olfactory cells are neurons. They are shaped a little like bowling pins (fig. 16.7c). The widest part, the neurosoma, contains the nucleus. The neck and head of the cell are a modified dendrite with a swollen tip. The head bears 10 to 20 cilia called **olfactory hairs**. These cilia are immobile, but they have binding sites for odor molecules. They lie in a tangled mass embedded in a thin layer of mucus. The basal end of each cell tapers to become an axon. These axons collect into small fascicles that leave the nasal cavity through pores (*cribriform foramina*) in the ethmoid bone. Collectively, the fascicles are regarded as cranial nerve I (the olfactory nerve).

Olfactory cells are the only neurons in the body directly exposed to the external environment. Apparently this is hard on them, because they have a life span of only 60 days. Unlike most neurons, however, they are replaceable. The basal cells continually divide and differentiate into new olfactory cells.

Physiology

Humans have a poorer sense of smell than most other mammals; it seems to have declined as the primate visual system increased in significance. A 3 kg cat, for example, has a total of about 20 cm² of olfactory mucosa in its two nasal fossae, whereas a human with 20 times that body weight has only half as much olfactory mucosa. Nevertheless, our sense of smell is much more sensitive than our sense of taste; we can detect odor concentrations as low as a few parts per trillion. On average, women are more sensitive to odors than men are, and they are measurably more sensitive to some odors near the time of ovulation as opposed to other phases of the menstrual cycle. Olfaction is highly important in the social interactions of other animals and, in more subtle ways, to humans (see Insight 16.1).

Most people can distinguish 2,000 to 4,000 odors, and some can distinguish up to 10,000. Attempts to group these into odor classes have been inconclusive and controversial; suggested classes have included pungent, floral, musky, and earthy. Olfaction researchers Linda Buck and Richard Axel received the 2004 Nobel Prize for Physiology or Medicine for applying methods of molecular genetics to identify olfactory receptor proteins and their genes. Rats and mice have up to 1,200 functional genes coding for receptor proteins that bind odor molecules, but in humans, two-thirds of the olfactory genes have mutated to the point of being inoperative *pseudogenes*; we have only about 350 kinds of olfactory receptors left. Each olfactory cell has only one receptor type and therefore binds only one odorant.

The first step in smell is that an odorant molecule must bind to a receptor on one of the olfactory hairs. Hydrophilic odorants diffuse freely through the mucus of the olfactory epithelium and bind directly to a receptor. Hydrophobic odorants are transported to the receptor by an *odorant-binding protein* in the mucus. When the receptor binds an odorant, it activates a G protein and

through it, the cyclic adenosine monophosphate (cAMP) second-messenger system. The cAMP system ultimately opens ion channels in the plasma membrane, admitting cations (Na^+ or Ca^{2+}) into the cell and depolarizing it, creating a receptor potential. This triggers action potentials in the axon of the olfactory cell, and a signal is transmitted to the brain.

INSIGHT 16.1 Evolutionary Medicine

Human Pheromones

There is an abundance of anecdote, but only equivocal evidence, that human body odors affect sexual behavior. There is more conclusive evidence, however, that a person's sweat and vaginal secretions affect other people's sexual physiology, even when the odors cannot be consciously smelled. Experimental data show that a woman's apocrine sweat can influence the timing of other women's menstrual cycles. This can produce a so-called *dormitory effect*, in which women who live together tend to have synchronous menstrual cycles. The presence of men seems to influence female ovulation. Conversely, when a woman is ovulating or close to it, and therefore fertile, her vaginal secretions contain pheromones called *copulines*, which have been shown to raise men's testosterone levels.

Some odorants, however, act on nociceptors of the trigeminal nerve rather than on olfactory cells. These odorants include ammonia, menthol, chlorine, and the capsaicin of hot peppers. "Smelling salts" revive unconscious persons by strongly stimulating the trigeminal nerve with ammonia fumes.

Projection Pathways

When olfactory fibers pass through the roof of the nose, they enter a pair of **olfactory bulbs** beneath the frontal lobes of the brain (see fig. 14.27, p. 550). Here they synapse with the dendrites of two types of neurons higher in the bulb, called *mitral cells* and *tufted cells*. Olfactory axons reach up, and mitral and dendritic cell dendrites reach down, to meet each other in spherical clusters called *glomeruli* (fig. 16.7b). All olfactory fibers leading to any one glomerulus come from cells with the same receptor type; thus each glomerulus is dedicated to a particular odor. Higher brain centers interpret complex odors such as chocolate, perfume, or coffee by decoding signals from a combination of odor-specific glomeruli. This is similar to the way our visual system decodes all the colors of the spectrum using input from just three color-specific receptor cells of the eye.

The tufted and mitral cells carry the output from the glomeruli. Their axons form bundles called **olfactory tracts**, which course posteriorly along the underside of the frontal lobes. Most fibers of the olfactory tracts end in various neighboring regions of the inferior surface of the temporal lobe (fig. 16.8); collectively, we can regard all these regions as the **primary olfactory cortex**. It is noteworthy that olfactory signals can reach the cerebral cortex directly, without first passing through the thalamus; this is not true of any of our other senses. Even in olfaction,

FIGURE 16.8 Olfactory Projection Pathways in the Brain.

however, some signals from the primary olfactory cortex continue to a relay in the thalamus on their way to olfactory association areas elsewhere.

From the primary olfactory cortex, signals travel to several other secondary destinations in the cerebrum and brainstem. Two important cerebral destinations are the insula and orbitofrontal cortex. The orbitofrontal cortex is where we identify and discriminate among odors. It receives inputs for both taste and smell and integrates these into our overall perception of flavor. Other secondary destinations for olfactory signals include the hippocampus, amygdala, and hypothalamus. Considering the roles of these brain areas, it is not surprising that the odor of certain foods, a perfume, a hospital, or decaying flesh can evoke strong memories, emotional responses, and visceral reactions such as sneezing or coughing, the secretion of saliva and stomach acid, or vomiting.

Most areas of olfactory cortex also send fibers back to the olfactory bulbs by way of neurons called *granule cells*. Granule cells can inhibit the mitral and tufted cells. An effect of this feedback is that odors can change in quality and significance under different conditions. Food may smell more appetizing when you are hungry, for example, than when you have just eaten or when you are ill.

Think About It

Which taste sensations could be lost after damage to (1) the facial nerve or (2) the glossopharyngeal nerve? A fracture of which cranial bone would most likely eliminate the sense of smell?

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

12. What is the difference between a lingual papilla and a taste bud? Which is visible to the naked eye?
13. List the primary taste sensations and discuss their adaptive significance (survival value).
14. Which cranial nerves carry gustatory impulses to the brain?
15. What part of an olfactory cell binds odor molecules?

16.4 Hearing and Equilibrium

Objectives

When you have completed this section, you should be able to

- identify the properties of sound waves that account for pitch and loudness;
- describe the gross and microscopic anatomy of the ear;
- explain how the ear converts vibrations to nerve signals and discriminates between sounds of different intensity and pitch;
- explain how the vestibular apparatus enables the brain to interpret the body's position and movements; and
- describe the pathways taken by auditory and vestibular signals to the brain.

Hearing is a response to vibrating air molecules and *equilibrium* is the sense of motion, body orientation, and balance. These senses reside in the inner ear, a maze of fluid-filled passages and sensory cells. We will study how the fluid is set in motion and how the sensory cells convert this motion into an informative pattern of action potentials.

The Nature of Sound

To understand the physiology of hearing, it is necessary to know some basic properties of sound. **Sound** is any audible vibration of molecules. It can be transmitted through water, solids, or air, but not through a vacuum. Our discussion is limited to airborne sound.

Sound is produced by a vibrating object such as a tuning fork, a loudspeaker, or the vocal cords. Consider a loudspeaker producing a pure tone. When the speaker cone moves forward, it pushes air molecules ahead of it. They collide with other molecules just ahead of them, and energy is thus transferred from molecule to molecule until it reaches the eardrum. No one molecule moves very

far; they simply collide with each other like a series of billiard balls until finally, some molecules collide with the eardrum and make it vibrate. The sensations we perceive as the pitch and loudness of the sound are related to the physical properties of these vibrations.

Pitch

Pitch is our sense of whether a sound is “high” (treble) or “low” (bass). It is determined by the frequency at which the sound source, eardrum, and other parts of the ear vibrate. One movement of a vibrating object back and forth is called a *cycle*, and the number of cycles per second (cps or hertz, Hz) is called **frequency**. The lowest note on a piano, for example, is 27.5 Hz, middle C is 261 Hz, and the highest note is 4,176 Hz. The most sensitive human ears can hear frequencies from 20 to 20,000 Hz. The *infrasonic* frequencies below 20 Hz are not detected by the ear, but we sense them through vibrations of the skull and skin and they play a significant role in our appreciation of music. The inaudible vibrations above 20,000 Hz are *ultrasonic*. Human ears are most sensitive to frequencies ranging from 1,500 to 5,000 Hz. In this range, we can hear sounds of relatively low energy (volume), whereas sounds above or below this range must be louder to be audible (fig. 16.9). Normal speech falls within this frequency range. Most of the hearing loss suffered with age is in the range of 250 to 2,050 Hz.

FIGURE 16.9 The Range of Human Hearing. People with very sensitive ears can hear sounds from 20 to 20,000 hertz (Hz), but to be heard, sounds at these extremes must be louder than those in the midrange. Our ears are most sensitive to frequencies of 1,500 to 5,000 Hz, where we can hear relatively soft sounds. Thus, the threshold of hearing varies with the frequency of the sound. Most sounds above 120 decibels (dB) are painful to the ear.

◀ How would the shape of this graph change in a case of moderate hearing loss between 200 and 5,000 Hz?

Loudness

Loudness is the perception of sound energy, intensity, or the **amplitude** of vibration. In the speaker example, amplitude is a measure of how far forward and back the cone vibrates on each cycle and how much it compresses the air molecules in front of it. Loudness is expressed in decibels (dB), with 0 dB being the threshold of human hearing. Every 10 dB step up the scale represents a sound with 10 times greater intensity. Thus, 10 dB is 10 times threshold, 20 dB is 100 times threshold, 30 dB is 1,000 times threshold, and so forth. Normal conversation has a loudness of about 60 dB. At most frequencies, the threshold of pain is 120 to 140 dB, approximately the intensity of a loud thunderclap. Prolonged exposure to sounds greater than 90 dB can cause permanent loss of hearing.

Anatomy of the Ear

The ear has three sections called the *outer*, *middle*, and *inner ear*. The first two are concerned only with transmitting sound to the inner ear, where vibration is converted to nerve signals.

Outer Ear

The **outer (external)** ear is essentially a funnel for conducting airborne vibrations to the *tympanic membrane* (eardrum). It begins with the fleshy **auricle (pinna)** on the side of the head, shaped and supported by elastic cartilage except for the earlobe. The auricle has a predictable arrangement of named whorls and recesses that direct sound into the auditory canal (fig. 16.10).

FIGURE 16.10 Anatomy of the Auricle (Pinna) of the Ear.

The **auditory canal** is the passage leading through the temporal bone to the tympanic membrane. Beginning at the external opening, the **external acoustic meatus**, it follows a slightly S-shaped course for about 3 cm (fig. 16.11). It is lined with skin and supported by fibrocartilage at its opening and by the temporal bone for the rest of its length.

The outer end of the canal is protected by stiff **guard hairs**. The canal has ceruminous and sebaceous glands whose secretions mix with dead skin cells and form **cerumen** (earwax). Cerumen is sticky and coats the guard hairs, making them more effective in blocking foreign particles from the auditory canal. Its stickiness may also be a deterrent to insects, ticks, or other pests. In addition, it contains lysozyme and has a low pH, both of which inhibit bacterial growth; it waterproofs the canal and protects its skin and the tympanic membrane from absorbing water; and it keeps the tympanic membrane pliable. Cerumen normally dries and falls from the canal, but sometimes it becomes impacted and interferes with hearing.

Middle Ear

The **middle ear** is located in the **tympanic cavity** of the temporal bone. What we colloquially call the eardrum is anatomically known as the **tympanic¹⁷ membrane**. It closes the inner end of the auditory canal and separates it from the middle ear. The membrane is about 1 cm in diameter and slightly concave on its outer surface. It is suspended in a ring-shaped groove in the temporal bone and vibrates freely in response to sound. It is innervated by sensory branches of the vagus and trigeminal nerves and is highly sensitive to pain.

Posteriorly, the tympanic cavity is continuous with the mastoidal air cells in the mastoid process. It is filled with air that enters by way of the **auditory (eustachian)¹⁸ tube**, a passageway to the nasopharynx. (Be careful not to confuse *auditory tube* with *auditory canal*.) The auditory tube is normally flattened and closed, but swallowing or yawning opens it and allows air to enter or leave the tympanic cavity. This equalizes air pressure on both sides of the tympanic membrane, allowing it to vibrate freely. Excessive pressure on one side or the other muffles the sense of hearing. Unfortunately, the auditory tube also allows throat infections to spread to the middle ear (see Insight 16.2).

The tympanic cavity, a space only 2 to 3 mm wide between the outer and inner ears, contains the three smallest bones and the two smallest skeletal muscles of the body. The bones, called the **auditory ossicles¹⁹**, connect the tympanic membrane to the inner ear. Progressing inward, the first is the **malleus²⁰**, which has an elongated *handle* attached to the inner surface of the tympanic membrane; a *head*, which is suspended by a ligament

¹⁷tympan = drum

¹⁸Bartholomeo Eustachio (1524–74), Italian anatomist

¹⁹oss = bone + icle = little

²⁰malleus = hammer

FIGURE 16.11 Internal Anatomy of the Ear.

from the wall of the tympanic cavity; and a *short process*, which articulates with the next ossicle. The second bone, the **incus**,²¹ has a roughly triangular *body* that articulates with the malleus; a *long limb* that articulates with the stapes; and a *short limb* (not illustrated) suspended by a ligament from the wall of the cavity. The **stapes**²² (STAY-pee-z) has an arch and footplate, which give it a shape like a stirrup. The *footplate*, shaped like the sole of a steam iron, is held by a ringlike ligament in an opening called the **oval window**, where the inner ear begins.

INSIGHT 16.2 Clinical Application

Middle-Ear Infection

Otitis²³ **media** (middle-ear infection) is common in children because their auditory tubes are relatively short and horizontal. They allow upper respiratory infections to spread easily from the throat to the tympanic cavity and mastoidal air cells. Fluid accumulates in the cavity and produces pressure, pain, and impaired hearing. If otitis media goes untreated, it may spread from the mastoidal air cells and cause meningitis, a potentially deadly infection (see Insight 14.1). Chronic otitis media can also cause fusion of the middle-ear bones and result in hearing loss. It is sometimes necessary to drain fluid from the tympanic cavity by lancing the tympanic membrane and inserting a tiny drainage tube—a procedure called *tympanostomy*.²⁴ The tube, which is eventually sloughed out of the ear, relieves the pressure and permits the infection to heal.

The muscles of the middle ear are the stapedius and tensor tympani. The **stapedius** (sta-PEE-dee-us) arises from the posterior wall of the cavity and inserts on the stapes. The **tensor tympani** (TEN-sor TIM-pan-eye) arises from the wall of the auditory tube, travels alongside it, and inserts on the malleus. The function of these muscles is discussed under the physiology of hearing.

Inner Ear

The **inner (internal) ear** is housed in a maze of temporal bone passageways called the **bony (osseous) labyrinth**, which is lined by a system of fleshy tubes called the **membranous labyrinth** (fig. 16.12). Between the bony and membranous labyrinths is a cushion of fluid called **perilymph** (PER-ih-limf), similar to cerebrospinal fluid. Within the membranous labyrinth is a fluid called **endolymph**, similar to intracellular fluid. The bony and membranous labyrinths form a tube-within-a-tube structure, somewhat like a bicycle inner tube within the tire.

The labyrinths begin with a chamber called the **vestibule**, which contains organs of equilibrium to be discussed later. The organ of hearing is the **cochlea**²⁵ (COC-lee-uh), a coiled tube that arises from the anterior side of the vestibule. In other vertebrates, the cochlea is straight or slightly curved. In most mammals, however, it assumes the form of a snail-like spiral, which allows a longer cochlea to fit in a compact space. In humans, the spiral is about 9 mm wide at the base and 5 mm high. Its apex points anterolaterally. The cochlea winds for about 2.5 coils around a screwlike axis of spongy bone called the **modiolus**²⁶ (mo-DY-oh-lus). The “threads of the

²¹incus = anvil

²²stapes = stirrup

²³ot = ear + itis = inflammation

²⁴tympano = eardrum + stomy = making an opening

²⁵cochlea = snail

²⁶modiolus = hub

FIGURE 16.12 Anatomy of the Membranous Labyrinth. (a) Position and orientation within the petrous part of the temporal bone. (b) Structure of the membranous labyrinth and nerves. (c) Relationship of the perilymph (green) and endolymph (blue) to the labyrinth.

screw” form a spiral platform that supports the fleshy tube of the cochlea.

A vertical section cuts through the cochlea about five times (fig. 16.13a). A single cross section looks like figure 16.13b. It is important to realize that the structures seen in cross section actually have the form of spiral strips winding around the modiolus from base to apex.

The cochlea has three fluid-filled chambers separated by membranes. The superior chamber is called the **scala²⁷ vestibuli** (SCAY-la vess-TIB-you-lye) and the inferior one is the **scala tympani**. These are filled with perilymph and communicate with each other through a narrow channel at the apex of the cochlea. The scala vestibuli begins near

the oval window and spirals to the apex; from there, the scala tympani spirals back down to the base and ends at the **round window** (fig. 16.12). The round window is covered by a membrane called the *secondary tympanic membrane*.

The middle chamber is a triangular space, the **cochlear duct (scala media)**. It is separated from the scala vestibuli above by a thin **vestibular membrane** and from the scala tympani below by a much thicker **basilar membrane**. Unlike those chambers, it is filled with endolymph rather than perilymph. The vestibular membrane separates the endolymph from the perilymph and helps to maintain a chemical difference between them. Within the cochlear duct, supported on the basilar membrane, is the **spiral organ**, also known as the *acoustic organ* or

²⁷scala = staircase

FIGURE 16.13 Anatomy of the Cochlea. (a) Vertical section. The apex of the cochlea faces downward and anterolaterally in anatomical position. (b) Detail of one section through the cochlea. (c) Detail of the spiral organ.

*organ of Corti*²⁸ (COR-tee)—a thick epithelium of sensory and supporting cells and associated membranes (fig. 16.13c). This is the device that converts vibrations into nerve impulses, so we must pay particular attention to its structural details.

The spiral organ has an epithelium composed of **hair cells** and **supporting cells**. Hair cells are named for the long, stiff microvilli called **stereocilia**²⁹ on their apical surfaces. (Stereocilia should not be confused with true cilia. They do not have an axoneme of microtubules as seen in

cilia, and they do not move by themselves.) Resting on top of the stereocilia is a gelatinous **tectorial**³⁰ **membrane**.

The spiral organ has four rows of hair cells spiraling along its length (fig. 16.14). About 3,500 of these, called **inner hair cells (IHCs)**, are arranged in a row on the medial side of the basilar membrane (facing the modiolus). Each of these has a cluster of 50 to 60 stereocilia, graded from short to tall. Another 20,000 **outer hair cells (OHCs)** are neatly arranged in three rows across from the inner hair cells. Each OHC has about 100 stereocilia arranged in the form of a V, with their tips embedded in

²⁸Alfonso Corti (1822–88), Italian anatomist

²⁹stereo = solid

³⁰tect = roof

FIGURE 16.14 Apical Surfaces of the Cochlear Hair Cells. All signals that we hear come from the inner hair cells on the right.

the tectorial membrane. All that we hear comes from the IHCs, which supply 90% to 95% of the sensory fibers of the cochlear nerve. The function of the OHCs is to adjust the response of the cochlea to different frequencies and enable the IHCs to work with greater precision. We will see later how this is done. Hair cells are not neurons, but synapse with nerve fibers at their base—the OHCs with both sensory and motor neurons and the IHCs with sensory neurons only.

The Physiology of Hearing

We can now examine the way sound affects the ear and produces action potentials. Sound waves enter the auditory canal on one side and nerve signals exit the inner ear on the other. Connecting these is the middle ear, so we begin with an analysis of its contribution.

The Middle Ear

One might wonder why we have a middle ear at all—why the tympanic membrane doesn't simply vibrate against the fluid-filled labyrinth of the inner ear. The reason is that the tympanic membrane, which moves in air, vibrates quite easily, whereas the stapes footplate must push against the fluid of the inner ear. This fluid puts up a much greater resistance to motion than air does. If airborne sound waves struck the stapes footplate directly, or if the inner-ear perilymph directly contacted the inner side of the tympanic membrane, the sound waves would not have enough energy to move the perilymph adequately. The tympanic membrane, however, has 18 times the area of the oval

window. By concentrating the energy of the vibrating tympanic membrane on an area $1/18$ that size, the ossicles create a greater force per unit area at the oval window and overcome the inertia of the perilymph.

The auditory ossicles do not, however, provide any mechanical advantage, any amplification of sound. Vibrations of the stapes against the inner ear normally have the same amplitude as vibrations of the tympanic membrane against the malleus. Why, then, have a lever system composed of three ossicles? Why not simply have one ossicle concentrating the mechanical energy of the tympanic membrane directly on the inner ear?

The answer is that the ossicles serve at times to *lessen* the transfer of energy to the inner ear. They and their muscles have a protective function. In response to a loud noise, the tensor tympani pulls the tympanic membrane inward and tenses it, while the stapedius reduces the motion of the stapes. This **tympanic reflex** muffles the transfer of vibrations from the tympanic membrane to the oval window. The reflex probably evolved in part for protection from loud but slowly building natural sounds such as thunder. The reflex has a latency of about 40 msec, which is not quick enough to protect the inner ear from sudden artificial noises such as gunshots. The tympanic reflex also does not adequately protect the ears from sustained loud noises such as factory noise or loud music. Such noises can irreversibly damage the hair cells of the inner ear. It is therefore imperative to wear ear protection when using firearms or working in noisy environments.

The middle-ear muscles also help to coordinate speech with hearing. Without them, the sound of your own speech would be so loud it could damage your inner ear, and it would drown out soft or high-pitched sounds from other sources. Just as you are about to speak, however, the brain signals these muscles to contract. This dampens the sense of hearing in phase with the inflections of your own voice and makes it easier to hear other people while you are speaking.

Think About It

What type of muscle fibers—slow oxidative or fast glycolytic (see p. 428)—do you think constitute the stapedius and tensor tympani? That is, which type would best suit the purpose of these muscles?

Stimulation of Cochlear Hair Cells

The next step in hearing is based on movement of the cochlear hair cells relative to stationary structures nearby. In this section, we will see how movements of the inner-ear fluids and basilar membrane move the hair cells and why it is important that the tectorial membrane near the hair cells remains relatively still.

A simple mechanical model of the ear can help in visualizing how this happens (fig. 16.15). (The vestibular membrane is omitted from the model for simplicity,

FIGURE 16.15 Mechanical Model of Auditory Function. Each inward movement of the tympanic membrane pushes inward on the auditory ossicles of the middle ear and fluid of the inner ear. This pushes down on the basilar membrane, and pressure is relieved by an outward bulge of the secondary tympanic membrane. Thus the basilar membrane vibrates up and down in synchrony with the vibrations of the tympanic membrane.

❖ *Why would high air pressure in the middle ear reduce the movements of the basilar membrane of the inner ear?*

because it has no significant effect on the mechanics of the cochlea.) As you listen to your favorite music, each inward movement of the tympanic membrane pushes the middle-ear ossicles inward. The stapes, in turn, pushes on the perilymph in the scala vestibuli. Perilymph, like other liquids, cannot be compressed, so it flows away from the stapes footplate. The resulting pressure in the scala vestibuli pushes the vestibular membrane downward; this pushes on the endolymph in the cochlear duct; the endolymph pushes down on the basilar membrane; the basilar membrane pushes on the perilymph in the scala tympani; and finally, the secondary tympanic membrane bulges outward to relieve the pressure. As the cycle of vibration continues, the stapes pulls back from the oval window and all of this happens in reverse.

In short, as the stapes goes in-out-in, the secondary tympanic membrane goes out-in-out, and the basilar membrane goes down-up-down. It is not difficult to see how this happens—the only thing hard to imagine is that it can happen as often as 20,000 times per second! The important thing about all this is that the hair cells, affixed to the basilar membrane, go along for the ride, bobbing up and down as the basilar membrane moves.

To understand how all of this leads to electrical excitation of the hair cells, we must seemingly digress for a moment to examine the tips of the hair cells. These are bathed in a high-potassium fluid, the endolymph. Why is this fluid so rich in potassium, and why is that important?

Potassium is secreted into the endolymph by cells around the circumference of the cochlear duct (on the wall opposite from the modiulus). The vestibular membrane retains this fluid in the duct. Relative to the perilymph, the endolymph has an electrical potential of about

+80 mV, and the interior of the hair cell about -40 mV. Thus there is an exceptionally strong electrochemical gradient from the endolymph to the hair cell cytoplasm. This gradient provides the potential energy that ultimately enables the hair cell to work.

On the inner hair cells—the ones that generate all the signals we hear—each stereocilium has a single transmembrane protein at its tip that functions as a mechanically regulated ion gate. A fine, stretchy protein filament called a **tip link** extends like a spring from the ion channel of one stereocilium to the sidewall of the stereocilium next to it (fig. 16.16). The stereocilia increase in height progressively, so that every stereocilium but the tallest one has a tip link leading to the next taller stereocilium beside it.

Now what of the tectorial membrane? This is a conspicuous structure of the spiral organ that is anchored to the core of the cochlea and remains relatively still as the hair cells dance up and down to the beat of the music. Each time the basilar membrane rises upward toward the tectorial membrane, the hair cell stereocilia are pushed against that membrane and tilt toward the tallest one. As each taller stereocilium bends over, it pulls on the tip link. The tip link, connected to the ion gate of the next shorter stereocilium, pulls the gate open and allows ions to flood into the cell. The gate is nonselective, but since the predominant ion of the endolymph is K^+ , the primary effect of this gating is to allow a quick burst of K^+ to flow into the hair cell. This depolarizes the hair cell while the gate is open, and when the basilar membrane drops and the stereocilium bends the other way, the gate closes and the cell becomes briefly hyperpolarized. During each moment of depolarization, a hair cell releases a burst of neurotransmitter from its base, exciting the sensory dendrite with which the hair cell synapses. Each depolarization thus generates action potentials in the cochlear nerve.

To summarize this process: Each sound wave pushes the tympanic membrane and ossicles inward, creating pressure on the perilymph in the upper chamber (scala vestibuli) of the cochlea. The pressure wave in the inner-ear fluids pushes down on the basilar membrane and is then relieved by the outward bulge of the secondary tympanic membrane. As the tympanic membrane vibrates outward, all of this happens in reverse—the basilar membrane moves up and the secondary tympanic membrane vibrates inward.

Each upward movement of the basilar membrane pushes the inner hair cells closer to the stationary tectorial membrane. This forces the stereocilia to bend in the direction of the tallest one. Each stereocilium has a tip link connecting it to an ion gate at the top of the next shorter stereocilium. When the taller one bends over, it pulls the gate open. Potassium ions flow into the hair cell and depolarize it. The hair cell releases a burst of neurotransmitter, exciting the sensory processes of the cochlear nerve cells below it. Thus a signal is generated in the cochlear nerve and transmitted to the brain.

FIGURE 16.16 Potassium Gates of the Cochlear Hair Cells. Each stereocilium has a K^+ gate at its tip. Vibrations of the cochlea cause each stereocilium to bend and, with its tip link, pull open the K^+ channel of the adjacent stereocilium. The inflow of K^+ depolarizes the hair cell.

Sensory Coding

For sounds to carry any meaning, we must distinguish differences in loudness and pitch. Our ability to do so stems from the fact that the cochlea responds differently to sounds of different amplitude and frequency. Variations in loudness (amplitude) cause variations in the intensity of cochlear vibration. A soft sound produces relatively slight up-and-down movements of the basilar membrane. Hair cells are stimulated only moderately, and a given sound frequency stimulates hair cells in a relatively limited, or focused, region of the cochlea. A louder sound makes the basilar membrane vibrate more vigorously. Hair cells respond more intensely, generating a higher firing frequency in the cochlear nerve, and a given sound frequency excites a greater number of hair cells over a broader expanse of the cochlea. If the brain detects moderate firing rates associated with hair cells in relatively narrow bands of the cochlea, it interprets this as a soft sound. If it detects a high firing frequency in nerve fibers associated with broad bands, it interprets this as a loud sound.

Frequency discrimination is based on a structural gradient in the basilar membrane. At its proximal end (the base of the cochlea), the membrane is attached, narrow, and stiff. At its distal end (the apex of the cochlea), it is unattached, five times wider, and more flexible. Think of the basilar membrane as analogous to a wire stretched

tightly between two posts. If you pluck the wire at one end, a wave of vibration travels down its length and back. This produces a standing wave, with some regions of the wire vertically displaced more than others. Similarly, a sound causes a standing wave in the basilar membrane. The peak amplitude of this wave is near the distal end in the case of low-frequency sounds and nearer the proximal end with sounds of higher frequencies. When the brain receives signals mainly from inner hair cells at the distal end, it interprets the sound as low-pitched; when signals come mainly from the proximal end, it interprets the sound as high-pitched (fig. 16.17). Speech, music, and other everyday sounds, of course, are not pure tones—they create complex, ever-changing patterns of vibration in the basilar membrane that must be decoded by the brain.

Cochlear Tuning

Just as we tune a radio to receive a certain frequency, we also tune our cochlea to receive some frequencies better than others. The outer hair cells (OHCs) are supplied with a few sensory fibers (5%–10% of those in the cochlear nerve), but more importantly, they receive motor fibers from the brain.

In response to sound, the OHCs send nerve signals to the medulla by way of the sensory neurons, and the pons sends signals immediately back to the OHCs by way of the motor neurons. In response, the hair cells shorten

FIGURE 16.17 Frequency Response of the Basilar Membrane of the Cochlea. (a) The cochlea, uncoiled and laid out straight. (b) Sounds produce a standing wave of vibration along the basilar membrane. The peak amplitude of the wave varies with the frequency of the sound, as shown here. The amount of vibration is greatly exaggerated in this diagram to clarify the standing wave. (c) The taper of the basilar membrane and its correlation with sound frequencies. High frequencies (7,000–20,000 Hz) are best detected by hair cells near the narrow proximal end at the left, and low frequencies (20–800 Hz) by hair cells near the wider distal end at the right.

about 10% to 15%. Remember that an OHC is anchored to the basilar membrane below and its stereocilia are embedded in the tectorial membrane above. Therefore, contraction of an OHC reduces the basilar membrane's mobility. This results in some regions of the cochlea sending fewer signals to the brain than neighboring regions, so the brain can better distinguish between the more active and less active hair cells and sound frequencies. When OHCs are experimentally incapacitated, the inner hair cells (IHCs) respond much less precisely to differences in pitch.

There is another mechanism of cochlear tuning involving the inner hair cells. The pons sends efferent fibers to the cochlea that synapse with the sensory nerve fibers near the base of the IHCs. The efferent fibers can inhibit the sensory fibers from firing in some areas of the cochlea, and thus enhance the contrast between signals from the more responsive and less responsive regions. Combined with the previously described role of the OHCs, this sharpens the tuning of the cochlea and our ability to discriminate sounds of different pitch.

INSIGHT 16.3 Clinical Application**Deafness**

Deafness means any hearing loss, from mild and temporary to complete and irreversible. *Conductive deafness* results from any condition that interferes with the transmission of vibrations to the inner ear. Such conditions include a damaged tympanic membrane, otitis media, blockage of the auditory canal, and otosclerosis. *Otosclerosis*³¹ is fusion of the auditory ossicles to each other, or fusion of the stapes to the oval window. Either way, it prevents the bones from vibrating freely. *Sensorineural (nerve) deafness* results from the death of hair cells or any of the nervous elements concerned with hearing. It is a common occupational disease of factory and construction workers, musicians, and other people exposed to frequent or sustained loud sounds. Deafness leads some people to develop delusions of being talked about, disparaged, or cheated. Beethoven said his deafness drove him nearly to suicide.

The Auditory Projection Pathway

The sensory nerve fibers beginning at the bases of the hair cells belong to bipolar sensory neurons. Their somas form a coil, the **spiral ganglion**, around the modiolus (see fig. 16.13), and their axons lead away from the cochlea as the **cochlear nerve**. This nerve joins the *vestibular nerve*, discussed later, and the two together become the *vestibulocochlear nerve* (cranial nerve VIII).

Each ear sends nerve fibers to both sides of the pons. There, they end in the *cochlear nuclei*, synapsing with second-order neurons that ascend to the nearby *superior olivary nucleus* of the pons (fig. 16.18). By way of cranial nerve VIII, the superior olivary nucleus issues the efferent fibers back to the cochlea that are involved in cochlear tuning. By way of cranial nerves V₃ and VII, it also issues motor fibers to the tensor tympani and stapedius muscles, respectively. The superior olivary nucleus also functions in **binaural**³² **hearing**—comparing signals from the right and left ears to identify the direction from which a sound is coming.

Other fibers from the cochlear nuclei ascend to the inferior colliculi of the midbrain. The inferior colliculi help to locate the origin of a sound in space, process fluctuations in pitch that are important for such purposes as understanding another person's speech, and mediate the startle response and rapid head turning that occur in reaction to loud or sudden noises.

Third-order neurons begin in the inferior colliculi and lead to the thalamus. Fourth-order neurons complete the pathway from there to the primary auditory cortex; thus the auditory pathway, unlike most other sensory pathways,

involves not three but four neurons from receptor to cerebral cortex. The primary auditory cortex lies in the superior margin of the temporal lobe deep within the lateral sulcus (see fig. 14.21, p. 544). The temporal lobe is the site of conscious perception of sound, and it completes the information processing essential to binaural hearing. Because of extensive decussation in the auditory pathway, damage to the right or left auditory cortex does not cause a unilateral loss of hearing.

Equilibrium

The original function of the ear in vertebrate evolution was not hearing, but **equilibrium**—coordination, balance, and orientation in three-dimensional space. Only later did vertebrates evolve the cochlea, outer- and middle-ear structures, and auditory function of the ear. In humans, the receptors for equilibrium constitute the **vestibular apparatus**, which consists of three **semicircular ducts** and two chambers—an anterior **saccul**³³ (SAC-yule) and a posterior **utricle**³⁴ (YOU-trih-cul) (see fig. 16.12b, c).

The sense of equilibrium is divided into **static equilibrium**, the perception of the orientation of the head when the body is stationary, and **dynamic equilibrium**, the perception of motion or acceleration. There are two kinds of acceleration: *linear acceleration*, a change in velocity in a straight line, as when riding in a car or elevator, and *angular acceleration*, a change in the rate of rotation, as when your car turns a corner or you swivel in a rotating chair. The saccul and utricle are responsible for static equilibrium and the sense of linear acceleration; the semicircular ducts detect only angular acceleration.

The Saccul and Utricle

The saccul and utricle each contain a 2 by 3 mm patch of hair cells and supporting cells called a **macula**.³⁵ The **macula sacculi** lies nearly vertically on the wall of the saccul, and the **macula utriculi** lies nearly horizontally on the floor of the utricle (fig. 16.19a).

Each hair cell of a macula has 40 to 70 stereocilia and one true cilium called a **kinocilium**.³⁶ The tips of the stereocilia and kinocilium are embedded in a gelatinous **otolithic membrane**. This membrane is weighted with calcium carbonate–protein granules called **otoliths**³⁷ (fig. 16.19b), which add to the weight and inertia of the membrane and enhance the sense of gravity and motion.

Figure 16.19c shows how the macula utriculi detects tilt of the head. With the head erect, the otolithic membrane bears directly down on the hair cells, and stimulation is minimal. When the head is tilted, however, the heavy otolithic membrane sags and bends the stereocilia,

³¹*oto* = ear + *scler* = hardening + *osis* = process, condition

³²*bin* = two + *aur* = ears

³³*saccul* = little sac

³⁴*utricle* = little bag

³⁵*macula* = spot

³⁶*kino* = moving

³⁷*oto* = ear + *lith* = stone

FIGURE 16.18 Auditory Pathways in the Brain. (a) Schematic. (b) Brainstem and frontal section of the cerebrum, showing the locations of auditory processing centers. (cranial nerve V_3 = trigeminal nerve, mandibular division; CN VII = facial nerve; CN VIII = vestibulocochlear nerve)

stimulating the hair cells. Any orientation of the head causes a combination of stimulation to the utricles and saccules of the two ears. The brain interprets head orientation by comparing these inputs to each other and to other input from the eyes and stretch receptors in the neck, thereby detecting whether only the head is tilted or the entire body is tipping.

The inertia of the otolithic membranes is especially important in detecting linear acceleration. Suppose you are sitting in a car at a stoplight and then begin to move. The otolithic membrane of the macula utriculi briefly lags behind the rest of the tissues, bends the stereocilia backward, and stimulates the cells. When you stop at the next light, the macula stops but the otolithic membrane keeps

FIGURE 16.19 The Sacculle and Utricle. (a) Locations of the macula sacculi and macula utriculi. (b) Structure of a macula. (c) Action of the otolithic membrane on the hair cells when the head is tilted.

going for a moment, bending the stereocilia forward. The hair cells convert this pattern of stimulation to nerve signals, and the brain is thus advised of changes in your linear velocity.

The macula sacculi is more nearly vertical and its hair cells therefore respond to vertical acceleration and deceleration. If you are standing in an elevator and it begins to move up, the otolithic membrane of the macula sacculi lags behind briefly and pulls down on the hairs. When the elevator stops, the otolithic membrane keeps going for a moment and bends the hairs upward. In both cases, the hair cells are stimulated and the brain is made aware of your

vertical movements. These sensations are important in such ordinary actions as sitting down, falling, and as your head bobs up and down during walking and running.

The Semicircular Ducts

The head also experiences rotary movements, such as when you spin in a rotating chair, walk down a hall and turn a corner, bend forward to pick something up from the floor, or tilt your head laterally when you lie down in bed. Such movements are detected by the three **semicircular ducts** (fig. 16.20), housed in the bony *semicircular canals*

FIGURE 16.20 The Semicircular Ducts. (a) Structure of the semicircular ducts, with each ampulla opened to show the crista ampullaris and cupula. (b) Detail of the crista ampullaris. (c) Action of the endolymph on the cupula and hair cells when the head is rotated.

of the temporal bone. The *anterior* and *posterior semicircular ducts* are oriented vertically at right angles to each other. The *lateral semicircular duct* is about 30° from the horizontal plane. The orientation of the ducts causes a different duct to be stimulated by rotation of the head in different planes.

The ducts are filled with endolymph. Each one opens into the utricle and has a dilated sac at one end called the **ampulla**.³⁸ Within the ampulla is a mound of hair cells and supporting cells called the **crista**³⁹ **ampullaris**. The hair cells have stereocilia and a kinocilium embedded in

the **cupula**,⁴⁰ a gelatinous cap that extends from the crista to the roof of the ampulla. When the head turns, the duct rotates but the endolymph lags behind. It pushes the cupula, bends the stereocilia, and stimulates the hair cells. After 25 to 30 seconds of continual rotation, however, the endolymph catches up with the movement of the duct and stimulation of the hair cells ceases.

Think About It

The semicircular ducts do not detect motion itself, but only acceleration—a change in the rate of motion. Explain.

³⁸ampulla = little jar

³⁹crista = crest, ridge

⁴⁰cupula = little tub

Projection Pathways

Hair cells of the macula sacculi, macula utriculi, and semicircular ducts synapse at their bases with sensory fibers of the **vestibular nerve**. This and the cochlear nerve merge to form the vestibulocochlear nerve (cranial nerve VIII). Fibers of the vestibular apparatus lead to a complex of four **vestibular nuclei** on each side of the pons and medulla. Nuclei on the right and left sides of the brainstem communicate extensively with each other, so each receives input from both the right and left ears. They process signals about the position and movement of the body and relay information to five targets (fig. 16.21):

1. The cerebellum, which integrates vestibular information into its control of head movements, eye movements, muscle tone, and posture.
2. Nuclei of the oculomotor, trochlear, and abducens nerves (cranial nerves III, IV, and VI). These nerves produce eye movements that compensate for movements of the head (the *vestibulo-ocular reflex*). To observe this effect, hold this book in front of you at a comfortable reading distance and fix your gaze on the middle of the page. Move the book left and right about once per second, and you will be unable to read it. Now hold the book still and shake your head
3. The reticular formation, which is thought to adjust breathing and blood circulation to changes in posture.
4. The spinal cord, where fibers descend the two vestibulospinal tracts on each side (see fig. 13.4, p. 487) and synapse on motor neurons that innervate the extensor (antigravity) muscles. This pathway allows you to make quick movements of the trunk and limbs to keep your balance.
5. The thalamus, which relays signals to two areas of the cerebral cortex. One is at the inferior end of the postcentral gyrus adjacent to sensory regions for the face. It is here that we become consciously aware of body position and movement. The other is slightly rostral to this, at the inferior end of the central sulcus in the transitional zone from primary sensory to motor cortex. This area is thought to be involved in motor control of the head and body.

FIGURE 16.21 Vestibular Projection Pathways in the Brain.

• Before You Go On

Answer the following questions to test your understanding of the preceding section:

16. What physical properties of sound waves correspond to the sensations of loudness and pitch?
17. What is the benefit of having auditory ossicles and muscles in the middle ear?
18. Explain how vibration of the tympanic membrane ultimately produces fluctuations of membrane voltage in a cochlear hair cell.
19. How does the brain recognize the difference between the musical notes high C and middle C? Between a loud sound and a soft one?
20. How does the function of the semicircular ducts differ from the function of the saccule and utricle?
21. How is sensory transduction in the semicircular ducts similar to that in the saccule and utricle?

16.5 Vision

Objectives

When you have completed this section, you should be able to

- describe the anatomy of the eye and its accessory structures;
- discuss the structure of the retina and its receptor cells;
- explain how the optical system of the eye creates an image on the retina;
- discuss how the retina converts this image to nerve signals;
- explain why different types of receptor cells and neural circuits are required for day and night vision;
- describe the mechanism of color vision; and
- trace the visual projection pathways in the brain.

Light and Vision

Vision (sight) is the perception of objects in the environment by means of the light that they emit or reflect. *Light* is visible electromagnetic radiation. Human vision is limited to wavelengths ranging from about 400 to 700 nm. The *ultraviolet (UV)* radiation just below 400 nm and the *infrared (IR)* radiation just above 700 nm are invisible to us, although some animals can see a little farther into those ranges than we can. Most solar radiation that reaches the surface of the earth falls within this range; most radiation of shorter and longer wavelengths is filtered out by ozone, carbon dioxide, and water vapor in the atmosphere. Vision is thus adapted to take advantage

of the radiation that is most available to us. Furthermore, radiation in the ultraviolet range has such high energy that it destroys macromolecules rather than producing the controlled chemical reactions needed for vision, and radiation in the infrared range has such low energy that it merely warms the tissues, also failing to energize chemical reactions.

Accessory Structures of the Orbit

Before considering the eye itself, we will survey the accessory structures located in and around the orbit (figs. 16.22 and 16.23). These include the *eyebrows*, *eyelids*, *conjunctiva*, *lacrimal apparatus*, and *extrinsic eye muscles*:

- The **eyebrows** probably serve mainly to enhance facial expressions and nonverbal communication (see p. 201), but they may also protect the eyes from glare and help to keep perspiration from running into the eye.
- The **eyelids**, or **palpebrae** (pal-PEE-bree), block foreign objects from the eye, prevent visual stimuli from disturbing our sleep, and blink periodically to moisten the eye with tears and sweep debris from the surface. The eyelids are separated from each other by the **palpebral fissure** and meet each other at the corners called the **medial** and **lateral commissures (canthi)**. The eyelid consists largely of the orbicularis oculi muscle covered with skin (fig. 16.23a). It also contains a supportive fibrous **tarsal plate**, which is thickened along the margin of the eyelid. Within the plate are 20 to 25 **tarsal glands** that open along the edge of the eyelid. They secrete an oil that coats the eye and reduces tear

FIGURE 16.22 External Anatomy of the Orbital Region.

FIGURE 16.23 Accessory Structures of the Orbit. (a) Sagittal section of the eye and orbit. (b) The lacrimal apparatus. The arrows indicate the flow of tears from the lacrimal gland, across the front of the eye, into the lacrimal sac, and down the nasolacrimal duct.

• What would be the effect of a blockage of the lacrimal puncta?

evaporation. The **eyelashes** are guard hairs that help to keep debris from the eye. Touching the eyelashes stimulates hair receptors and triggers the blink reflex.

- The **conjunctiva** (CON-junk-TY-vuh) is a transparent mucous membrane that covers the inner surface of the eyelid and anterior surface of the eyeball, except for the cornea. Its primary purpose is to secrete a thin mucous film that prevents the eyeball from drying. It is richly innervated and highly sensitive to pain. It is also very vascular, which is especially evident when the vessels are dilated and the eyes are “bloodshot.” Because it is vascular and the cornea is not, the conjunctiva heals more readily than the cornea when injured.
- The **lacrimal**⁴¹ **apparatus** (fig. 16.23b) consists of the lacrimal (tear) gland and a series of ducts that drain the tears into the nasal cavity. The **lacrimal gland**, about the size and shape of an almond, is nestled in a shallow fossa of the frontal bone in the superolateral corner of the orbit. About 12 short ducts lead from the lacrimal gland to the surface of the conjunctiva. Tears function to cleanse and lubricate the eye surface, deliver oxygen and nutrients to the conjunctiva, and prevent infection by means of a bactericidal enzyme, *lysozyme*. After washing across the eye, the

tears collect near the medial commissure and flow into a tiny pore, the **lacrimal punctum**,⁴² on the margin of each eyelid. The punctum opens into a short **lacrimal canal**, which leads to the **lacrimal sac** in the medial wall of the orbit. From this sac, a **nasolacrimal duct** carries the tears to the inferior meatus of the nasal cavity—thus an abundance of tears from crying or watery eyes can result in a runny nose. Once the tears enter the nasal cavity, they normally flow back to the throat and are swallowed. When we have a cold, the nasolacrimal ducts become swollen and obstructed, the tears cannot drain, and they may overflow from the brim of the eye.

- The **extrinsic eye muscles** are the six muscles attached to the walls of the orbit and to the external surface of the eyeball. **Extrinsic** means arising externally; it distinguishes these from the **intrinsic** muscles inside the eyeball, to be considered later. The extrinsic muscles move the eye (fig. 16.24). They include four *rectus* (“straight”) muscles and two *oblique* muscles. The **superior, inferior, medial, and lateral rectus** originate on the posterior wall of the orbit and insert on the anterior region of the eyeball, just beyond the visible “white of the eye.” They move the eye up, down, medially, and laterally. The **superior oblique** travels along the medial wall of the

⁴¹lacrim = tear

⁴²punct = point

orbit. Its tendon passes through a fibrocartilage ring, the **trochlea**⁴³ (TROCK-lee-uh), and inserts on the superolateral aspect of the eyeball. The **inferior oblique** extends from the medial wall of the orbit to the inferolateral aspect of the eye. To visualize the function of the oblique muscles, suppose you turn your eyes to the right. The superior oblique muscle will slightly depress your right eye, while the inferior oblique slightly elevates the left eye. The opposite occurs when you look to the left. This is the primary function of the oblique muscles, but they also slightly rotate the eyes, turning the “twelve o’clock pole” of each eye slightly toward or away from the nose.

⁴³trochlea = pulley

The superior oblique muscle is innervated by the trochlear nerve (cranial nerve IV), the lateral rectus by the abducens (VI), and the rest of these muscles by the oculomotor nerve (III).

The eye is surrounded on the sides and back by **orbital fat**. It cushions the eye, allows it to move freely, and protects blood vessels and nerves as they pass through the rear of the orbit.

Anatomy of the Eye

The eyeball itself is a sphere about 24 mm in diameter (fig. 16.25) with three principal components: (1) three layers (tunics) that form the wall of the eyeball; (2) optical

FIGURE 16.24 Extrinsic Muscles of the Eye. (a) Lateral view of the right eye. The lateral rectus muscle is cut to show a portion of the optic nerve. (b) Superior view of the right eye. (c) Innervation of the extrinsic muscles; arrows indicate the eye movement produced by each muscle.

● What would cause the greatest loss of visual function—trauma to cranial nerve III, IV, or VI? Why?

components that admit and focus light; and (3) neural components, the retina and optic nerve. The retina is not only a neural component but also part of the inner tunic. The cornea is part of the outer tunic as well as one of the optical components.

The Tunics

The three tunics of the eyeball are as follows:

- The outer **fibrous layer (tunica fibrosa)**. This is divided into two regions: the sclera and cornea. The **sclera**⁴⁴ (white of the eye) covers most of the eye surface and consists of dense collagenous connective tissue perforated by blood vessels and nerves. The **cornea** is the anterior transparent region of modified sclera that admits light into the eye.
- The middle **vascular layer (tunica vasculosa)**. This is also called the **uvea**⁴⁵ (YOU-vee-uh) because it resembles a peeled grape in fresh dissection. It consists of three regions—the choroid, ciliary body, and iris. The **choroid** (CO-royd) is a highly vascular, deeply pigmented layer of tissue behind the retina. It gets its name from a histological resemblance to the

chorion of a fetus. The **ciliary body**, a thickened extension of the choroid, forms a muscular ring around the lens. It supports the iris and lens and secretes a fluid called aqueous humor. The **iris** is an adjustable diaphragm that controls the diameter of the **pupil**, its central opening. It has two pigmented layers: a posterior *pigment epithelium* that blocks stray light from reaching the retina and the *anterior border layer*, which contains pigmented cells called **chromatophores**.⁴⁶ A high concentration of melanin in the chromatophores gives the iris a black, brown, or hazel color. If the melanin is scanty, light reflects from the posterior pigment epithelium and gives the iris a blue, green, or gray color.

- The **inner layer (tunica interna)**. This consists of the retina and beginning of the optic nerve.

The Optical Components

The optical components of the eye are transparent elements that admit light rays, bend (refract) them, and focus images on the retina. They include the *cornea*, *aqueous humor*, *lens*, and *vitreous body*. The cornea has been described already.

⁴⁴scler = hard, tough

⁴⁵uvea = grape

⁴⁶chromato = color + phore = bearer

FIGURE 16.25 The Eye. Sagittal section.

- The **aqueous humor** is a serous fluid secreted by the ciliary body into a space between the iris and lens called the **posterior chamber** (fig. 16.26). It flows through the pupil into the **anterior chamber** between the cornea and iris. From here, it is reabsorbed by a ringlike blood vessel called the **scleral venous sinus (canal of Schlemm)**⁴⁷. Normally the rate of reabsorption balances the rate of secretion (see Insight 16.4 for an important exception).
- The **lens** is composed of flattened, tightly compressed, transparent cells called *lens fibers*. It is suspended behind the pupil by a ring of fibers called the **suspensory ligament** (figs. 16.25 and 16.27), which attaches it to the ciliary body. Tension on the ligament somewhat flattens the lens so it is about 9.0 mm in diameter and 3.6 mm thick at the middle.
- The **vitreous**⁴⁸ **body (vitreous humor)** is a transparent jelly that fills a large space called the *vitreous chamber* behind the lens. An oblique channel through this body called the *hyaloid canal* is the remnant of a *hyaloid artery* present in the embryo (see fig. 16.25).

The Neural Components

The neural components are the retina and optic nerve. The **retina** forms from a cup-shaped outgrowth of the diencephalon (see fig. 14.4, p. 519); it is actually a part of the brain—the only part that can be viewed without dissection. It is a thin transparent membrane attached to the rest of the eye at only two points: the **optic disc**, where the optic nerve leaves the rear (*fundus*) of the eye, and its

INSIGHT 16.4 Clinical Application

Cataracts and Glaucoma

The two most common causes of blindness are cataracts and glaucoma. A *cataract* is clouding of the lens. It occurs as the lens fibers darken with age, fluid-filled bubbles (vacuoles) and clefts appear between the lens fibers, and the clefts accumulate debris from degenerating fibers. Cataracts are a common complication of diabetes mellitus, but can also be induced by heavy smoking, ultraviolet radiation, radiation therapy, certain viruses and drugs, and other causes. They cause the vision to appear milky or as if one were looking from behind a waterfall.⁴⁹ Cataracts can be treated by replacing the natural lens with a plastic one. The implanted lens improves vision almost immediately, but glasses still may be needed for near vision.

Glaucoma is a state of elevated pressure within the eye that occurs when the scleral venous sinus is obstructed so aqueous humor is not reabsorbed as fast as it is secreted. Pressure in the anterior and posterior chambers drives the lens back and puts pressure on the vitreous body. The vitreous body presses the retina against the choroid and compresses the blood vessels that nourish the retina. Without a good blood supply, retinal cells die and the optic nerve may atrophy, producing blindness. Symptoms often go unnoticed until the damage is irreversible. Illusory flashes of light are an early symptom of glaucoma. Late-stage symptoms include dimness of vision,⁵⁰ a narrowed visual field, and colored halos around artificial lights. Glaucoma can be halted with drugs or surgery, but lost vision cannot be restored. This disease can be detected at an early stage in the course of regular eye examinations. The field of vision is checked, the optic nerve is examined, and the intraocular pressure is measured with an instrument called a *tonometer*.

⁴⁹*cataract* = waterfall

scalloped anterior margin, the **ora serrata**.⁵¹ The vitreous body presses the retina smoothly against the rear of the eyeball. The retina can separate from the wall of the eyeball because of blows to the head or insufficient pressure from the vitreous body. Such a *detached retina* may cause blurry areas in the field of vision. It leads to blindness if the retina remains separated for too long from the choroid, on which it depends for oxygen, nutrition, and waste removal.

The retina is examined with an illuminating and magnifying instrument called an *ophthalmoscope*. Directly posterior to the center of the lens, on the visual axis of the eye, is a patch of cells called the **macula lutea**⁵² about 3 mm in diameter (fig. 16.28). In the center of the macula is a tiny pit, the **fovea centralis**,⁵³ which produces the most finely detailed images for reasons that will be apparent later. About 3 mm medial to the macula lutea is the optic disc. Nerve fibers from all regions of the retina converge on this point and exit the eye to form the optic nerve. Blood vessels enter and leave the eye by way of the optic disc. Eye examinations serve for more than evaluating the visual system; they allow for a direct, non-invasive examination of blood vessels for signs of hypertension, diabetes mellitus, atherosclerosis, and other vascular diseases.

The optic disc contains no receptor cells, so it produces a **blind spot** in the visual field of each eye. You can detect your blind spot and observe an interesting visual phenomenon with the help of figure 16.29. Close or cover

FIGURE 16.28 The Fundus (Rear) of the Eye. (a) As seen with an ophthalmoscope. (b) Anatomical features of the fundus. Note the blood vessels diverging from the optic disc, where they enter the eye with the optic nerve. An eye examination also serves as a partial check on cardiovascular health.

❏ *Is this the subject's right or left eye? How can you tell?*

your right eye and hold the page about 30 cm (1 ft) from your face. Fixate on the X with your left eye. Without taking your gaze off the X, move the page slightly forward and back, or right and left, until the red dot disappears. This occurs because the image of the dot is falling on the blind spot of your left eye.

You should notice something else happen at the same time as the dot disappears—a phenomenon called **visual filling**. The green bar seems to fill in the space where the dot used to be. This occurs because the brain uses the image surrounding the blind spot to fill in the area with similar but imaginary information. The brain acts as if it is better to assume that the unseen area probably looks like its surroundings than to allow a dark blotch to disturb your vision.

Formation of an Image

The visual process begins when light rays enter the eye, focus on the retina, and produce a tiny inverted image. When fully dilated, the pupil admits five times as much light as it does when fully constricted. Its diameter is controlled by two sets of contractile elements in the iris: (1) The **pupillary constrictor** consists of smooth muscle cells that encircle the pupil. When stimulated by the parasympathetic nervous system, it narrows the pupil and admits less light to the eye. (2) The **pupillary dilator** consists of a spokelike arrangement of modified contractile epithelial cells called *myoepithelial cells*. When stimulated by the sympathetic nervous system, these cells contract, widen the pupil, and admit more light to the eye (see fig. 15.9, p. 579). Pupillary constriction and dilation occur in two situations: when light intensity changes and when we shift our gaze between distant and nearby objects. Pupillary constriction in response to light is called the **photopupillary reflex**. It is also described as a *consensual light reflex* because both pupils constrict even if only one eye is illuminated. Constriction in response to a shift in gaze is part of the *near response* described later.

The photopupillary reflex is mediated by a parasympathetic reflex arc. When light intensity rises, signals are transmitted from the eye to the *pretectal region* of the upper midbrain. Preganglionic parasympathetic fibers travel by way of the oculomotor nerve from here to the ciliary ganglion in the orbit. From the ganglion, postganglionic fibers continue into the eye, where they stimulate the pupillary constrictor.

Sympathetic innervation to the pupil originates, like all other sympathetic efferents, in the spinal cord. Preganglionic fibers lead from the thoracic cord to the superior cervical ganglion. From there, postganglionic fibers follow the carotid arteries into the head and lead ultimately to the pupillary dilator.

Refraction

Image formation depends on **refraction**, the bending of light rays. Light travels at a speed of 300,000 km/sec in a vacuum, but it slows down slightly in air, water, glass, and other media. The *refractive index* of a medium (n) is a measure of how much it retards light rays relative to air. The refractive index of air is arbitrarily set at $n = 1.00$. If light traveling through air strikes a medium of higher refractive index at a 90° *angle of incidence*, it slows down but does not change course—the light rays are not bent. If it strikes at any other angle, however, the light ray changes direction—it is refracted (fig. 16.30a). The greater the difference in refractive index between the two media, and the greater the angle of incidence, the stronger the refraction is.

As light enters the eye, it passes from a medium with $n = 1.00$ (air) to one with $n = 1.38$ (the cornea). Light rays striking the very center of the cornea pass straight through,

FIGURE 16.30 Principles of Refraction. (a) A refractive medium does not bend light rays that strike it at a 90° angle but does bend rays that enter or leave it at any other angle. (b) Refractive indices of the media from air to retina. The greater the difference between the refractive indices of two media, the more strongly light rays are refracted when passing from one to the next. In vision, most refraction (focusing) occurs as light passes from air to cornea. The lens makes only fine adjustments in the image.

but because of the curvature of the cornea, rays striking off-center are bent toward the center (fig. 16.30b). The aqueous humor has a refractive index of 1.33 and does not greatly alter the path of the light. The lens has a refractive index of 1.40. As light passes from air to cornea, the refractive index changes by 0.38; but as it passes from aqueous humor to lens, the refractive index changes by only 0.07. Thus, the cornea refracts light more than the lens does. The lens merely fine-tunes the image, especially as you shift your focus between near and distant objects.

The Near Response

Emmetropia⁵⁴ (EM-eh-TRO-pee-uh) is a state in which the eye is relaxed and focused on an object more than 6 m (20 ft) away, the light rays coming from that object are essentially parallel, and the rays are focused on the retina without effort. (An *emmetropic eye* does not need a corrective lens to focus the image.) If the gaze shifts to something closer, light rays from the source are too divergent to be focused without effort. In other words, the eye is automatically focused on things in the distance unless you make an effort to focus elsewhere. For a wild animal or our prehistoric ancestors, this arrangement would be

⁵⁴*em* = in + *metr* = measure + *opia* = vision

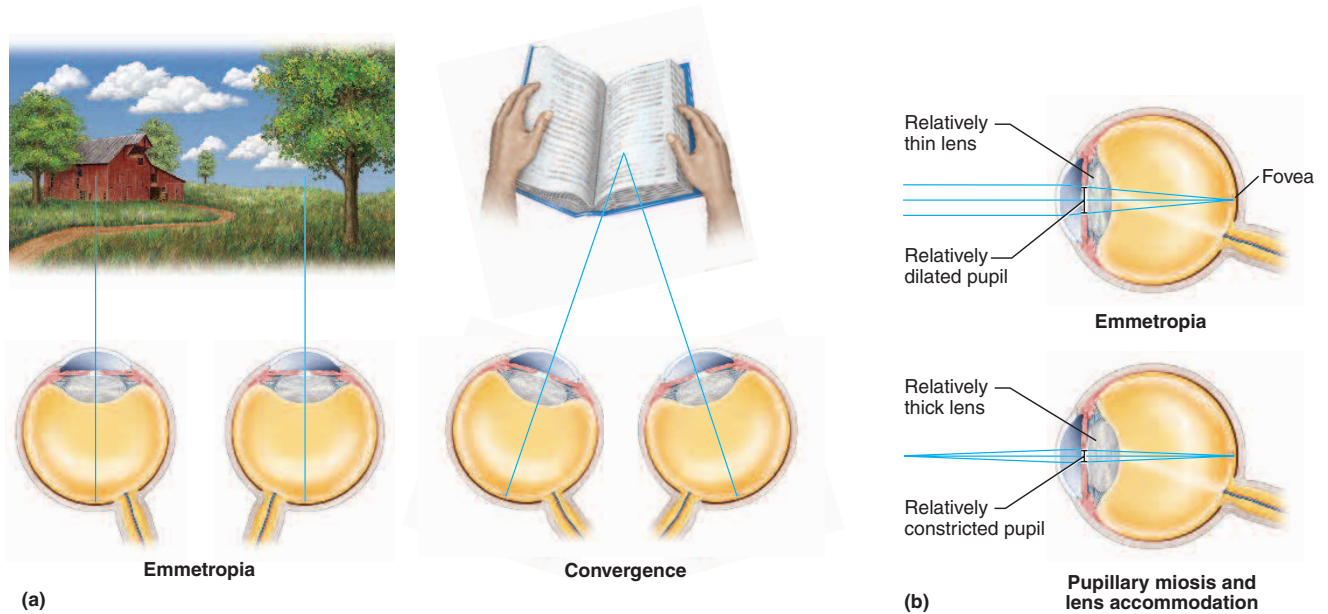

FIGURE 16.31 Emmetropia and the Near Response. (a) Superior view of both eyes fixed on an object more than 6 m away (left), and both eyes fixed on an object closer than 6 m (right). (b) Lateral view of the eye fixed on a distant object (top) and nearby object (bottom).

adaptive because it allows for alertness to predators or prey at a distance.

The **near response** (fig. 16.31), or adjustment to close-range vision, involves three processes to focus an image on the retina:

1. **Convergence of the eyes.** Move your finger gradually closer to a baby's nose and the baby will look cross-eyed at it. This **convergence** of the eyes orients the visual axis of each eye toward the object in order to focus its image on each fovea. If the eyes cannot converge accurately—for example, when the extrinsic muscles are weaker in one eye than in the other—double vision, or *diplopia*,⁵⁵ results. The images fall on different parts of the two retinas and the brain sees two images. You can simulate this effect by pressing gently on one eyelid as you look at this page; the image of the print will fall on noncorresponding regions of the two eyes and cause you to see double.
2. **Constriction of the pupil.** Lenses cannot refract light rays at their edges as well as they can closer to the center. The image produced by any lens is therefore somewhat blurry around the edges; this *spherical aberration* is quite evident in an inexpensive microscope. It can be minimized by screening out these peripheral light rays and looking only at the

better-focused center. In the eye, the pupil serves this purpose by constricting as you focus on nearby objects. Like the diaphragm setting (f-stop) of a camera, the pupil thus has a dual purpose: to adjust the eye to variations in brightness and to reduce spherical aberration.

3. **Accommodation of the lens.** **Accommodation** is a change in the curvature of the lens that enables you to focus on a nearby object. When you look at something nearby, the ciliary muscle surrounding the lens contracts. This narrows the diameter of the ciliary body, relaxes the fibers of the suspensory ligament, and allows the lens to relax into a more convex shape (fig. 16.32). In emmetropia, the lens is about 3.6 mm thick at the center; in accommodation, it thickens to about 4.5 mm. A more convex lens refracts light more strongly and focuses the divergent light rays onto the retina. The closest an object can be and still come into focus is called the **near point of vision**. It depends on the flexibility of the lens. The lens stiffens with age, so the near point averages about 9 cm at the age of 10 and 83 cm by the age of 60.

Some common defects in image formation are described in table 16.2.

Think About It

Which extrinsic muscles of the eyes are the prime movers in convergence?

⁵⁵diplo = double + opia = vision

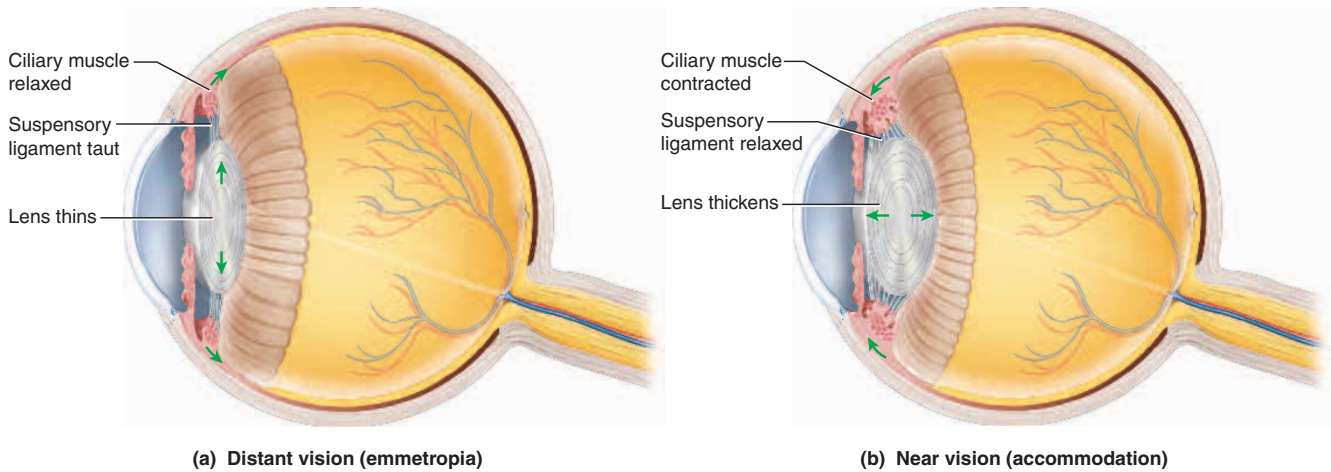

FIGURE 16.32 Accommodation of the Lens. (a) In the emmetropic eye, the ciliary muscle is relaxed and dilated. It puts tension on the suspensory ligament and flattens the lens. (b) In accommodation, the ciliary muscle contracts and narrows in diameter. This reduces tension on the suspensory ligament and allows the lens to relax into a more convex shape.

TABLE 16.2 Common Defects of Image Formation

Astigmatism ⁵⁶	Inability to simultaneously focus light rays that enter the eye on different planes. Focusing on vertical lines, such as the edge of a door, may cause horizontal lines, such as a tabletop, to go out of focus. Caused by a deviation in the shape of the cornea so that it is shaped like the back of a spoon rather than like part of a sphere. Corrected with cylindrical lenses, which refract light more in one plane than another.
Hyperopia ⁵⁷	Farsightedness—a condition in which the eyeball is too short. The retina lies in front of the focal point of the lens, and the light rays have not yet come into focus when they reach the retina (see top of fig. 16.33b). Causes the greatest difficulty when viewing nearby objects. Corrected with convex lenses, which cause light rays to converge slightly before entering the eye.
Myopia ⁵⁸	Nearsightedness—a condition in which the eyeball is too long. Light rays come into focus before they reach the retina and begin to diverge again by the time they fall on it (see top of fig. 16.33c). Corrected with concave lenses, which cause light rays to diverge slightly before entering the eye.
Presbyopia ⁵⁹	Reduced ability to accommodate for near vision with age. Caused by declining flexibility of the lens. Results in difficulty reading and doing close handwork. Corrected with bifocal lenses or reading glasses.

FIGURE 16.33 Two Common Visual Defects and the Effects of Corrective Lenses. (a) The normal emmetropic eye, with light rays converging on the retina. (b) Hyperopia (farsightedness) and the corrective effect of a convex lens. The lens causes light rays to begin converging before they enter the eye, so they reach their focal point farther forward than usual, on the retina of the shortened eyeball. (c) Myopia (nearsightedness) and the corrective effect of a concave lens. By causing light rays to diverge before they enter the eye, this lens shifts the focal point posteriorly so that it falls on the retina of the elongated eye.

Sensory Transduction in the Retina

The conversion of light energy into action potentials occurs in the retina. We begin our exploration of this process with the cellular layout of the retina (fig. 16.34). From there we go to the pigments that absorb light and then to what happens when light is absorbed.

The most posterior part of the retina is the **pigment epithelium**, a darkly pigmented layer that serves, like the black inside of a camera, to absorb stray light so it does not degrade the visual image.

The neural components of the retina consist of three principal cell layers. Progressing from the rear of the eye forward, these are composed of *photoreceptor cells*, *bipolar cells*, and *ganglion cells*:

1. **Photoreceptor cells.** The photoreceptors are cells that absorb light and generate a chemical or electrical signal. There are three kinds: rods, cones, and certain ganglion cells. Only the rods and cones produce visual images; the ganglion cells are discussed later. **Rods** and **cones** are derived from the

same stem cells that produce ependymal cells of the brain. Each rod or cone has an **outer segment** that points toward the wall of the eye and an **inner segment** facing the interior (fig. 16.35). The two segments are separated by a narrow constriction containing nine pairs of microtubules; the outer segment is actually a highly modified cilium specialized to absorb light. The inner segment contains mitochondria and other organelles. At its base, it gives rise to a cell body, which contains the nucleus, and to processes that synapse with retinal neurons in the next layer.

In a rod, the outer segment is cylindrical and resembles a stack of coins in a paper roll—there is a plasma membrane around the outside and a neatly arrayed stack of about 1,000 membranous discs inside. Each disc is densely studded with globular proteins—the visual pigment *rhodopsin*, to be discussed later. The membranes hold these pigment

molecules in a position that results in the most efficient light absorption. Rod cells are responsible for **night (scotopic⁶⁰) vision** and produce images only in shades of gray (monochromatic vision).

A cone cell is similar except that the outer segment tapers to a point, and the discs are not detached from the plasma membrane but are parallel infoldings of it. Cones function in brighter light; they are responsible for **day (photopic⁶¹) vision** as well as color (trichromatic) vision.

- Bipolar cells.** Rods and cones synapse with the dendrites of **bipolar cells**, the first-order neurons of the visual pathway. They in turn synapse with the ganglion cells described next (fig. 16.34b).
