About the Editors

Ann M. Coulston
Ann Coulston is retired from the practice of nutrition and dietetics. She has a more than 20-year history of clinical research at Stanford University Medical Center where her research centered on carbohydrate and lipid metabolism, the nutritional management of diabetes, and insulin resistance. She has provided nutrition consultation to the food and healthcare industry, public relations firms, and Internet companies. She is Past-President of the Academy of Nutrition and Dietetics (formerly the American Dietetic Association) and has been recognized by the Academy of Nutrition and Dietetics Foundation for excellence in the practice of clinical nutrition and the practice of research.

Carol J. Boushey
Carol Boushey is an Associate Research Professor in the Epidemiology Program at the University of Hawaii Cancer Center and an Adjunct Professor in Nutrition Science at Purdue University. Her research focuses on dietary assessment and examining the relationship of dietary intakes or dietary patterns as an exposure for health or risk for disease. Her research has appeared in book chapters and journals, such as the *Journal of the Academy of Nutrition and Dietetics (JAND)*, *Pediatrics, the Journal of Nutrition, the American Journal of Clinical Nutrition*, and *JAMA*. She received a BSc from the University of Washington, a Masters of Public Health from the University of Hawaii at Manoa, and a PhD from the University of Washington through the interdisciplinary nutrition program and the epidemiology program.

Mario G. Ferruzzi
Mario Ferruzzi is a Professor in the Plants for Human Health Institute and the Department of Food, Bioprocessing and Nutrition Science at North Carolina State University. He received his BS in Chemistry from Duke University and PhD in Food Science and Nutrition from the Ohio State University. Previously, Dr. Ferruzzi served as a Professor in the Department of Food Science at Purdue University and previously as a Research Scientist with Nestlé Research & Development. His research focuses on understanding the impact of food formulation and processing on bioavailability, metabolism and biological activity of plant bioactives and micronutrients. He is a Member of the Institute of Food Technologist (IFT), the American Society for Nutrition (ASN), the American Chemical Society (ACS), and the Royal Society of Chemistry (RSC). He currently serves on the editorial board for Critical Reviews in Food Science and Nutrition, Nutrition Research, Nutrition Today and as an Associate Editor for the journal *Food & Function*.

Linda M. Delahanty
Linda Delahanty is Chief Dietitian and Director of Nutrition and Behavioral Research at Massachusetts General Hospital's Diabetes Center and Assistant Professor of Medicine at Harvard Medical School. She is a nationally recognized authority on nutrition and lifestyle interventions for the treatment of diabetes and obesity. She was a recipient of the National Award for Excellence in the Practice of Dietetics Research and the Medallion Award for lifetime achievement in the dietetics profession from the Academy of Nutrition and Dietetics and received the American Diabetes Association's Outstanding Educator in Diabetes Award in 2015. She received her BS in Nutrition and Food Science from the University of Massachusetts Amherst and her MS in Clinical Nutrition from Boston University. Her research focuses on the design of nutrition and lifestyle interventions and examining their impact on diabetes, obesity, hyperlipidemia, breast cancer, quality-of-life and genetics outcomes in both clinical and comparative effectiveness trials.

Preface

Our purpose in creating this text is to provide a compilation of current knowledge in clinical nutrition and an overview of the rationale and science base of its application to practice in the prevention and treatment of disease. The first section addresses the basic principles and concepts that are central to clinical nutrition research methodology. Because nutrition information is gathered from a variety of study designs, research methodology, epidemiology, and intervention studies are reviewed, coupled with data analysis, intervention techniques, and application of behavioral principles to nutrition intervention. In this edition, we have added two new chapters on topics that have come to be used in nutrition research. Metabolomics is discussed in Chapter 5 followed by a technique starting to be used in clinical research, Translational Research in Chapter 6. Throughout these chapters, new areas of study are discussed with the perspective that the application of the scientific method is by definition an evolutionary process. Specific examples, drawn from recently published reports, bring the principles to life.

The second section covers areas of study that contribute to knowledge in clinical nutrition, including disease-relevant biochemistry, metabolism, dietary factors within tissues and cells, and attitudes about food and the eating patterns and behaviors of targeted individuals or groups. This section presents a rich array of topics that cover areas of general interest and nutrition guidelines.

We are continuing with topics on dietary bioactive compounds for health, which explores bioactive components present in edible plants of particular interest for the prevention of disease. Their widespread use has the potential to impact human health on the population level. Uses of these compounds are explored in cognition, eye disease, and obesity. Also, physiological factors that enhance digestion, absorption, and metabolism bring a greater understanding of bioactives to overall health.

Clinical nutrition is the aspect of nutrition science that is related to the development, progression, or management of disease, as differentiated from the issues of normal requirements, cellular functions, and activities. Interventions range from efforts to maintain health during short-term illness to optimization of health status in individuals at risk for or diagnosed with chronic diseases and to major nutritional and dietary modifications as specific or adjuvant treatments for disease. The first condition addressed is the ever-growing concern with overweight and obesity. As with many of the following disease groups, this grouping begins with a chapter on the genetics of human obesity and moves on to issues related to treatment, the role of physical activity, nutrient-related considerations, childhood and adolescent issues, environmental cues controlling energy intake, and surgical therapies.

Cardiovascular disease, also a condition closely related to nutrition, is summarized in three chapters that examine genetic considerations, lipid disorders, and hypertension. Closely related to obesity and cardiovascular disease is diabetes mellitus. It is interesting how many of the clinical nutrition areas interrelate: Obesity is a risk factor for cardiovascular disease and diabetes, whereas diabetes is an independent risk factor for cardiovascular disease. New to the section on diabetes is a chapter on Genetics and Diabetes. Dietary intake or nutritional status may be altered as a result of disease or by the treatment modalities that are used, such as surgical treatments or medical management strategies, including prescription medications. The altered needs must be met by dietary or nutrition interventions in order to prevent malnutrition and the associated consequences that contribute to morbidity and mortality.

Nutrition intervention can be a critical component of disease prevention, an important aspect of disease management, or the primary treatment for disease. This is exemplified by the chapters dealing with cancer, beginning again with a discussion of the genetic components, followed by a discussion of malignancies that have connections to nutrition and specific nutrients. Gastrointestinal diseases, especially the newer knowledge about diet and microflora of the gastrointestinal tract, demonstrate the importance of food choices in disease prevention, treatment, and management. New to the Gastrointestinal section is a chapter on the Microbiome, a burgeoning area many believe will offer new and helpful treatment information. The bone health chapters cover three important topics linked by the nutrients calcium and

vitamin D and tell an important story of the value of early nutrition on health in later years.

Generating and analyzing data that summarize dietary intake and its association with disease are valuable tasks in treating disease and developing disease-prevention strategies. Well-founded medical nutrition therapies can minimize disease development and related complications. Providing scientifically sound, creative, and effective nutrition interventions is challenging and rewarding. We plan to update our knowledge and its application through future editions of this text.

Chapter 1

Dietary Assessment Methodology

Frances E. Thompson and Amy F. Subar
National Cancer Institute, Bethesda, MD, United States

I INTRODUCTION

This chapter is a revision of the similarly named chapter in the earlier editions [1−3] of this book, which itself was based on the "Dietary Assessment Resource Manual" [4] by Frances E. Thompson and Tim Byers, adapted with permission from the *Journal of Nutrition*. Dietary assessment encompasses food supply and production at the national level, food purchases at the household level, and food consumption at the individual level. This review focuses only on individual-level food intake. It is intended to serve as a resource for those who wish to assess diet in a research study, for example, to describe the intakes of a population, using individual measurements for group-level analysis. This chapter does not address clinical assessment of individuals for individual counseling. The first section reviews major dietary assessment methods, their advantages and disadvantages, and validity. The next sections describe which dietary assessment methods are most appropriate for different types of studies and for various types of populations. Finally, specific issues that relate to all methods are discussed.

II DIETARY ASSESSMENT METHODS

A Dietary Records

In the dietary record approach, the respondent records the foods and beverages and the amounts of each consumed over one or more days. Ideally, the recording is done at the time of the eating occasion in order to avoid reliance on memory. The amounts consumed may be measured, using a scale or household measures (e.g., cups or tablespoons), or estimated using models, pictures, or no aid. If multiple days are recorded, they are usually consecutive, and no more than 7 days are included. Recording periods of more than 4 consecutive days are usually unsatisfactory, as reported intakes decrease [5] due to respondent fatigue, and individuals who do comply may differ systematically from those who do not. Because the foods and amounts consumed on consecutive days of reporting may be related (e.g., leftovers and eating more one day and less the next day), it may be advantageous to collect nonconsecutive single-day records in order to increase representativeness of the individual's diet.

To complete a dietary record, each respondent must be trained in the level of detail required to adequately describe the foods and amounts consumed, including the name of the food (brand name, if possible), preparation methods, recipes for food mixtures, and portion sizes. In some studies, this is enhanced if the investigator contacts the respondent and reviews the report after 1 day of recording. At the end of the recording period, a trained interviewer should review the records with the respondent to clarify entries and to probe for forgotten foods [6]. Dietary records also can be recorded by someone other than the subject, such as parents reporting for their children.

The dietary record method has the potential for providing quantitatively accurate information on food consumed during the recording period [7]. By recording foods as they are consumed, the problem of omission may be lessened and the foods more fully described. Furthermore, reporting amounts of food as they are consumed should provide more accurate portion size information than if the respondents were recalling portion sizes of foods previously eaten.

Although intake data using dietary records are typically collected in an open-ended form, close-ended forms have also been developed [8−10]. These forms consist of listings of food groups; the respondent indicates whether that food group has been consumed. In format, these "checklist" forms resemble food frequency questionnaires

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00001-1
2017, Published by Elsevier Inc.

(FFQs) (see Section II.C). Unlike FFQs, which generally query about intake over a specified time period such as the past year or month, checklists are intended to be filled out concurrently with actual intake or at the end of a day for that day's intake. A checklist can be developed to assess particular "core foods" that contribute substantially to intakes of some nutrients [11], and it also has been used to track food contaminants [12]. Portion size can also be asked, either in an open-ended manner or in categories.

A potential disadvantage of the dietary record method is that it is subject to bias both in the selection of the sample and in the sample's completion of the number of days recorded. Dietary record keeping requires that respondents or respondent proxies be both motivated and literate (except for photograph-based methods), which can potentially limit the method's use in some population groups (e.g., low literacy, recent immigrants, children, and some elderly). The requirements for cooperation in keeping records can limit who will respond, compromising the generalizability of the findings from the dietary records to the broader population from which the study sample was drawn. Research indicates that incomplete records increase significantly as more days of records are kept, and the validity of the collected information decreases in the later days of a 7-day recording period, in contrast to information collected in the earlier days [5]. Part of this decrease may occur because many respondents develop the practice of filling out the record retrospectively rather than concurrently. When respondents record only once per day, the record method becomes similar to the 24-hour dietary recall in terms of relying on memory rather than concurrent recording.

An important disadvantage of this method is that recording foods as they are being eaten can affect both the types of food chosen and the quantities consumed [13–15]. The knowledge that foods and amounts must be recorded and the demanding task of doing it may alter the dietary behaviors the tool is intended to measure [16], creating "reactivity bias." This effect is a weakness when the aim is to measure typical dietary behaviors. However, when the aim is to enhance awareness of dietary behaviors and change them, as in some intervention studies, this effect can be seen as an advantage [17]. Recording, by itself, is an effective weight loss technique [18,19]. Recent interest in "real-time" assessment has led to the development of numerous mobile "apps" for self-monitoring that enable concurrent recording and immediate, automated feedback. This approach generally has been found to improve self-monitoring and adherence to dietary goals compared with traditional paper-and-pencil dietary records [20,21].

A third disadvantage is that unless dietary records are collected electronically, the data can be burdensome to code and can lead to high personnel costs. Dietary assessment software that allows for easier data entry using common spellings of foods can save considerable time in data coding. Even with high-quality data entry, maintaining overall quality control for dietary records can be difficult because information often is not recorded consistently among different respondents, nor is the information coded consistently among different coders. This highlights the need for training of both the respondents and the coders.

Several approaches using a variety of technological advances have been used to allow easier data capture and less respondent burden; some may be particularly beneficial among low-literacy groups. For example, a computer-administered instrument allows the respondent to select the food consumed and the appropriate portion size from photographs on a screen [22,23]; this can be done using touch-screen technology [24]. The proliferation of mobile devices with cameras allows simultaneous photographic records of the foods selected [25]. However, for this approach to be quantifiable, before and after pictures of a consumption event and training of the participant in how to consistently take pictures using a standard reference object are required. Wearable cameras which can continuously take pictures or videos have been developed [26,27], lessening the burden on the respondent and potentially allaying some reactivity (i.e., changes in the respondent's behavior that are caused by the instrument). These methods have great potential to improve portion size accuracy.

Automated processing of the image information for these methods is not yet fully developed. The images that illustrate the beginning of the consumption event and its completion must be selected, the food has to be identified [28], and the mathematical properties of the food image need to be quantified [29] in order to develop an accurate estimate of the food's volume. However, if these problems can be solved, the foods can be linked to appropriate databases (see Section V.E), dramatically reducing the burden of coding [30]. In the meantime, the images could be identified manually by staff or the respondent in an accompanying application, and later coded.

Respondent burden and reactivity bias may be less pronounced for the "checklist" [31], because checking off a food item is easier than recording a complete description of the food [32], and the costs of data processing can be minimal, for example, paper forms that are machine scannable, or electronic forms on a computer or mobile device. Checklists are often developed to assess particular foods that contribute substantially to intakes of some nutrients. As the comprehensiveness of the nutrients to be assessed increases, the length of the form also increases, and it becomes more burdensome to complete at each eating occasion and may increase reactivity. Nonetheless, precoded food diaries to assess diet have been developed,

evaluated, and used: the precoded food diary used in the 2005−08 Danish National Survey of Diet and Physical Activity contained about 400 items and portion size choices [33]; a precoded food diary used in Norway contained 277 items [34]. However, checklists are limited in their ability to assess the diet, because of lack of details on the particular food consumed, food preparation, portion sizes, and other relevant information.

Food records have been evaluated most frequently through comparison to another instrument, often 24-hour recalls. However, no self-report instrument is without reporting error, and thus relative validation is not necessarily useful. Instead, when possible, validation studies should consider using "recovery" biomarkers that are unbiased reference instruments. Only a few are currently available. These are total energy expenditure from doubly labeled water for energy [35], and protein (nitrogen) [36], potassium [37], and sodium based on 24-hour urine collections [38]. Many studies in selected small samples of adults indicate that reported energy and protein intakes on dietary records are underestimated in the range of 4−37% compared to energy expenditure as measured by doubly labeled water and protein intake as measured by urinary nitrogen [18,39−53]. In the largest doubly labeled water study using food records, with about 450 postmenopausal women in the Women's Health Initiative, energy and protein intakes reported on food records were underestimated by about 20% and 4%, respectively, and protein density (kcal of protein as a percentage of total kcal) was overestimated by about 17% [54]. Underreporting on dietary records is probably a result of the combined effects of incomplete and inaccurate recording and the impact of the recording process on dietary choices leading to undereating, and thus not typical of usual intake [18,48,55,56]. The highest levels of underreporting on dietary records have been found among individuals with greater body mass index (BMI) [41,43,44,54,57,58], particularly women [41,43,44,52,59−61]. This effect, however, may be due, in part, to the fact that overweight individuals are more likely to be dieting on any given individual day [62]. These relationships between underreporting and BMI and sex have also been found among elderly individuals [63]. Other research shows that demographic or psychological indices such as education, employment, social desirability, body image, or dietary restraint also may be important factors related to underreporting on diet records [41,48,60,61,64−67]. A few studies suggest that energy underreporters compared to others have reported intakes that are lower in absolute intake of most nutrients [58], higher in percentage of energy from protein [58,61], and lower in percentage of energy as carbohydrate [58,61,68,69] and in percentage of energy from fat [69]. Correspondingly, energy underreporters may report lower intakes of desserts, sweet baked goods, butter, and alcoholic beverages [58,69], but more grains, meats, salads, and vegetables [58]. Some research has examined the performance of food checklists relative to accelerometry [70] or, more commonly, complete dietary records [8,9,32], 24-hour dietary recalls [11], dietary history [71], and biological markers [71]. An evaluation study of the 7-day precoded food diary used in the Danish National Survey of Dietary Habits and Physical Activity 2000−02 reported that energy intake was underestimated by 12% compared to accelerometer [70].

Some approaches have been suggested to overcome underreporting in the dietary record. These include enhanced training of respondents and incorporating psychosocial questions known to be related to underreporting in order to control for the effect of underreporting [56]. Another approach is to calibrate dietary records to doubly labeled water or urinary nitrogen, biological indicators of energy expenditure and protein intake, respectively, including covariates of sex, weight, and height, to more accurately predict individuals' energy and protein intake [72]. This approach was applied to a subcohort of the Women's Health Initiative. Calibration equations that included BMI, age, and ethnicity explained much more of the variation in the energy and protein biomarkers than did calibration without the covariates, for example, 45% versus 8% for energy [54]. Further research is needed to test this approach in other populations and to develop and test other modeling approaches.

B 24-Hour Dietary Recall

In the 24-hour dietary recall, the respondent is asked to remember and report all the foods and beverages consumed in the preceding 24 hours or on the preceding day. The recall typically is conducted by interview, in person or by telephone [73,74], either computer-assisted [75] or using a paper-and-pencil form, although self-administered computer administration is becoming more prevalent [76−80]. When interviewer-administered, well-trained interviewers are crucial because much of the dietary information is collected by asking probing questions. Interviewers should be knowledgeable about foods available in the marketplace and about preparation practices, including prevalent regional or ethnic foods.

The interview is often structured, usually with specific probes, to help the respondent remember all foods consumed throughout the day. An early study found that respondents with interviewer probing reported 25% higher dietary intakes than did respondents without interviewer probing [81]. Probing is especially useful in collecting necessary details, such as how foods were prepared. It is also useful in recovering many items not originally reported, such as common additions to foods (e.g., butter on toast) and eating occasions not originally reported

(e.g., snacks and beverage breaks). However, interviewers should be provided with standardized neutral probing questions so as to avoid leading the respondent to specific answers when the respondent really does not know or remember.

The current state-of-the-art 24-hour dietary recall protocol in the United States is the U.S. Department of Agriculture's (USDA) Automated Multiple-Pass Method (AMPM) [82,83], which is used in the U.S. National Health and Nutrition Examination Survey (NHANES). The AMPM five-pass method consists of (1) an initial "quick list," in which the respondent reports all the foods and beverages consumed, without interruption from the interviewer; (2) a forgotten foods list of nine food categories commonly omitted in 24-hour recall reporting; (3) time and occasion, in which the time each eating occasion began and what the respondent would call it are reported; (4) a detail pass, in which probing questions ask for more detailed information about the food and the portion size, in addition to review of the eating occasions and times between the eating occasions; and (5) final review, in which any other item not already reported is asked [82,83]. In addition, a two-dimensional Food Model Booklet [84], developed from USDA research, is used in the NHANES in order to facilitate more accurate portion size estimation. A 24-hour recall interview using the multiple-pass approach typically requires between 30 and 45 minutes.

Data processing software systems are currently available in most developed countries, allowing direct coding of most foods reported during the interview. This is highly efficient with respect to processing dietary data, minimizing missing data, and standardizing interviews [85,86]. If direct coding of the interview is done, methods for the interviewer to easily enter those foods not found in the existing database should be available, and appropriate use of these methods should be reinforced by interviewer training and quality control procedures.

A huge technological advance in 24-hour dietary recall methodology is the development of automated self-administered data collection instruments [76,78–80,87–91]. These systems vary in their design, inclusion of probes regarding details of foods consumed and possible additions and omissions, the approach to asking about portion size, and the number of foods in their databases. The Automated Self-Administered 24-hour dietary recall (ASA24) developed at the National Cancer Institute (NCI) [76,90,91] incorporates many elements of the AMPM 24-hour interview developed by USDA [82]. Prompts used in the AMPM are asked in the program. Portion sizes are reported using digital photographs depicting up to eight sizes as portion size aids [91]. The system uses the most current USDA survey database [92] to allow automated coding and processing and ultimately estimation of nutrient and food group intakes. The ASA24 system is freely available for web or mobile phone administration [76]. Such automated tools make feasible the collection of high-quality dietary data in large-scale population research. Automated self-administered recalls have been compared to interviewer-administered recalls. One study in adolescents found that differences between interviewer- and self-administered recalls were minimal [80]. A feeding study of 86 adults found that the AMPM and the ASA24 were comparable in their agreement with observed intake [93]. Additionally, a large field study in 1083 adults found that nutrient and food group intakes estimated from AMPM and ASA24 recalls were comparable, and that the ASA24 was preferred over the AMPM by 70% of the participants [94].

There are many advantages to the 24-hour recall. When an interviewer administers the tool and records the responses, literacy of the respondent is not required. For self-administered versions, literacy can be a constraint. Because of the immediacy of the recall period, respondents are generally able to recall most of their dietary intake. Because there is relatively little burden on the respondents, those who agree to do 24-hour dietary recalls are more likely to be representative of the population than are those who agree to keep food records. Thus, the 24-hour recall method is useful across a wide range of populations. In addition, interviewers can be trained to capture the detail necessary so that new foods reported can be researched later by the coding staff and coded appropriately. Finally, in contrast to record methods, dietary recalls occur after the food has been consumed, and if unscheduled, reactivity is not a problem.

The main weakness of the 24-hour recall approach is that individuals may not report their food consumption accurately for various reasons related to knowledge, memory, and the interview situation. These cognitive influences are discussed in more detail in Section V.A. A potential limitation, as is true for food records, is that multiple days of recalls may be needed for the study objective. Whereas a single 24-hour recall can be used to describe the average dietary intake of a population, multiple days of recalls are needed to model estimates of the population's usual intake distributions. Multiple administrations of 24-hour recalls also allow more precise estimation of relationships with other factors (see Section V.G).

As with other self-report instruments, relative validation, for example, comparing 24-hour recalls with food records, is not particularly useful. The validity of the 24-hour dietary recall has been studied by comparing respondents' reports of intake either with intakes unobtrusively recorded/weighed by trained observers or with recovery biomarkers. Numerous observational studies of the performance of the 24-hour recall have been conducted with

children (see Section IV.C). In studies of adults, group mean nutrient estimates from 24-hour recalls have been found to be similar to observed intakes [5,95], although respondents with lower observed intakes have tended to overreport energy and those with higher observed intakes have tended to underreport energy [95]. One observational study found energy underreporting during a self-selected eating period in both men and women, similar underreporting during a controlled diet period in men, and accurate reporting during a controlled diet period in women; underestimates of portion sizes accounted for much of the underreporting [96]. A study of adults comparing AMPM and ASA24 to observed intake found that both protocols captured about 80% of the foods and drinks actually consumed; there were few differences in nutrient and food group intakes between observed and reported for both protocols [93]. Studies with the recovery biomarkers of doubly labeled water and urinary nitrogen generally have found underreporting using 24-hour dietary recalls for energy in the range of 3−34% [22,42,79,83,97−103], with the largest two studies in adults using a multiple-pass method showing average underreporting to be between 12% and 23% [83,100]. For protein, underreporting tends to be in the range of 11−28% [97,100,101,103−107]. An analysis of data pooled from five of the larger recovery biomarker studies found an average rate of underreporting of 15% for energy and 5% for protein [108]. However, underreporting is not always found. Some studies found overreporting of energy from 24-hour dietary recalls compared to doubly labeled water in proxy reports for young children and adolescents [109,110]. In addition, it is likely that the commonly reported phenomenon of underreporting in Western countries may not occur in all cultures; for example, Harrison et al. [111] reported that 24-hour recalls collected from Egyptian women were well within expected amounts. Finally, in many studies, energy adjustment has been found to reduce error. For example, for protein density (i.e., percentage energy from protein), 24-hour dietary recalls conducted in the large biomarker studies were in close agreement or somewhat higher compared to a biomarker-based measure [54,100,101].

In past national dietary surveys using multiple-pass methods, findings suggest that energy underreporting may affect up to 15% of all 24-hour recalls [112,113]. Underreporters compared to nonunderreporters tended to report fewer numbers of foods, fewer mentions of foods consumed, and smaller portion sizes across a wide range of food groups and tended to report more frequent intakes of low-fat/diet foods and less frequent intakes of fat added to foods [112]. As was found for records, factors such as BMI, sex, social desirability, restrained eating, education, literacy, perceived health status, and race/ethnicity have been shown in various studies to be related to underreporting in recalls [48,54,62,64,83,98,106,108,112−116]. The 24-hour dietary recall is considered the least biased self-report instrument, and thus is useful for most research purposes. The NCI Dietary Assessment Primer gives extensive guidance as to its use in research studies [117].

C Food Frequency

The food frequency approach asks respondents to report their usual frequency of consumption of each food from a list of foods for a specific period. Information is collected on frequency, but little detail is collected on other characteristics of the foods as eaten, such as the methods of cooking, or the combinations of foods in meals. Many FFQs also incorporate usual portion size questions or specify portion sizes as part of each question. Overall nutrient intake estimates are derived by summing, over all foods, the products of the reported frequency of each food by the amount of nutrient in a specified (or assumed) serving of that food to produce an estimated daily intake of nutrients, dietary constituents, and food groups. In most cases, the purpose of an FFQ is to obtain a crude estimate of usual total daily intakes over a designated time period.

There are many FFQ instruments, and many continue to be adapted and developed for different populations and purposes. Among those evaluated and commonly used are the Block Questionnaires [118], the Harvard University Food Frequency Questionnaires or Willett Questionnaires [119], the Fred Hutchinson Cancer Research Center Food Frequency Questionnaire [120,121], and the NCI's Diet History Questionnaire [122], which was designed with an emphasis on cognitive ease for respondents [123,124]. FFQs have been developed for use with specific populations in the United States (e.g., African Americans, Hispanics) and throughout the world. Because of the number of FFQs available, investigators planning to use an FFQ need to carefully consider which best suits their research needs. "Brief" FFQs that assess a limited number of dietary exposures are discussed in the next section.

The appropriateness of the food list is crucial in the food frequency method. The entire breadth of an individual's diet, which includes many different foods, brands, and preparation practices, cannot be fully captured with a finite food list. Obtaining accurate reports for foods eaten both as single items and in mixtures is particularly problematic. FFQs can ask the respondent either to report a combined frequency for a particular food eaten both alone and in mixtures or to report separate frequencies for each food use. (For example, one could ask about beans eaten alone and in mixtures, or one could ask separate questions about refried beans, bean soups, beans in burritos, etc.) The first approach is cognitively complex for the respondent, but the second approach may lead to double

counting (e.g., burritos with beans may be reported as both beans and as a Mexican mixture). Often, FFQs will include similar foods in a single question (e.g., beef, pork, or lamb). However, such grouping can create a cognitively complex question (e.g., for someone who often eats beef and occasionally eats pork and lamb). Differences in definitions of the food items asked may also be problematic; for example, rice is judged to be a vegetable by many nonacculturated Hispanics living in the United States, a judgment not shared in other race/ethnic groups [125]. Finally, when a group of foods is asked as a single question, assumptions about the relative frequencies of intake of the foods constituting the group are made in the assignment of values in the nutrient database. These assumptions are generally based on information from an external study population (such as from a national survey sample) even though true eating patterns may differ considerably across population subgroups and over time.

Each quantitative FFQ must be associated with a database to allow estimation of nutrient intakes for an assumed or reported portion size of each food queried [126]. For example, the FFQ item of macaroni and cheese encompasses a wide variety of different recipes with different nutrient composition, yet the FFQ database must have a single nutrient composition profile. There are several approaches to constructing such a database. One approach uses quantitative dietary intake information from the target population to define the typical nutrient density of a particular food group category. For example, for the food group macaroni and cheese, all reports of the individual food codes reported in a population survey can be collected, and a mean or median nutrient composition (by portion size if necessary) can be estimated. Values can also be calculated by sex and age. Dietary analysis software, specific to each FFQ, is then used to compute nutrient intakes for individual respondents. These analyses are available commercially for the Block, Willett, and Fred Hutchinson FFQs, and are publicly available for the NCI Diet History Questionnaire.

In pursuit of improving the validity of the FFQ, investigators have addressed a variety of frequency questionnaire design issues, such as length, closed- versus open-ended response categories, portion size, seasonality, and time frame. Frequency instruments designed to assess total diet generally list more than 100 individual line items, many with additional portion size questions, requiring 30–60 minutes to complete. In fact, some research suggests that FFQs with even longer food lists (e.g., 200 items) may perform better than those with shorter food lists (e.g., 100 items) [127]. This raises concern about the length and its effect on response rates. Although respondent burden is a factor in obtaining reasonable response rates for studies in general, a few studies have shown that respondent burden does not seem to be a decisive factor for FFQs [124,128,129]. This tension between length and specificity highlights the difficult issue of how to define a closed-ended list of foods for a food frequency instrument. Using food record intake information, a recently described mathematical approach considers the length, coverage, and explained variance to derive an optimized food list [130]. It is suggested that this tool be used in conjunction with expert judgment from a research nutritionist.

Although the amounts consumed by individuals are considered an important component in estimating dietary intakes, it is controversial as to whether or not portion size questions should be included on FFQs [127]. Frequency has been found to be a greater contributor than serving size to the variance in intake of most foods [131,132], suggesting that the additional respondent burden of reporting serving sizes is not worthwhile. Others cite small improvements in the performance of FFQs that ask the respondents to report a usual serving size for each food [133,134]. Some incorporate portion size and frequency into one question, asking how often a particular portion of the food is consumed [135]. Although some research has been conducted to determine the best ways to ask about portion size on FFQs [123], the marginal benefit of such information in a particular study may depend on the study objective and population characteristics [136]. The ramifications of using self-reported versus standard portion sizes were illustrated in a case–control study that found different odds ratios depending on which metric was used [137].

Another design issue is the time frame about which intake is queried. Most instruments inquire about usual intakes during the past year, but others ask about the past week or month [138], depending on specific research situations. Even when intake during the past year is asked, some studies have indicated that the season in which the questionnaire is administered has an influence on reporting for the entire year [139–141].

Finally, analytical decisions are required in how food frequency data are processed. In research applications in which there are no automated quality checks to ensure that all questions are asked, decisions about how to handle missing data are needed. In particular, in self-administered situations, there are usually many initial frequency questions that are not answered. One approach is to assign null values because some research indicates that respondents selectively omit answering questions about foods they seldom or never eat [142,143]. Another approach is the imputation of frequency values for those not providing valid answers. Only a few studies have addressed this issue [144,145], and it is currently unclear whether imputation is an advance in FFQ analyses. Recently, however, paper and pencil administration has declined and has been replaced by electronic administration which, because of programmable skip patterns, greatly reduces missing data.

Strengths of the FFQ approach are that it is inexpensive to administer and process and it asks about the respondent's usual intake of foods over an extended period of time. Unlike other methods, the FFQ can be used to circumvent recent changes in diet (e.g., changes due to disease) by obtaining information about individuals' diets as recalled about a prior time period. Retrospective reports about diet nearly always use a food frequency approach. Food frequency responses are used to rank individuals according to their usual consumption of nutrients, foods, or groups of foods. Nearly all food frequency instruments are designed to be self-administered, and most are either optically scanned paper versions or administered electronically [118,120,122,146–148]. Because the costs of data collection and processing and the respondent burden have traditionally been much lower for FFQs than for multiple diet records or recalls, FFQs have been a common way to estimate usual dietary intake in large epidemiological studies.

The major limitation of the food frequency method is that it contains a substantial amount of measurement error [54,100–103,149]. Many details of dietary intake are not measured, and the quantification of intake is not as accurate as with recalls or records. Inaccuracies result from an incomplete listing of all possible foods and from errors in frequency and usual serving size estimations. The estimation tasks required for an FFQ are complex and difficult [150]. As a result, the scale for nutrient intake estimates from an FFQ may be shifted considerably, yielding inaccurate estimates of the average intake for the group. Research suggests that longer food frequency lists may overestimate whereas shorter lists may underestimate intake of fruits and vegetables [151], but it is unclear whether or how this applies to nutrients and other food groups.

Portion size of foods consumed is difficult for respondents to evaluate and is thus problematic for all assessment instruments (see Section V.D). However, the inaccuracies involved in respondents attempting to estimate usual portion size in FFQs may be even greater because a respondent is asked to estimate an average for foods that may have highly variable portion sizes across eating occasions and time periods [152].

Because of the error inherent in the food frequency approach, it is generally considered inappropriate to use FFQ data to estimate quantitative parameters, such as the mean and variance, of a population's usual dietary intake [153–158]. Although some FFQs seem to produce estimates of population average intakes that are reasonable [153,159,160], different FFQs will perform in often unpredictable ways in different populations, so the levels of nutrient intakes estimated by FFQs should best be regarded as only approximations [154]. FFQ data are usually energy adjusted and then used for ranking subjects according to food or nutrient intake rather than for estimating absolute levels of intake, and they are used widely in case–control or cohort studies to assess the association between dietary intake and disease risk [161–163]. For estimating relative risks, the degree of misclassification of subjects is more important than is the quantitative scale on which the ranking is made [164].

The definitive validity study for a food frequency–based estimate of long-term usual diet would require nonintrusive observation of the respondent's total diet over a long time. Such studies are not possible in free-living populations. One early feeding study, with three defined 6-week feeding cycles (in which all intakes were known), showed some significant differences in known absolute nutrient intakes compared to the Willett FFQ for several fat components, mostly in the direction of underestimation by the FFQ [165]. Many studies have compared food frequency estimates with those from multiple food recalls or records over a period of time (see [166] for a register of such studies). However, recalls and records cannot be considered as accurate reference instruments because they themselves have error. Validation studies of various FFQs using recovery biomarkers have found that FFQs underestimate energy intake by 11%–35% [42,48,51,54,79,97,99–103] and protein intake by up to 30% [46,47,54,97,100,101,103,167–171]. In a pooled analysis of five larger U.S. biomarker studies, FFQs underestimated energy by 28% and protein by 10% [108]. A few studies show that correlations between a biomarker for protein density constructed from both urinary nitrogen and doubly labeled water and self-reported protein density on an FFQ (kcal of protein as a percentage of total kcal) are higher than correlations between urinary nitrogen and FFQ-reported absolute protein intake [101,103,149], indicating that energy adjustment may alleviate some of the error inherent in food frequency instruments. Various statistical methods employing measurement error models and energy adjustment are used not only to assess the validity of FFQs but also to adjust estimates of relative risks for disease outcomes [54,172–182]. However, analyses indicate that correlations between an FFQ and a reference instrument, such as the 24-hour recall, may be overestimated because of correlated errors [54,101,149]. Furthermore, a few analyses comparing relative risk estimation from FFQs to dietary records [183,184] in prospective cohort studies indicate that observed relationships are attenuated with FFQs, thereby obscuring associations that might exist; however, not all analyses have found this result [185]. Some epidemiologists have suggested that the error in FFQs is a serious enough problem that more accurate methods (e.g., food records or 24-hour recalls) of assessing dietary intake in large-scale prospective studies should be considered [186–188].

Because of relatively large measurement error and bias found with FFQs, the NCI Dietary Assessment Primer suggests they be used sparingly, especially when other instruments such as 24-hour dietary recalls could be used. When FFQs are used as the main instrument, a concurrent calibration study on a subsample of the population using more accurate instruments should be included in the design [117]. See Section V.C for more discussion of calibration. Because FFQ data might be combined with recall or record data to improve estimates of intake and relative risks [188–190], the use of both instruments may be optimal [117].

D Brief Dietary Assessment Instruments

Many brief dietary assessment instruments, also known as "screeners," have been developed. These instruments can be useful in situations that do not require either assessment of the total diet or quantitative accuracy in dietary estimates. For example, a brief diet assessment of some specific dietary components may be used to triage large numbers of individuals into groups to allow more focused attention on those at greatest need for intervention or education. Measurement of dietary intake, even if imprecise, can also serve to activate interest in the respondent, which in turn can facilitate nutrition education. Brief instruments may therefore have utility in clinical settings or in situations in which health promotion and health education is the goal. In the intervention setting, brief instruments focused on specific aspects of a dietary intervention have been used to track changes in diet. However, because of concern that responses to questions of intake that directly evolve from intervention messages may be biased [191] and that these instruments lack sensitivity to detect dietary change [192], this use is not recommended. Brief instruments of specific dietary components such as fruits and vegetables have been used for population surveillance at the state or local level, for example, in the Centers for Disease Control and Prevention's (CDC) Behavioral Risk Factor Surveillance System (BRFSS) [193,194] and the California Health Interview Survey (CHIS) [195] (see Section III.A). Brief instruments have also been used to examine relationships between some specific aspects of diet and other exposures, such as in the National Health Interview Survey (NHIS) [196]. Finally, some suggest the use of brief instruments to evaluate the effectiveness of policy initiatives [195,197,198], although others question the ability of short measures to adequately evaluate dietary changes [199].

Brief instruments can be simplified or targeted FFQs, questionnaires that focus on specific eating behaviors other than the frequency of intake of specific foods, or daily checklists. Complete FFQs typically contain 100 or more food items to capture the range of foods contributing to the many different nutrients in the diet. If an investigator is interested only in estimating the intake of a single nutrient or food group, however, then far fewer foods need to be assessed. Often, only 15–30 foods might be required to account for most of the intake of a particular food component [200,201].

Numerous short questionnaires using a food frequency approach have been developed and compared with multiple days of dietary records, 24-hour recalls, complete FFQs, and/or biological indicators of diet. The NCI has developed a Register of Validated Short Dietary Assessment Instruments [202], which contains descriptive information about short instruments and their validation studies and publications, as well as copies of the instruments when available. To be included, publications are required to be in English language peer-reviewed journals and published since January 1998. Currently, the register includes nearly 140 instruments assessing more than 30 dietary factors from 31 different countries. Instruments in the register may be searched by dietary factors, questionnaire format, and number of questions. Descriptive information about the validation study includes the reference tool, the study population (age, sex, and race/ethnicity), and the geographical location.

Much of the focus in brief instrument development has been on fruits and vegetables and on fats. Some work has addressed other food components that are found in relatively few foods, such as calcium, added sugars, soy, phytoestrogens, and heterocyclic amines [202].

1 Brief Instruments Assessing Fruit and Vegetable Intake

Food frequency-type instruments to measure fruit and vegetable consumption range from a single overall question to 45 or more individual questions [203–207]. An early 7-item tool developed by the NCI and private grantees for NCI's 5 A Day for Better Health Program effort was used widely in the United States [208–210]. This tool was similar to one used in CDC's BRFSS [193,211,212]. Validation studies of the BRFSS and 5 A Day brief instruments to assess fruit and vegetable intake suggested that without portion size adjustments, they often underestimated actual intake [203,208,212–214]. Using cognitive interviewing findings (see Section V.A), NCI revised the tool, including adding portion size questions; some studies indicate improved performance [215] and utility in surveillance studies. However, its performance in community interventions was mixed. In six of eight site/sex comparisons, fruit and vegetable consumption was significantly overestimated in relation to results from multiple 24-hour recalls [216]. More important, the screener indicated change in consumption in both men and women when none was

seen with the 24-hour recalls [217]. The BRFSS fruit and vegetable screener used in 2011−15 in odd years [193] assessed intake of solid fruit and 100% fruit juice and subgroups of vegetables that were particularly relevant to 2010 Dietary Guidelines for Americans [218]. Intake estimates from the 2011 and 2013 assessments with the new tool have been reported [194,219]. The instrument is being redesigned, using questions developed at NCI.

2 Brief Instruments Assessing Fat Intake

The MEDFICTS (meats, eggs, dairy, fried foods, fat in baked goods, convenience foods, fats added at the table, and snacks) questionnaire, initially developed to assess adherence to low total fat (<30% energy from fat) and saturated fat diets [219], asks about frequency of intake and portion size of 20 individual foods that are major food sources of fat and saturated fat in the U.S. diet. Its initial evaluation showed high correlations with dietary records [219]. In addition to the cross-sectional studies, the MEDFICTS underestimated percentage calories from fat; it was effective in identifying very high-fat intakes but was not effective in identifying moderately high-fat diets [220] or correctly identifying low-fat diets [221]. The number of mixtures reported on an FFQ (e.g., pizza and macaroni and cheese), which were not specifically included in the MEDFICTS tool, was negatively related to its predictive ability [221]. In a longitudinal setting, positive changes in the MEDFICTS score have been correlated with improvements in serum lipids and waist circumference among cardiac rehabilitation patients [222]. The instrument has been adapted for other populations with varying success [221,223]. Other fat screeners have been developed to preserve the between-person variability of intake [224−226]—that is, to focus on the fat sources that most distinguish differences in fat intake among individuals or groups. A 20-item screener was developed and tested at the German site of European Prospective Investigation into Cancer and Nutrition correlated with 7-day dietary records ($r = 0.84$) and a complete FFQ ($r = 0.82$) [224,225]. A 16-item percentage energy from fat screener had a correlation of 0.6 with 24-hour recalls in an older U.S. population [226]. However, its performance in overweight African-American women was poorer (mean of 33.0% vs 35.5% energy from fat for screener vs 24-hour recall) [227]. Its performance in an intervention study of adults varied by site [228].

Often, dietary fat reduction interventions are designed to target specific food preparation or consumption behaviors rather than frequency of consuming specific foods. Such behaviors might include trimming the fat from red meats, removing the skin from chicken, or choosing low-fat dairy products. Many questionnaires have been developed in various populations to measure these types of dietary behaviors [229−238], and many have been found to correlate with fat intake estimated from other more detailed dietary instruments [239,240] or with blood lipids [233,241,242]. In addition, some studies have found that changes in dietary behavior scores have correlated with changes in blood lipids [234,241,243]. The instrument has been updated and modified for use in different settings and populations [242,244,245]. A modification tested in African-American adolescent girls had a relatively low correlation ($r = 0.31$) with multiple 24-hour recalls [246]. In another modification developed for African-American women [247], a subset of 30 items from the SisterTalk Food Habits Questionnaire correlated with change in BMI ($r = -0.35$) as strongly as did the original 91 items ($r = -0.36$) [248].

3 Brief Multifactor Instruments

Recognizing the utility of assessing a few dimensions of diet simultaneously, several multifactor short instruments have been developed and evaluated. For example, PrimeScreen is composed of 18 FFQ items asking about consumption of fruits and vegetables, whole and low-fat dairy products, whole grains, fish and red meat, and sources of saturated and trans-fatty acids. The average correlation with estimates from a full FFQ over 18 food groups was 0.6 and over 13 nutrients was also 0.6 [249]. The NCI developed a dietary screener administered in the 2009−10 NHANES that included 28 items addressing consumption of fruits and vegetables, whole grains, added sugars, dairy, fiber, calcium, red meats, and processed meats [250]. This screener was also used in the 2010 and 2015 NHIS Cancer Control Supplement.

Some multicomponent behavioral questionnaires have also been developed. For example, Schlundt et al. [251] developed a 51-item Eating Behavior Patterns Questionnaire targeted at assessing fat and fiber consumption among African-American women. Newly incorporated in this questionnaire were questions to reflect emotional eating and impulsive snacking.

Some instruments combine aspects of food frequency and behavioral questions to assess multiple dietary patterns. For example, the Rapid Eating and Activity Assessment for Patients is composed of 27 items assessing consumption of whole grains, calcium-rich foods, fruits and vegetables, fats, sugary beverages and foods, sodium, and alcohol. When compared to dietary records, correlations were 0.49 with the original Healthy Eating Index (HEI) [252], a measure of overall diet quality, and moderately high (range of $r = 0.33−0.55$) for HEI subscores of fat, saturated fat, cholesterol, fruit, and meat. Correlations for other HEI subscores for sodium, grains, vegetables, and dairy were low (range of $r = 0.03−0.27$) [253].

Because the cognitive processes for answering food frequency-type questions can be complex, some attempts have been made to reduce respondent burden by creating brief instruments with questions that require only "yes−no" answers. This approach has been applied as a modification of the 24-hour recall [254]. These "targeted" 24-hour recall instruments aim to assess particular foods, not the whole diet [71,255−257]. They present a precoded close-ended food list and ask whether the respondent ate each food on the previous day; portion size questions may also be asked. For example, a web-administered checklist has been developed to measure the Dietary Approaches to Stop Hypertension diet. It includes a listing of foods grouped into 11 categories, and it includes serving size information [258].

4 Limitations of Brief Instruments

The brevity of these instruments and their correspondence with dietary intake as estimated by more extensive methods create a seductive option for investigators who would like to measure dietary intake at a low cost. Although brief instruments have many applications, they have several limitations. First, they do not capture information about the entire diet. Most measures are not quantitatively meaningful and, therefore, estimates of dietary intake for the population usually cannot be made. Even when measures aim to provide estimates of total intake, the estimates are approximations and have large measurement error. Finally, the specific dietary behaviors found to correlate with dietary intake in a particular population may not correlate similarly in another population or even in the same population at another time period. For example, a brief instrument developed to assess fast-food and beverage consumption in a primarily white, adolescent population [259] was not useful in an overweight Latina adolescent population [260]. Investigators should carefully consider the needs of their study and their own population's dietary patterns before choosing an "off-the-shelf" instrument designed to briefly measure either food frequency or specific dietary behaviors. Because of these limitations, the NCI Dietary Assessment Primer recommends that short instruments be used sparingly and when used, to be calibrated to a more accurate instrument such as 24-hour dietary recalls [117]. See Section V.C for more discussion on calibration.

E Diet History

The term *diet history* is used in many ways. In the most general sense, a dietary history is any dietary assessment that asks the respondent to report about past diet. Originally, as coined by Burke, the term *dietary history* referred to the collection of information not only about the frequency of intake of various foods but also about the typical makeup of meals [261,262]. Many now imprecisely use the term dietary history to refer to the food frequency method of dietary assessment. However, several investigators have developed diet history instruments that provide information about usual food intake patterns beyond simply food frequency data [263−266]. Some of these instruments characterize foods in much more detail than is allowed in food frequency lists (e.g., preparation methods and foods eaten in combination), and some of these instruments ask about foods consumed at every meal [265,267]. The term diet history is therefore probably best reserved for dietary assessment methods that are designed to ascertain a person's usual food intake in which many details about characteristics of foods as usually consumed are assessed in addition to the frequency and amount of food intake.

The Burke diet history included three elements: a detailed interview about usual pattern of eating, a food list asking for amount and frequency usually eaten, and a 3-day dietary record [261,262]. The detailed interview (which sometimes includes a 24-hour recall) is the central feature of the Burke dietary history, with the food frequency checklist and the 3-day diet record used as cross-checks of the history. The original Burke diet history, which requires administration by an interviewer, has not often been exactly reproduced because of the effort and expertise involved in capturing and coding the information. However, many variations of the Burke method have been developed and used in a variety of settings [263−266,268−272]. These variations attempt to ascertain the usual eating patterns for an extended period of time, including type, frequency, and amount of foods consumed; many include a cross-check feature [273,274].

Some diet history instruments have been automated and adapted for self-administration, sometimes with audio, thus eliminating the need for an interviewer to ask the questions [24,265,275]. Other diet histories have been automated but still continue to be administered by an interviewer [276,277]. Short-term recalls or records are often used for validation or calibration rather than as a part of the tool.

The major strength of the diet history method is its assessment of meal patterns and details of food intake rather than intakes for a short period of time (as in records or recalls) or only frequency of food consumption. Details of the means of preparation of foods can be helpful in better characterizing nutrient intake (e.g., frying vs baking), as well as exposure to other factors in foods (e.g., charcoal broiling). When the information is collected separately for each meal, analyses of the joint effects of foods eaten together are possible (e.g., effects on iron absorption of concurrent intake of tea or foods containing vitamin C). Although a meal-based approach

often requires more time from the respondent than does a food-based approach, it may provide more cognitive support for the recall process. For example, the respondent may be better able to report total bread consumption by reporting bread as consumed at each meal.

A weakness of the approach is that respondents are asked to make many judgments about both the usual foods consumed and the amounts of those foods eaten. These subjective tasks may be difficult for many respondents. Burke cautioned that nutrient intakes estimated from these data should be interpreted as relative rather than absolute. All of these limitations are also shared with the food frequency method. The meal-based approach is not useful for individuals who have no particular eating pattern and may be of limited use for individuals who "graze" (i.e., eat throughout the day rather than at defined mealtimes). The approach, when conducted by interviewers, requires trained nutrition professionals and is thus costly. Finally, the diet history as a method is not well standardized, and thus methods differ from each other and are difficult to reproduce, making comparisons across studies difficult.

Relative to other assessment approaches, few validation studies of diet history questionnaires using biological markers as a basis of comparison have been conducted. The studies found that reported mean energy intakes using the diet history approach in selected small samples of adults were underestimated in the range of 2−23% compared to energy expenditure as measured by doubly labeled water [278−281]. Generally, underreporting of protein, compared to urinary nitrogen, was less than that for energy and only sometimes significantly different [279,281−283]. These results have also been seen in children [284], adolescents [285,286], and the elderly [264]. Because of small sample sizes in these studies, few were able to examine characteristics related to underreporting, and their results were mixed, with some finding more underreporting with higher BMI [283,284] and others finding no relationship [264,280,287]. Although the diet history approach was extensively used as the main study instrument in European cohorts initiated in the 1990s, the approach is seldom used now in new cohort studies as other approaches have evolved. The approach is sometimes used as a reference instrument [288−290].

F Blended Instruments/Combined Instruments

Better understanding of various instruments' strengths and weaknesses has led to creative blending of instruments with the goal of maximizing the strengths of each instrument. For example, a record-assisted 24-hour recall has been used in several studies with children [291,292]. The child keeps notes of what he or she has eaten and then uses these notes as memory prompts in a later 24-hour recall. A mobile phone food record app that includes before and after meal photographs with text entry has been tested in adolescents [293].

Analytical methods for using information from two different instruments are available. For example, Thompson et al. [294] combined information from a series of daily checklists (i.e., precoded record) with frequency reports from an FFQ to form checklist-adjusted estimates of intake. In an evaluation of this approach, agreement with 24-hour recalls improved for energy and protein but was unchanged for protein density [294]. A two-part statistical model developed by NCI uses information from two or more 24-hour recalls, allowing for the inclusion of daily frequency estimates derived from a food propensity questionnaire (a frequency questionnaire that does not ask about portion size), as well as other potentially contributing characteristics (e.g., age and race/ethnicity), as covariates [295]. Frequency information contributes to the model by providing additional information about an individual's propensity to consume a food, and is particularly useful for episodically consumed foods and nutrients [296]. The recalls, however, provide information about the nature and amount of the food consumed. Such methods are used to better measure usual intakes (see Section V.G). Several approaches consisting of multiple dietary assessment instruments are available to estimate associations between diet and disease. A prominent use is to calibrate a frequency questionnaire completed by all study subjects with information from a more accurate instrument, such as a 24-hour recall, completed by a subset. See Section V.C for more discussion of calibration. Carroll et al. [188] explored the number of days of 24-hour recall required to estimate associations between diet and disease in a cohort study and whether an FFQ, in addition, is beneficial. They concluded that for most nutrients and foods, 4−6 nonconsecutive days of 24-hour recall and an FFQ are optimal. The combination of FFQ and multiple 24-hour recalls was superior in estimating some nutrients and foods, especially for episodically consumed foods. Finally, the addition of biomarker information to self-reported dietary information has been shown to increase accuracy and statistical power to estimate associations between diet and disease [297,298].

Table 1.1 summarizes the important characteristics of the main self-report dietary assessment methods.

III DIETARY ASSESSMENT IN DIFFERENT STUDY DESIGNS

The choice of the most appropriate dietary assessment method for a specific research question requires careful

TABLE 1.1 Comparison of Self-Report Dietary Assessment Methods by Important Characteristics

	Dietary Record	24-Hour Recall	FFQ	Diet History	Screener
Type of Information Attainable					
Detailed information about foods consumed	X	X		X	
General information about food groups consumed			X		X
Meal-specific details	X	X		X	
Scope of Information Sought					
Total diet	X	X	X	X	
Specific components					X
Time Frame Asked					
Short term (e.g., yesterday, today)	X	X		X	
Long term (e.g., last month, last year)			X	X	X
Adaptable for Diet in Distant Past					
Yes			X	X	X
No	X	X			
Cognitive Requirements					
Measurement or estimated recording of foods and drinks as they are consumed	X				
Memory of recent consumption		X		X	
Ability to make judgments of long-term diet			X	X	X
Potential for Reactivity					
High	X				
Low		X	X	X	X
Time Required to Complete					
<15 minutes					X
>20 minutes	X	X	X	X	
Suitable for Cross-Cultural Comparisons Without Instrument Adaptation					
Yes	X	X		X	
No			X	X	X

consideration. The primary research question must be clearly formed, and questions of secondary interest should be recognized as such. Projects can fail to achieve their primary goal because of too much attention to secondary goals. The choice of the most appropriate dietary assessment tool depends on many factors. Questions that must be answered in evaluating which dietary assessment tool is most appropriate for a particular research need include the following [162]: (1) Is information needed about foods, nutrients, other food components, or specific dietary behaviors? (2) Is the focus of the research question on describing intakes using estimates of average intake, and does it also require distributional information? (3) Is the focus of the research question on describing relationships between diet and health outcomes? (4) What level of accuracy and precision is needed? (5) What time period is of interest? (6) What are the research constraints in terms of money, interview time, staff, and respondent characteristics?

The NCI Dietary Assessment Primer conceptualizes research questions into four categories: to describe a population's dietary intake; to examine associations between diet as an independent variable and another variable; to examine associations between an independent

variable and diet as a dependent variable; and to evaluate the effect of an intervention on dietary intake. The role of measurement error in tool selection for each research objective is discussed in depth [117].

A Cross-Sectional Surveys

One of the most common types of population studies is the cross-sectional survey, a set of measurements of a population at a particular point in time. Such data can be collected solely to describe a particular population's intake. Alternatively, data can be used for surveillance at the national, state, and local levels as the basis for assessing risk of deficiency, toxicity, and overconsumption; to evaluate adherence to dietary guidelines and public health programs; and to develop food and nutrition policy. Cross-sectional data also may be used for examining associations between current diet and other factors including health. However, caution must be applied in examining many chronic diseases believed to be associated with past diet because the currently measured diet is not necessarily related to past diet. If the study objective requires quantitative estimates of intake, the 24-hour recall and possibly the food record instruments are recommended [117]. Less detailed instruments, such as FFQs or behavioral indicators, may be appropriate when qualitative estimates on limited exposures are sufficient—for example, frequency of consuming sugar-sweetened beverages and frequency of eating from fast-food restaurants.

1 Surveillance/Monitoring

When measurements are collected on a sample at two or more times, the data can be used for purposes of monitoring dietary trends. To assess trends in intakes over time, it would be ideal for the dietary surveillance data collection methods, sampling procedures, and food composition databases to be similar from survey to survey. As a practical matter, however, this is difficult, and the benefits of trend analysis may not outweigh the benefits of improving the methods over time. The dietary assessment method used consistently throughout the years in U.S. national dietary surveillance is the interviewer-administered 24-hour recall. However, recall methodology has improved over time based on cognitive research, the addition of multiple interviewing passes, standardization of probes, automation of the interview, and automation of the coding. The availability of automated self-administered 24-hour recall instruments may lead to further changes in methodology.

Another issue that affects the assessment of trends over time is changes in the nutrient or food grouping databases and specification of default foods. Changes in the food supply are reflected in additions or subtractions to food composition databases, whereas changes in consumption trends may lead to subsequent reassignment of default codes for foods not fully specified in 24-hour recalls or records (e.g., when type of milk is not specified, the default code is now 2% milk as opposed to whole milk in the past). Food composition databases, too, are modified over time because of true changes in food composition, improved analytic methods for particular nutrients, or inclusion of information for new dietary components. Since 1999, the major cross-sectional surveillance survey in the United States has been the NHANES [299]. This survey is conducted by the National Center for Health Statistics. The dietary component of the survey, called "What We Eat in America" [75], consists of 24-hour recalls collected using the USDA's AMPM (see Section II.B). The USDA also processes and analyzes the data. The 24-hour recalls in NHANES query the intake of dietary supplements as well as foods and beverages. Since 2003–04, NHANES has conducted two 24-hour dietary recalls on each respondent, allowing for estimation not only of average usual intake but also of the distributions of usual intake of the dietary components (see Section V.G).

NHANES provides high-quality dietary intake data at the national level, but these data are of limited use for state and local researchers planning and evaluating their programs and policies [300]. Collection of state and local data is often constrained by lack of resources or interview time, leading to the frequent use of less expensive brief instruments. For example, the CDC has used telephone-administered brief instruments to periodically assess fruit and vegetable intake within the BRFSS [193]. The California Department of Public Health, in its California Dietary Practices Survey, has assessed dietary practices among adults biennially since 1989 [301]. The CHIS used telephone-administered brief instruments to assess fruit and vegetable intake in 2001, 2005, and 2009 [195].

B Case–Control (Retrospective) Studies

A case–control study design classifies individuals with regard to current disease status (as cases or controls) and relates this to past (retrospective) exposures. In etiologic research, information about diet before onset of disease is needed. Dietary assessment methods that focus on current behavior, such as the 24-hour recall, are obviously not useful in retrospective studies of long past diet. The food frequency and diet history methods are the only viable choices for case–control (retrospective) studies.

In any food frequency or diet history interview, the respondent is not asked to recall specific memories of each eating occasion but, rather, to respond on the basis of general perceptions of how frequently he or she ate a food. In case–control studies, the relevant period is often the year before diagnosis of disease or onset of symptoms or at particular life stages, such as adolescence and

childhood. Thus, in assessing past diet, an additional requirement is to orient the respondent to the appropriate time period.

The validity of recalled diet from the distant past is difficult to assess because definitive recovery biomarker information (e.g., doubly labeled water, urinary nitrogen) is not available for large samples from long ago. Instead, relative validity and long-term reproducibility of various FFQs have been assessed in various populations by asking participants from past dietary studies to recall their diet from that earlier time [302−304]. These studies have found that correlations between past and current reports about the past vary by nutrient and by food group [135,305], with higher correspondence for very frequently consumed and rarely consumed foods compared to that for foods consumed moderately often [305,306]. Evidence suggests that correspondence between past and recalled past decreases with the length of time between reports [302,307]. In particular, retrospective reports of diet in adolescence after long recall periods (i.e., >30 years) have shown little correspondence with the original reports [308−310]. Maternal reports about diets of their children in early childhood or adolescence and siblings reports of each other's diets in adolescence have also shown low correspondence with the original reports [310,311].

Correspondence of retrospective diet reports with the diet as measured in the original study usually has been greater than the correspondence of current diet with past diet. This observation implies that if diet from years in the past is of interest, it is usually preferable to ask respondents to recall it than to consider current diet as a proxy for past diet. Nonetheless, the current diets of respondents may affect their retrospective reports about past diets. In particular, retrospective diet reports from seriously ill individuals may be biased by recent dietary changes [302,312]. Some studies of groups in whom diet was previously measured indicate no consistent differences in the accuracy of retrospective reporting between those who recently became ill and others [313,314]. However, in two of three studies that have compared baseline prospective dietary information to later retrospective recall of the earlier diet, the correspondence of the information differed between those who later became cases and controls, introducing attenuation into risk estimates [310,315,316].

C Cohort (Prospective) Studies

In a cohort study design, exposures of interest are assessed at baseline and possibly at later times in a group (cohort) of people and disease outcomes occurring over time (prospectively) are then related to the baseline exposure levels. For many chronic diseases, large numbers of individuals need to be followed for years before enough new cases with that disease accrue to have adequate power for statistical analyses. A broad assessment of diet is usually desirable in prospective studies because many dietary exposures and many disease end points will ultimately be investigated, and areas of interest may not even be recognized at the beginning of a cohort study.

In order to relate diet at baseline prior to disease to the eventual occurrence of disease, a measure of the usual intake of foods (see Section V.G) by study subjects is needed. Multiple dietary recalls, multiple records, diet histories, and food frequency methods have all been used effectively in prospective studies. Cost and logistic issues have favored food frequency methods because many prospective studies require thousands of respondents. However, because of concern about significant measurement error and attenuation attributed to the FFQ [183,186,187,317−320], other approaches are being considered. One approach is the use of multiple automated self-administered 24-hour recall instruments (see Section II.B). Another approach is collecting multiple days of dietary records at baseline, with later coding and analysis of records for those respondents selected for analysis, using a nested case−control design [321,322]. The incorporation of emerging technological advances, such as mobile phones, in obtaining dietary records increases the feasibility of such approaches in prospective studies.

If using an FFQ as the main instrument in the cohort, it is desirable to include multiple recalls or records in representative subsamples of the population (preferably before beginning the study) to construct or modify the food frequency instrument and to calibrate it (see Section V.C). Information on the foods consumed could be used to ensure that the FFQ includes the major food sources of key nutrients, with appropriate portion size categories. Because the diets of individuals change over time, it is desirable to measure diet throughout the follow-up period rather than just at baseline. If diet is measured repeatedly over years, repeated calibration is also desirable. Information from calibration studies can be used for three purposes: to assist in study design, such as the sample size needed [164]; to calibrate values from the food frequency tool to values from the recalls/records [180]; and to determine the degree of attenuation/measurement error in the estimates of association observed in the study (e.g., between diet and disease) [175,178,180,182,323−327] (see Section V.C). Some research indicates that an optimal approach to dietary assessment in prospective studies may be the use of both multiple recalls or records and FFQs [188]. The FFQ can be particularly useful in contributing information about episodically consumed foods.

D Intervention Studies

Dietary intervention study designs usually consist of measures of interest for at least two time periods (typically, before and after intervention), and for at least two groups

of participants, those receiving the intervention and those not (i.e., controls). Intervention studies range from relatively small, highly controlled, clinical studies of targeted participants to large trials of population groups.

The need for careful planning and formative research in designing useful community dietary intervention trials has been described [328]. A critical element is the existence of evidence that a particular intervention would create a measurable change in a particular group and setting. Intentional behavior change is a complex and sequential phenomenon, as has been shown for tobacco cessation [329], and this is also true for dietary change [330].

Interventions that aim to change the existing diet may use dietary assessment for two purposes: (1) initial screening for inclusion (or exclusion) into the study and (2) baseline measurement against which dietary changes resulting from the intervention are assessed. Not all intervention trials require initial screening. For those that do, screening can be performed using very detailed instruments or less burdensome instruments. For example, food frequency instruments were used in the Women's Health Trial [331] and in the Women's Health Initiative Dietary Modification Trial [332] to identify groups with high fat intake and thus determine eligibility.

Measurement of the effects of a dietary intervention requires a valid measure of change from baseline to the conclusion of the intervention period, and often, postintervention to assess the durability of any change. Dietary interventions that are expected to change an objective marker, for example, weight or blood lipids, are relatively straightforward to measure and analyze. However, if evaluation of the intervention requires measurement of change in self-reported diets, the task is complex, due to many possible biases.

Although not intending to be deceptive, some respondents may tend to report what they think investigators want to hear, leading to social desirability [333] and social approval [334] biases. Because of their greater subjectivity, behavioral questions, short instruments, and the food frequency method may be more susceptible to social desirability biases than the 24-hour recall method [73,191]. On the other hand, repeated measurement may lead to greater awareness of diet and enhanced reporting skills and thus may enhance accuracy [335]. Dietary records and scheduled 24-hour recalls are vulnerable to reactivity bias. If assessment is by 24-hour recalls, unannounced administration would avoid reactivity but possibly at the expense of participation as successful contact may be more difficult (and expensive). Most importantly, the potential for differential misreporting of diet between study groups (whether the misreporting in each group is similar or different) can affect the integrity of the results. Repeated measures of diet among study subjects can reflect reporting bias in the direction of the change being promoted [336].

Some work has been done to evaluate the use of self-report dietary assessment methods to measure dietary changes [245,336]. Researchers have found that dietary records and scheduled 24-hour recalls are associated with changed eating behavior during the record days and less correspondence with biological measures [337] and expected weight change [338], and increased underreporting [339]. One study using dietary screeners and a reference measure of multiple nonconsecutive unannounced 24-hour recalls found that change in fruit and vegetable intake in the intervention group was overestimated relative to the control group [217]. However, in the same study, a fat screener and the 24-hour recalls were consistent in finding no change in percentage energy from fat in the two groups [340]. Because of resource constraints and respondent burden, large intervention studies have often relied on less precise measures of diet, including FFQs and brief instruments. However, resource constraints may be less relevant with the availability of automated self-administered 24-hour dietary recall instruments and less burdensome dietary records.

Because self-reports of diet are subject to differential response bias in the context of an intervention study [335,336], an independent objective assessment of dietary change should be considered. For example, food availability and/or sales in worksite cafeterias, school cafeterias, or vending machines could be monitored. One such method useful in community-wide interventions is monitoring food sales [341]. Often, cooperation can be obtained from food retailers [342]. However, because the number of food items may be large, it may be possible to monitor only a small number, and the large effects on sales of day-to-day pricing fluctuations should be carefully considered. Another method to consider is measuring changes in biomarkers of diet, such as serum carotenoids [335,343] or serum cholesterol [344]. Consistency of changes in self-reported diet and appropriate biomarkers provides further evidence for real changes in the diet. Finally, social desirability biases could be measured and the resulting scales incorporated into intervention analyses. See Chapter 10, Nutritional Intervention: Lessons from Clinical Trials, and Chapter 11, Biomarkers and Their Use in Nutrition Intervention, for more in-depth discussions of the evaluation of diet in nutrition interventions and use of biomarkers in intervention studies, respectively.

IV DIETARY ASSESSMENT IN SPECIAL POPULATIONS

A Respondents Unable to Self-Report

In many situations, respondents are unavailable or unable to report about their diets. Dietary assessment in young children relies on surrogate reports. In case–control

studies, surrogate reports may be obtained for cases who have died or who are too ill to interview. Although the accuracy of surrogate reports has not been examined using the recovery biomarkers of doubly labeled water or urinary nitrogen, comparability of reports by surrogates and subjects has been studied with the goal that surrogate information might be used interchangeably with information provided by subjects [345]. Common sense indicates that individuals who know most about a subject's lifestyle would make the best surrogate reporters [346]. Adult siblings provide the best information about a subject's early life, and spouses or children provide the best information about a subject's adult life. When food frequency instruments are used, the level of agreement between subject and surrogate reports of diet varies with the food and possibly with other variables, such as number of shared meals, interview situation, case status, and sex of the surrogate reporter. Mean frequencies of use computed for individual foods and food groups between surrogate reporters and subject reporters tend to be similar [347–349], but agreement is much lower when detailed categories of frequency are compared. Several studies have shown that agreement is better for alcoholic beverages, coffee, and tea than for foods.

When subjects themselves report intakes in the extremes of a distribution, their surrogates seldom report intakes in the opposite extreme, although the surrogates tend to report intakes in the middle of the distribution [350]. This may limit the usefulness of surrogate information for analyses that rely on accurate ranking. Furthermore, the quality of surrogate reports between spouses of deceased subjects and spouses of surviving subjects may differ substantially [351]. Thus far, however, little evidence suggests that dietary intakes are systematically overreported or underreported depending on the case status of the subject [352–354]. Nonetheless, use of surrogate respondents should be minimized for obtaining dietary information in analytical studies. When used, analyses excluding the surrogate reports should be done to examine the sensitivity of the reported associations to possible errors or biases in the surrogate reports. If planning a study using surrogate reports, sample size should be inflated to account for higher incidence of missing data, inability to recruit surrogates for some number of cases, and reduced precision of dietary estimates.

B Minority Populations

The widespread use of many "ethnic" foods in the United States throughout the population and the increasing diversity of the population have broadened the food composition databases and food lists used for the general population. Nonetheless, special modifications may be needed in dietary assessment methods when the study population is composed of individuals whose cuisine or cooking practices are not adequately represented in the instrument and/or database [355]. If the method requires an interview, interviewers of the same ethnic or cultural background are preferable so that dietary information can be more effectively communicated. If dietary information is to be quantified into nutrient estimates, examination of the nutrient composition database is necessary to ascertain whether ethnic foods are included and whether those foods and their various preparation methods represent those consumed by the target population [356]. It is also necessary to examine the recipes and assumptions underlying the nutrient composition of certain ethnic foods. Some very different foods may be called the same name, or identical foods may be called by different names [357,358]. For these reasons, it may be necessary to obtain detailed recipe information for all ethnic mixtures reported.

To examine the suitability of the initial database, preliminary information about typical diets should be collected from individuals in the minority groups. This information could come from recalls or records with accompanying interviews or from focus group interviews. These interviews should focus on the foods eaten and the ways in which foods are prepared in that culture. Recipes and alternative names of the same food should be collected, and field interviewers should be familiarized with the results of these focus groups. Recipes and food names that are relatively uniform should be included in the nutrient composition database. Even with these modifications, it may be preferable for the field interviewers to collect detailed descriptions of ethnic foods reported rather than to directly code these foods using preselected lists most common in computer-assisted methods. This would prevent the detail of food choice and preparation from being lost by a priori coding.

USDA continues to incorporate new foods into the National Nutrient Database for Standard Reference (SR) as does the University of Minnesota Nutrient Database System (see Section V.F). If a newly reported food is not available in the food composition database being used, a default code that is thought to closely mirror the nutrient composition of the new food can be used.

Use of FFQs developed for the majority population may be suboptimal for many individuals with different eating patterns. Many individuals consume both foods common in the mainstream culture and foods that are specific to their own culture. Modification of the existing food list can be accomplished through expert judgment, qualitative interviews with the target population [359], and/or examination of the frequency of reported foods in the population from a set of dietary records or recalls. For example, FFQs for Alaska Natives [360], Hispanics [361,362], and African Americans in the southern United States [363] have been developed using these approaches.

In addition to the food list, however, there are other important issues to consider when adapting existing FFQs for use in other populations. The relative intake of different foods within a food group line item may differ, thus requiring a change in the nutrient database associated with each line item. For example, Latino populations may consume more tropical fruit nectars and less apple and grape juice than the general U.S. population and therefore would require a different nutrient composition standard for juices. In addition, the portion sizes generally used may differ [364]. For example, rice may be consumed in larger quantities in Latino and Asian populations; the amount attributed to a large portion for the general population may be substantially lower than the amount typically consumed by Latino and Asian populations. Adaptation of an existing FFQ considering all of these factors has been done for an elderly Puerto Rican population [365], for white and African-American adults in the Lower Mississippi Delta [366], and for the Hawaii–Los Angeles Multiethnic Cohort Study [367]. The Southern Community Cohort Study incorporated both race/ethnicity and geographic region into its FFQ database [368].

With some populations, it may be preferable to administer an FFQ using an interviewer rather than self-administration because literacy and language barriers may limit participation in the study as well as quality of response. In addition, portion size models, which interviewers can bring to a home interview, may be preferable to portion size pictures available in a self-administered instrument [360].

The NCI Dietary Calibration/Validation Studies Register [166] can be used to search for studies using FFQs in specific race/ethnicity groups. Questionnaires aimed at allowing comparison of intakes across multiple cultures have been developed. Although some studies have found no appreciable performance differences across various race/ethnicity groups [369], most have found differences [365,367,370–374]. Understanding these differences is crucial to the appropriate interpretation of study results.

C Children

Assessing the diets of children is considered to be even more challenging than assessing the diets of adults. Children tend to have diets that are highly variable from day to day, and their food habits can change rapidly over time. Younger children are less able to recall, estimate, and cooperate in usual dietary assessment procedures than older children [375], so much information by necessity has to be obtained by surrogate reporters. Although they are more able to report, adolescents may be less motivated to give accurate reports. Baranowski and Domel [376] have posited a cognitive model of how children report dietary information.

Dietary assessment in children and adolescents has been discussed and reviewed [375,377–382]. The 24-hour recall, dietary records (including precoded checklists [8]), dietary histories, FFQs, brief instruments [383–385], and blended instruments such as a dietary record-assisted 24-hour recall [291] have all been used to assess children's intakes. The use of direct observation of children's diets has also been used extensively, most often as a reference method to compare with self-reported instruments [386,387]. As predicted from Baranowski and Domel's model, it has been found that children's estimates of portion size have large error [388], and they are less able than adults to estimate portion sizes [389] (see Section V.D). Overall, the consensus seems to be that the characteristics of different age groups call for the use of different assessment approaches [380].

For preschool-aged children, information is obtained from surrogates, usually the primary caretaker(s), typically a parent or external caregiver. If information is obtained only from one surrogate reporter, the reports are likely to be less complete. Even for periods when the caregiver and child are together, foods tend to be underestimated [390]. A "consensus" recall method, in which the child and parents report as a group on a 24-hour recall, has been shown to give more accurate information than a recall from either parent or child alone [391]. Sobo and Rock [392] describe such interviews and suggest tips for interviewers to maximize data accuracy. Food records have been used in many European population studies [393]. This approach may be acceptable, but is likely to be inappropriate for some populations. The U.S. NHANES administers 24-hour recalls to proxy reporters for children under 6 [394].

For older children, extensive research has been conducted on the self-reported 24-hour recall [395]. Baxter et al. [396] found that among fourth graders, accuracy of the 24-hour recall improves as the time between reporting and eating decreases, and meal-specific intrusions (i.e., reports of foods not consumed) are fewer in an open format interview than in a time-forward format interview (i.e., beginning at the earliest meal in the time period and working forward to the next meal). These intrusions are often associated with additional intrusions at the same meal [396]. Because accuracy of recall is greater when the time between eating and reporting is shorter, there will be differential error by meal; meals further away (e.g., at the beginning of the 24-hour recall period) will have substantially more error [397,398].

To make 24-hour recalls more feasible, self-administered automated 24-hour recall tools have been developed and tested for children [88]. An interviewer-administered 24-hour recall and a self-administered 24-hour recall using the Food Intake Recording Software System (FIRSSt) were compared to unobtrusive

observations in fourth graders. Compared to observed intake, the interviewer-administered 24-hour recall was associated with a 59% match, 17% intrusion, and 24% omission rates, whereas the automated recall was associated with a 46% match, 24% intrusion, and 30% omission rates [88]. The most recent version, FIRSSt4, is an adaptation of the ASA24, simplified for children [399,400] and is available as ASA24-Kids [76]. Particular challenges of self-administered 24-hour recalls in this age group include instigating and maintaining motivation to complete the task, and, because of difficulty in estimating portion size incorporating training for portion size estimation within the application [401]. Other web-based 24-hour recall systems have been developed especially for children and adolescents, for example, SCRAN24 in Great Britain [402], Web DASC in Denmark [403], and CANAA-W in Belgium [404]. The Synchronized Nutrition and Activity Program (SNAP), a partial recall, directs children to report the previous day's food intake by ticking the number of times they consumed each of 40 foods and 9 drinks [405]. Another approach that has been taken with school-age children is a blended instrument, the record-assisted 24-hour recall, in which the children record only the names of foods and beverages consumed throughout a 24-hour period. This information serves as a cue for the later 24-hour recall interview. The European Food Consumption Validation Project, a consortium of 13 institutes from 11 European countries, provisionally recommended a similar approach—a food recording booklet for foods eaten away from home—for school children 7−14 years old. Studies examining the validity of this approach have had mixed results [291,292,406]. For children ages 6−11, the U.S. NHANES administers 24-hour recalls to the child assisted by an adult household member. Children 12 years old and older report for themselves and may have a proxy reporter if necessary [394].

Food frequency approaches are even more challenging for children and adolescents as they are for adults. Children's diets change more quickly over time, and may also be more variable from day to day than adults. In addition, children are less able to conceptualize intake over a long period of time. The instrument itself requires adaptation of the food list, question wording and format, and portion size categories, and consequently the database for converting responses to nutrient intakes. Food frequency instruments, some web administered, have been developed and tested for use in child and adolescent populations [146,407−410]. A web-based food behavioral questionnaire underestimated the intake of middle-school children compared to a multiple-pass 24-hour recall [411]. Generally, correlations between food frequency type instruments and more precise reference instruments have been lower in child and adolescent populations than in adult populations. For these reasons, the food frequency approach is not recommended for children and adolescents.

New technology has been incorporated into some dietary assessment approaches. Williamson et al. [412] developed and tested an observational method using digital photography in school cafeterias. The method consists of standardized photography of the food selected before the meal and the plate waste following the meal. Using reference portions of measured quantities of the foods, expert judgment is used to estimate the amount of each food consumed [413]. Technology-based methods, such as disposable cameras, mobile phones with cameras [414], and smart phones, are being developed for collecting records and may be particularly useful among adolescents, who prefer these methods to traditional methods [415]. Examples of these new methods are the Remote Food Photography Method [416] and Technology Assisted Dietary Assessment [417]. Generally, these methods require more development, and eventual large-scale evaluation.

In addition to performance considerations, the choice of which dietary assessment approach instrument to use in a given study may depend on the study objectives and study design factors, all of which will influence the appropriateness and feasibility of different approaches [418].

D Elderly

Measuring diets among the elderly can, but does not necessarily, present special challenges [419−422]. Both recall and food frequency techniques are inappropriate if memory or cognitive functioning is impaired. Similarly, self-administered tools may be inappropriate if physical disabilities such as poor vision are present. Interviewer administration is difficult when hearing problems are present [421]. Direct observation in institutional care facilities [419] or shelf inventories for elders who live at home can be useful. Even when cognitive integrity is not impaired, several factors can affect the assessment of diet among the elderly. Because of the frequency of chronic illness in this age group, it is more probable that special diets (e.g., low sodium, low fat) would have been recommended. Such recommendations could not only affect actual dietary intake but also bias reporting because individuals may report what they should eat rather than what they do eat. Alternatively, respondents on special diets may be more aware of their diets and may more accurately report them. When dentition is poor, the interviewer should probe regarding foods that are prepared or consumed in different ways. Relative to other age groups, the elderly are more apt to take multiple types of nutritional supplements [423−425], which present special problems

TABLE 1.2 Optimal Strategies for Special Populations

Special Population	Optimal Strategies
Respondents unable to self-report	Use best-informed surrogate
	Analyze effect of potential bias on study results
Ethnic populations	Use interviewers of same ethnic background
	Use nutrient composition database reflective of foods consumed
	For FFQs, use appropriate food list and nutrient composition database
Children	For young children, use caretakers in conjunction with child
	For older children and adolescents, blended instrument and other creative ways of engagement and motivation may work best
	For FFQs, use appropriate food list and portion size categories
Elderly	Assess any special considerations, including memory, special diets, dentition, use of supplements, etc., and adapt methods accordingly

in dietary assessment (see Chapter 2: Assessment of Dietary Supplement Use). Because of the concern of malnutrition among the elderly, specific instruments to detect risk of malnutrition [426], such as the Mini Nutritional Assessment [427] and the Mini Nutritional Assessment Short Form [428,429], the Geriatric Nutritional Risk Index [430–432], the Subjective Global Assessment [426,428], and the Scored Patient-Generated Subjective Global Assessment [433] have been developed. While all of these tools focus on the elderly, they vary by setting, purpose, and administration mode.

Some researchers have suggested that the short-term memory required for the 24-hour recall may be more difficult for the elderly, who are more adept at long-term memory [419]. However, interviewers conducting an FFQ among elderly respondents noted difficulty in maintaining interest and concentration, whereas these issues were not found during the more engaging 24-hour recall interview [420].

Validation studies using doubly labeled water and/or urinary biomarkers among the elderly are limited [42,434–436]. Generally, energy underreporting has been found to be positively related to elevated BMI and lower education, similar to younger populations. However, in the NIH-funded Health, Aging, and Body Composition Study cohort, Shahar et al. [436] found that a substantial portion of elderly reporters were undereaters, losing more than 2% of their weight over a year. The distinction between undereating and underreporting is particularly relevant in the elderly.

Adaptations of standard dietary assessment methods have been suggested and evaluated, including using memory strategies, notifying the respondent prior to the dietary interview [437], combining methods [438], conducting multiple interviews for long protocols [419], and adapting existing instruments [439]. Specific adaptations that have been made in elderly populations include use of household measures rather than pictures to portray portion size for sight-impaired respondents [420] and tailoring the food list and portion sizes to be characteristic of the elderly rather than all adults in FFQs and their related databases [440,441].

Some have suggested including measures of cognitive function within a study to aid interpretation of results, but one such study found no relationship between cognitive functioning score and the validity of an FFQ [442]. In another study those showing cognitive dysfunction were excluded, but this creates selection bias [443]. Another approach is to solicit surrogate information for those considered cognitively unfit [444]. Mobile and web-based methods may prove useful, but currently the acceptance, feasibility, and validity of such methods in the elderly are unknown [422].

The variability in functional status among the elderly suggests the need for a flexible approach in assessing dietary intake. Mixed mode design in survey research [445] has certain advantages with regard to enhancing coverage and decreasing nonresponse, but it may cause other biases [446].

Table 1.2 summarizes special considerations for specific populations.

V SELECTED ISSUES IN DIETARY ASSESSMENT METHODS

A Cognitive Testing Research Related to Dietary Assessment

Nearly all studies using dietary information about subjects rely on the subjects' own reports of their diets. Because such reports are based on complex cognitive processes, it is important to understand and take advantage of what is

known about how respondents remember dietary information and how that information is retrieved and reported to the investigator. The need for and importance of such considerations in the assessment of diet has been discussed by several investigators [302,376,447–449], and research using cognitive testing methods [10,90,123,197,215,253,267,448,450–454] and other qualitative research techniques [400,402,404,455–458] has been reported. A thorough description of cognitive interviewing methods is found in Willis [459,460].

Specific and generic memories of diet are distinctly different. Specific memory relies on particular memories about episodes of eating and drinking, whereas generic memory relies on general knowledge about typical diet. A 24-hour recall relies primarily on specific memory of all actual events in the very recent past, whereas an FFQ that directs a respondent to report the usual frequency of eating a food during the previous year relies primarily on generic memory. As the time between the behavior and the report increases, respondents may rely more on generic memory and less on specific memory [448].

Investigators can do several things to enhance retrieval and improve reporting of diet. Research indicates that the amount of dietary information retrieved from memory can be enhanced by the context in which the instrument is administered and by use of specific memory cues and probes. For example, for a 24-hour recall, foods that were not initially reported by the respondent can be recovered by interviewer probes. The effectiveness of these probes is well-established and is therefore part of the interviewing protocols for all standardized high-quality 24-hour recalls, including those administered in the NHANES. Probes can be useful in improving generic memory, too, when subjects are asked to report their usual diets from periods in the past [302,449]. Such probes can feature questions about past living situations and related eating habits.

The way in which questions are asked can affect responses. Certain characteristics of the interviewing situation may affect particular responses for foods viewed as "good" or "bad." For example, the presence of other family members during the dietary interview may increase bias due to social approval or social desirability traits [333,334], especially for certain items such as alcoholic beverages. An interview in a health setting, such as a clinic, may also increase social approval bias in reporting about foods that were previously proscribed or recommended in that setting. In all instances, interviewers should be trained to refrain from either positive or negative feedback and should repeatedly encourage subjects to accurately report all foods.

B Validation Studies

Validation studies yield information about how well the primary or main method used to collect dietary data is measuring what it is intended to measure. It is important and desirable that the main dietary assessment method be evaluated against a less-biased reference method [179,180,182,461]. Furthermore, even if an instrument has been evaluated and shows satisfactory results, its proposed use in a different population may warrant additional validation research in that population. The purposes of such studies are to better understand how the method works in the particular research setting, to improve it if possible, and to use that information to better interpret results from the overall study.

There are two types of validation studies. The first assesses the validity of reported intakes for a specific number of days or meals in comparison to reference measures that approximate truth such as direct observation, feeding studies, or recovery biomarkers for a time period exactly consistent with each self-reported intake day. The results of this type of study provide estimates of differences in true versus reported intakes of nutrients and food groups, proportion of foods and drinks accurately reported and omitted, and correlation coefficients. This type of study can only be used for short-term instruments such as 24-hour recalls or food records. For example, if the 24-hour recall or food record is the main instrument in a study, available reference instruments include observational techniques, feeding studies, or recovery biomarkers [115,390,462,463]. In observation or feeding studies, accuracy can be assessed by determining the matches, intrusions and exclusions in the foods reported compared to true intakes, and for matches differences between actual and reported nutrient and food group intakes and portion sizes [93,464,465]. Recovery biomarkers are unbiased reference instruments and include 24-hour urine collections to measure protein, sodium, and potassium intakes and doubly labeled water which measures energy expenditure and is used as a measure of energy intake when individuals are in energy balance [41–47,98,167,168,170,171,466,467]. In studies using recovery biomarkers as the reference instruments, intakes estimated from the biomarkers can be compared to reported intakes from recalls or food records to assess reporting error. However, the high cost and increased respondent burden can make the collection of recovery biomarkers impractical for many studies. Additionally, known recovery biomarkers are limited in number.

The second type of validation study assesses how well reported intakes match true usual intakes and collects reference measures such as recovery biomarkers or less-biased self-report dietary assessment instruments for a time period not exactly consistent with each self-reported intake day. This type of validation study can be used across all self-report dietary assessment instruments when interest is in obtaining validation measures of usual intake. For example, when an FFQ is used as the main

study instrument, it can be evaluated in a study that compares it to another less-biased dietary assessment method, such as 24-hour recalls or dietary records and, preferably, to recovery biomarkers. The results are summarized by statistics such as correlation coefficients, bias, and attenuation factors. Correlation coefficients are related to the loss of power to detect relationships between diet and health outcomes. They are also useful for estimating the sample size required in a study because the less precise the diet measure, the more individuals will be needed to attain the desired statistical power [468]. Bias provides information about the difference between average reported intake and average true intake, at the group level. Attenuation factors represent bias in the estimated effect of self-reported dietary components on a health outcome. Some of this "attenuation bias," can be addressed through the use of measurement error models that allow for within-person error in the reference instrument, resulting in estimates that more nearly reflect the correlation between the diet measure and true diet [325,468]. It is important to note that when an FFQ is being evaluated using other biased and imperfect self-report reference instruments such as dietary records or 24-hour recalls, reporting errors between an FFQ and records/recalls are correlated, therefore, the statistical measures that result, such as correlation, bias, and attenuation, will be overly optimistic compared to those determined from unbiased reference instruments such as recovery biomarkers.

Validation and calibration studies (see below) are challenging because of the difficulty and expense in collecting reference dietary information. Because of this, such studies are done frequently on subsamples of the total study sample. If possible, the subsample should be chosen randomly. In addition, it should be sufficiently large to estimate the relationship between the study instrument and a reference method with reasonable precision. Increasing the numbers of individuals sampled and decreasing the number of repeat measures per individual (e.g., for an FFQ validation, collecting two nonconsecutive 24-hour recalls on 100 people rather than four recalls on 50 people) often can help to increase precision without extra cost [469]. The subsequent analyses quantify the relationship between the primary or main dietary intake tool and the reference method, and the resulting statistics can be used for a variety of purposes.

Too often, the term "validated" is used indiscriminately in research publications, to imply that the instrument is "valid," rather than that the instrument has been evaluated [470]. Thus the existence of a validation study is used by some to imply that the instrument is valid, regardless of the validation study's results. Often, validation coefficients in the range of 0.4−0.6 are presented as evidence that an instrument is valid. In reality, however, such findings should not be used to answer a "yes" or "no" question with respect to whether or not an instrument is "valid." Instead, readers should consider how the instrument performed for the purpose of study planning or instrument improvement. One should also consider whether the validation study design used unbiased or imperfect reference measures to evaluate the main instrument. The identification of additional unbiased references is needed to allow more extensive evaluation of self-report dietary assessment instruments.

The NCI maintains a register of validation/calibration studies and publications on the web [166].

C Calibration and Regression Calibration

The term "calibration" is used to refer to the rescaling of dietary data obtained from a more biased, less accurate instrument using information obtained from a less-biased, more accurate instrument. A calibrated instrument can be used to estimate population means and compare subpopulation means more accurately than an instrument that has not been calibrated. Calibration is distinct from "regression calibration," a term used to describe a method that uses calibration as part of a statistical procedure to better estimate associations (e.g., relative risks) between diet and other factors, such as health outcomes.

Calibration can be used to relate reported intakes on an FFQ or screener to a more accurate reference instrument administered in the same population. For example, a study may administer an FFQ to all respondents and the reference instrument (such as 24-hour dietary recalls) to a subsample. Alternatively, external calibration using data from a reference population different from the study population can be performed. In this case, the external population should be similar to the study population. In both situations, scoring algorithms are estimated and used to rescale the dietary data from the screener. The use of such scoring algorithms for screeners has been shown to lead to estimates of mean intakes that are closer to means estimated with 24-hour recall than those derived solely from screeners.

Regression calibration is a method used to adjust estimates of associations between diet and health outcomes for measurement error. This requires a main dietary assessment instrument collected among all study subjects and a reference instrument collected in at least a subsample. This data to accomplish regression calibration often come from a validation study (described above). In cohort studies, the main instrument has most often been an FFQ, although the use of multiple recalls or multiple-day food records is now more feasible than in the past. The estimated regression relationship between an FFQ and the reference method is used to adjust the relationships between diet and outcome (e.g., relative risk of disease for subjects with high nutrient intake compared to those

with low intake) as assessed in the larger study [164,175,176,325,471,472]. Many of these adjustments require the assumption that the reference method is unbiased [175,323]. However, as discussed above, at least for most nutrients and food groups, the reported intakes from reference instruments such as recalls and records are biased in a manner correlated with FFQ [149], violating this assumption, which leads to overestimates of validity. For these reasons, researchers use recovery biomarkers such as urinary nitrogen and doubly labeled water when possible because they are unbiased measures of intake. However, because these are available for only a few nutrients, data from imperfect reference instruments such as 24-hour dietary recalls or food records are used. Such data are assumed to be unbiased for true usual intake, even though they fall short of this ideal. Although using these imperfect reference instruments does not completely adjust estimated diet-outcome associations for the bias caused by dietary measurement error, on average, it may produce less-biased results than an unadjusted standard analysis based solely on FFQ data. Another area in need of further study is the effect of measurement error in a multivariate context because most research thus far has been limited to the effect on univariate relationships [178,182,473,474].

D Mode of Administration

Instruments may be interviewer-administered or self-administered. Interviewer-administered questionnaires may be in person or by telephone. A self-administered instrument may be completed on paper or electronically. All of these modes are currently used for dietary assessment.

For interviewer-administered instruments, telephone administration is less costly than in-person administration. However, concern is increasing about response rates in telephone surveys, given the public's distaste for prevalent telemarketing, technology that allows for screening of calls, the increase in the proportion of the population (especially young adults [475]) who use only wireless telephones, and the general resistance of the public to engage in telephone interviews. For these reasons, response rates obtained using random digit dialing techniques have been dropping.

Despite these difficulties, many surveys and studies do collect dietary data over the telephone. For example, BRFSS [193] and the CHIS [195], both, include dietary screeners. NHANES [299] administers an initial 24-hour recall at the examination site and a second 24-hour recall later by telephone. For 24-hour recalls collected by telephone, the difficulty of reporting serving sizes can be eased by mailing picture booklets or other portion size estimation aids to participants before the interview. Many studies have evaluated the comparability of data from telephone versus in-person 24-hour recall interviews. Several have found substantial but imperfect agreement between dietary data collected by telephone and that estimated by other methods, including face-to-face interviews [74,476–478] or observed intakes [479]. Godwin et al. [480] and Yanek et al. [481] examined the accuracy of portion size estimates for known quantities of foods consumed that were assessed by telephone and by in-person interviews. Both estimates were found to be similarly accurate.

Self-administration is less costly than interviewer-administration. In addition, self-administered surveys tend to minimize social desirability bias [482]. However, self-administration may not be feasible for segments of the population who have low literacy levels or limited motivation. Thus, selection bias is a potential problem.

Web-administered questionnaires have cost advantages and have become popular as the penetrance of the Internet increases. In 2013, 79% of households in the United States had Internet access [483]. Various FFQs [122], dietary history questionnaires [484], screeners [250,485], and 24-hour recall instruments [76,88,486] have been developed for web administration. In general, it has been found that initial response rates for web questionnaires are substantially lower than those for mailed or telephone interviewer questionnaires [487]. One study conducted in Sweden found a lower initial response rate to a web questionnaire compared to a mailed printed questionnaire but greater compliance in answering follow-up questions over the web [488]. Web-administered questionnaires may be more effective than telephone interviewer-administered questionnaires for presentation of complex questions that are better processed visually than aurally by respondents and that can be answered at a pace set by the respondent rather than by the interviewer [489]. Beasley et al. [490] found that the responses to questions about diet on a web-administered FFQ were not significantly different from responses on a paper version of the same questionnaire. One large-scale survey found that self-administered 24-hour recalls using the Internet yielded nutrient intake estimates similar to interviewer telephone-administered 24-hour recalls [94]. The Internet version was preferred over the telephone-administered version by 70% to 30% [94].

Dietary assessment with mobile phones or tablets is an active area of development and research. Several self-administered 24-hour recalls instruments are available on mobile devices [76]. Use of mobile phones to record and photograph foods is also possible [491,492]. Sharp et al. recently reviewed evaluative studies of mobile phones to assess diet [493] and found that validity was comparable but not superior to other conventional methods. Further studies in larger and more diverse populations comparing these mobile devices to other modes of data collection are

needed to examine comparability as well as the potential for self-selection biases.

E Estimation of Portion Size

Research has shown that untrained individuals have difficulty in estimating portion sizes of foods, both when examining displayed foods and when reporting about foods previously consumed [91,389,399,480,494–510]. One study indicates that literacy, but not numeracy, is an important factor in an individual's ability to accurately estimate portion size [511]. Furthermore, respondents appear to be relatively insensitive to changes made in portion size amounts shown in reference categories asked on FFQs [512]. Portion sizes of foods that are commonly bought and/or consumed in defined units (e.g., bread by the slice, pieces of fruit, and beverages in cans or bottles) may be more easily reported than amorphous foods (e.g., steak, lettuce, and pasta) or poured liquids [91,509]. Other studies indicate that small portion sizes tend to be overestimated and large portion sizes underestimated [496,508,513].

Aids are commonly used to help respondents estimate portion size. Research showing that different types of aids are more or less effective for different types of foods [417,510,514] indicates that having multiple types of aids available may be optimal. The NHANES What We Eat in America uses an extensive set of three-dimensional models for an initial in-person 24-hour dietary recall [515]. Respondents then are given a Food Model Booklet developed by the USDA [516] along with a limited number of three-dimensional models and household measures (e.g., measuring cups and spoons) for recalls collected by telephone. Food pictures and models have been developed for other eating patterns, for example, Asian foods [517] and foods consumed in Mexico [518]. The accuracy of reporting using either models or household measures can be improved with training [412,519–521], but the effects may deteriorate with time [522]. Studies comparing the use of either household measures or pictures among children and adolescents indicate that pictures outperform household measures [514,518]. Studies that have compared three-dimensional food models to two-dimensional photographs in adults have shown that there is little difference in the reporting accuracy between methods [388,480,523,524]. One study in children, however, showed that using food models resulted in somewhat larger error than using digital images [506]. Portion size pictures, however presented, should be tailored to the particular populations and ages.

With the increased use of technology in dietary assessment, digital food images in multiple portion sizes are being tested. Studies have investigated the effects of number of portion pictures, size of picture, and concurrent versus sequential display on accuracy of report [91,399,505]. Such studies indicate preferences by respondents but generally little difference in accuracy. However, in two studies, one with adults [91] and the other with children [400], accuracy was higher when more portion size choices were offered. An emerging use of digital technology removes respondent judgments of portion size, instead relying on digital images of foods taken before and after consumption, either actively by the respondent [525,526] or passively by a wearable camera [527,528]. Computer software is then used to both identify foods and estimate the amount consumed.

F Choice of Nutrient and Food Database

It is necessary to use a nutrient composition database when dietary data are to be converted to nutrient intake data. Typically, such a database includes the description of the food, a food code, and the nutrient composition per 100 g of the food. The number of foods and nutrients included varies with the database. Research on nutrients, other dietary components, and foods is ongoing, and there is constant interest in updating current values and providing new values for a variety of dietary components of interest.

Some values in nutrient databases are obtained from laboratory analysis; however, because of the high cost of laboratory analyses, many values are estimated based on conversion factors or other knowledge about the food [529]. In addition, accepted analytical methods are not yet available for some nutrients of interest [530], analytical quality of the information varies with nutrient [530,531], and the variances or ranges of nutrient composition of individual foods are in most cases unknown but are known to be large for some nutrients [532]. Rapid growth in the food processing sector and the global nature of the food supply add further challenges to estimating the mean and variability in the nutrient composition of foods eaten in a specific locale.

One of the USDA's primary missions is to provide nutrient composition data for foods in the U.S. food supply, accounting for various types of preparation [533]. Information about the USDA's nutrient composition databases is available at the USDA's Nutrient Data Laboratory home page [534]. The USDA produces and maintains the Nutrient Database for SR. New releases are issued yearly; these include information on new foods and revised information on already included foods, and they identify foods deleted from the previous version of the database. The most recent release, SR28, includes information on up to 150 food components for 8789 foods [535], and is available online.

Interest in nutrients and food components potentially associated with diseases has led the USDA to develop specialized databases for a smaller number of food

components, such as flavonoids [534]. A separate database developed by the USDA Food Surveys Research Group—the Food and Nutrient Database for Dietary Studies (FNDDS)—is used by many investigators in analyses of foods reported in NHANES' What We Eat in America dietary recalls and is based on nutrient values in the USDA SR database [92]. The FNDDS provides information for 65 nutrients and food components, and has no missing data for nutrient fields.

Nutrient composition data are also compiled by a number of other countries, and the International Network of Food Data Systems maintains an international directory of nutrient composition tables [536]. Combining different food composition databases across countries poses comparability challenges, however. The European Food Information Resource [537] was formed to support the harmonization of food composition data among the European nations [538]. The International Nutrient Databank Directory, an online compendium developed by the National Nutrient Databank Conference, provides information about the data included in a variety of databases, national reference databases, and specialized databases developed for software applications, such as the date the database was most recently updated, the number of nutrients provided for each food, and the completeness of the nutrient data for all foods listed [539].

In addition to nutrient databases, databases that relate dietary intake to dietary guidance have been developed in the United States [540,541]. The USDA Food Patterns Equivalents Database (FPED) provides quantities of specific food groups consistent with dietary guidance recommendations in order to allow for evaluation of whether diets meet dietary guidelines at a variety of calorie levels [542]. Just as FNDDS provides nutrient composition data, the FPED provides food group data per 100 g of each food code in FNDDS. Importantly, mixed dishes, such as pizza, are disaggregated to their food group components. The FPED contains data for 37 food group components (e.g., dairy, fruits, vegetables) [543].

Other databases are available in the United States for use in analyzing dietary records and 24-hour recalls, but most are based fundamentally on the USDA SR database, often with added foods and specific brand names. One prominent such database is the University of Minnesota's Nutrition Coordinating Center's (NCC) Food and Nutrient Database [544]. This database includes information on 165 nutrients, nutrient ratios, and other food components for more than 18,000 foods, including 8000 brand-name products. The NCC is constantly updating its database to reflect values in the latest release of the USDA SR database.

One limitation in all nutrient databases is the variability in the nutrient content of foods within a food category and the volatility of nutrient composition in manufactured foods. Recent changes in the sodium and fatty acid composition of manufactured foods, for example, illustrate the difficulty in maintaining accurate nutrient composition databases [545,546]. Obviously, a key consideration is how the database is maintained and supported.

Estimates of nutrient intake from 24-hour recalls and dietary records are often affected by the nutrient composition database that is used to process the data [547–549]. Inherent differences in the database used for analysis include factors such as the number of food items included in the database, how recently nutrient data were updated, and the number of missing or imputed nutrient composition values. Therefore, before choosing a nutrient composition database, a prime factor to consider is the completeness and accuracy of the data for the nutrients of interest. For some purposes, it may be useful to choose a database in which each nutrient value for each food also contains a code for the quality of the data (e.g., analytical value, calculated value, imputed value, or missing). Investigators need to be aware that a value of zero is assigned to missing values in some databases, whereas for other databases, the number of nutrients provided for each food may fluctuate depending on whether or not a value is missing, and for others all unknown values may be imputed.

The nutrient database should also include weight/volume equivalency information for each food item. Many foods are reported in volumetric measures (e.g., 1 cup) and must be converted to weight in grams in order to apply nutrient values. The number of common mixtures (e.g., spaghetti with sauce) available in the database is another important factor. If the study requires precision of nutrient estimates, then procedures for calculating the nutrients in various mixtures must be developed and incorporated into nutrient composition calculations.

Developing a nutrient database for an FFQ presents additional challenges [550] because each item on the FFQ represents a food grouping rather than an individual food item. Various approaches that rely on 24-hour recall data, either from a national population sample or from a sample similar to the target population, have been used [551–553]. Generally, individual foods reported on 24-hour recalls are grouped into FFQ food groupings, and a composite nutrient profile for each food grouping is estimated based on the individual foods' relative consumption in the population. For this approach to be effective, the 24-hour recall data must be representative of the population for whom the FFQ is designed and connected to a trustworthy nutrient database.

G Choice of Dietary Analysis Software

Data processing of 24-hour recalls and dietary record requires creating data that include a food code and an

amount consumed for each food reported. Computer software then links the nutrient composition of each food on the separate nutrient composition database file, converts the amount reported to multiples of 100 g, multiplies by that factor, stores that information, and sums across all foods for each nutrient for each individual for each day of intake. Many software packages have been developed that include both a nutrient composition database and software to convert individual responses to specific foods and, ultimately, to nutrients. A listing of many commercial dietary analysis software products has been compiled [539].

Software should be chosen on the basis of the research needs, the level of detail necessary, the quality of the nutrient composition database, and the hardware and software requirements [554]. If precise nutrient information is required, it is important that the system be able to expand to incorporate information about newer foods in the marketplace and to integrate detailed information about food preparation by processing recipe information (e.g., the ingredients and cooking steps for homemade stew). Sometimes the study purpose requires analysis of dietary data to derive intake estimates not only for nutrients but also for food groups (e.g., fruits and vegetables), food components other than standard nutrients (e.g., nitrites), or food characteristics (e.g., fried foods). These additional requirements limit the choice of appropriate software.

The semiautomated food coding system used for NHANES is USDA's Dietary Intake System, consisting of the AMPM for collecting food intakes; the Post-Interview Processing System, which translates the AMPM data and provides initial food coding; and the Survey Net food coding system for the final coding of the intake data [86]. Survey Net is a network dietary coding system that provides online coding, recipe modification and development, data editing and management, and nutrient analysis of dietary data; multiple users can use the software to manage the survey activities. It is available to government agencies and the general public only through special arrangement with the USDA. NCI's ASA24 instrument performs automated coding of all reported foods. Foods which are not completely described are assigned default values.

Many diet history and food frequency instruments have also been automated. Users of these software packages should be aware of the source of information in the nutrient database and the assumptions about the nutrient content of each food item listed in the questionnaire.

H Estimating Usual Intakes of Nutrients and Foods

Usual intake is conceptualized as the long-term average intake of a food or nutrient. The concept of long-term average daily intake, or "usual intake," is important because dietary recommendations are intended to be met over time and diet–health hypotheses are based on dietary intakes over the long term. Consequently, it is the usual intake that is often of most interest to policymakers (e.g., the proportion of the population at or below a certain level of intake) or to researchers (e.g., relationships between diet and health).

Data from FFQs, 24-hour recalls, and dietary records have all been used to estimate usual intake at the group level. Obtaining accurate estimates of usual intake at the individual level is generally not possible with the dietary assessment tools available even for FFQs which attempt to estimate usual intake generally over a longer period such as the past year. FFQs are known to contain a substantial amount of measurement error (see Section II.C) [54,79,100–103,117,149]. Dietary recalls or records generally provide more accurate short-term intake estimates than frequency-type instruments.

For estimates of mean usual intake in the population, data from just a single day of recall or record can be used. Multiple days of recalls and records are needed to estimate the distribution of intakes. However, the distribution of simple within-person averages of intakes across a few days does not adequately represent the population's usual intake distribution [555], because of the large day-to-day variability of individuals' diets. Distributions generated from averaging only a few days of data are generally substantially wider than those of true usual intakes, and thus lead to overestimating the proportion of the population above or below a certain cut point, as illustrated in Fig. 1.1.

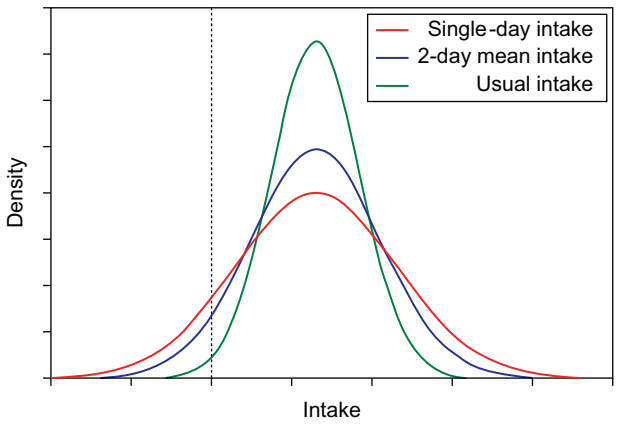

FIGURE 1.1 Effect of day-to-day variability on distributions. *Adapted from NCI Dietary Assessment Primer, Epidemiology and Genomics Research Program, Division of Cancer Control and Population Sciences, National Cancer Institute. Available from https://dietassessmentprimer.cancer.gov/.*

Statistical modeling can be used to more accurately portray the population's distribution by analytically estimating and removing the effects of day-to-day variation in dietary intake [555]. These methods rely on a minimum of two administrations of 24-hour recalls or dietary records to capture day-to-day variation. The earliest efforts at statistical modeling of usual intake were made by the Institute of Medicine [556] for nutrients, most of which are consumed nearly every day by most everyone, and then extended and updated for nutrients or foods that are more episodically consumed (e.g., dark green vegetables) by researchers at Iowa State University [557–559]. Others have developed usual intake statistical approaches as well [189,560–563]. The NCI method uses a minimum of two 24-hour recalls to estimate intake of both nutrients and episodically consumed foods [296]. This model as well as others [189] allows for covariates such as sex, age, race/ethnicity, or information from an FFQ to supplement the model [562]. One study using the NCI method showed that including FFQ data as covariates in modeling usual intakes from 24-hour recalls increased precision for assessing the relationship of a highly episodically consumed food, fish, with blood mercury levels [190]. Modeling usual intakes to assess relationships to health outcomes by combining data from a few 24-hour recalls with an FFQ has been shown to provide better estimates compared to a single FFQ or a few 24-hour recalls alone [188,189,295].

The NCI Measurement Error Webinar Series [564] provides a thorough discussion of dietary measurement error, including usual intake estimation.

ACKNOWLEDGMENTS

We gratefully acknowledge the contributions of Susan M. Krebs-Smith and Thea Zimmerman in reviewing and editing portions of this chapter. We also thank Penny Randall-Levy for invaluable research assistance.

Chapter 2

Assessment of Dietary Supplement Use

Johanna T. Dwyer, Rebecca B. Costello and Joyce Merkel
National Institutes of Health, Bethesda, MD, United States

I INTRODUCTION

A Rationale

Nutritional status assessment is incomplete without assessing both the intake of food and dietary supplements because supplements provide many essential nutrients and other bioactive substances that may affect health outcomes in both beneficial and harmful ways. For those suffering from health problems, specific dietary supplements may be recommended or self-prescribed. Moreover, the prevalence of supplement use is high [1,2].

Dietary supplements are marketed in a variety of formulations, including drinks, bars, tablets, pills, and powders. For the purpose of discussion in this chapter, they are defined using the legal definitions in the Dietary Supplement Health and Education Act (DSHEA) of 1994: "a product (other than tobacco) that is *intended to supplement the diet; contains one or more dietary ingredients* (including vitamins, minerals, herbs, or other botanicals, amino acids, and other substances) or their constituents; is *intended to be taken by mouth* as a pill, capsule, tablet, or liquid; and is *labeled on the front panel as being a dietary supplement*" [3]. Note that in the United States herbals, botanicals, and other nonvitamin, nonmineral products are included in the definition of dietary supplements; in many other countries they are categorized as medicines.

B Purposes of Dietary Supplement Intake Assessment

1 Obtain Total Intakes of Nutrients

Dietary supplements contribute substantial amounts to total intakes of some nutrients, such as calcium and vitamin D in postmenopausal women, and in "renal vitamins" (folic acid, vitamin B_6, and vitamin B_{12}) provided to hemodialysis patients to replace losses of water-soluble vitamins during dialysis. Failure to include these nutrient sources would lead to serious underestimation of intakes and overall diet quality. This is important since more than half of American adults use dietary supplements, and nearly half of them use multivitamin−mineral (MVM) supplements. Most of the rest use single or multiple vitamin or mineral preparations that also contribute substantial amounts of nutrients to dietary intakes [2]. Therefore, it is essential to assess total intakes, including dietary supplements among users of these products.

2 Assess Risk of Toxicities

Supplements are often highly concentrated sources of nutrients, especially when use of highly fortified foods is high. Some individuals may have nutrient intakes that are so excessive that tolerable upper levels of nutrients may be exceeded, placing the individual at risk of toxicity. Some of the bioactives in supplements can also have toxic effects, as was the case with the botanical ephedra, which was used in many weight-loss and performance-enhancing dietary supplements until banned by the Food and Drug Administration (FDA) in 2004 [4]. For example, in 2012 in the United Kingdom, 84 illegal products, such as energy and muscle gain products, were found to contain dangerous ingredients including steroids, stimulants, and hormones [5]. Some dietary supplements may be spiked with active drugs not declared on the label; others are adulterated with other substances or contaminated by heavy metals, pesticides, filth, or other toxic ingredients—another reason for noting supplement use on medical records. Finally, dietary supplements include herbals and botanicals that are sometimes used as medicines by those who are ill, and who may be taking other medications as well that may interact with them to produce adverse effects. Although the DSHEA prohibits the use of supplements for the prevention, mitigation, or cure of disease, these uses appear to persist, increasing the risk of toxicities.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00002-3

3 Assess Supplement–Drug and Supplement–Nutrient Interactions

These interactions are important to document in order to avoid drug or nutrient–supplement interactions. Supplement–nutrient and supplement–drug interactions are of particular concern. Some dietary supplements, particularly botanicals, contain many bioactive substances that may interact with other drugs or nutrients [6]. The Centers for Disease Control and Prevention (CDC) estimated that 23,000 emergency department visits in the United States every year were due to adverse effects related to dietary supplements of which 2154 resulted in hospitalizations [7]. Many older persons are already taking multiple medications, and they are at risk of polypharmacy even without use of supplements. There is evidence that the use of prescription medications and dietary supplements often increases the risk of interacting medications, and that a substantial and growing proportion of older adults are at risk for major drug–drug interactions [8].

4 Clarify Associations Between Dietary Supplement Intake, Healthcare, and Health Status

It is important to clarify associations between dietary supplement use and health, including risk of various diseases and changes in supplement use with changes in health status. The associations between use of supplements and both conventional and alternative medicines or other lifestyle factors may also be revealing [9,10].

5 Assess Conformity with Health Promotion and Disease Prevention Recommendations and Guidelines

The Food and Nutrition Board (FNB) of the Division of Medicine, National Academy of Medicine, the U.S. Preventive Health Services Task Force, Healthy People 2020, the Committee on Nutrition of the American Academy of Pediatrics, and consensus statements issued on behalf of these and other professional societies make recommendations on the use of dietary supplements. Health screening tools may include queries to ascertain if patients are following these guidelines. For example, the FNB recommends that women in the child-bearing years who are at risk of becoming pregnant should take a dietary supplement of folic acid and ensure that their food intake of folate is adequate.

C Dietary Supplements Available

It is estimated that over 7000 entities are involved in the manufacturing, marketing, and distribution of dietary supplements. The number of supplement products is very large, with estimates ranging to as high as 80,000, with a turnover as high as 30% per year. There are at least 5600 manufacturers, packagers, and suppliers of supplements in the United States, and there are many more concerns abroad that provide the ingredients in supplements. These operations run the gamut from very sophisticated facilities with high pharmaceutical standards and quality controls to very poor facilities. This is important since both the safety and efficacy of supplements depend on high quality ingredients and products. The Office of Dietary Supplements (ODS) at the National Institutes of Health's (NIH's) web-based Dietary Supplement Label Database (DSLD) contains 60,000 labels, and continues to add 1000 labels per month. The DSLD provides images of each product and all information on the label. This resource can be accessed at https://www.dsld.nlm.nih.gov.

D Health Profiles of Dietary Supplement Users

The health profiles of dietary supplement users differ from those of nonusers in important respects that affect health, making causative associations between supplement use and health status difficult to establish without first correcting for supplement use. These factors include physical activity, smoking status, age, income, education, and prior health status. For example, MVM supplement users tend to have better diets and to be healthier than nonusers, probably because of the differential presence of factors mentioned previously. However, generalization is hazardous, and those who are ill often use supplements as well. In a prospective cohort study of 25,874 overweight older adults with multiple risk factors for chronic diseases, 44.8% were consuming multivitamins, 42.6% consumed $<$800 IU/day of vitamin D, and 26.4% consumed $<$1200 mg/day of calcium [11]. Cancer survivors often have very high rates of dietary supplement use in the hope that the use of supplements will stave off a return of the malignancy, and those with advanced stages of cancer often have even higher rates of use [12]. Users of "condition-specific" supplements often suffer from specific health problems. There are many illnesses that consumers believe will be alleviated or cured by dietary supplement use. For example, glucosamine and chondroitin or chondroitin sulfate are often used as medicines by those who are already ill or suffering from joint pain or osteoarthritis [13]. Saw palmetto is commonly used by those with prostate problems or by prostate cancer survivors [14,15]. Use of dietary supplements in pregnant women at risk of developing diabetes is also exceedingly high—92% of women enrolled in The Environmental Determinants of Diabetes in the Young (TEDDY) study used one or more supplements during pregnancy [16].

E Prevalence of Dietary Supplement Use

The prevalence of dietary supplement use increased when supplements became more widely available after the passage of DSHEA in 1994. Today, prevalence is high, with more than half of all adults using some dietary supplements. There are substantial, but somewhat lesser, numbers of children using dietary supplements. The best data on prevalence of use are from population-based samples, such as the National Health and Nutrition Examination Survey (NHANES). On the basis of such studies, it is evident that use is particularly high in certain subgroups. For example, it is very high among elders, somewhat less but also high among young children, and lower in adolescents and adults [17,18]. Supplement use is also often positively associated with educational status, income, and, in most cases, better health status. However, those whose current health status is poor are often also heavy users of particular supplements in the hope that the products will mitigate or cure their conditions. Other studies reveal that some individuals, such as those on hemodialysis for end-stage renal disease; those postbariatric surgery with a form of malabsorption; and old, frail institutionalized patients, often take special supplements.

Limited surveys of dietary supplement use have also been done for health professionals such as dietitians, but the response rates in existing surveys are too low to provide data that can be extrapolated to the profession as a whole [19].

The *Nutrition Business Journal* publishes a list of the most popular dietary supplements each year, and the latest data are summarized in Table 2.1. Although the sales data on which these lists are based combine sales volume and the price of the product, and so they do not conform precisely to dietary supplement use. However, they do give some idea of what dietary supplements Americans are buying today. Data in *Nutrition Business Journal 2014* show that many herbal and botanical products, including most "super fruit" products and category leaders such as green tea and ginkgo biloba, decreased in sales compared to earlier years, whereas sales of magnesium, probiotics, and melatonin experienced double-digit increases from prior years [20].

The dietary supplement marketplace is constantly changing, and as it does, consumption patterns also change, so it is important to keep up with industry trends [21]. According to proprietary data collected by the Natural Marketing Institute using Harris Interactive survey data of U.S. adults (18 + years) from 2005 to 2015, use of "condition-specific supplements" (used for specific health issues such as memory, weight loss, and bone and joint health) has remained stable, 44% in 2005 and 44% in 2015. Use of herbal supplements also remained relatively stable with 46% of U.S. adults using in 2005 and 48% using today. Use of single minerals and vitamins exhibited some minor declines, both declining approximately 6% since 2005. In addition, other supplements, such as omega-3 fatty acids and probiotics, continue to drive growth in the dietary supplement category [22]. A 2010 Ipsos-Reid survey showed that 73% of Canadians regularly take natural health products such as vitamins and minerals, herbal products, and homeopathic medicines [23].

The FDA completed a national telephone survey of 2480 adults in the continental United States in 2014 [24]. Over the previous year, 60% of adults reported using multivitamin/multimineral or single ingredient vitamins or minerals, and 32% reported using herbal and nonvitamin/mineral supplements. Up to 83% of the vitamin mineral users looked for product information before using a product for the first time, and they got most of their information from product labels or traditional healthcare professionals. Among the herbal users, 93% got product information before using a product for the first time from the label, but they reported getting information mostly from product labels, family and friends, and the Internet. While 60% of the vitamin mineral users thought the government set standards or preapproved these products before they were sold, only 40% believed this for herbal products.

F Patterns of Dietary Supplement Use Among the Ill

Nutrition professionals need to be aware that people use dietary supplements in various ways when they fall ill, and that they are not always forthcoming about what they are doing when discussing their health problems with their physicians or other health professionals. In part, this is due to many physicians not asking their patients about supplement use. Also, patients sometimes assume that it is not important to mention supplement use, or they lack candor because they are afraid that the doctor will disapprove of use of the supplement.

Dietary supplements sold over the counter are not viewed as medications. DSHEA classified dietary supplements as foods, for which there are less stringent standards for quality and efficacy than would be true if they were categorized as drugs. By definition, under the DSHEA law, dietary supplements are designed to supplement the diet. They are not to be used for the prevention, mitigation, or cure of disease, although in fact many people use them for these purposes [25].

The vast majority of the American public turns first to prescription drugs if they are ill. A smaller proportion of the public turns first to dietary supplements or other alternative medicines for treating their illnesses, and as a

TABLE 2.1 Most Popular Dietary Supplements Based on 2013 Sales as Reported in *Nutrition Business Journal 2014*

Product	Consumer Sales ($ Millions)
Multivitamins	5712
Sports nutrition powders/formulas	3867

result they may delay obtaining care from licensed medical practitioners. Despite the limitations of the legitimate uses of dietary supplements solely to supplement the diet under DSHEA, data presented above would support that dietary supplements are often used in ways that are different than the law intends. Caution is indicated, especially for those who are undergoing medical treatment or who are ill. Dietary supplements are inappropriate as substitutes for evidence-based medical therapies prescribed by physicians and should not be used by the ill

without checking with a knowledgeable physician since they are not manufactured as pharmaceutical grade products. In most cases, the effectiveness of dietary supplements has not been demonstrated, and the potential for supplement–drug interactions also exists. Some consumers use a combination of prescribed drugs, over-the-counter drugs, and dietary supplements which they take simultaneously. Those who are ill run the highest risks of potential supplement–drug interactions, particularly if they are taking many medications and if they are taking medications or supplements that are especially likely to interact adversely with each other. For example, those on coumadin, a commonly used anticoagulant, may experience adverse reactions if they self-medicate with various herbal and botanical drugs that affect blood clotting [26,27].

Many consumers still view dietary supplements as harmless and possibly even helpful in the prevention and treatment of many conditions, including arthritis, colds and flu, osteoporosis, lack of energy, memory problems, and cancer, and hence they often self-medicate for these purposes. Individuals may also think that supplements have a role in the prevention or treatment of depression, stress, heartburn, high cholesterol, vision, and heart and blood pressure problems. Indeed this may not be the case. Vitamin mineral supplements are used more commonly than herbals and botanicals and other nonvitamin, nonmineral supplements for overall health and wellness, and for prevention and treatment, although their efficacy in many of these regards is unproven.

The FDA periodically issues health advisories on dietary supplements that pose special health risks. The alerts are at http://www.fda.gov/safety/recalls/default.htm. Websites that are helpful in assessing possible interactions of dietary supplements with drugs include the National Library of Medicine (NLM) MedLine Plus at https://www.nlm.nih.gov/medlineplus/druginformation.html, a portal for reliable health information in English and Spanish easily accessible in a variety of formats, including a mobile app, widgets, and buttons. The National Center for Complementary and Integrative Health (NCCIH) website at http://www.nccih.nih.gov, the Natural Medicines Database, https://naturalmedicines.therapeuticresearch.com/ (subscription database), Consumer Lab at http://www.Consumerlab.com, and the Center for Education and Research on Therapeutics at NCCIH suggest that physicians and patients discuss together the use of dietary supplements to maximize benefits and minimize risks. "Time to talk" materials to facilitate professional–patient dialogue on use of supplements are available at the NCCIH website at http://nccih.nih.gov/health/providers. Some disease focused groups such as the National Kidney foundation provide disease-specific advice to patients, such as lists of herbs that kidney patients should avoid, which can be accessed at https://www.kidney.org/atoz/content/herbalsupp.

Populations with poor reported physical or emotional health status tend to be users of herbal, botanical, condition-specific, and other types of supplements. Therefore, it is vitally important to check dietary supplement use in the ill. If patients are undergoing medical treatment and prescription drugs have been prescribed, they should be encouraged to use them as directed first and by themselves to gain the full effects of the therapy. If the patient insists on continuing dietary supplement use, possible adverse interactions with the drug regime should be investigated, and the patient should then be counseled on how to avoid potential adverse interactions. Any interactions identified should be entered into the patient's chart. If the interaction is severe or life threatening, it should be reported to the FDA at 1-800-FDA-1088 or http://www.fda.gov/Safety/MedWatch/HowToReport/ucm053074.htm.

G Motivations for Dietary Supplement Use

Consumer confidence is high regarding how supplements can improve health and help manage many conditions [28]. People have many different motivations for dietary supplement use. Motivation varies not only from person to person and by such factors as demographics (age, sex, income, education, and ethnicity) but also by attitudes such as concerns about deficiencies, who prescribes it, readiness to engage in preventive behaviors, and health status. Motivation also varies over time within and between individuals, depending on the type of product, whether it is a nutrient or nonnutrient supplement, and the definition of dietary supplement that is employed.

Motivation and use of dietary supplements are related to each other but probably in complex ways that differ from one individual to another. One theory is that knowledge and attitudes (motivations) cause supplement use. It is also possible that people use supplements and then attitudes and knowledge (motivation) follow perhaps to rationalize or justify use. That is, some people apparently get into the habit and then find reasons for their behavior, often due to social influence, whereas others operate in a more deliberate manner, gathering knowledge and then forming attitudes that determine their use. The implications for nutrition and other health professionals of these different ways that people arrive at supplement use are that they must consider both ways to influence behavior when interviewing on dietary supplement use. For example, social influence may have utility in developing methods for persuading women in the reproductive age group who might become pregnant to increase their use of folic acid.

II METHODS FOR ASSESSING DIETARY SUPPLEMENT INTAKE

A Dietary Supplement Intake (Exposure)

Most of the methods for assessing intake of dietary supplements are similar to those discussed in Chapter 1, Dietary Assessment Methodology. The methods have the same strengths and limitations as those mentioned in that chapter. Another method that is applicable to supplements but not to foods is the use of pill inventories, which are widely used in obtaining information about other medications. These can be lists of commonly used supplements, or use the "brown bag" method; the healthcare provider asks the patient to bring in all their supplements to the office in a bag, or medication inventory "apps" can also be used. For some supplements, inferences about use can be made from blood or urine biomarkers, if available, although they provide only qualitative rather than quantitative information, and the tests are not available in most clinical settings. The unique features of the methods for collecting dietary supplement information are detailed in Table 2.2.

B Assessing Supplement Intake in Clinical Settings

1 Inpatient Settings

The chances of drug−drug, drug−supplement, and other adverse reactions are great among hospitalized patients. Most hospitals prohibit self-medication with dietary supplements or other over-the-counter medications without the written permission of the physician, and so supplement use in hospital inpatient settings is usually limited. However, prior use is of interest because some botanicals may take days or weeks to be excreted from the body, and it never hurts to ask about current use, since some patients disregard instructions. In the Joint Commission Comprehensive Accreditation Manual for Hospitals (JCAHO), a medication is defined as: "any prescription medication, sample medication, herbal remedies, vitamins, nutriceuticals, over the counter drugs, vaccines, diagnostic and contrast agents, used on or administered to person to diagnose, treat, or prevent disease or other abnormal conditions…" [29].

JCAHO's National Patient Safety Goal #8 Medical Reconciliation Act requires documentation of any patient use of herbal remedies, vitamins, nutriceuticals, over-the-counter drugs, just like any other medication [30]. This is a standard that applies to all accredited hospitals in the United States.

Details can be found at http://www.jointcommission.org/standards_information/npsgs.aspx. The patient or a family member/caregiver should be asked to provide a list of the types and amounts of dietary supplements that the patient uses or has used in the recent past, and this information should be entered into the chart and electronic medical records as part of the dietary assessment. It is important for all health professionals who see the patient to query him or her about dietary supplement use; some patients are reluctant to tell the doctor but are willing to share their usage patterns with dietitians. Everyone is responsible to collect this information, and so dietitians, nurses, and pharmacists as well as physicians should be alert to these issues. When electronic medical records are developed, a question on use of dietary supplements should be included, and the supplements that are used should be named in the medical record.

2 Outpatient Settings

Box 2.1 provides some guidelines for health professionals when they are considering making recommendations to patients on dietary supplements. During nutritional assessment, all patients should be asked about their use of dietary supplements: what supplements they use, how much they use, how often, and where they obtained them (e.g., drugstore, friends, the Internet). Replies should be written in the medical record. Dietary supplement use should be included in diet history and in the calculation of nutrient intake. Some food frequency questionnaires and food checklists include items on the intake of the most commonly consumed dietary supplements, but these may not include less commonly used products or supplements used only occasionally that may also be important to health. Therefore, it is prudent to probe for additional supplement use and to encourage patients to write these dietary supplements on their questionnaires. If questions remain or there is need for further documentation, the patient can be asked to keep a supplement intake record that he or she can bring to the next visit. One useful way to elicit further information about dietary supplement use from ambulatory patients who report very high use but cannot remember details of what they take at home is the "brown bag" technique. The patient is asked to bring in a bag all of the dietary supplements and medications that he or she uses to the next visit. The doses and types of dietary supplements and other medications can be recorded in the chart, and their potential impact can be taken into account in dietary assessment and assessment of possible supplement−nutrient interactions. NIH's brochure "Dietary Supplements: What You Need to Know" provides answers to some questions about dietary supplement use and medications; it can be downloaded and printed from the ODS website at https://ods.od.nih.gov/HealthInformation/DS_WhatYouNeedToKnow.aspx.

TABLE 2.2 Dietary Supplement Assessment Methods

Method	Advantages	Disadvantages	Comments
Pill inventories	Actual labels available and can be examined, doses recorded.	Patients/clients may forget or refuse to bring supplements when requested, or only produce socially acceptable/legal products. May change dietary supplement use reporting. UPC codes for dietary supplements are not unique and the formulations in a given specific UPC-coded product may change.	Technique is commonly used in studies of medication use. A variant is to ask the patient/respondent to provide drug or grocery receipts, and if these include UPC codes it may be possible to identify the supplement.
Diet records	May be useful in clinical settings with willing patients to improve adherence and obtain specific details about usage patterns. Provides actual record of intake going forward. Respondent has the bottle from which he or she records information and recall of items used is not necessary. May provide useful contextual information for improving adherence.	May change eating or dietary supplement use behavior, especially if supplements have been prescribed. The process is extremely time-consuming for the recorder, usual intake may only be revealed with use over many days and forgetting to record is common.	Usually, the record includes food and drink as well as dietary supplement use; can be expanded to also cover other medications when drug–supplement or food–supplement interactions are of interest.
Frequency questionnaires	Retrospective so does not affect food consumption. Lists may help to prod memory and make recall easier. May provide an estimate of usual intake. Quick to fill out. The standardized format makes it useful for large-scale studies. Important that write-ins can be accommodated.	Lists not usually complete and may be very nonspecific. For some condition-specific and other supplements, use is very infrequent and may not show up if the window of recall is approximately 30 days. Semiquantitative dietary supplement intake forms are not quantitatively precise.	Frequency questionnaires for dietary supplement use range from simple checklists for categories of dietary supplements (e.g., MVM supplements, single vitamin or mineral supplements, and others) or specific supplements to semiquantitative questionnaires that tap not only frequency but also amount used.
24-Hour recalls	Retrospective so does not affect food consumption. Quantifies intake, usually easy for patient to recall. May point to problems with timing or other aspects of supplement use. Some computerized dietary assessment programs include a dietary supplement assessment module so that both food and supplement intakes can be ascertained.	Relies on memory and some items may be forgotten or individual may not be able to provide sufficient detail about the exact supplement name, dose, etc. Many days are needed to estimate usual intake. May be useful clinically but more difficult to use in large studies in which standardization is necessary.	Individual is usually asked to provide his or her intake of dietary supplements as well as food and drink that has been consumed in the past 24 hours.
Diet histories	Food intake is not changed because method is retrospective. However, respondent may not recall usual pattern of supplement intake or may not have a usual pattern. Permits obtaining information on total diet.	Recall is involved and memory may be faulty. The amounts are usually not precise. Time-consuming for both investigator and respondent.	Individual provides the professional with information on "usual" diet.
Brief dietary supplement assessment forms	Do not change eating behavior because they are retrospective. Focus solely on dietary supplement use. Easy to fill out and inexpensive.	Only a small number of supplements or foods or both can be asked about. Often, information on dose, type of supplement, timing, etc. is not provided.	Individual is asked to respond with "usual" dietary supplement intake.

(*Continued*)

TABLE 2.2 (Continued)

Method	Advantages	Disadvantages	Comments
Blood and urine	Does not change supplement use because it is retrospective. If the only source of the biomarker is the dietary supplement, it is possible to state with certainty that the product was consumed.	Not all micronutrients, other nutrients, or botanicals have easily identifiable biomarkers. Method is not quantifiably precise.	A blood (e.g., folic acid) or urine (e.g., creatine) biomarker is used to ascertain intake, either in conjunction with or instead of usage data on dietary supplements.

BOX 2.1 Guidelines for Health Professionals When Considering Recommendations for Dietary Supplements

- Is there a shortfall in nutrient intakes from recommendations when all sources of nutrients (food, beverages, and medications such as antacids that contain nutrients and dietary supplements) are taken into account? If so, try to satisfy needs first by the use of usual foods or fortified foods, or are dietary supplements in order?
- Does the supplement contain more than 100% DV and especially more than the upper level of nutrient intake recommended? If so, choose a supplement that contains lesser amounts; there is no known benefit to consuming more than the Recommended Dietary Allowance (or Adequate Intake) of a particular nutrient.
- Is the dietary supplement standardized and certified by an accredited source, such as the U.S. Phamacopoeia (USP) National Formulary (NF) showing that the USP standards for identity, purity, packaging, and labeling were followed? If so, they are labeled with the USP/verified symbol. The USP website is http://www.usp.org.
- Is the product fresh? If so, it has not exceeded its expiration date on the label.
- Does the supplement contain labeled amounts of nutrients or other constituents? Currently, there is no single source that provides verifications for label claims for nutrients and other constituents in supplements. Some useful information may be available if the product has been tested by ConsumerLab.com, USP, or NSF, and found to contain amounts of constituents claimed on the label. An Informed Choice label is certified for sports specific supplements. It can be accessed at http://informed-choice.org/.
- Is the dietary supplement reasonable in cost and within the patient's economic means?
- Has the patient read the patient package insert and cautionary directions and dosage limits on the label? If so, the patient should be alert to adverse reactions specified and report them to his or her physician if they arise.
- Does the dietary supplement claim to prevent or cure a condition or disease? By law, dietary supplements cannot be claimed to prevent or cure disease, and so the claim is not supportable and conventional methods for doing so should be sought.
- Is the dietary supplement safe? Certain dietary supplements such as ephedra (Ma huang) have been declared unsafe by the FDA and the U.S. Department of Health and Human Services. Check the CFSAN website at FDA for updates on other products.
- Is the dietary supplement efficacious? If so, authoritative bodies such as the Food and Nutrition Board, of the Division of Medicine, National Academy of Medicine, the Consensus Conferences of the Agency for Healthcare Research on Quality should have indicated that such uses are safe and effective. The website www.ods.od.nih.gov summarizes information on many studies of safety and efficacy.

Source: *Adapted and modified from R.B. Costello, M. Leser, P.M. Coates, Dietary supplements for health maintenance and risk factor reduction, in: C.W. Bales, C.S. Ritchie (Eds.), Handbook of Clinical Nutrition and Aging, Humana Press, Totowa, NJ, 2005. [59].*

For patients with "smart" devices such as phones and tablets, there are numerous applications ("apps") available for keeping track of dietary supplements and medications. Each app provides different features, including tracking, reminders, background information, and the ability to share the information with a health professional at a later time.

Sources such as the "Healthcare Professional's Guide to Popular Dietary Supplements" [31] and "A Healthcare Professional's Guide to Evaluating Dietary Supplements" [32] may be helpful for obtaining estimates of ingredients and content.

For those in healthcare facilities, clinical pharmacists are an underutilized resource for questions that may arise on supplements, particularly if there is reason to suspect that a supplement may generate adverse reactions.

C Estimating Dietary Supplement Intake

Once the patient's reported intake has been obtained, the information must be evaluated. When total nutrient intake is needed, nutrients from food, beverages, and nutrient-containing supplements must be added together to get an estimate of the individual's total dietary intake. For some, this may include capturing intakes not only from pills and tablets but from food bars or sports drinks that are often very highly fortified and sold as supplements.

In large populations, especially if adequacy or excess are of interest, it is best to present intakes of supplement users separate from those of nonusers. Means for the entire population are less informative of such problems.

D Assessment of Dietary Supplement Intake in Some Large-Scale National Surveys

1 National Health and Nutrition Examination Survey

NHANES is a population-based survey to assess the dietary intakes, health, and nutritional status of noninstitutionalized adults and children in the United States. Approximately, 5000 people are surveyed each year in five communities nationwide. In addition to food intake, information on dietary supplement use (frequency, amount, and duration) is collected from respondents during the interview in their households. The dietary supplements include vitamins, minerals, other prescription and nonprescription dietary supplements, and antacids (a major source of calcium) that have been taken in the past month. Prescription dietary supplements are also listed but in separate files. During the household interview, details on supplement use are collected. Respondents who say that they have taken dietary supplements are then asked to provide the supplement containers. Approximately two-thirds of them do so. Supplement containers are viewed, and the interviewer records from the product label the name, strength of the ingredient (for certain vitamins and minerals), and other information. During the household interview, details on supplement use, such as how long the product has been used, how often it was taken during the past month, and how much was taken, are established [33]. Since 2007, NHANES has also collected two 24-hour recall interviews as well as interval estimates during the past 30 days. An advantage of NHANES is that estimates of usual intakes of the nutrients in foods as well as in dietary supplements can be obtained. These are necessary to estimate the proportion of the population under the estimated average requirement or over the upper tolerable level (UL). Since NHANES collects both information on dietary intake and supplement use, along with anthropometric, biochemical, clinical reports of the presence of various conditions, it is possible to obtain information on the associations between supplement use, total intakes of the ingredient in question, and health status. Since the data are cross-sectional, causal inference is weak, but hypotheses generated from it can be tested in other populations to obtain more definitive answers. General questions on the motivations for supplement use are included in NHANES.

2 National Health Interview Survey

The National Health Interview Survey (NHIS) is a very large population-based survey that has periodically obtained information on dietary supplement intake in years when complementary and alternative medicine (CAM) supplements were included (2002, 2007, and 2012 survey years, with another supplement likely in 2018) [34]. The NHIS now has combined data on 88,962 adults aged 18 and over. The large sample size allows for estimation of the use of dietary supplements, including seldom consumed supplements, by a wide variety of population subgroups. The data products are available at the NHIS website: http://www.cdc.gov/nchs/nhis/index.htm. These data are useful in assessing the use of supplements in the context of CAM use [10,34]. Unfortunately, no information on dietary intake, biochemical, anthropometric or clinical data is collected simultaneously. Nevertheless, the survey has been used in studying issues such as use of dietary supplements in adults who reported that they suffered from gastrointestinal conditions [35]. The advantage is that the survey obtains detailed information on motivations, associations with conventional medical treatments and costs, as well as some information on dietary supplement use. Although the sampling frame is complicated, the questions asked about CAM and use of dietary supplements provide material not available in other national surveys. The disadvantage is that supplement dose information, food intake, and health indices are not included and so little can be concluded about health status other than that provided by respondent report. The NHIS will be updated in 2018 to better meet the needs of data users. Questions will focus on the health of one sample adult and one sample child per household, and information on other members of the household will be limited. A fixed core questionnaire will be used annually, and additional core areas will rotate on or off the questionnaire. Topics and items are currently being considered for the sample adult and child interviews; it is unclear if information on dietary supplement use will be collected.

3 National Cancer Institute's Diet and Health Questionnaire: A Public-Use Semiquantitative Food Frequency Questionnaire

The National Cancer Institute (NCI) has developed a semiquantitative food frequency questionnaire that is publicly available. The questionnaire can be reprogrammed to add specific dietary supplements. As issued, it includes specific questions on multivitamins, herbals, antioxidant supplements, and vitamins A, C, and E use during the past year and also a question on how long calcium-containing supplements or antacids have been used. There are also limited queries on approximately 10 vitamins and minerals, as well as fatty acids, and approximately 24 different herbals and botanicals that are frequently used. The questionnaire includes both foods and supplements, and it can be used for many purposes, not simply cancers. The 2006 version of the Diet and Health Questionnaire (DHQ) was validated using a checklist approach and was found to be an improvement over previous versions of the NCI questionnaire known as the 1992 NCI/Block questionnaire [36]. There have been no such validation studies with the DHQ II. However, validation findings are unlikely to be greatly modified by the minimal modifications to the food list and the updated nutrient database. The DHQ can be accessed at http://riskfactor.cancer.gov/dhq2.

4 Other Instruments for Assessing Dietary Supplement Intake in Epidemiological Studies

Many different proprietary semiquantitative questionnaires that are variations of food frequency questionnaires with additional questions on dietary supplements exist for assessing dietary supplement intakes in epidemiological studies of various large cohorts. However, the questions vary from one questionnaire to another, depending on the focus of the study. The core components of all the questionnaires are the U.S. Department of Agriculture's (USDA's) Food Composition tables, combined into groups to correspond to items or recipes on the questionnaires. The lists of dietary supplements on the various semiquantitative food frequency questionnaires vary greatly from one another. In the future, it would be helpful to develop common questions or lists that would improve comparability from one study to the next. In 24-hour recall programs or data analysis systems, often questions to probe dietary supplement use are not included. Data on dietary supplement composition from self-entered values, when available, are usually obtained from manufacturers; they can now also be obtained from the NIH DSLD available on the web. Total intakes reported should reflect intakes not only from food but also from the specific dietary supplements that were queried.

There are many examples of tools for adults that query dietary supplements as well as foods; those for children and infants are fewer in number. The questionnaires require specific food composition and dietary supplement databases to be analyzed, and these are not generally in the public domain. Adult questionnaires that query some dietary supplements include the Harvard (Willett) semiquantitative food frequency questionnaire, different versions of which have been used in a number of studies; the various semiquantitative food frequency questionnaires developed by Block's group now available at Nutriquest.com; the University of Hawaii Cancer Center's multiethnic cohort questionnaire (a particularly detailed and well-validated questionnaire); the Women's Health Initiative semiquantitative food frequency questionnaire; the Women's Health Study questionnaire; the National Institute of Environmental Health Sciences' Sisters Study Questionnaire; and the American Cancer Society's food frequency questionnaire. The availability of these questionnaires varies, and use depends on obtaining permission from the owners of the questionnaires and their willingness to collaborate with other investigators. Some university research groups, such as the dietary assessment groups at the University of Washington−Fred Hutchinson Cancer Center, Harvard University, and the University of Hawaii Cancer Center, will permit their questionnaires to be used, and some will even analyze study results for a fee.

The Fred Hutchinson Cancer Research Center at the University of Washington was the Data Coordinating Center for the Women's Health Initiative. It has developed a module based on that work and refined it, for two other large NIH-sponsored clinical trials of adults, the SELECT (Selenium and Vitamin E Cancer Prevention Trial) and the VITAL (Vitamin and Lifestyle Cohort Study). It has made them available to outside groups and will process them for a fee. The VITAL study questionnaire has been further revised. The questionnaires have lists of both nutrient supplements and herbal/botanical supplements, and they come in both male and female versions. The center's website (http://sharedresources.fredhutch.org/core-facilities/nutrition-assessment) describes the services it provides to outside users.

Although use of dietary supplements is widespread, intakes from supplements, particularly by subgroups in the populations who may be heavy users, are difficult to quantify. The Supplement Reporting (SURE) study at the University of Hawaii Cancer Center developed a unique inventory method to quantify dietary supplement use. Interviewers visited participants' homes to record supplement purchase and the number of pills in each supplement bottle every 3 months over a year. The resulting inventory method markedly improved the in-depth measurement of supplement use [37]. Based on the results of the SURE study, a 1-page questionnaire for dietary supplement use (SURE-QX; Fig. 2.1) has been developed and is available

DID YOU TAKE ANY DIETARY SUPPLEMENTS DURING THE PAST YEAR, AT LEAST ONCE A WEEK?

① YES ↓ If yes, did you take any of the following? ② No

VITAMIN TYPE	HOW OFTEN?			FOR HOW MANY YEARS?			
	1 to 3 times a week	4 to 6 times a week	Once a day	1 year or Less	2 to 4 years	5 to 9 years	10 years or more
MULTIPLE VITAMINS Regular one-day-type, Centrum® or Thera-type	①	②	③	①	②	③	④
B-complex or Stress-tab type	①	②	③	①	②	③	④
SINGLE SUPPLEMENTS Vitamin C	①	②	③	①	②	③	④
Vitamin E	①	②	③	①	②	③	④
Folic acid, folate	①	②	③	①	②	③	④
Vitamin B-12	①	②	③	①	②	③	④
Vitamin B-6	①	②	③	①	②	③	④
Calcium, alone or combined with something else such as in a bone health supplement OR in an antacid	①	②	③	①	②	③	④
Vitamin D, alone	①	②	③	①	②	③	④
Selenium	①	②	③	①	②	③	④
Iron	①	②	③	①	②	③	④
Zinc	①	②	③	①	②	③	④
Fish oil or omega-3 fatty acids	①	②	③	①	②	③	④
Flaxseed	①	②	③	①	②	③	④
Garlic, as a pill, tablet, or capsule	①	②	③	①	②	③	④
Glucosamine, alone or combined with something else	①	②	③	①	②	③	④
Coenzyme Q-10	①	②	③	①	②	③	④
Saw Palmetto	①	②	③	①	②	③	④

IF YOU TOOK VITAMIN C OR VITAMIN E:

When you took VITAMIN C, how much did you usually take?
- F 250mg or less
- F 300 to 500mg
- F 600 to 1000mg
- F More than 1000mg

When you took VITAMIN E, how much did you usually take?
- F 200IU or less
- F 250 to 400IU
- F 450 to 1000IU
- F More than 1000IU

ID#._____

FIGURE 2.1 Sure-QX: short supplement questionnaire developed by the University of Hawaii Cancer Center, Honolulu, Hawaii. *From The Supplement Reporting (SURE) Study, University of Hawaii, Cancer Research Center of Hawaii, J. Food Compost. Anal. 22 (Suppl. 1) (2009) S83–S87.*

for use by researchers. The longer University of Hawaii Cancer Center food frequency questionnaire has 180 foods and 10 supplements; it is available to investigators, who can purchase it from the center and then return it for processing into nutrient intakes. The analysis provides separate variables for the intake of nutrients from food ($n = 54$) and the intake of nutrients from supplements ($n = 22$). A less extensive list of supplements is provided in the SURE-QX questionnaire described previously. The SURE-QX questionnaire has detailed questions and many defaults to permit more precise and accurate information on the dietary supplements that are used. This questionnaire also includes many supplements used by Asian-Americans.

Other semiquantitative questionnaires are available from commercial services. Perhaps the best known is the Nutritionquest group, which provides the Nutritionquest or Block semiquantitative food frequency questionnaire; it can be purchased and accessed at http://www.nutritionquest.com. The basic 2005 food frequency questionnaire has approximately 110 foods and also items on multiple vitamin supplements, single vitamins and minerals, and

one item on herbals. The latest version of this instrument was developed in 2014. Upon request and for a fee, the Block questionnaires can be tailored for individual research purposes. The Block Nutritionquest group has also developed a brief calcium/vitamin D screener that includes 19 foods and 3 supplements as well as questions to adjust for food fortification practices. Another Block screener is the Block Folic Acid/Dietary Folate Equivalents Screener, which is based on NHANES 1999−2001 dietary recall data. It includes 21 questions and provides separate estimates of total, supplement, and food-only intakes [38]. A questionnaire is available for dialysis patients consisting not only of foods but also supplements and liquids. Recently a sodium screener has been developed; fat/sugar/fruit/vegetable screeners are also available. The Block Soy Foods Screener focuses on 10 food and supplement items and was designed to measure intakes of daidzein, genistein, coumestrol, and total isoflavones. The drawback is that the lists of dietary supplements are usually short.

E Other Instruments Used for Assessing Dietary Supplement Intake in Clinical Research Studies

Many other techniques have been used to obtain information on dietary supplement intakes. Serial random 24-hour recalls that included foods as well as supplement intakes were used successfully in the Women's Intervention Nutrition Study, a large randomized trial of diet as adjuvant therapy in women who had been treated for breast cancer [39]. In the Hemodialysis study of patients undergoing renal replacement therapy, food and dietary supplement intake were assessed using a 2-day diet diary-assisted recall technique, in addition to medication inventories and other techniques to check on adherence to use of high-dose B vitamin supplements [40].

III DIETARY SUPPLEMENT COMPOSITION DATABASES FOR ANALYSIS OF DIETARY SUPPLEMENT INTAKE

The analysis of dietary supplement intakes ideally requires complete analytically verified tables of dietary supplement composition by chemical analyses, which still do not exist for all nutrients and even more rarely for other bioactives in supplements. Therefore, results tend to be imprecise and inaccurate, particularly for intakes of some of the botanical ingredients in dietary supplements. The situation is slowly changing, but dietary supplement databases are still incomplete with respect to both how representative they are of the universe of dietary supplements marketed and sold in the United States and how well the levels of ingredients are documented. Currently, virtually all of them rely on label claims rather than analytically verified data. For dietary supplements and many highly fortified processed foods that lack analytical data on micronutrients, intake estimates obtained from product label declarations are likely to be biased. Overages are likely, especially for vitamins because labeling regulations require that the actual nutrient content of products be equal to or greater than the declared level on the label, after taking into account processing effects and shelf life losses [41].

A Dietary Supplement Label Databases

1 NHANES Survey Label Database

The composition of dietary supplements consumed in the NHANES is available at the National Center for Health Statistics website, although the primary purpose of the database is to store information on nutrients taken from the dietary supplement labels collected from NHANES respondents. NHANES research nutritionists obtain additional label data for the dietary supplement database by contacting manufacturers and distributors, company websites, and other Internet sources. Changes in supplement composition are tracked and entered into the database when reformulations are identified. The NHANES label database is publicly available and permits nutrition scientists to better assess total intakes of nutrients from all sources than ever before. However, it has its limitations. Only supplements that were used by respondents in the survey are provided in the database. Approximately 10,000 respondents are included in each NHANES data release. Although this may seem like a large number of respondents, for rarely used supplements, there may be few or no users who respond. Only levels of nutrients are noted, although the names of other ingredients are recorded as well. The quantitative data on nutrients that it provides rely on nutrient content declarations on the labels and are not analytically verified. Because it is a violation of the law to declare levels of a nutrient on the label as being more than what is provided, manufacturers tend to add more than the declared label value to many products. The amount added depends on the particular nutrient in question, its stability, cost, bulk, and other characteristics; there is no single "correction factor" that can be used. The supplements that are reported in NHANES during the most recent interview cycle are released every 2 years. Unfortunately, supplements on the market change rapidly, and many of the products may not be on the market at the time the database is accessed. Default values are also included in the database because many respondents are unable to supply the exact supplement or strength that was consumed, although some information is available. Because NHANES uses a nationally

representative sampling procedure, defaults developed with the NHANES data may be useful in other surveys as well, particularly if it is not possible to collect data with this level of detail. The defaults are based on the frequency of supplements reported in the latest 2-year NHANES release that is available, as well as on manufacturer information on sales. For example, default matches for adults include matching multivitamins to multivitamin minerals, as well as single ingredient formulations such as vitamin A to 8000 IU, vitamin C to 500 mg, vitamin B_6 to 100 mg, vitamin D to 400 IU, vitamin E to 400 IU, folic acid to 400 μg, calcium to 500 mg, iron to 65 mg, and zinc to 50 mg.

2 Dietary Supplement Label Database

The DSLD from the NIH contains information taken from the labels of approximately 60,000 dietary supplement products available in the U.S. marketplace. Launched in 2013, this free resource will grow to include most of the different dietary supplement products sold. The DSLD is available at http://www.dsld.nlm.nih.gov/dsld.

The DSLD offers these features:

- *Quick Search*: Search for any ingredient or specific text on a label.
- *Search for Dietary Ingredients*: An alphabetical list of ingredients is provided.
- *Search for Specific Products*: An alphabetical list of products is provided.
- *Browse Contact Information*: Search by supplement manufacturer or distributor.
- *Advanced Search*: Search by using a combination of search options including dietary ingredient, product/brand name, health-related claims, and label statements.

The DSLD provides product information that can be organized and searched by users. Research scientists, for example, will use the DSLD to determine total nutrient intakes from food and supplements in populations they study. Healthcare providers can learn the content of products their patients are taking. The DSLD is a collaborative project of the ODS and the NLM at NIH, with input from many federal stakeholders including most NIH institutes and centers, the USDA's Agricultural Research Service, the CDC's National Center for Health Statistics Division of Health and Nutrition Examination Surveys, and the U.S. FDA's Center for Food Safety and Applied Nutrition.

3 Natural Medicines Comprehensive Database

This database, formerly called the Natural Medicines Database, provides objective and reliable information for clinicians based on an evidence-based, consensus-based, peer-reviewed procedure with reproducible grading scales. Access is by subscription, and it is available at Natural Medicines Database, https://naturalmedicines.therapeuticresearch.com. Subscribers also have access to a compendium of evidence-based reviews on herbs and dietary supplements that is available online as well as in print. Information also includes risk assessments. It is used in the Veterans Administration, the Department of Defense (DOD), and other agencies within government. This database provides not only an in-depth information about the composition of dietary supplement products and ingredients but also ratings for the safety and effectiveness of products along with the uses, benefits, side effects, drug interactions, etc. of the ingredients found in dietary supplement products.

4 Trade Associations: Council for Responsible Nutrition and the Natural Products Association Database

The Council for Responsible Nutrition (CRN), a trade association for the dietary supplement and functional food industry, announced in July 2016 that it had retained UL, a global independent safety science company, to develop and administer the dietary supplement product registry that CRN hopes "will help create a fuller picture about the dietary supplement industry for industry regulators and serve retailers as a one-stop shop to help compare product labels." The online product registry will include full label information for dietary supplements and be accessible via the web. CRN member companies will be required as a condition of membership to input all their product labels into the product registry by July 2017, and all dietary supplement companies will be strongly encouraged to do the same.

The Natural Products Association (NPA) is a trade association (formerly the National Nutritional Foods Association) and an associated foundation. The NPA operates a two-part quality assurance program that includes a third-party certification program for good manufacturing practice (GMP) standards as determined by NPA based on a dialogue between suppliers and others. Those who meet the standard and pass audits can use the NPA logo. Members can also participate in the TruLabel program, which includes data on ingredients in members' product labels. The database is not available to the public. A description is available at http://www.npainfo.org/NPA/EducationCertification/TruLabelProgram.aspx.

5 Other Label Databases

Several other private compilations of dietary supplement label information are becoming available and may be purchased in the future.

B Dietary Supplement Databases With Verified Chemical Analyses

Although databases for dietary supplements are based on chemical analyses, usually the data on the label are proprietary and analytic data are disclosed only at the manufacturer's discretion. Several publicly available chemically analyzed dietary supplement databases now exist, but they contain only a few types of products, are not always based on representative numbers of products, and some are proprietary. The major ones are described here.

1 USDA Dietary Supplement Ingredient Database

The ODS at NIH collaborated with the USDA to develop an analytically substantiated dietary supplement ingredient database (DSID) for the micronutrients and eventually for other constituents as well in popular highly consumed supplements. Initial efforts focused on MVM supplements because these are the most commonly consumed supplements by Americans [41]. The database is now publicly available for adult MVM, child MVM, prenatal over-the-counter MVM, and omega-3 fatty acids. In the future, calcium-vitamin D supplements and green tea supplements will be assessed. The DSID is based on chemical analysis of the nutrient content in dietary supplements, compared with label-reported ingredient levels. For example, the DSID provides estimated levels of 18 vitamin and mineral ingredients derived from analytical data for 115 representative unspecified adult MVM supplements. The DSID also includes a calculator, which allows the consumer to compare his/her product's contents to that of a representative sample of similar products in the United States. It is available on the web free of cost at http://www.dietarysupplementdatabase.usda.nih.gov/index.html.

2 Consumerlabs.com

ConsumerLab.com, LLC, is a provider of independent test results and information to help consumers and healthcare professionals evaluate dietary supplements and other health, wellness, and nutrition products. Data are published only on products that have been tested. The products are bought off the shelf in consumer outlets and chemically analyzed for various substances of interest. ConsumerLabs does not publish a comprehensive database that is publicly available. However, a subscription to its reports is available for a reasonable cost at http://www.consumerlab.com.

3 NSF

NSF is an independent, not-for-profit testing organization offering product testing of dietary supplements in its NSF/American National Standards Institute. The organization does not simply evaluate test data submitted by manufacturers or analyze a single sample of a product and approve it; rather, NSF conducts its own product testing in its accredited laboratories. The three main components of the NSF Dietary Supplements Certification Program are verification that the contents of the supplement actually match what is printed on the label, assurance that there are no ingredients present in the supplement that are not openly disclosed on the label, and assurance that there are no unacceptable levels of contaminants present in the supplement. The major disadvantage of the values published by NSF is that they do not constitute a comprehensive database. Only products that have been certified are included in the database. Currently, approximately 590 products from 79 companies are certified on the NSF website at http://info.nsf.org/Certified/Dietary/.

C Computerized Dietary Assessment Programs that Include Dietary Supplements

1 University of Minnesota Dietary Supplement Module

Some computerized dietary assessment programs include dietary supplements in the interview and also have databases on their composition. For example, the University of Minnesota's Nutrient Data System has developed a dietary supplement assessment module that can be used in conjunction with existing software so that nutrient intake from both foods and dietary supplements may be quantified. This can be accessed at http://www.ncc.umn.edu/products/.

2 NCI's Automated Self-Administered 24-Hour Dietary Recall

The Automated Self-Administered 24-Hour Dietary Recall (ASA24) is a free web-based software tool, developed by the NCI and Westat, that enables automated self-administered 24-hour recalls and food records. The system includes an optional dietary supplement module that allows respondents to report supplements based on the NHANES dietary supplement data set. The ASA24 Respondent website guides the participant through the completion of either a 24-hour recall for the previous day (from midnight-to-midnight or for the past 24 hours) or for a single or multiple day food record and a Researcher application for researchers to manage study logistics and obtain data analyses. The system allows for probing (based on USDA's automated multiple pass method), coding, and the calculation of dietary intakes using the USDA's Food and Nutrient Database for Dietary Studies and the NHANES Dietary Supplement Database. The tool

is a highly interactive web-based application employing approximately 1500 unique probe question pathways and more than 12,000 food images to estimate portion size. ASA24 can be used by researchers for epidemiologic, interventional, behavioral, or clinical research. Clinicians may also find it useful for dietary assessment or nutrition counseling, and educators may find it to be a useful teaching tool. Detailed information about ASA24, including information on registering a study and a demonstration of the Respondent application, is available at http://epi.grants.cancer.gov/asa24/. A listserv is available on ASA24 at http://epi.grants.cancer.gov/asa24/. The content from the current website is being moved and so links and bookmarks may be changed in the future.

3 Other Computerized Dietary Assessment Programs

Other computerized dietary assessment programs permit the addition of supplement information to the database even if they are not included in the food composition database, but none yet provide complete lists of the most commonly used supplements in the software package.

IV THE DIETARY SUPPLEMENT LABEL

Many of the labels for dietary supplements are now included in the NIH's DSLD described earlier in this chapter and can be downloaded if that is desired. FDA regulations require certain label information on dietary supplements, including a descriptive name of the product stating that it is a "supplement"; the name and place of business of the manufacturer, packer, or distributor; a complete list of ingredients; and the net contents of the product. In 2016, FDA announced the final rule for an update of the food label, which will include updated Daily Values (DVs) and other changes. Since, under U.S. law, dietary supplements are considered to be foods, the Supplement Facts label will change accordingly. Fig. 2.2 shows changes to the Nutrition Facts Label on food and the new Facts label as of 2016.

The regulations are described in-depth in the FDA's Dietary Supplement Labeling Guide (accessible at http://www.fda.gov/food/guidanceregulation/guidancedocumentsregulatoryinformation/dietarysupplements/ucm2006823.htm). FDA has issued regulations for GMP that touch upon such topics as verification of identity, purity, strength, and supplement composition, and these are soon to be in effect.

Nutrition Facts

A Dietary Supplement Label: Ingredients

1 Differences Between Food and Dietary Supplement Labels

The Supplement Facts panel on dietary supplements must list dietary ingredients that have, as well as those that do not have, recommended daily intakes (RDIs) or daily reference values (DRVs or DVs). Listing the source of a dietary ingredient on the label is optional. In contrast, sources of a dietary ingredient and ingredients without RDIs or DVs are not permitted on the food Nutrition Facts label. Also, the part of the plant from which a dietary ingredient is derived must be listed on the Supplement Facts panel for dietary supplements, although it cannot be listed on the food label. In contrast, the Supplement Facts panel does not permit listing of "zero" amounts of nutrients, although the Nutrition Facts panel for food requires it. The percent DV (i.e., % DV or the Reference Daily Intake or DRV) of a dietary ingredient contained in a serving of the product must be declared for all ingredients for which there are DVs except protein. Supplements for infants, children younger than 4 years, and pregnant and lactating women do not require this, however.

2 Supplement Facts Label

The panel must list the names and amounts of the dietary ingredients present in the product, the serving size, and servings per container. A serving for a dietary supplement is the maximum amount recommended for consumption at one time or, if recommendations are not given, 1 unit (e.g., tablet, capsule, packet, or teaspoon). Thus, if the label says to take one to three tablets with breakfast, the serving size is three tablets.

3 Ingredient List

Other dietary ingredients that do not have DVs are also listed in the Supplement Facts panel after the ingredients that do have them, and in addition with their correct botanical (Latin) names. They are also listed by their common or usual names and must be accompanied by their weight per serving.

B Dietary Supplement Label: Claims

Box 2.2 describes the three categories of claims that can be used on dietary supplements: health claims, nutrient content claims, and structure–function claims.

V AUTHORITATIVE INFORMATION AND RESOURCES ABOUT DIETARY SUPPLEMENTS

A Office of Dietary Supplements, National Institutes of Health

The ODS at NIH has as its mission to strengthen knowledge and understanding of dietary supplements by evaluating scientific information, stimulating and supporting research, disseminating research results, and educating the public about the efficacy and safety of dietary supplements in order to foster enhanced quality of life and health for the U.S. population. Their website contains much useful information for health professionals and can be accessed at http://ods.od.nih.gov.

1 NIH RePORTER

NIH provides statistics and data about its applications and grants through the Research Portfolio Online Reporting Tools (RePORT) website. The NIH RePORTER database is available to all public users at http://exporter.nih.gov/. Researchers can use a keyword search function to search the database for grants supporting research on specific nutrients or dietary supplements by current year or by a specified year as well as search for a specific investigator's work.

Clinicaltrials.gov, maintained by NIH, is a list of all registered clinical trials, including those using dietary supplements. The purpose of the study, dosing levels, and other details are provided. This resource can be accessed at https://clinicaltrials.gov/.

2 Other ODS Resources

ODS also provides a number of other authoritative health information materials on its website. Of particular use to health professionals are dietary supplement fact sheets that also include both consumer English and Spanish versions (http://ods.od.nih.gov).

B Food and Drug Administration

1 Center for Food Science and Nutrition (for Health Claims)

The FDA's Center for Food Science and Nutrition's (CFSAN's) website and its ODS have a variety of materials on dietary supplements, including recent recalls, frequently asked questions, and some materials for consumers. These resources can be accessed at www.fda.gov/food/default.htm.

BOX 2.2 Claims That Can Be Used on Dietary Supplements

Health Claims

Health claims describe a relationship between a food, food component, or dietary supplement ingredient and reducing risk of a disease or health-related condition. A "health claim" definition has two essential components: (1) a substance (whether a food, food component, or dietary ingredient) and (2) a disease or health-related condition. A statement lacking either one of these components does not meet the regulatory definition of a health claim.

FDA has oversight in determining which health claims may be used on a dietary supplement label. Its authority comes from several laws:

- *NLEA Authorized Health Claims*: The Nutrition Labeling and Education Act (NLEA) of 1990, the Dietary Supplement Act of 1992, and the Dietary Supplement Health and Education Act of 1994 (DSHEA) provide for health claims used on labels that characterize a relationship between a food, a food component, dietary ingredient, or dietary supplement, and risk of a disease provided the claims meet certain criteria and are authorized by an FDA regulation. FDA authorizes these types of health claims based on an extensive review of the scientific literature, generally as a result of the submission of a health claim petition, using the significant scientific agreement standard to determine that the nutrient–disease relationship is well established. For an explanation of the significant scientific agreement standard, see the FDA website.
- *Qualified Health Claims*: FDA permits the use of qualified health claims when there is emerging evidence for a relationship between a food, food component, or dietary supplement and reduced risk of a disease or health-related condition. When this is the case, the evidence is not well enough established to meet the significant scientific agreement standard required for FDA to issue an authorizing regulation. Qualifying language is included as part of the claim to indicate that the evidence supporting the claim is limited. Both conventional foods and dietary supplements may use qualified health claims. FDA uses its enforcement discretion for qualified health claims after evaluating and ranking the quality and strength of the totality of the scientific evidence. Although FDA's "enforcement discretion" letters are issued to the petitioner requesting the qualified health claim, the qualified claims are available for use on any food or dietary supplement product meeting the enforcement discretion conditions specified in the letter. FDA has prepared a guide on interim procedures for qualified health claims and on the ranking of the strength of evidence supporting a qualified claim. Qualified health claim petitions that are submitted to FDA will be available for public review and comment. A listing of petitions open for public comment is at the FDA Dockets Management website. A summary of the qualified health claims authorized by FDA may be found at its website.

Nutrient Content Claims

Most nutrient content claim regulations apply only to those nutrients or dietary substances that have an established daily value and are expressed as percent DV. Percentage claims for dietary supplements are another category of nutrient content claims used to describe a percentage level of a dietary ingredient for which there is no established DV.

Structure–Function Claims

Statements that address a role of a specific substance in maintaining normal healthy structures or functions of the body are considered to be structure–function claims. Structure–function claims may not explicitly or implicitly link the relationship to a disease or health-related condition.

Structure–function claims on dietary supplements describe the role of a nutrient or dietary ingredient intended to affect normal structure or function in humans—for example, "calcium builds strong bones." In addition, they may characterize the means by which a nutrient or dietary ingredient acts to maintain such structure or function—for example, "fiber maintains bowel regularity" or "antioxidants maintain cell integrity"—or they may describe general well-being from consumption of a nutrient or dietary ingredient. Structure–function claims may also describe a benefit related to a nutrient deficiency disease (e.g., vitamin C and scurvy), as long as the statement also tells how widespread such a disease is in the United States. If a dietary supplement label includes such a claim, it must state in a "disclaimer" that FDA has not evaluated the claim. The disclaimer must also state that the dietary supplement product is not intended to "diagnose, treat, cure or prevent any disease" because only a drug can legally make such a claim.

2 CFSAN's Consumer Adverse Events Reporting System and MedWatch

The CFSAN has developed the Consumer Adverse Events Reporting System (CAERS), which replaces the patchworks of existing adverse event systems that were maintained previously by individual offices within CFSAN. FDA uses the CAERS as a monitoring tool to identify potential public health issues that may be associated with the use of a particular product already in the marketplace. Information gathered in CAERS also assists FDA in the formulation and dissemination of CFSAN's postmarketing policies and procedures. Currently, adverse event reports

from the dietary supplement industry by consumers and health professionals should be submitted to MedWatch. In the future, it is hoped that even better coordination between Poison Control Centers, and information developed by the DOD on adverse events in service members will evolve.

3 FDA Constituent Update

FDA produces updates for constituents that also provide other information. This information is available at http://www.fda.gov/food/newsevents/constituentupdates/default.htm.

C National Center for Complementary and Integrative Health

The NIH's NCCIH sponsors some research on dietary supplements and also provides fact sheets on a number of products, especially those that are being used for the prevention or treatment of disease. The "herbs at a glance" series contains authoritative fact sheets on a number of different herbs and botanicals, including common names, uses, potential side effects, and resources for more information. Visit http://nccih.nih.gov/health/herbsataglance.htm.

CAM on PubMed is a subset of PubMed that offers free access to more than 462,000 citations of journal articles related to CAM research from the NLM's MEDLINE database and other life science journals. Access it at http://nccih.nih.gov/research/camonpubmed.

D National Cancer Institute

The NIH's NCI operates a number of research programs that involve dietary supplements. Units also occasionally produce fact sheets and papers on cancer treatment and prevention measures that include dietary supplements. The NCI's Division of Cancer Prevention and the Division of Cancer Control and Population Sciences develop and maintain a website called the Dietary Assessment Calibration and Validation Register. These resources are a means of keeping the international and health community aware of worldwide calibration/validation studies on dietary assessment methods. The website is accessible at http://appliedresearch.cancer.gov/cgi-bin/dacv/index.pl. It is particularly useful for researchers intending to do studies that involve nutritional assessment.

Healthcare providers who are treating cancer patients may wish to consult the NCI website for information on dietary supplements and other alternative and complementary therapies for cancer patients. This link can be accessed at http://www.cancer.gov/cancertopics/treatment/cam.

Health professionals and patients who are seeking to enroll in clinical trials of dietary supplements or other therapies for cancers or other diseases should consult the federal government's list of registered clinical trials at http://www.clinicaltrials.gov.

E Agency for Healthcare Research and Quality, U.S. Department of Health and Human Services

The Agency for Healthcare Research and Quality works closely with the NIH and other federal agencies to develop systematic evidence-based reviews of the health literature on topics of public health significance. This agency also operates state-of-the-science and consensus conferences on these topics and publishes the deliberations. Several evidence-based reviews and conferences have involved dietary supplements, including MVM supplements, omega-3 fatty acids, ephedra, and ephedrine for weight loss and athletic performance; antioxidants and vitamins C, E, and CoQ10 for cardiovascular disease and cancer; B vitamins and berries for neurodegenerative diseases; and calcium and vitamin D for bone. The web address is http://www.ahrq.gov.

F National Library of Medicine

1 PubMed and MEDLINE (Public Use)

This is a world famous computerized bibliography, which includes biomedical information on dietary supplements; and access is freely available to the public over the web at www.pubmed.gov. ODS and the NLM partnered to create this Dietary Supplement Subset of NLM's PubMed. PubMed provides access to citations from the MEDLINE database and additional life science journals. Also included are links to many full-text articles at journal websites and other related Web resources.

The subset is designed to limit search results to citations from a broad spectrum of dietary supplement literature, including vitamin, mineral, phytochemical, ergogenic, botanical, and herbal supplements in human nutrition and animal models.

The PubMed Dietary Supplement Subset follows the prior International Bibliographic Information on Dietary Supplements database which was in place from 1999 to 2010, which was a collaboration between the two U.S. government agencies—ODS and the USDA's National Agricultural Library; see https://ods.od.nih.gov/Research/PubMed_Dietary_Supplement_Subset.aspx. The subset provides useful articles on dietary supplements.

2 MedlinePlus

MedlinePlus is the NLM's authoritative consumer health website. It includes consumer health information from the NIH, plus links to information from other U.S. government agencies and trusted health information providers, such as the CDC.

G USDA National Agricultural Library/Food and Nutrition Information Center

The Food and Nutrition Information Center compiles and disseminates authoritative bibliographies for laypeople and generalist practitioners on various topics, including dietary supplements, with partial support for these efforts from the ODS at NIH. These are available free of cost at www.nal.usda.gov/fnic.

H Department of Defense

The DOD has conducted many surveys of dietary supplement use, including the U.S. Army, Air Force, and Navy warfighter personnel [42–51]. The survey questionnaires are well designed and may be useful to other researchers studying very active young men and women. The department has also sponsored expert consensus conferences and also reports by the Committee on Military Nutrition, National Academies of Sciences that deal with dietary supplement use in the military [52,53].

I Uniformed Services University

The Consortium for Health and Military Performance (CHAMP), within the Uniformed Services University, provides resources on various health issues for members of the armed forces as well as the general public through their Human Performance Resource Center (HPRC: hprc-online.org). The HPRC was established to collect, organize, and disseminate the most current information available on all aspects of human performance and provides excellent materials for laypeople, particularly information on dietary supplements and performance. CHAMP also hosts Operation Supplement Safety (OPSS), the DOD initiative focused on dietary supplement education through information, modules, and various multimedia resources (hprc-online.org/opss). The OPSS website also provides access to a High Risk Supplement List and a simple algorithm for risk stratifying supplements.

J Canadian Government Resources

The Canadian government's Natural Health Product Ingredients Database (http://webprod5.hc-sc.gc.ca/lnhpd-bdpsnh/index-eng.jsp) includes a display of toxicity restrictions, registry numbers for the chemicals by Chemical Abstracts Service and other registry numbers, herbals, and hyperlinks to the Natural and Non-Prescription Health Products Directorate.

K U.S. Pharmacopoeia

The U.S. Pharmacopoeial Convention (USP) is an independent, science-based public health organization and official public standards-setting authority for all prescription and over-the-counter medicines, dietary supplements, and other healthcare products manufactured and sold in the United States. The standards are legally enforceable for drugs, and a dietary supplement program also exists. Quality standards are determined by a voluntary expert committee, and products that are submitted for evaluation and pass audits are listed on their website; those products that fail the evaluation are not listed. Currently, there are approximately 100 certified products. Consumer information regarding the USP certification program on dietary supplements can be found on its website as well. Occasionally, USP conducts systematic reviews of various supplements, such as amino acids that are used by body builders to purportedly improve performance. The data can be accessed at www.usp.org/usp-nf.

L Academy of Nutrition and Dietetics

1 Position Papers and Other Materials

The Academy of Nutrition and Dietetics (AND) is the professional association for dietitians. It has developed a number of useful position papers, journal articles, and other materials on dietary supplements [54].

2 Evidence Analysis Library

The AND has created an evidence analysis library that provides authoritative evaluation of the evidence on various clinical topics, including some that involve dietary supplements. Members receive access to the library as part of their dues; access to it by others is by subscription. To learn more, access the AND website at http://www.eatright.org.

3 Practice Groups

The Complementary and Alternative Medicine Practice Group of the AND focuses specifically on dietary supplements. This group produces an excellent newsletter, and members also receive free or reduced prices on many professional resources that are useful in assessing dietary supplement intakes.

M Books

Among the useful reference books are the "Physician's Desk Reference for Nonprescription Drugs, Dietary Supplements and Herbs" [55], which covers the full spectrum of nutritional supplements, including vitamins, minerals, amino acids, probiotics, metabolites, hormones, enzymes, and cartilage products. This resource describes precautions, contraindications, side effects, and possible interactions with medications. The "Commission E Monographs" [56] summarizes the German Commission E monographs on various herbal medicines. "Herbs of Commerce" [57] is a comprehensive listing of more than 2000 botanicals that have current and historical uses as therapeutic agents. Botanical synonyms are included so that older botanical names that are no longer accepted can be cross-referenced. Also included are the Ayurvedic names and the Chinese names for more than 500 herbs. The book contains the Latin binomials (Linnaean classification), the standardized common names, the Ayurvedic names, the Pinyin name (simplified Chinese name), and other common names. The "Encyclopedia of Dietary Supplements" [58] reviews many over-the-counter supplements carried in today's nutritional products marketplace and presents peer-reviewed, objective entries that review the most significant scientific research, including basic chemical, preclinical, and clinical studies. Other authoritative sources are also available [59,60].

VI HOW TO REPORT PROBLEMS WITH DIETARY SUPPLEMENT INTAKE

A Food and Drug Administration

The MedWatch program allows healthcare providers to report problems possibly caused by FDA-regulated products such as drugs, medical devices, medical foods, and dietary supplements. The identity of the patient is kept confidential. Reported adverse effects and drug interactions are also posted on the FDA Dietary Supplement Information Page of its website. If a consumer or healthcare provider thinks a patient has suffered a serious harmful effect or illness from a dietary supplement, it can be reported by calling FDA's MedWatch hotline at 1-800-FDA-1088 or through the FDA website http://www.fda.gov/medwatch/report/hcp.htm. Consumers may also report an adverse event or illness they believe to be related to the use of a dietary supplement by calling FDA at 1-800-FDA-1088 or using the website http://www.fda.gov/medwatch/report/consumer/consumer.htm.

B Federal Trade Commission

The Federal Trade Commission (FTC) has authority over the advertising of dietary supplements. The agency can be accessed at http://www.ftc.gov/bcp/edu/microsites/whocares/supplements.shfm. The FTC has issued advertising guidelines for the supplement industry that explain how truth in advertising applies to this industry and the kinds of claims manufacturers can and cannot make. The guidelines, titled "Dietary Supplements: An Advertising Guide for Industry," can be accessed at the FTC website. The FTC can take action against supplement manufacturers that make claims that lack "sound scientific evidence" in their advertising or that they deem false or misleading. FTC consumer protection can be accessed at www.ftc.gov/bcp/index.shtml.

C Poison Control Centers

The American Association of Poison Control Centers operates a hotline for suspected poisonings from drugs or dietary supplements at 1-800-222-1222. The website can be accessed at http://www.aapc.org. The Poison Post, the free quarterly eNewsletter, frequently has articles on herbals and dietary supplements geared to consumers.

CONCLUSIONS

Best practices today include a careful assessment of dietary supplement use by consumers and patients in order to better assess their health effects. Chapter 1, Dietary Assessment Methodology, provides some additional resources for those working on dietary supplement assessment. In some cases, health professionals will find it useful to encourage the use of specific supplements, and in other cases they will not; in all cases, however, use should be documented.

Chapter 3

Physical and Clinical Assessment of Nutritional Status

Patricia A. Hume[1] and Tim Ackland[2]

I INTRODUCTION

A Why Assess Body Size, Shape, and Composition for Health?

The assessment of body size, shape, and composition for health has taken on greater significance because of a worrying increase in the global prevalence of obesity and its related morbidity and mortality. The consequences of obesity are manifest in diminished quality of life, and are felt acutely in the associated healthcare costs. Despite considerable advances in research efforts to understand obesity, the implementation of lifestyle change at the population level has largely failed, so that trends we observe today are likely to continue, increasing the global burden of obesity. This reality mandates a number of important research priorities relating to lifestyle and behaviors, as well as many within the domain of body composition itself.

Research priorities include the need to document and understand the tracking and heritability of body fatness, the need to relate fat patterning in childhood with fat patterning in adults, linking changes in the prevalence of obesity in order to predict disease, mortality, and healthcare costs, and quantifying the protective role of exercise on health in an integrated way using a life-span approach. Although it has been recognized that the development of physical fitness is protective over general health, culminating in the term "health-related fitness" [1], we still require a strategic approach to quantify the dose–response of exercise for enhancing such physiological parameters as blood pressure, insulin resistance, and lipid profile, and provide culturally specific exercise advice matched to developmental stage.

B Why Are Standardized Protocols and Valid and Reliable Measures Needed?

Nutrition status is manifest in body size, shape, and composition. Clinicians must have access to valid, reliable, and cost-effective measures that are comfortable and meaningful for the client undergoing assessment. For an assessment test to be of value it must be sufficiently specific to measure the performance variable of interest, but also reliable so as to detect small changes.

The International Society for the Advancement of Kinanthropometry (ISAK) provides protocols for clinic/field physical assessment of body size and shape (girths, waist:hip circumference ratios, breadths, and somatotype) and body composition (skinfolds). The international training and certification scheme promotes accurate and standardized measurement. For example, ISAK Level 1 is designed for measurement of height, weight, five girths (arm relaxed, arm contracted, waist, hips, and calf), eight skinfolds (subscapular, triceps, biceps, iliac crest, supraspinal, abdominal, thigh, and calf), and two breadths (elbow and knee). These measures enable health and growth monitoring and calculation of the somatotype. Landmarks (identifiable skeletal points) identify the exact location of a measurement site, or from which a soft tissue site is located, to ensure greater accuracy and reliability of measurement. The advantages and disadvantages of ISAK surface anthropometry methods need to be understood.

Clinicians should keep up to date with new technologies and protocols such as the new ultrasound international standards for adipose measurement currently being developed. Assessment of body shape using three-dimensional (3D) scanning is becoming popular in

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00003-5

research situations. An international standard for 3D body shape measurement for clinical practice is currently being developed by the J.E. Lindsay Carter Kinanthropometry Clinic and Archive. Body composition measurement using multicomponent models, dual-energy X-ray absorptiometry (DXA), ultrasound, and magnetic resonance imaging (MRI) are available for clinical assessment. Variations between machines can result in substantial differences in measurements, therefore the implications of types of machines, operator training, and client presentation need to be understood.

The accuracy of body composition measurements must be taken into account when tracking people over time [2]. Assessing body composition in the growing and developing individual is difficult due to a range of issues. Increasing energy expenditure can reduce fat mass (FM) while fat-free mass (FFM) can be maintained. However, the dual metabolic challenges of exercise and growth deplete the same reserve, violating methodological assumptions concerning stability of the FFM and rendering change detection problematic. Even though a range of methods suitable for children is available, including anthropometry and body density, accuracy in predicting FM and FFM can be poorer than assumed. Individual variability is such that the threshold of performance impairment due to chronic depletion of energy reserves will tend to differ between individuals. In this context, the pragmatic solution is to align anthropometric data with those of performance, fatigue, and general health. Full dialogue with the patient/client is needed.

II ASSESSMENT OF BODY SIZE AND SHAPE

A Field Techniques—Anthropometry

Anthropometric measures are used in clinical practice, population screening, and research to assess growth, the prevalence of underweight or overweight, and to estimate disease risk for conditions such as type-2 diabetes. The ISAK protocols should be followed to improve accuracy, therefore correct land marking is required [3].

1 Height

Stretched stature (height) is measured on a stadiometer. The client stands with the heels together and the heels, buttocks, and upper part of the back touching the scale. The clinician aligns the head in the Frankfort plane (technically the lower edge of the eye socket is in the same horizontal plane as the notch superior to the tragus of the ear) and the client takes a deep breath in whilst the clinician applies upward lift through the mastoid processes (base of the skull) ensuring the clients heels remain on the stadiometer base. The stadiometer head board is lowered onto the head ensuring the hair is compressed. A loss of approximately 1% in stature is common over the course of the day; therefore the stretched stature method is used [4].

Measurement of height is necessary to track changes in growth, calculate body mass index (BMI), and waist-to-height ratio. Height should be directly measured using a stadiometer, except for infants, where body length is best measured using a length board [5]. Height begins to decline at approximately 30 years for men and women, and this decline accelerates with age. In one longitudinal series, between the ages of 30 and 80 years, women lost 8 cm and men lost 5 cm [6]. Height decreases as a result of vertebral bone loss as well as thinning of intervertebral disks and weight-bearing cartilage. Height may also decrease due to vertebral compression fractures in the settings of osteoporosis or trauma. Loss of vertebral mass and disk compression may induce kyphosis (curvature with backward convexity of the spine), which will further reduce measured height.

When height cannot be accurately measured, such as in acutely ill or immobilized patients, alternatives include self-reported height, estimated height, or surrogate anthropometric measures (arm span, knee height, and seated height) [6]. For example, knee height is measured with specialized calipers and is performed either in sitting or recumbent positions, making this useful in most ambulatory and hospital settings [7]. Prediction equations for the estimation of height from anthropometric surrogates are applied for specific age, gender, racial, and ethnic groups. Several trials, that directly compared measured height to surrogates, showed mean differences between measured height and self-reported height (0−2 cm), knee height (−0.6 to 4 cm), and arm span (0−7 cm) when the measurement was conducted in ill patients instead of healthy subjects [8]. Self-reported height is less accurate than measured height because men tend to over report and women tend to underreport their height [9]. Estimation of height by visualization of supine patients has been found to overestimate height so patient self-reported height is more accurate [10].

2 Body Mass (Weight)

Body mass (weight) is measured using calibrated scales (e.g., quality load cell electronic, beam-type, bed scales, chair scales, or wheelchair scales). The accuracy of these instruments should be within 50 g. Calibration of scales using calibration weights totaling at least 150 kg should be conducted regularly. The client needs to stand on the center of the scales without support, with the weight distributed evenly on both feet, and with the head/eyes facing forward (not looking down at the feet). Looking down

or moving the body weight center of mass away from the base of support between the feet will result in a different reading than if the correct stance is followed.

To monitor changes in weight over time, use of the same scale is recommended given the variability between scales. When a person cannot be weighed or provide a self-reported weight (often inaccurate), weight may be estimated; this inaccurate practice does improve with experience [10]. Overweight women and men tend to underestimate weight, whereas lower weight men tend to overestimate [9].

Technological advances now allow automatic remote monitoring of home scales via telephone or the Internet. This method has gained popularity for management of chronic diseases such as congestive heart failure and obesity. Involuntary loss of body weight due to illness is associated with increased risk of morbidity and mortality. In patients with cancer who were undergoing chemotherapy, a loss of 5% or more of usual body weight was associated with impaired functional status and significantly decreased median survival compared to patients without weight loss [11]. Changes in weight are commonly due to alterations in body water with conditions such as congestive heart failure, cirrhosis, and renal failure or with treatments for these conditions such as diuretics.

3 Weight for Height (BMI)

Weight for height is more commonly known as BMI. BMI is calculated as body mass divided by height squared (kg/m^2). The use of BMI to assess weight for height in individuals reflects recommendations of the National Institutes of Health and World Health Organization [12]. BMI correlates with body fat for populations, but there remains considerable variation in body composition among individuals at each level of BMI. BMI may be elevated despite relatively low levels of body fat in those with edema or in athletes. The relationship between BMI and body fat differs between sexes, varies among racial and ethnic groups, and changes over the life span. A single BMI classification scheme for the entire adult age range does not reflect the loss of FFM and gain in FM that accompany aging. Older (>65 years) men and women have a higher percentage of body fat compared to younger counterparts with the same BMI. Women have a higher percentage of body fat compared to men of the same BMI [13]. BMI should only be used as a guide for populations. Both low and high BMI correlate with morbidity and mortality, although there is ongoing debate regarding issues such as the magnitude of risk for those with BMI in the overweight range ($25-30\ kg/m^2$) and how age modifies risk for morbidity and mortality. Low levels of BMI are classified as BMI $<17.5\ kg/m^2$.

4 Arm Span

Arm span is the distance from the tip of the middle finger of one hand to the other. The client stands against the wall with feet together, facing the clinician and raises the arms to horizontal position. The heels, buttocks, and upper back, together with dorsal aspects of the arms contact the wall. The client inspires maximally and the arms are stretched maximally while arm span is measured. The easiest way to conduct this measurement is to have a chart strip attached to the wall close to a corner where one finger is placed. A nonpermanent marker pen is used to mark the distance to the other finger.

Arm span for patients who cannot stand can be measured with arms stretched at right angles to the body by using a measuring tape crossing in front of the clavicles. Demi-arm span (the distance from the sternal notch to the tip of the middle finger of one hand) can also be measured and then doubled to calculate arm span.

5 Girths

Girths are measured with steel tapes to eliminate tape stretching as may occur in material or plastic tapes. A flexible steel tape of at least 1.5 m in length calibrated in centimeters with 1 mm gradations is recommended. The tape should be aligned perpendicular to the length of the limb (e.g., upper arm girth, calf), and should be tight enough so there are no large gaps against the skin, but not too tight to cause skin indentation.

Waist girth should be taken at the minimum girth in the horizontal plane. If the client does not have a minimum waist girth, then the measurement is half way between the bottom rib and the hip bones. The client needs to be breathing normally and the measurement is taken at end tidal breath (end of expiration—but not forced expiration).

Hip girth is taken at the maximum posterior protuberance of the gluteal muscles. If the measurement is taken over clothing, then the tape needs to be pulled more firmly to ensure the measurement is representative of the underlying body structures.

Circumferences of the trunk and limbs reflect amounts of underlying FFM and FM. The "Healthy Hearts" longitudinal study of cardiometabolic health in 902 youth aged 6–15 years showed that children with low cardiorespiratory fitness were characterized by larger waist circumference and disproportionate weight gain over a 12-month follow-up period [14].

6 Circumference Ratios (Waist:Hip)

Central distribution of body fat increases risk for type-2 diabetes, metabolic syndrome, hypertension, and coronary heart disease [15]. Measures of central adiposity include a single circumference, or more commonly, a waist-to-hip

ratio (WHR). WHR correlates well with abdominal fat content and is a predictor of coronary heart disease and type-2 diabetes when using a cut-off ratio of 0.5 as an indicator of risk [16]. WHR has been found to be accurate in children and adults, men and women, and across ethnic groups.

7 Bone Breadths

A small sliding caliper is used for biepicondylar humerus (elbow) and biepicondylar femur (knee) breadths. The caliper should have branch lengths of at least 10 cm, an application face width of 1.5 cm, and be accurate to within 0.05 cm. The caliper needs to be held correctly so that the fingers can palpate the bony landmarks and the caliper branches can be placed correctly. The underlying soft tissue must be compressed so that the correct bone breadth is measured.

8 Somatotype

Somatotype is a quantification of the shape and composition of the human body. Somatotype can be calculated from the restricted ISAK profile items, and has useful applications in growth and aging, body image, and in sports profiling. The somatotype reduces a large number of measures or visual observations to a simple, three number rating (Endomorphy-Mesomorphy-Ectomorphy) which is independent of size, age, and gender. Endomorphy represents relative adiposity of a physique, mesomorphy represents relative musculoskeletal robustness of a physique, and ectomorphy represents relative linearity or slenderness of a physique. Rating values and relative meanings for all three components are 0.5 to 2.5 = low, 3.0 to 5.0 = moderate, 5.5 to 7.0 = high, >7.5 above = extremely high. A novel iPad-based application to rapidly assess body image using somatotype comparisons is now available. It simultaneously assesses body fat, muscle, and leanness using realistic quasi-3D images to provide healthcare professionals with an enhanced tool when dealing with body image disorders [17].

B Laboratory Techniques—3D Scanning

The availability of reliable 3D whole-body scanners and software−hardware suites capable of rapid measurement, data extraction, and analysis has the potential to revolutionize surface anthropometry. The main driver behind 3D scanning has been the apparel industry, envisaging the possibility of "garments on demand," tailored to fit each individual perfectly. 3D scanning has parallel applications in human factors, where humanoid "manikins" can be rescaled using measurements extracted from 3D scans and animated to interact with the built environment. These techniques are already being employed in military contexts and in the design of mass transportation and workspaces.

The basics of a 3D scanning system are four columns each with two laser safety (Class 1) cameras, and software to automatically extract measures. Most scanners work by projecting straight lines or grids onto the human body, which are then distorted by the curves and contours of the body. This distortion is captured by the cameras and decoded to infer the 3D shape. A body scan usually consists of several hundred thousand points, each represented by an XYZ coordinate. These points are joined to their near neighbors to form polygonal meshes. The tiny facets formed by the polygonal mesh can be shaded and smoothed, producing a "rendered" body (the metaphor is that of a plasterer smoothing render over a wire frame).

The resulting images vary depending on the accuracy of the scanner. Body posture during scanning is important to ensure accurate measures can be made from the images. Inside the 3D scanning booth, participants are positioned into standard scanning poses and instructed to hold their breath (at end tidal expiration) for the duration of each 10-second scan (Fig. 3.1).

Prior to scanning, landmark sites are located by palpating underlying bony structures and a physical landmark is attached to the located point. In order to be able to extract traditional measurements, the software must be able to identify these landmarks. There are three common land marking systems used in 3D anthropometry: automatic landmark recognition (ALR), where the software identifies landmarks from the scan without human intervention; digital landmark placement (DLP), where landmarks are located on a digital image by identifying surface features; and physical-digital landmark location (PDL), where landmarks are placed physically on the body and these landmarks are then digitally located on the scanned image. ALR has proved to be unacceptably inaccurate, while DLP is often difficult on fat or very muscular subjects where underlying bony landmarks are hard to locate. Therefore, we rely heavily on PDL, which has the disadvantage of requiring more time and operator skill. There is no universally accepted protocol for 3D scanning; however, protocols are being lodged in the J.E. Lindsay Carter Anthropometry Archive [18].

Three-dimensional analysis can be extended to calculate segmental and whole-body volumes and hence, to estimate body fat percentage. If we know the mass of the subject and the volume estimated by 3D scanning, we can calculate the whole-body density and hence (with certain assumptions regarding tissue density), to estimate body fat percentage. Studies examining the accuracy and precision of using 3D scans to predict whole-body density measured against a criterion standard such as DXA or hydrostatic weighing are needed.

Body changes due to growth, maturation, dietary, and training interventions can be assessed. 3D scanning can be used to visualize and better quantify size and shape

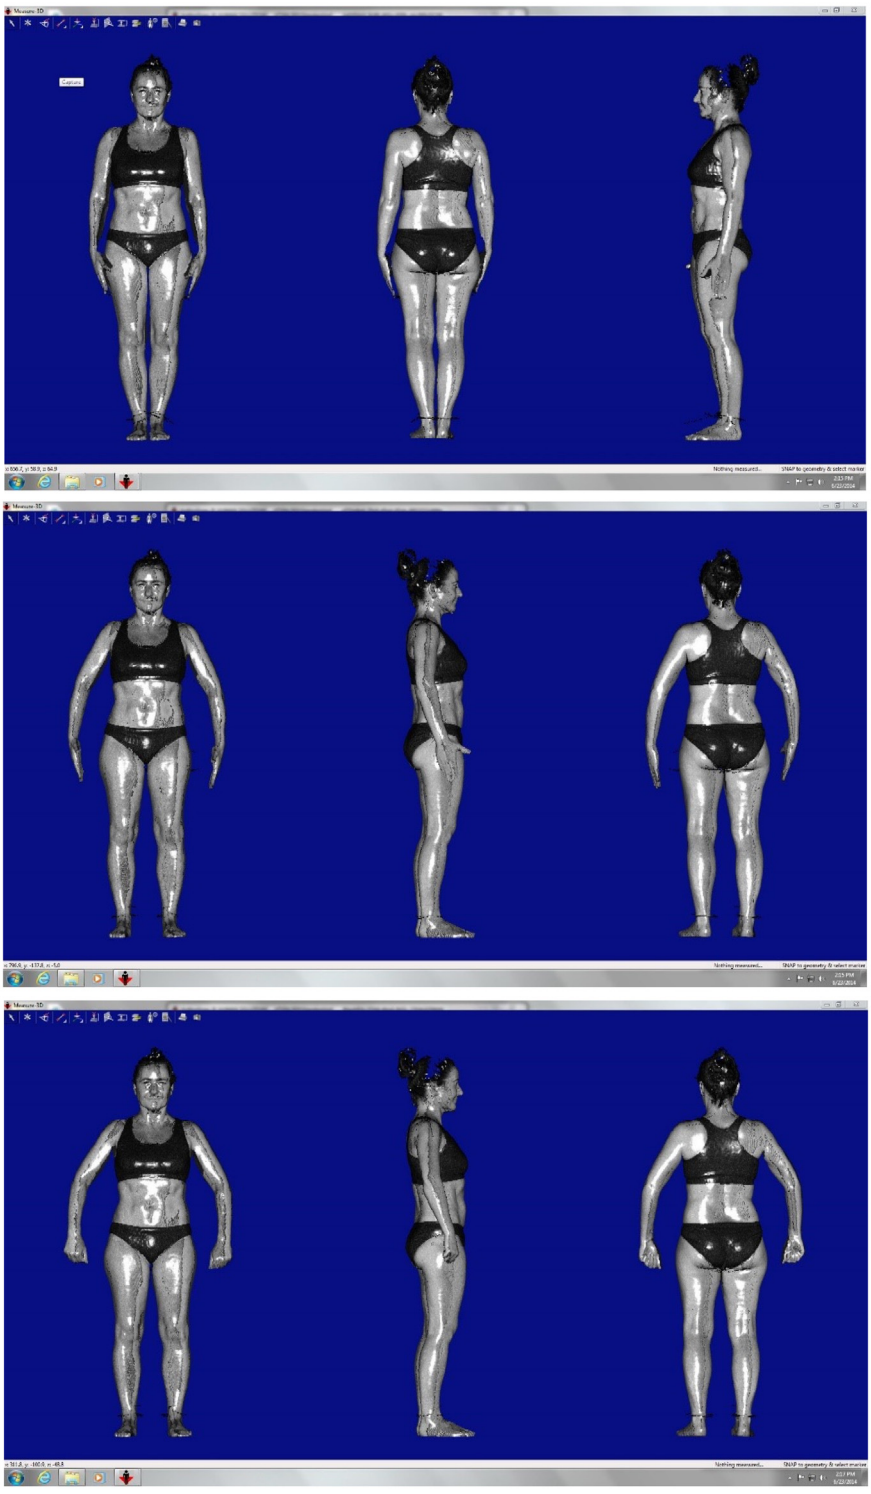

FIGURE 3.1 Example postures for 3D body scanning.

changes that occur due to aging and exercise or nutrition interventions. Somatotyping using 3D anthropometry has been conducted [19], and applications to health and exercise science have been reported [20].

III ASSESSMENT OF BODY COMPOSITION

Quantifying human body composition has been prominent in medical research and allied health clinical practice for many decades. While progress has been significant in recent years, with new and combined analytical methods, various ethical and methodological limitations still prevent the identification of an absolute measurement standard for use in humans. As a consequence, much of the research to validate new and old methods is indirect, and despite considerable advances in methods, today there is still no gold standard for body fat assessment with accuracy better than 1%.

Estimation of body fat has been the prime focus of attention, but many scientists and practitioners recognize that the amount and distribution of lean tissues like bone and muscle can be just as important in determining an individual's health status. Making sense of the myriad techniques for estimating each tissue component requires a clear framework by which these may be properly compared. When monitoring body composition, scientists and practitioners are often limited by assessment time and complexity, as well as equipment cost, ease of use, and portability. These factors conspire against the desire for accurate measurements, with the inevitable consequence that captured data may be misleading, misinterpreted, or perhaps used inappropriately. This reality has forced many to consider acceptable surrogates for fatness, without recourse to quantifying tissue mass.

The discussion in this section will concentrate only on body composition techniques, both field and laboratory-based, that were supported in a recently published Position Statement under the auspices of the International Olympic Committee's Medical and Scientific Commission [21]. The review paper provides a critique of all commonly employed body composition techniques with special consideration of the assumptions, cautions, advantages, and disadvantages of each methodology.

A Field Techniques

Field techniques—those which are portable and allow data collection away from the laboratory—including skinfolds, bioelectrical impedance analysis (BIA), and several relative weight indices (including BMI) have recently been reviewed [21]. Due to the overwhelming limitations and unsubstantiated assumptions associated with the latter techniques, only the use of skinfolds was supported for assessing and monitoring the thickness of subcutaneous adipose tissue (SAT) (as a surrogate measure of body fatness).

1 Skinfolds

Skinfold thickness describes the amount of subcutaneous fat when the fold is lifted and its thickness measured by specialized calipers. The sum of skinfolds (generally from eight sites in the standard ISAK protocol) provides data for comparison with population norms, or for monitoring changes over time within the same individual.

Devices to measure the thickness of a compressed, double layer of skin plus the underlying SAT have been used ubiquitously for well over 50 years. Unfortunately, much of the published data cannot be relied upon due to vast differences in caliper specifications, the number and location of skinfold sites, and a lack of standardization in operator technique and data treatment. There are over 100 body fat prediction equations derived from skinfold measurements [1] and their inconsistent results stem from differences in the populations that were sampled.

The ISAK manual contains details of standardized protocols [3] to help minimize the technical error of measurement for repeat skinfold measures at various measurement sites. The standard ISAK protocol for skinfolds has the following requirements:

- Use approved skinfold caliper that is regularly calibrated. Skinfold caliper requires a constant closing compression of 10 g/mm^2 throughout the range of measurements. They should be calibrated to at least 40 mm in 0.2 mm divisions.
- Precise marking of eight standard measurement sites on the right side of the body.
- Though more skinfold sites are supported, using these eight sites helps to address both intra- and interindividual differences in subcutaneous fat deposition.
- A standard measurement protocol that prescribes the operator technique and order of measurement, as well as providing for a minimum of two (but preferably three) repeated measures at each site.

The importance of accurate skinfold measurement site location has been examined in 12 healthy participants. Nine measurements, in a one-centimeter grid pattern, centered on each of eight ISAK-specified skinfold sites, were taken three times at each grid point by each of two ISAK Criterion (Level 4) measurers using Harpenden skinfold caliper. Skinfolds taken at the eight peripheral grid points in a 1 cm grid pattern were generally different (45 out of 64 = 70%) from the skinfolds taken at a central ISAK grid point. There was also an effect by direction (anterior, posterior, superior, or inferior). The subscapular was the most robust skinfold site with small measurement deviation away from the central ISAK point. All other skinfold

sites showed some variation, with most care needed in marking the biceps and triceps skinfold sites. Measuring 1 cm away from a defined ISAK site produced significant differences in the majority of skinfold measurement values obtained and no site was totally free from this variation. Therefore, adherence to identifying, marking, and measuring at the defined site is essential [2].

Despite the benefits accrued by this standardized technique, there are several unresolved assumptions and limitations of the skinfold methodology [21], that:

- there exists consistency in adipose tissue deposition (fat patterning);
- a fixed relationship of subcutaneous to internal fat exists;
- skinfolds have a constant compressibility;
- the skin contributes to a constant fraction of the skinfold value;
- the lipid comprises a constant fraction of the adipose tissue; and
- water comprises a constant fraction of the adipose tissue.

Furthermore, several studies have shown that skinfold thickness is influenced by age, sex, race, and the state of hydration.

Another important consideration relates to predicting body composition from surface anthropometry. ISAK supports the reporting of individual values as well as a simple arithmetic sum of eight skinfolds when monitoring participants over time, or when comparing individual results to normative data. This reporting standard minimizes the aggregation of assumptions and limitations associated with the use of regression equations for predicting a body fat percentage (%BF). All body fat regression equations use several raw skinfold values to predict a %BF. The equations are generally derived using another surrogate measure of %BF, such as hydrostatic weighing, air displacement plethysmography (ADP), or bioelectric impedance (BIA), as the dependent variable. However, since these supposed "reference" measures are neither valid nor reliable, the value of such regression equations is highly questionable.

B Laboratory Techniques

Several established and emerging laboratory techniques are widely supported [21], including multicomponent models, DXA, and the use of medical diagnostic devices such as ultrasound and MRI. Other common techniques such as densitometry (via hydrostatic weighing, ADP, and 3D scanning) and hydrometry (e.g., total body water) have been employed extensively in research and clinical settings, but these were not supported due to myriad limitations and unassailable assumptions.

1 Multicomponent Models

Elaborate 3-, 4-, 5-, and 6-component models are available for body fat estimation [22]. Their precision and accuracy are in the order of 1−2%. The 4-component model employs separate techniques to estimate body density, body water, and bone mineral, and is the leading method in current use. The equation is in the form:

$$FM = C_1 \cdot BV - C_2 \cdot TBW + C_3 \cdot M - C_4BM$$

where FM is fat mass, C_n is a constant, BV is body volume, TBW is total body water, M is bone mineral, and BM is body mass.

Precision of multicomponent models is high [22], and technical errors of estimating body volume, body water, and bone mineral have been combined to yield a %BF error of approximately 1%.

The multicomponent models are considered the most accurate means of estimating body composition to date, since they accommodate variability in bone mineral and water content; both an issue that invalidates the general two component model. However, this technique assumes a constant proportion of protein to water and that the density of each tissue component is constant. Furthermore, it involves expensive technology, a long analysis process, and its utility suffers for a lack of normative data.

2 Dual-Energy X-ray Absorptiometry

DXA scanners were originally designed to measure bone mineral content and density, though software developments during the 1990s also permitted the estimation of soft tissue masses. This is achieved by passing filtered X-ray beams at two photon energies through the body that are attenuated differentially by the material in their path. The synthesized data map provides the mass and composition of each pixel in terms of bone mineral, FM, and FFM. This chemical assessment of the body should not be confused with an anatomical (tissue) compartment approach. Common interpretation errors include that the FM equates to adipose tissue, that the bone mineral equates to skeletal tissue, and that the FFM equates to muscle. In fact, the FFM aggregates all remaining tissue components that are not fat (lipid) or bone mineral (calcium carbonate and calcium phosphate).

The whole-body DXA scan delivers a low dose of radiation (equivalent to a long-haul plane journey) which varies according to scanner type and beam configuration (i.e., pencil or fan beam). Consequently, this method is not suitable for pregnant women, or for multiple scanning of individuals over time. Clients should not be measured more than four times per year, due to the cumulative radiation dose, and also the error of measurement which limits the ability to detect small changes in body composition over time [21]. Early DXA machines were quite limited

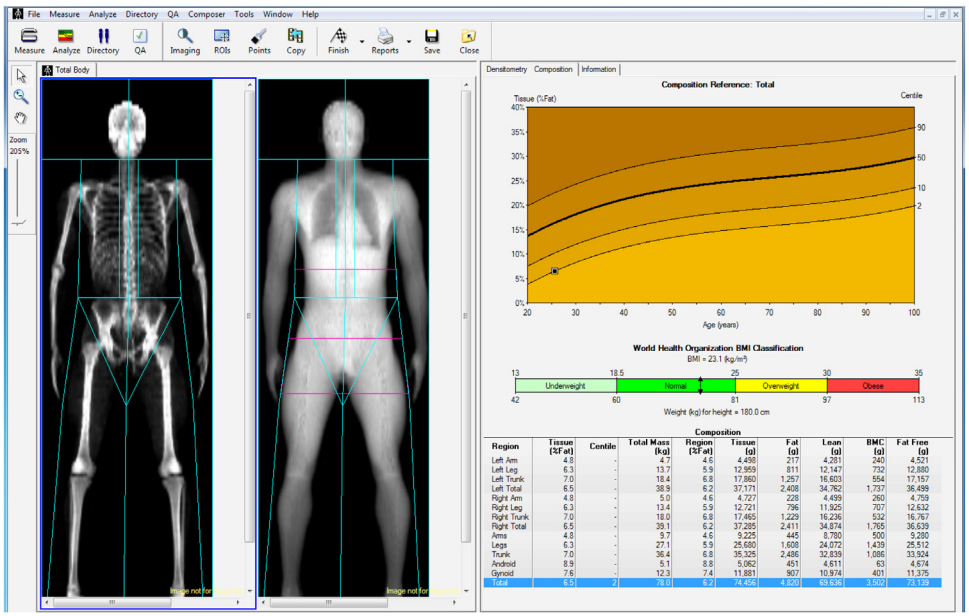

FIGURE 3.2 Whole-body scan report for a lean male participant aged 25 years using a Lunar Prodigy DXA machine (GE Medical Systems). With an overall 6.2% body fat, this individual has 4.82 kg of fat, 3.50 kg of bone mineral, and 69.64 kg of lean tissue.

in the dimensions of the scan bed which presented a problem for whole-body assessments. While more recent models can accommodate clients up to 120 kg mass, most scan beds will not fit clients greater than ~192 cm in length (Fig. 3.2).

Following a standardized DXA scanning protocol is essential for achieving accurate and repeatable measures. One study [23] scanned young physically active participants on five occasions within a 2-day period. The first scan was in the morning after an overnight fast, then approximately 5 minutes later after repositioning the participant on the scanning bed. The next scan followed after an 8-hour period of normal daily activities, followed by a fourth scan the next morning, and a final measurement after breakfast 30 minutes later. There was a negligible effect of participant repositioning; however, daily activities and the consumption of food produced a substantial increase in the typical error and mean values of lean mass and total body mass. Taking these results into account, recommended standard protocols for DXA scanning require clients to be fasted (approximately 12 hours), well-hydrated, and with bowel and bladder recently voided.

DXA-derived body composition estimates have been validated against multicomponent models [24] with SEE (standard error of the estimate) for predicting %BF reported between 2% and 3%. Several assumptions are made in the soft tissue estimates from DXA including beam hardening due to the depth of tissues, magnification errors, and errors of estimating fat quantity in approximately 40% of scan pixels that contain bone [25].

In summary, DXA provides a reasonably precise whole-body method for body composition assessment for most individuals, though it is not reliable in producing accurate fat estimates in very lean individuals (due to the high proportion of pixels containing bone). Differences between machine manufacturers, beam configurations, and software algorithms prevent simple comparison of data that have been derived from different apparatus.

3 Magnetic Resonance Imaging

Though costly and time consuming, medical imaging techniques offer an opportunity to account for both subcutaneous and deep adipose tissue depots, as well as providing estimates for other tissues such as bone, muscle, and viscera. No ionizing radiation is involved, so the method is noninvasive, though the confined space of the scanner may induce claustrophobia.

Whole-body MRI scans are possible and these must be acquired as an integrated series of stacks. The pixel size within slices of 2×2 mm for whole-body scans does limit the accuracy of measurement for lean individuals, while difficulty in discriminating boundaries between tissue layers, further limits sensitivity. MRI produces 3D tissue volumes which require assumptions to be made about tissue density and chemical composition before tissue masses can be estimated. As a consequence of these limitations, medical imaging technologies are not considered to be practical for body composition assessment and monitoring at this point in time. Future advances in hardware

and software, however, may improve the utility of MRI for body composition assessment.

4 Ultrasound

A novel ultrasound measurement and analysis method [26] allows quantification of SAT layers without compression and with high measurement accuracy. For example, a comparison of ultrasound SAT measurements in excised pig tissue with Vernier caliper measurements of 0.1 mm resolution resulted in a very high correlation ($r = 0.998$; $n = 140$) between scores with an SEE of 0.21 mm [27].

The standard eight ultrasound site locations [26] are defined relative to the standing stature of the client for upper abdomen (UA), lower abdomen, erector spine, distal triceps, brachioradialis, lateral thigh, front thigh, and medial calf. These sites help account for interindividual differences in SAT patterning and allow a sum of eight SAT thicknesses to ensure high accuracy and reliability. The sites are marked on the skin with the participant standing or seated, while ultrasound images are captured with the participant lying on a plinth in prone (Fig. 3.3), supine or side-lying postures. Any B-mode ultrasound machine can be used to capture an image for analysis, provided a linear transducer of 5−20 MHz is used. The transducer must have a thick (3−5 mm) layer of gel applied which allows contact with the skin but without compression of the underlying tissues.

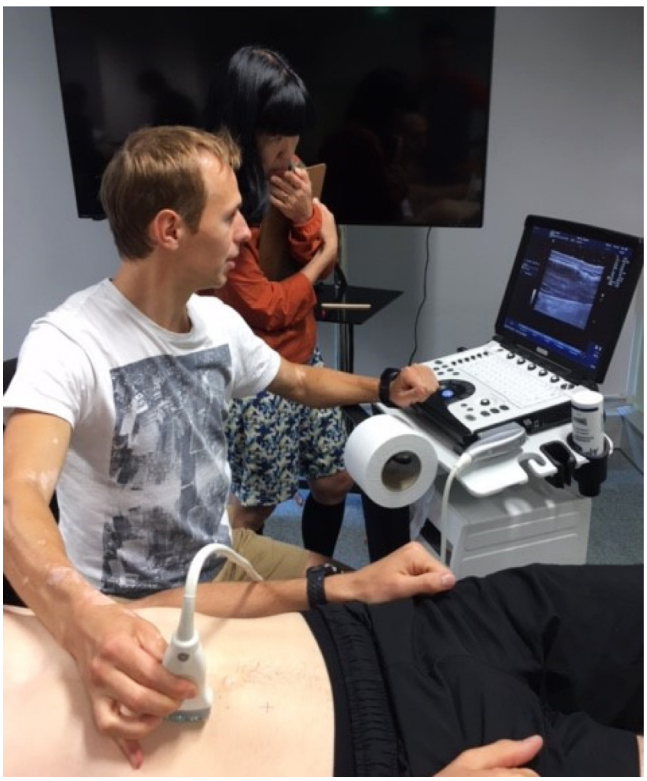

FIGURE 3.3 Dr. Andrius Ramonas (New Zealand) and Dr. Kazuko Ishikawa-Takata (Japan) using an ultrasound to capture an image at the UA site during an ultrasound body composition training course at the J.E. Lindsay Carter Kinanthropometry Clinic in Auckland, New Zealand.

All sites overlie muscle with a clearly visible fascia enabling clear acquisition of ultrasound images and the SAT layers show little variation in thickness in the vicinity of selected site landmarks. Fibrous structures embedded in the SAT, such as the Camper's fascia in the abdominal sites, can be quantified using the semiautomatic image evaluation software [26]. Visual control of the FAT measurement algorithm eliminates errors associated with automatic contour detection algorithms. The routine measurement of many thickness values in a single image, the possibility to include or exclude embedded structures like fibrous tissues and blood vessels in these thickness values, and the ability to quantify their depth is greatly advantageous for the scientist or clinician.

With training and practice, the land marking, image capture, and evaluation of eight sites takes about 20 minutes per individual. This technique has the potential to fill a void in our ability to measure and monitor body fat with accuracy and repeatability using a relatively inexpensive technology. While assumptions are necessarily made about the relationship between SAT and internal adipose tissue depots, this methodology removes several of the limitations attributed to skinfolds. Published reference data using this ultrasound technique for a variety of subpopulations are now needed so that the methodology may reach its full utility.

IV CLINICAL CONSIDERATIONS IN ASSESSMENT OF NUTRITION STATUS

A Consent to Conduct Measurements

Body measurement can be stressful for patients/clients, so a clear explanation of the measurement process should be outlined. It is recommended that an information sheet be provided to the client explaining what will be happening to them, what they should wear, what measurements will be taken, by whom, and approximately how long the measurements will take. Written and verbal informed consent expressed in plain language should be obtained from every client, or from their legal parent or guardian, if they are minors or are incapable of making or communicating an informed decision.

B Understanding Growth Changes

Body composition changes during childhood, adolescence, and adulthood impact health and physical performance. By understanding the biology of growth we can

anticipate adult morphology, and relate this to optimal skeletal size and proportions (morphological optimization), and change in soft tissue for maximum functional effectiveness (morphological prototype). Proportionality is important for the changing physical parameters during growth. Segment breadths are most useful for predictive purposes because they remain stable in relation to stature throughout adolescence. However, there is nonuniformity of the tempo and timing of body tissues and systems undergoing growth. Recognition of the wide individual variability in maturation rate by clinicians helps interpretation of data and the caution needed for database normative comparison values.

Normal growth can be undermined by nutritional deficiency, impairment of hormone production, or both. Growth hormone facilitates protein synthesis, and mediates the proliferation of cartilage cells at the epiphyseal boundary which promotes somatic growth. Thyroid hormone promotes growth of the central nervous system and works in conjunction with growth hormone to stimulate bone and cartilage formation, while insulin-like growth factor is influential in protein synthesis and muscle growth. Puberty commences with increasing complexity and interaction of hormonal influence (growth hormone, insulin-like growth factor, thyroid hormone and cortisol, plus testosterone in boys and estrogen in girls). Hormones largely determine the tissue mass gained during adolescence—mainly muscle in boys and fat (and also muscle) in girls.

C Tracking Somatic Growth Through the Life Span

Anthropometric measurements allow comparison to population norms or to values collected over time in the same individual. Several markers of somatic growth are typically used to track children to adolescence. Stature and mass velocity curves rapidly decelerate in early childhood until three years of age when stature deceleration is reduced and the rate of weight gain begins to increase. However, due to the inability of younger children to tolerate measurement procedures, assessments of stature and mass (and hence BMI) are prone to error, and data need to be interpreted with caution.

The growth rate in infancy exceeds that of the adolescent growth spurt. Less widely recognized is the mid-growth spurt typically occurring between 6.5 and 8.5 years, which is much smaller and less marked. Importantly, the capacity to detect this mid-growth spurt is limited by measurement frequency and measurement precision. Many children might only be measured annually, in which case the mid-growth spurt is unlikely to be detected. Precision error of measurements must be sufficiently small, so the modest effect of this spurt is not masked by the error of measurement. The typical adolescent growth spurt, later and more marked in boys, is more apparent and easily detected. The difference in stature between adult men and women is mostly because boys grow approximately 5 cm per year for two extra years before commencing their growth spurt.

Peak height velocity typically displays a 2-year difference between boys and girls. Since the 1950s there has been a secular trend for an earlier peak height velocity in both boys and girls. The gain in body mass also exhibits a similar profile, with males showing the same time lag, relative to females. However, different body tissues experience differential growth. For example, an average healthy boy of 14 years might have achieved 91% of his adult stature, but only 72% of his adult muscle mass, and only by 18 years will muscle mass rise to 91%, when stature growth might be approaching zero [28]. The primary tissues of the skeletal system, muscular system as well as adipose tissue all follow a trajectory in adulthood which is a function of the interactions between genetic, hormonal, and environmental factors.

D Body Fat Changes Through the Life Span

Alteration in the relative quantities of fat during childhood is viewed as a health risk factor later in life. While BMI is inadequate for assessing body composition on an individual basis, there appears to be evidence of a link to disease in population studies.

The assessment of body composition in children has taken on greater significance because of the likelihood of obese children becoming obese adults, and that lifestyle behaviors acquired in childhood are resistant to change. While our understanding of etiology of childhood obesity remains incomplete, several factors have a direct or indirect influence over energy intake and energy expenditure. Higher body fat content is associated with early maturation in girls (early menarche) and greater fat acquisition throughout adolescence. The effect of body fat content on maturation is less well established in boys, possibly as a result of the rapid increase in muscle mass at this time. Earlier sexual maturation in girls, relative to boys, means that physical activity is de-emphasized, commonly in favor of social activity. While physical performance capability of boys may exceed that of girls, the importance of maintaining physical activity in terms of health, can be argued to be of greater importance for girls. Increasing energy expenditure via exercise can help reduce fat while FFM is maintained. However, assessment of change in FM and FFM needs to take into account the instability of the latter during the growth and developmental processes [29], which is rarely appreciated.

Adipose tissue tends to be gained systematically in both males and females during adulthood. Observations of fat patterning, and typically the android and gynecoid shapes attributed to its distribution, are well established. Males accumulate more visceral fat than women and tend to accumulate fat on the torso, while females accumulate fat in the gluto-femoral region. Gluto-femoral deposition of fat appears to be protective of health if it offers an alternative depot for excess fat. After menopause, females show signs of increased centralization of excess fat to the torso, including both the subcutaneous and visceral depots.

E Skeletal Size, Shape, and Bone Mineral Density

Bone mineral gain during adolescence is greater than the subsequent loss in later life after peaking around 30 years of age. Because up to 40% of the variation in peak bone mass is considered to be modifiable by environmental factors, exposure to adequate high impact exercise and calcium intake during adolescence is essential to acquire a high peak value, and safeguard against osteopenia and osteoporosis in later life.

Skeletal size and shape are configured earlier in the growth trajectory than bone density. After peak height velocity is attained in the adolescent growth spurt, stature declines to zero growth, although incremental growth in skeletal breadth (e.g., biacromial breadth and bicristal breadth) and chest depth commonly continue after the adolescent growth spurt. Final stature does not indicate that the skeletal shape or peak bone density are finalized. Significant height (commonly up to 8 cm) may be lost in old age as a result of postural changes and structural alterations in the spine caused by osteoporosis. Weight bearing exercise in adulthood generally maintains or reduces the rate of loss of bone, rather than adding bone.

Skeletal age assessment, which is perhaps the most reliable of maturation indices, incurs X-ray exposure and consequent ethical issues. Segment breadths remain relatively stable throughout adolescence and can be used for predictive purposes; however, segment lengths are usually unstable. Segment length variability (e.g., a 6% change in leg length to sitting height ratio) can form the basis for a final stature prediction based on a maturity offset [30].

F Muscle Tissue Changes

Chest depth enlarges as a result of loss of compliance of the thorax. During young adulthood, muscle mass tends to accumulate, however, the extent of accrual depends on activity and interaction between genetic and environmental factors. The widely recognized decline in FFM commencing in adulthood until old age tends to be primarily the loss of muscle tissue, which in turn is related to a decline in growth hormone. Loss of muscle mass has been estimated to be 3 kg per decade on average in sedentary individuals [31], with males losing approximately 1.5 times that of females. Exercise can reduce the rate of muscle loss by about 25% [32]. Muscles in regular use experience less atrophy, and the regeneration of muscle tends to replace slow twitch fibers more than fast twitch fibers, with the effect that slower, less forceful muscle action is facilitated. Elderly individuals undergoing surgery may be unable to restore presurgery levels of the affected muscle mass despite intensive exercise intervention.

G Use of Growth Charts and Normative Data Sets

The scope for body composition change throughout life (childhood, adolescence, and adulthood) from a health perspective is vast. The physique trajectory which has both genetic and environmental determinants can be anticipated up to a point, for identifying disease.

Growth charts have been in routine use since the late 1950s, but are not as straightforward to apply as they might seem [33]. A secular trend for increased stature of between 0.5 and 1.5 cm per decade reported during the 1970s appeared to have ceased by 1980. The validity of this or other secular trends is contingent on the similarity in morphology of the source data to those under investigation, and the sample size reflecting population parameters of ethnic variation and socioeconomic status. Consideration is required of source data for growth charts because cross-sectional growth data, while useful in some respects, cannot illustrate normal growth variation in the timing and duration of the growth spurt. The diagnosis of a growth disorder might be affected by the normative data used for comparison, as well as the measurement technique used, which highlights the importance of standardization of approach and the use of currently validated methods.

We need to be mindful of how to interpret the trajectory of body composition change in adulthood. As a person ages, the probability of death increases, and the mean survival age is less than the mean life expectancy in the absence of premature death. The aging population is increasingly highly selected so our interpretation of morphological changes needs to take this into account. The capabilities of modern medicine prolong life and slow disease progression. These factors are important when considering cross-sectional data, which typically form the evidence base for the study of aging.

Secular trends in life expectancy have shown changes in body composition in later stages of life being the

consequence of a health disorder which may at some future point prove fatal. For example, approximately 30% of Americans aged 60−69 years have no chronic health conditions, but this reduces to 10% for adults 80+ years. The shape of curves for body weight, BMI, or total fat, with respect to age, tend to decline in old age, reflecting the enhanced survival of less overweight individuals. The limits of variability of human physique with impaired health are being extended, as evidenced by living adults with body mass below 30 kg in severe undernourishment, and exceeded 600 kg in extreme obesity.

H Exercise and Changes in Body Composition

While muscle tissue obeys the law of specificity, in terms of use and retention, it does not recruit fat stores locally, so the concept of "spot reduction" in fat stores is unfounded. Interventions which reduce overall body fat will tend to reduce all depots of fat, and not target one depot in favor of others. Guidelines for the general population published by the U.S. Department of Agriculture recommend individuals to engage in moderate to vigorous intensity activity on most days per week, while not exceeding caloric requirements. This advice was tested in a 12-month randomized control trial of sedentary individuals [34] with modest, though significant reductions in weight, BMI, waist circumference, and body fat assessed by DXA. There was an effect of exercise preferentially utilizing abdominal fat in previously sedentary individuals. Increased exercise can add muscle mass while at the same time reducing FM, with the result that weight change is minimal. Individuals with only a small reduction in weight can, therefore, be healthier in terms of risk profile via a range of cardiorespiratory, metabolic, and neuromuscular factors, and have greater functional capacity as a result of adaptation to exercise.

Many studies of the efficacy of dietary interventions consider weight loss or change in BMI as the primary outcome variable. This is usually because they are easily measured, and have large data sets available for comparison, even though body composition measurement would be more valid.

I Athletes and Body Composition

An International Olympic Committee Medical Commission working group on Body Composition, Health, and Performance was commissioned in 2010 to investigate how to protect the health of athletes. It identified three categories of sports that represent a health risk due to training and precompetition practices associated with manipulating body mass: gravitational sports, weight category sports, and aesthetic sports. Gravitational sports involve the body working in a vertical plane by applying forces to overcome gravity, such as endurance running, cycling, and ski jumping. Weight category sports include all types of combative sport such as judo and taekwondo, as well as rowing and weightlifting. Aesthetic sports involve appearance, poise, and highly skilled body movements such as figure skating, gymnastics, and diving. These sports share a common influence of the pressure for leanness, minimizing fat levels, and optimizing power to weight ratio. Several important publications resulted from the activity of this working group include:

- identifying medical problems due to unhealthy practices in sport leading to extremes of underweight, weight reduction, and dehydration [35];
- recognizing research needs in body composition, health, and performance [21,26,36];
- identifying the current practice for body composition assessment globally [36];
- developing suggestions for practical strategies to solve body composition and underweight problems in sports [37]; and
- establishing, if practicable, optimum body composition and/or minimum weight values for healthy competition in sports [35].

V CONCLUSION

Nutrition status is manifest in body size, shape, and composition. ISAK protocols should be followed for clinic/field physical assessment of body size and shape (girths, breadths, waist:hip circumference ratios, somatotype) and body composition (skinfolds). The advantages of the ISAK surface anthropometry methods are that assessments take only 10 minutes for a restricted profile and 30 minutes for a full profile, and the equipment is easily calibrated and readily available. The methods have been shown to be valid and reliable if ISAK training is undertaken to ensure correct land marking is performed. International data are available for comparison of client measures. The disadvantage of the ISAK surface anthropometry techniques is that skinfold caliper compresses the adipose tissue resulting in variation in measurements. New methods such as ultrasound enable more accurate measurement of adipose tissue with improved accuracy. Assessment of body shape using 3D scanning is limited due to the expense of the scanners and correct body positioning in the scanner is essential to gain valid measurements. International standards for 3D body shape measurement are still being developed. Body composition measurement using multicomponent models, DXA, MRI, and ultrasound are expensive due to the cost of the technologies; however, they are becoming more available for clinical assessment. Variations between machines can

result in substantial differences in measurements, therefore the type of machine and the operator and client presentation characteristics for the assessment must be noted.

Chapter 4

Energy Requirement Methodology

James P. DeLany
University of Pittsburgh, Pittsburgh, PA, United States

I INTRODUCTION

Knowledge of energy requirements throughout the life cycle and during various physiological conditions and disease states is essential to the promotion of optimal human health. Unfortunately, available instruments for measurement of energy intake have demonstrated considerable misreporting [1]. Therefore, investigators have focused on measurement of energy expenditure, which can be accurately measured. However, with the application of the intake-balance technique, utilizing longitudinal assessments of total energy expenditure and body composition, accurate assessments of energy intake can be made [2,3]. Surprisingly, many of the same issues that are currently under investigation, such as gender differences, energy requirements of infants, the effect of different diets, caloric restriction, and physical activity, were first studied in the early 1900s [4–12]. The aim of this chapter is to familiarize the reader with current techniques available for measurement of energy expenditure used to estimate energy requirements.

II COMPONENTS OF DAILY ENERGY EXPENDITURE

Total daily energy expenditure (TEE) is the sum of resting metabolic rate (RMR), the thermic effect of food (TEF), and energy expended in physical activity (EEPA; Fig. 4.1). The methodology utilized to determine each component is indicated to the right and will be described in detail later. The pathway of energy production from the oxidation of macronutrients in the human body is depicted in Eq. (4.1):

$$\text{Macronutrients} + O_2 \rightarrow \text{heat} + CO_2 + H_2O \qquad (4.1)$$

Examination of this equation indicates that to estimate energy expenditure, one could measure macronutrient or oxygen consumption, or the production of heat or carbon dioxide. Most energy expenditure methods in use today rely on measurement of carbon dioxide production and/or oxygen consumption. Measurement of heat production, or directly calorimetry, is rarely used today.

A Resting Energy Expenditure

Resting metabolic rate (RMR), also called resting energy expenditure (REE), the largest component of TEE (Fig. 4.1), is the energy expended by a fasting individual at rest in a thermoneutral environment. The term basal metabolic rate (BMR) or basal energy expenditure (BEE), although often used to describe this component of energy expenditure, is not identical to RMR. By definition, BMR measurements are made early in the morning, in a thermoneutral environment, before the individual has engaged in any physical activity, and with no ingestion of food, tea, or coffee, or inhalation of nicotine-containing tobacco smoke for at least 12 hours before the measurement. If any of the conditions for BMR are not met, the energy expenditure should be termed the RMR. For practical reasons, BMR is rarely measured. In its place, RMR is used, which is generally higher than BMR. To estimate energy requirements, RMR is often measured or estimated based on standard equations and multiplied by a factor to account for physical activity.

1 Determinants of REE

The determinants of REE are well established in both adults and children. The principal factors contributing to individual variation in REE include body size and composition, gender, race, age, physical fitness, hormonal status, genetics, and environmental influences [13–19].

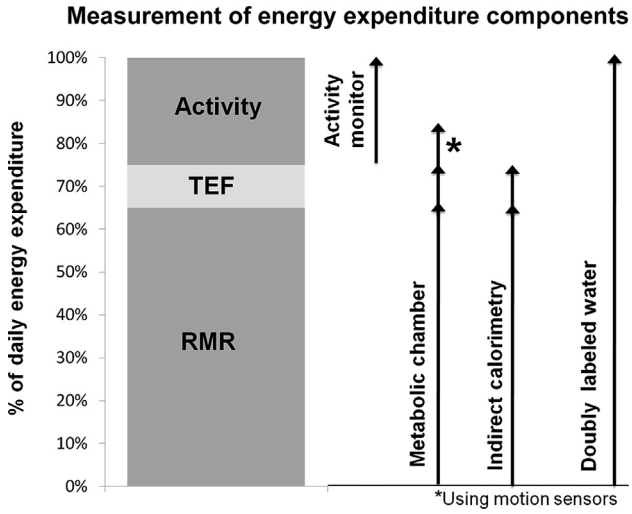

FIGURE 4.1 The components of total energy expenditure.

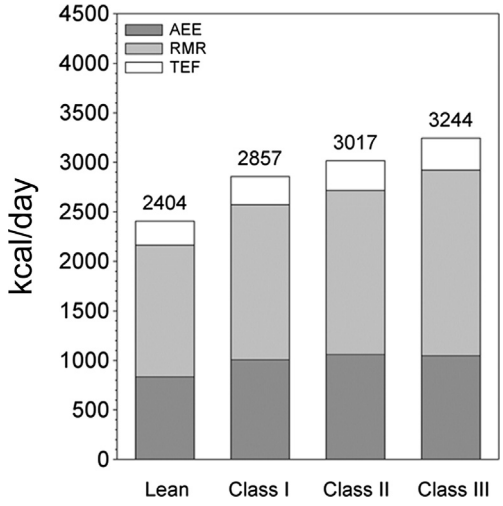

FIGURE 4.2 Increased energy expenditure with increased body size.

a Body Size

Larger people have higher energy requirements than do people of smaller size because additional body tissue requires additional metabolic activity. A recent study in which energy expenditure was measured in lean, Class I, Class II, and Class III obese individuals, with mean body weight from 63 to 124 kg, illustrates the increase in RMR with increasing body size (Fig. 4.2) [20]. Although REE is higher in larger individuals, many factors beyond body weight, such as proportion of body fat, tissue growth or repair, environment, race, and genetics, can induce major differences in metabolic rate.

b Body Composition

The composition of the body has a major effect on REE. FFM, which serves as a surrogate for the metabolically active tissue in the body, is the primary determinant of REE [14]. Hence, most of the variation in REE between people can be accounted for by the variation in their FFM [16]. Several factors influence the amount and proportion of FFM, including age, gender, and physical fitness. FFM can be accurately measured using a number of techniques, including underwater weighing, measuring total body water using stable isotopes of deuterium or oxygen-18, and dual-energy x-ray absorptiometry (DXA). DXA is a technique that accurately estimates FFM, fat mass, and bone mineral mass. Subjects lie supine on a padded table for 6–12 minutes, during which time two very low-energy x-ray beams are passed through the body (Fig. 4.3). The total x-ray dose is generally 1 mrem or less, on the order of a single day's background radiation for a whole-body composition analysis. The technique differentiates bone from soft tissue (Fig. 4.3, inset) and further differentiates soft tissue between lean and fat. Svendsen et al. [21] discuss in detail the calculation of fat mass and lean body mass.

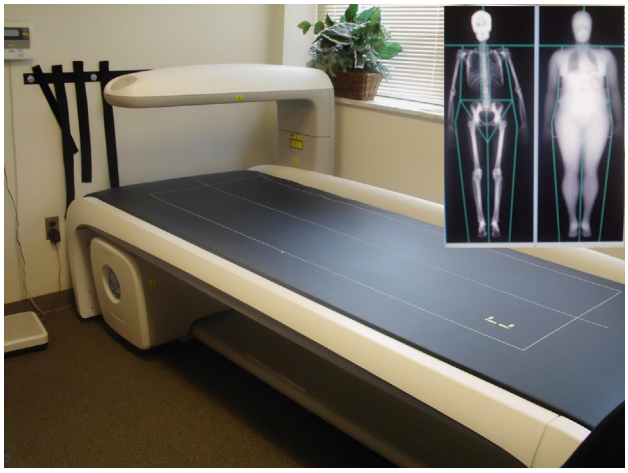

FIGURE 4.3 Dual-energy x-ray absorptiometer for body composition.

Because of the expense or impractical nature of research techniques for body composition, other, less accurate methods such as anthropometry and bioelectrical impedance are often used in practice to estimate body composition. However, in 1999, the National Health and Nutrition Examination Survey (NHANES) began performing DXA body composition measurements on survey subjects 8 years old or older in three mobile examination centers [22].

c Gender

Since men are generally bigger than females, and females typically have more fat in proportion to muscle than males, RMR is generally higher in males than in females. In the data set presented in Fig. 4.2, RMR was higher in

men than in women (2122 ± 453 vs 1659 ± 270 kcal/day; $p < 0.0001$). However, when adjusting for FFM, fat mass, age, and race, RMR was similar in men and women (1690 ± 58 vs 1720 ± 13 kcal/day; $p = 0.61$). Other investigators have also found similar RMR in men and women when adjusting for body composition differences [23,24], although gender differences have been observed in older adults [24,25].

d Age

There is a well-documented age-related reduction in RMR [26–29], with the decline occurring at approximately age 40 years in men and 50 years in women [26]. This decline in REE can be partly explained by a reduction in the quantity as well as the metabolic activity of lean body mass [30], including changes in the relative size of organs and tissues [31]. If individuals gain weight as they age, RMR may actually increase because of gains of FFM and fat mass.

e Physical Fitness and Activity

Athletes generally have a higher RMR compared to nonathletic individuals [32,33]. Whether physical activity has a direct effect on RMR beyond changes in body composition is unclear [19,34,35]. Nonetheless, aerobic exercise and strength training have been shown to result in significantly higher metabolic rates in men and women as well as lean and obese individuals [34–37].

f Hormonal Status

Hormonal status can impact metabolic rate, particularly in endocrine disorders affecting thyroid hormone status. Stimulation of the sympathetic nervous system, such as occurs during emotional excitement or stress, increases cellular activity by the release of epinephrine, which acts directly to promote glycogenolysis. There appear to be no major effects on RMR from the hormonal changes that occur during the menstrual cycle in African-American or Caucasian women [38–41]. Other hormones, such as cortisol, growth hormone, and insulin, can also influence metabolic rate [42–44].

Although leptin was initially considered to be the long-sought antiobesity hormone, leptin treatment in patients with common obesity has not been effective, although it may be useful in conditions such as lipodystrophy [45–50]. Some reports had suggested that a decrease in leptin levels may be responsible for the decrease in RMR observed with weight loss [51–53], but others have found that fasting leptin levels are not independently associated with the decrease in RMR [54,55]. However, recent data support a strong role for leptin signaling in energy expenditure and satiation in the weight-reduced state [56].

g Ethnicity and Genetics

Ethnic origin and genetic inheritance have been shown to affect RMR. Numerous studies have reported that RMR is lower in African-American adults and children compared to non-Hispanic whites even after appropriately adjusting for differences in body composition [39,57–64]. At least some of this difference may be due to the mass of highly metabolically active organs in the trunk region, which is often estimated as the FFM in the trunk region, which have been shown to be associated with the lower RMR in African-American women [57,65,66]. However, in at least one study, the racial difference in RMR was not explained by the FFM in the trunk [67]. However, in this study, the investigators found that European ancestry in African-Americans was strongly associated with a higher RMR, suggesting that population differences in RMR may be due to genetic variation. Another potential explanation for the lower RMR in African-Americans may come from observations of mitochondrial DNA haplogroups. Common African mitochondrial DNA haplogroups have been shown to be associated with lower RMR [68].

A lower RMR has also been reported in Polynesian women compared with Caucasian women after adjusting for FFM and fat mass [69]. No significant differences have been observed in RMR in other ethnic groups investigated. For example, in Pima Indians, a group believed to have a form of genetic obesity, neither RMR nor sleeping metabolic rate have been found to differ from that of non-Hispanic whites after adjustment for body composition [15,70]. Mohawk Indian children were reported to have higher values of TEE than those of non-Hispanic white children, but the difference was due to higher levels of EEPA [71].

Genetic inheritance that determines body composition has a major effect on RMR, accounting for 25–50% of interindividual variability [72]. There also appears to be genetic influence beyond body composition because a significant intrafamily influence on RMR independent of FFM, age, and gender has been reported [17]. Understanding the genetic determinants of human obesity is particularly challenging because common forms of human obesity are largely polygenic. A recent genome-wide association study and meta-analysis of BMI in up to 339,224 individuals revealed 97 BMI-associated loci, 56 of which were novel [73]. The 97 loci account for 2.7% of BMI variation and genome-wide estimates suggested that common variation accounts for >20% of BMI variation. For example, a variant of kinase suppressor of Ras 2, originally identified in a large-scale screen for obese phenotypes in mice, and recently identified as a human adiposity gene, is associated with an RMR that is ~180 kcal/day lower than in those without the variant [74].

Because currently identified genetic variants do not fully explain the heritability of obesity, other forms of variation, such as epigenetic marks, have been considered [75]. Epigenetic marks, which affect gene expression without changing the DNA sequence, have been shown to cause extreme forms of obesity such as Prader–Willi syndrome, but the epigenetic contribution to common forms of obesity is unknown.

h Environmental Influences

The effects of environmental temperature on RMR are conflicting. Well-controlled studies of the acute effect of heat and cold demonstrate significant elevations in metabolic rate [76–79]. However, results from longitudinal studies of the effect of season (temperature) are conflicting, with findings of no effect, a small effect, or as much as 14% increase in metabolic rate [80–82]. High altitude has also been shown to result in increased RMR [83].

i Weight Loss and Weight Gain

A potential barrier to sustaining weight loss is that as individuals lose weight, metabolic adaptation, or a reduction in energy expenditure is observed beyond that expected due to loss of FFM and fat mass [63,84–86]. One question that had been raised is whether this reduction in RMR could be blunted by the addition of physical activity. However, added physical activity has not been effective in blunting the decrease in RMR [55,87]. For example, RMR decreased by 356 kcal/day after 15 kg weight loss in response to 6 weeks of intensive intervention, including supervised physical activity in severely obese individuals [55]. Weight loss of 58 kg at 30 weeks resulted in a decrease in RMR of 851 kcal/day.

Another question about weight-loss-induced metabolic adaptation is whether it persists over time. However, long-term studies have shown that the reduced RMR persists. The reduction in RMR in individuals who lost at least a 10% body weight was shown to persist for >1 year [88]. A longer-term follow-up in the participants who lost 58 kg described above also showed that the lower RMR persists [89]. After 6 years, even though participants regained 41 kg of the initial weight loss, RMR was 704 kcal/day lower than at baseline. The fact that in response a 41 kg gain in body weight gain, there was no increase in RMR (1903 kcal/day vs 1996 kcal/day after 58 kg weight loss) was surprising. The observation of sustained metabolic adaptation even after weight regain is consistent with findings from the classic Minnesota semi-starvation experiment which demonstrated lower RMR during a period of weight regain with controlled feeding [90].

While there are numerous studies examining the decrease in RMR associated with weight loss, there are few reports of the increase in RMR with weight gain. Cross-sectional studies comparing individuals of increasing body weight, such as that presented in Fig. 4.2, indirectly support increased RMR with weight gain. In a study examining the effect of weight gain on energy expenditure, although weight gain was associated with a significantly higher TEE, the increase in RMR of 147 kcal/day in 13 nonobese and 134 kcal/day in 11 obese individuals, was not significant [85]. However, several short-term overfeeding studies have demonstrated an increase in RMR in response to weight gain. For example, a body weight gain of 6 kg induced by 42 days of overfeeding in lean young men was associated with a 12% increase in metabolic rate at rest [91]. Another 42-day overfeeding study in lean and obese men resulting in a weight gain of 7.6 kg was associated with a 12% increase in RMR [92]. In response to 100 days of overfeeding resulting in 8.1 kg of body weight gain, RMR increased by 9.7% [93]. Not taking into account the increase in RMR that occurs in response to weight gain has led to large underestimates of the energy imbalance gap, or the average daily imbalance between total energy intake and total energy expenditure responsible for long-term weight gain [94]. The actual energy flux gap, which is observed with higher energy intake and energy expenditure (e.g., see Fig. 4.2) associated with the higher weight is relatively large [94].

2 Adjustment of REE for Differences in Body Size

In order to properly compare energy expenditure between individuals varying in body size or composition, it is imperative that an appropriate strategy be employed to adjust energy expenditure for these differences. Surface area was used as an early normalizing factor because heat is lost through the skin, so it was assumed that metabolic rate would be proportional to the amount of skin [95,96]. Fat-free mass (FFM) is the normalizing factor used most often today, which is used as a proxy for the metabolically active tissues in the body. The use of these two factors to normalize RMR provides similar results, although higher correlations are generally observed with FFM [97].

In the past, when examining whether there were differences in RMR between groups differing in body weight and composition, some investigators adjusted RMR by dividing by FFM. However, although there is a very strong relationship between RMR and FFM, this relationship has a nonzero intercept, making this practice invalid [98,99]. As an example, in Fig. 4.4, RMR is plotted against FFM for 131 lean and obese African-American and Caucasian children [100]. It is fairly clear that even the most obese individuals, those with

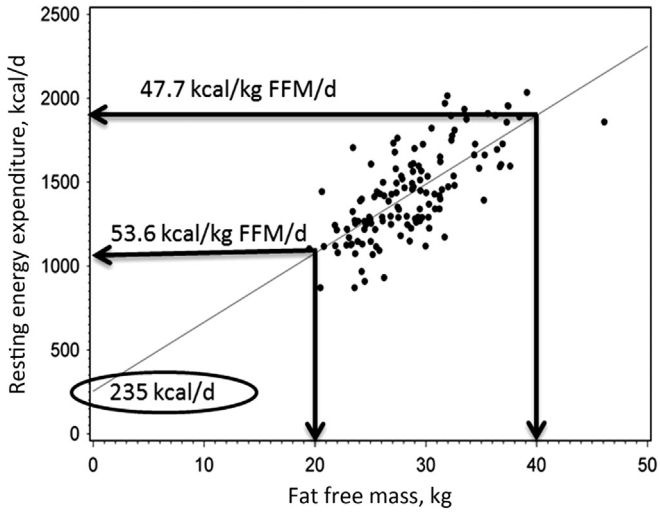

FIGURE 4.4 REE versus FFM.

FIGURE 4.5 Indirect calorimetry system for measurement of RMR.

FFM > 30 kg, fall on the regression line for all subjects (RMR (kcal/day) = 41.8 · FFM (kg) + 235; $r = 0.72$). It is also clear that the *y*-intercept is not equal to zero. When comparing a lean individual with 20 kg of FFM with an obese individual with 40 kg FFM, absolute RMR is of course higher in the obese individual (1907 kcal/day) than in the lean individual (1071 kcal/day). However, if one were to divide RMR by FFM to compare these two individuals, it would incorrectly appear that "adjusted" RMR is 11% lower in the obese individual (53.6 vs 47.7 kcal/kg FFM in the lean and obese individual), when in reality these two individuals fall on the same regression line and hence have normal RMR based on body size. In fact, the obese children in this study had a higher RMR when adjusted for FFM but similar RMR when adjusted for FFM and fat mass. Appropriate strategies to adjust for differences in body size are to include FFM as a covariate [20] or to utilize regression methods to adjust for FFM [98]. Other factors that have been included to improve energy expenditure prediction equations include age, race, fat mass, and sex [20,98,101].

3 Measuring REE: Indirect Calorimetry

Metabolic rate has been measured using direct calorimeters [102–104] and closed-circuit indirect calorimetry systems [105], but it is now generally measured with an open-flow indirect calorimetry system (Fig. 4.5). Room air is drawn through a clear plastic hood covering the individual's face, and the flow and concentration of oxygen and carbon dioxide in the intake and expired air are accurately measured for calculation of RMR [106]. This technique is known as indirect calorimetry because it does not directly measure heat but, rather, measures O_2 consumption and CO_2 production, which are then used to calculate energy expenditure. The pretesting environment impacts the measurement of RMR. Food, ethanol, caffeine, nicotine, physical activity, and room temperature impact RMR and should be controlled before measurements are taken [107]. A number of commercial indirect calorimetry systems are available, with some being more reliable than others [108]. Smaller, portable indirect calorimeters are also available, allowing investigators more mobility for field measurement of metabolic rate [109–111].

4 Estimating REE: Prediction Equations

Although numerous equations have been developed to estimate REE, the two most widely used equations are the Harris–Benedict equations [7] and those developed by the Institute of Medicine/Food and Nutrition Board to determine dietary reference intakes (DRIs).

a Harris–Benedict Equations

The Harris–Benedict equations remain the most commonly used tool by clinicians when estimating an individual's REE. The equations are often used as a basis for prescribing energy intake for hospitalized patients and to formulate energy intake goals for weight loss. A review of the data used in the formulation of the Harris–Benedict equations in the early 1930s deduced that the methods and conclusions of Harris and Benedict appear valid but not error-free [112]. The equations in use today are given in Table 4.1. Investigators have evaluated which equation performs best or developed new equations for specific populations [113–117]. The reader is encouraged to follow this literature as it applies to populations differing in body size, health status, race, sex, and age.

TABLE 4.1 Examples of Equations for Predicting Resting and BEE[a]

Harris–Benedict Equations	
Women	REE (kcal/day) = 655 + 9.56 (weight) + 1.85 (height) −4.68 (age)
	$r^2 = 0.53$, $F = 37.8$, $p < 0.001$
Men	REE (kcal/day) = 66.5 + 13.75 (weight) + 5.0 (height) −6.76 (age)
	$r^2 = 0.75$, $F = 135.2$, $p < 0.001$
DRI Equations	
Women	BEE (kcal/day) = 247 − (2.67 × age) + 401.5 × height + 8.6 × weight
	Residual = ± 156, $R^2 = 0.62$
Men	BEE (kcal/day) = 293 − (3.8 × age) + 456.4 × height + 10.2 × weight
	Residual = ± 156, $R^2 = 0.64$

[a]*Weight is in kilograms, height is in centimeters, and age is in years.*
DRI Equations for BEE: Institute of Medicine of the National Academies, Dietary Reference Intakes: Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids, The National Academy Press, Washington, DC, 2005.

b DRI Equations

The BEE prediction equations developed for the DRIs for lean, overweight, and obese men and women are given in Table 4.1. These equations were derived from observed BEE values found in the doubly labeled water (DLW) database [118]. This database was developed by searching published research that involved use of the DLW method. The investigators associated with the identified publications were solicited to contribute to the database. Twenty investigators responded and submitted individual TEE data and ancillary data including age, gender, height, weight, BEE (both observed and estimated), and descriptors for each individual in the data set. These data were not obtained from randomly selected individuals and thus are not a representative sample of the US population. However, because the measurements were obtained from men, women, and children, over a wide range of weights, heights, and ages, it is believed that the data still offer the best currently available information [118].

c Predicting REE in Disease and Physiological Conditions

REE has been characterized for a variety of disease states and physiological conditions, including burns [119–121], anorexia nervosa [122,123], severe central nervous system impairment [124], cerebral palsy [125], pregnancy [126], and lactation [127]. In addition, REE has been studied in both children [114] and the elderly [128–130]. Clinicians should not assume that prediction equations, which were developed in normal, healthy people, are valid in special populations [131].

d Thermic Effect of Food

TEF, sometimes referred to as diet-induced thermogenesis, represents a small (~10%) portion of TDEE (Fig. 4.1). TEF is the increase in energy expenditure that occurs after consumption of a meal. There are several protocols for measurement of TEF, but the general procedure utilizes a metabolic cart to measure metabolic rate for 3–6 hours after administration of a meal of ~35% of RMR, which is then compared to RMR measured either on the same day as the TEF or on a different day [64,100,132–135]. TEF is generally not measured in clinical settings but, rather, estimated as 10% of TEE. A major factor affecting the magnitude of the TEF is the macronutrient composition of the meal. When comparing isoenergetic protein, carbohydrate, or fat meals in lean and obese individuals, the TEF has been shown to be greater and more prolonged after a protein meal [136]. The TEF has also been shown to be higher after consuming mixed meals high in protein [137,138]. In a short-term (4 day) controlled metabolic chamber study of energy and substrate metabolism during consumption of a high protein diet (2.6 g/kg body weight) to maintain weight showed that sleeping metabolic rate, TEF, protein balance, and fat oxidation were increased, compared to an adequate (1 g/kg body weight) protein diet [139]. There is evidence that TEF is lower in children than in adults [64,100,140,141].

Whether TEF is lower in obesity is inconclusive. In one review of published TEF data, the authors concluded that TEF was lower in obesity, when appropriately accounting for known variables affecting TEF results, and that the lower TEF was associated with the degree of insulin resistance [142]. In a subsequent review of available literature by different investigators, the authors concluded that discrepant results and inconsistencies in methodology preclude a proper evaluation of the theory that TEF is lower in obesity [134].

e Energy Expended in Physical Activity

EEPA is the most variable component of total energy expenditure, varying between 100 and 800 kcal/day even in the confines of a metabolic chamber [143]. EEPA includes energy expended in voluntary exercise, which includes activities of daily living (e.g., bathing, feeding, and grooming), sports and leisure, and occupational activities. EEPA also includes the energy expended in nonexercise activity thermogenesis, which is associated with fidgeting, maintenance

of posture, and other physical activities of daily life [144]. Because of the alarmingly high rates of obesity in the United States, increasing EEPA through voluntary physical activity is being stressed as a potential method of achieving or maintaining a healthy weight [145].

5 Determinants of EEPA

Differences in EEPA are due both to patterns of activity and to body size and composition. The energy cost of activities in obese individuals is higher than in lean individuals due to higher body weight [146–148]. The energy expenditure (above resting) of several activities has been shown to be proportional to body weight [149]. For example, the gross energy cost of walking at the preferred walking speed has been shown to be similar in lean and obese men and women on a per kg basis (between 2.81 and 3.04 J/kg/m) [148]. The preferred walking speed was similar in obese and normal-weight individuals (1.41 m/s vs 1.47 m/s). Therefore, comparing the energy cost of walking for 1 hour at 1.4 m/s in a typical lean (63 kg) and Class III (124 kg) individual, using a gross energy cost of 3 J/kg/m, reveals that the energy cost of walking is nearly twice as high in the Class III obese individual (448 kcal vs 228 kcal). However, the EEPA recently observed in Class III obese individuals was only 20–25% higher than in lean individuals (Fig. 4.2) [20]. This is much lower than would be expected in light of the increased body weight ($\sim$100% higher in Class III compared to lean) if the obese were as active as the lean, suggesting that the obese individuals spent less time engaged in physical activity. Confirming that the obese individuals were less active, the total time spent in moderate-to-vigorous physical activity (1.2 ± 0.9 vs 2.5 ± 1.2 hours/day), and average daily metabolic equivalent (MET) level (1.1 ± 0.2 vs 1.6 ± 0.3 MET) were lower in the Class III obese compared to lean individuals [20].

When comparing the volume (intensity $\times$ time) of physical activity between individuals, a physical activity index has been calculated by dividing EEPA by body weight [149,150]. This approach has been utilized to compare EEPA in individuals with Prader–Willi syndrome [151] and when comparing EEPA in a wide variety of individuals across multiple studies [152].

Physical activity can also affect RMR in the postexercise period by 5% or more, up to 24 hours after exercise [153]. A decrease in the level of physical activity has been observed during the transition from childhood to adolescence [64,154]. A decrease in EEPA has also been observed in aging [130,155]. Cross-sectional and longitudinal studies have shown increases in body fat and decreases in muscle mass in older adults, often in the absence of differences or changes in body weight [156]. These changes in body composition are often associated with changes in physical function and metabolic risk. Fortunately, moderate-intensity PA intervention has been shown to improve physical function in older adults, and free-living activity energy expenditure has been shown to be strongly associated with lower risk of mortality in healthy older adults [157,158]. Table 4.2 provides average energy costs of typical activities, with the values expressed as multiples of RMR.

TABLE 4.2 Examples of Activity Energy Costs

Activity	Energy Cost (Multiple of Basal Metabolism)
Lying quietly	1.0
Riding in a vehicle	1.0
Light activity while sitting	1.5
Walking (2 mph)	2.5
Watering plants	2.5
Walking the dog	3.0
Cycling leisurely and household tasks (moderate effort)	3.5
Raking the lawn	4.0
Golfing (no cart) and gardening (no lifting)	4.4
Walking (4 mph)	4.5
Dancing, ballroom (fast), or square	5.5
Dancing, aerobic, or ballet	6.0
Walking (5 mph)	8.0
Jogging (10-min miles)	10.2
Skipping rope	12.0

6 Measuring EEPA

Obtaining a valid and appropriate measurement of EEPA is a challenging task. Measures are classified into three general categories: objective assessment tools, including the DLW technique combined with RMR, activity monitors, and heart rate monitoring; direct observation; and subjective reports, such as physical activity questionnaires. The objective activity assessment tools are often used to validate the subjective activity measures.

a Objective Measures of EEPA

Doubly Labeled Water EEPA can be assessed by measuring TEE by DLW and subtracting measured RMR and either measured or estimated (10% of TEE) TEF [20,64,87]. DLW has been used as a gold standard for validating other methods to measure EEPA in free-living individuals. DLW measurement of TEE is discussed in detail in Section III.

Activity Monitors A variety of devices (e.g., accelerometers and heart rate monitors) can provide minute-by-minute information regarding physical activity patterns. However, these devices have limitations that affect their validity for assessing EEPA [159–163]. Accelerometers are movement counters that can measure body movement and often intensity. Accelerometers cannot be used to measure the static component in exercises such as weight lifting or carrying loads. However, in normal daily life, it is assumed that the effect of static exercise on the total level of physical activity is negligible [164]. Since 1999, there has been a push to improve accelerometers because it was concluded that those available were not practical for large-scale studies due to high cost, uncertain reliability, and difficulties in interpreting data [165]. NHANES 2003–04 began using accelerometers on survey participants ages 6 years or older who agreed to wear them, representing the largest implementation of objective physical activity monitoring [165].

Whereas accelerometry has been shown to be accurate for estimating energy expenditure during level walking, it consistently underestimates energy expenditure during other forms of activity [159,166,167]. In addition, although many devices/algorithms have been shown to perform well in a laboratory setting, they perform less well under free-living conditions. New regression models have been proposed to improve estimated energy expenditure using accelerometry [168,169]. In addition, new, multisensor devices have been developed that show promise, but they require further refinement and validation [170–175]. Newer consumer versions of activity monitors are now available and have been compared against with research-grade devices, indirect calorimetry, and DLW [176–178].

Heart Rate Monitoring The use of heart rate monitoring as a proxy measure for EEPA is based on the principle that heart rate and oxygen consumption tend to be linearly related throughout a large portion of the aerobic work range. Heart rate monitors are often used to assess EEPA because the technique is relatively inexpensive and easy to use. One drawback is that the relationship between heart rate and oxygen consumption must be characterized for each subject for several exercise intensities [179]. Even when conducting individual calibration relationships and using complex modeling, heart rate monitoring can provide inaccurate estimates of energy expenditure compared to DLW and indirect calorimetry [161,180,181]. Investigators have combined heart rate monitoring and accelerometry to provide more accurate measures of EEPA [174,175].

Metabolic Chambers Metabolic chambers generally have radar sensors for detecting physical activity. The measured EEPA assessed in a metabolic chamber has been shown to be quite variable, varying between 100 and 800 kcal/day [143]. The physical activity assessed in a metabolic chamber is considerably lower than free-living physical activity, and is limited to activities of daily living due to the small confines of the chamber. However, the EEPA measured in a metabolic chamber has been shown to be correlated with EEPA measured under free-living conditions [182]. Fifty nondiabetic Pima Indians were studied during a 24-hour stay in a metabolic chamber followed by 7 days of free-living conditions during which TEE was assessed by DLW and EEPA calculated by subtracting TEF and sleeping metabolic rate from TEE. As expected, EEPA in the chamber was significantly lower (440 ± 160 kcal/day) compared to EEPA assessed under free-living conditions (930 ± 310 kcal/day). However, there was a significant correlation between the two measures ($r = 0.53$, $p < 0.0.01$) in men and women.

b Physical Activity Questionnaires

Physical activity questionnaires have been used in many studies because they are easy to administer to large numbers of people and do not intrude on people's everyday activities. Although questionnaires do not provide precise estimates of EEPA, they may be helpful in ranking groups of subjects from the least to the most active. The ranking can then be used to correlate activity levels with disease outcomes [144]. An accurate questionnaire is both reliable and valid. A reliable questionnaire consistently provides similar results in the same circumstances, whereas a valid questionnaire truly measures what it was designed to measure. The validity of a physical activity questionnaire should be determined by comparing it with an objective measure of EEPA such as the DLW method. Starling et al. [183] found that the Yale Physical Activity Survey estimates of EEPA compared favorably with DLW on a group basis. However, its use as a proxy measure for individual EEPA is limited. In the same study, the Minnesota Leisure Time Physical Activity Questionnaire significantly underestimated EEPA in free-living older men and women [183]. This highlights the importance of ascertaining the validity of a questionnaire before applying it in large epidemiological studies.

III TOTAL ENERGY EXPENDITURE

Measured TEE provides an estimate of energy requirements when individuals are in energy balance. If significant weight gain or loss occurs during a metabolic study, changes in body energy stores must be accounted for to assess energy intake [3].

A Measuring Total Energy Expenditure

1 Indirect Calorimetry

Metabolic chambers, also known as respiratory chambers, are utilized to study energy expenditure over periods of time from 24 hours to several days. The concepts of metabolic chambers are similar to that of metabolic carts, requiring measurement of CO_2 and O_2 concentrations and the flow rate through the chamber to calculate oxygen consumption, carbon dioxide production, respiratory quotient (RQ), and metabolic rate [2,143,184–186]. Metabolic chambers provide accurate measures of 24-hour and sleeping energy expenditure, as well as long-term substrate utilization. However, due to the confined environment of the chamber, they do not provide an estimate of free-living energy expenditure.

2 Doubly Labeled Water

The introduction of the DLW technique for use in humans in 1982 by Schoeller and van Santen [187] provided a scientific breakthrough in the measurement of TEE in free-living humans. The method was originally described by Lifson et al. in the 1950s for use in rodents [188,189]. The method is based on the principle that a dose of $^2H_2{}^{18}O$ mixes with total body water, and the oxygen atoms in body water are also in equilibrium with exhaled CO_2 [190]. The isotopes undergo differential elimination from the body, with ^{18}O eliminated as carbon dioxide and water and deuterium eliminated only as water. The difference between the elimination rates of oxygen and hydrogen from body water are used to calculate CO_2 flux and, hence, energy expenditure. The DLW method has been extensively validated by a number of investigators throughout the world and shown to be accurate and precise [191]. For example, very good agreement was observed between 24-hour energy expenditure using DLW (1934 ± 377 kcal/day) and metabolic chambers (1906 ± 327 kcal/day) during caloric restriction [2].

a DLW Details

The application of the DLW method can be quite flexible depending on the individuals studied, the questions being asked, and balancing of the ideal protocol with costs and subject burden. Baseline urine samples are collected followed by oral administration of the $^2H_2{}^{18}O$ dose. Initial urine samples are obtained 4–6 hours following dose administration and again at the end of the study period for measurement of final isotopic enrichment. The length of a DLW study depends on the turnover of the two isotopes, which is driven primarily by water turnover. The optimal period for studies in normal adults is 7–14 days. If measurement of energy expenditure over a longer period of time is necessary, individuals can be re-dosed with DLW [192].

The ^{18}O and deuterium isotope abundances are measured after appropriate sample preparation using a gas-inlet isotope ratio mass spectrometer (IRMS) [192]. Advancements in automated devices to prepare and introduce samples into the mass spectrometer have greatly improved the precision and throughput of the isotope analyses. For example, Fig. 4.6 shows an H-Device system for injection of purified urine sample into a chromium reactor heated to 850°C for conversion to hydrogen gas before being introduced into the IRMS (just below the H-Device) for measurement of deuterium enrichment. A GasBench system (Fig. 4.6, right) is used to equilibrate a cleaned urine sample with carbon dioxide gas before being introduced into a gas chromatograph to purify the CO_2 and then introduced into the IRMS for measurement of ^{18}O enrichment. The CO_2 production rate is estimated using the measured isotope dilution spaces and elimination rates [191,193]. Energy expenditure is calculated utilizing the energy equivalent of CO_2 for a typical RQ such as 0.86 or using a calculated RQ from the macronutrient content of the diet consumed and body energy stores used during the DLW measurement period [192].

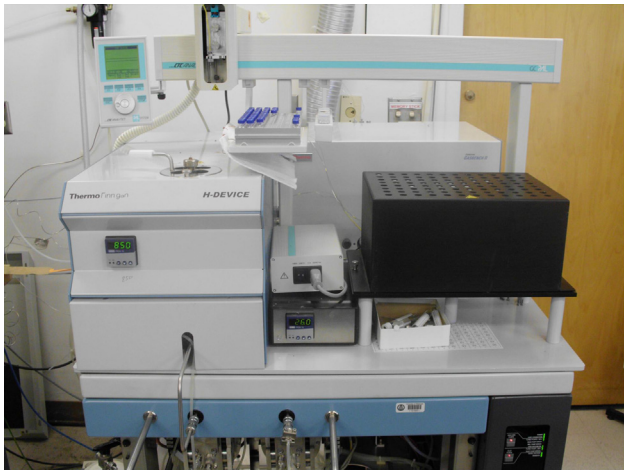

FIGURE 4.6 Mass spectrometry system used for the analysis of isotope enrichments for the DLW method.

TABLE 4.3 Advantages and Disadvantages of the DLW Technique to Measure Total Energy Expenditure

Advantages	Disadvantages
Noninvasive, unobtrusive, and easily administered	Availability and expense of oxygen-18 (varies between $300 and $1000 for 70-kg adult)
No reliance on participant to do anything except drink the labeled water and provide timed urine samples	Need for isotope ratio mass spectrometry for analysis of samples
Measurement performed under free-living conditions over extended time period (7–14 days)	A direct measure of CO_2 production, so need an estimate of RQ
Accurate and precise (2–8%)	Expensive for large-scale epidemiological studies
Can be used to estimate EEPA when combined with measurement of RMR	Does not provide information regarding time spent in activity or intensity of activities
Longitudinal measures of DLW and body composition can be used to objectively assess energy intake	

TABLE 4.4 Doubly Labeled Water Data for Individuals With a Body Mass Index (BMI) in the Range From 18.5 to 25 kg/m^2

Age Group (years)	*n*	Mean BMI (kg/m^2)	TEE (kcal/day)	BEE Mean (kcal/day)	Mean Physical Activity Level (TEE/BEE)
Females					
3–8	227	15.6	1487	1035	1.57
9–13	89	17.4	1907	1320	1.68
14–18	42	20.4	2302	1729	1.73
19–30	82	21.4	2436	1769	1.70
31–50	61	21.6	2404	1675	1.68
51–70	71	22.2	2066	1524	1.69
71 +	24	21.8	1564	1480	1.62
Males					
3–8	129	15.4	1441	1004	1.64
9–13	28	17.2	2079	1186	1.74
14–18	10	20.4	3116	1361	1.75
19–30	48	22.0	3081	1361	1.85
31–50	59	22.6	3021	1322	1.77
51–70	24	23.0	2469	1226	1.64
70 +	38	22.8	2238	1183	1.61

b Advantages and Disadvantages of the DLW Technique

Advantages of the DLW method (Table 4.3) are that it is a true field technique for accurate and precise (2–8%) assessment of free-living energy expenditure that requires no subject compliance, can be used to validate other techniques, and when combined with other methods can provide measures of EEPA, as described earlier. The DLW method also provides an objective criterion method for validation of more subjective estimates of energy expenditure and energy intake.

Disadvantages of the DLW method include the cost and availability of the ^{18}O-labeled water, need for expensive IRMSs and sample preparation systems, and technical difficulties with accurate measurements of isotope enrichments [194]. Another disadvantage of the DLW method is that it provides no information regarding time spent in physical activity, activity patterns, or intensity. Therefore, when conducting a DLW study, it is extremely advantageous to include other methodologies, including RMR so that EEPA can be assessed, as well as activity monitors so that activity intensity and patterns can also be assessed.

c Estimating Total Energy Expenditure

The introduction of the DLW technique in humans has produced a large and robust database of TEE measurements in a variety of populations. A meta-analysis of 574 DLW measurements helped to establish the average and range of habitual energy expenditures in different age and sex groups [155]. Since this study, many DLW studies have been completed. The Food and Nutrition Board used data from these DLW studies to compile a worldwide TEE database [118]. Table 4.4 is a summary of data from this database. The database provides a frame of reference for energy needs in the general population and can be used to evaluate other estimates of energy expenditure. Special circumstances such as illness or enforced exertion were excluded from this database.

Because of the high cost and small numbers of laboratories with the capacity to do DLW studies, clinicians continue to rely heavily on prediction equations to estimate energy requirements. The TEE database compiled for the DRIs was used to derive equations for predicting

TABLE 4.5 Equations to Predict Energy Requirements in Females and Males 19 Years and Older

For Females
EER = 354.1 − 6.91 × age + PA × (9.36 × weight + 726 × height), where PA is the physical activity coefficient:[a]
PA = 1.00 if PAL is estimated to be ≥1.0 < 1.4 (sedentary)
PA = 1.12 if PAL is estimated to be ≥1.4 < 1.6 (low active)
PA = 1.27 if PAL is estimated to be ≥1.6 < 1.9 (active)
PA = 1.45 if PAL is estimated to be ≥1.9 < 2.5 (very active)
For Males
EER = 661.8 − 9.53 × age + PA × (15.91 × weight + 539.6 × height), where PA is the physical activity coefficient:
PA = 1.00 if PAL is estimated to be ≥1.0 < 1.4 (sedentary)
PA = 1.12 if PAL is estimated to be ≥1.4 < 1.6 (low active)
PA = 1.27 if PAL is estimated to be ≥1.6 < 1.9 (active)
PA = 1.45 if PAL is estimated to be ≥1.9 < 2.5 (very active)

[a]*Weight is in kilograms, height is in centimeters, and age is in years.*

energy expenditure requirements. These equations are provided in Table 4.5.

d Total Energy Expenditure in Special Populations

During approximately the past 20 years, there has been a proliferation of studies using DLW to examine TEE in various disease states, physiological conditions, and across the life cycle. Hence, data are now available on energy expenditure during infancy [195], childhood [64,196], adolescence [197], and in the elderly [130]. TEE during pregnancy and lactation has been well characterized in some elegant longitudinal studies [198]. In addition, TEE has been examined in adults and children with obesity [94,199,200]; infants and children with cystic fibrosis [201,202]; children treated for acute lymphoblastic leukemia (ALL) [203] with burns [204] and Down syndrome [205], and adults with cerebral palsy [206], neuromuscular disease [207] Alzheimer's disease [208], and HIV/AIDs [209]. The effects of these various conditions on energy requirements are highlighted in Table 4.6.

TABLE 4.6 Effects of Disease States and Physiological Conditions on Energy Requirements: Results from DLW Studies

Disease or Condition	Effect on Energy Requirements	Explanation
Aging	Decreased	Decreased RMR, decreased EEPA in nonagenarians
Alzheimer's disease	No change	Energy expenditure not elevated, low-energy intake predisposes to weight loss
Anorexia	Increased	To counteract increased physical activity with underweight and hypometabolism
Burns	No change	Increased RMR counteracted by decreased physical activity
Cerebral palsy	Relative to individual	High interindividual variation in EEPA; ambulation status an important predictor
Children treated for ALL	Decreased	Reduced physical activity
Cystic fibrosis	Increased	Mechanism unknown
HIV/AIDS	No change	Energy expenditure not elevated, reduced energy intake causes weight loss
Lactation	Increased	Energy cost of milk production partially offset by reduced physical activity
Neuromuscular disease	Decreased	No difference in RMR, but TEE decreased
Obesity	Increased	Increased FFM and fat mass, but decreased time spent in physical activity
Pregnancy	Relative to individual	No prediction of metabolic response
Spinal cord	Decreased	Lower EEPA, RMR, and TEF

e Use of DLW to Estimate Energy Intake

Although knowledge of energy intake is essential for understanding energy balance, true dietary intake is consistently underreported, leading some to question whether investigators should discontinue the use of self-reported intake methods [210,211]. For example, the Observing Protein and Energy Nutrition Study in

484 men and women compared a food frequency questionnaire (FFQ) and a 24-hour recall (24HR) with DLW [1]. On average, men underreported energy intake by 12−14% using 24HR and 31−36% using FFQ. Women underreported energy intake by 16−20% using 24HR and by 34−38% using FFQ. Similar levels of underreporting (17−33%) have been observed in children when comparing 8-day food records with DLW, and greater underreporting has been observed in obese compared to lean children [212]. Even those defending self-reported intake, pointing out important information that has been gained using these instruments acknowledge that self-reported energy intake should not be used as a measure of true energy intake [213].

Objective measures of energy intake can be obtained by the intake-balance method, by measuring energy expenditure and changes in energy body stores. While estimation of TEE by DLW during over a 2-week period is accurate and precise, measurement of changes in body energy stores is considerably less accurate due to the relative error in measurements of fat mass and FFM [2]. However, if longer-term studies are conducted, with TEE and body composition measures conducted at baseline and 6 months later, the errors associated with body composition measures are negligible. This technique has been used during a multicenter 6-month study of caloric restriction [3], in a study to examine the effects of physical activity on energy expenditure and energy intake during behavioral weight loss intervention [87], in a study to explore reasons for the lower weight loss observed in African-American women during intervention [214] and during overfeeding [215].

IV RECOMMENDED ENERGY INTAKES

Classically, the Recommended Dietary Allowances (RDAs) have been used as a guide to determine energy intakes for groups of normal, healthy people. The last RDA for energy, which was labeled the recommended energy intake (REI), was set in 1989. RDAs for all nutrients except energy are set at levels well above those estimated to minimize the occurrence of deficiency syndromes. For energy, this obviously is not the case because there are adverse effects to individuals who consume energy above their requirements over time resulting in weight gain. Recommendations for energy have always been set as an average of energy requirements for a population group. In the past, REIs relied heavily on data from dietary surveys that estimate energy intake. This is based on the assumption that people are in energy balance at the time of measurement and that the estimates of energy intake are valid. A large body of evidence now demonstrates that self-reported estimates of food intake do not provide accurate or unbiased estimates of people's energy intake and that underreporting of food intake is pervasive in children, teens, and adults [212,216,217].

The DRIs [118] adopted an alternative approach and instead summarized data from multiple DLW studies to estimate energy requirements. There is no RDA for energy because it would be inappropriate to recommend levels that would exceed requirements of 97% or 98% of individuals. Instead, the requirement for energy for individuals of normal weight is expressed as an estimated energy requirement (EER), which reflects the energy expenditure based on the individual's sex, age, height, weight, and physical activity (see Table 4.5 for equations). For overweight individuals, these equations estimate TEE rather than the EER, which is reserved for normal-weight individuals. The equations are estimates of energy needs based on maintaining current weight and activity level and therefore were not designed to lead to weight loss in overweight individuals [118].

As the prevalence of obesity has reached epidemic proportions in the United States, people's EEPA has become so low that it may become increasingly difficult to meet the micronutrient needs on the energy intakes required to keep people in energy balance. Hence, it will become increasingly imperative that emphasis be placed on increased EEPA for the maintenance of optimal health.

I INTRODUCTION

The field of metabolomics focuses on the study of the multiple of small molecules present in biological samples such as biofluids, cells, and tissues, as well as plants, foods, etc. It offers new avenues for understanding biological phenotypes, deciphering mechanisms, and identifying biomarkers or drug targets for a variety of conditions [1,2] (Fig. 5.1). Metabolites represent the downstream products of gene expression and protein action, and thus provide an instantaneous snapshot of biological phenotype. Changes in metabolite levels as well as their transformation rates (fluxes) in biological systems result from a variety of stresses including disease (pathophysiological stimuli) [3,4]. Metabolomics also offers a window into the downstream biochemical changes that result from a combination of environmental exposures and genetics [3,4]. In addition to studies and developments in related "omics" fields such as genomics and proteomics, further information on the molecular products' biological stresses or perturbations is highly desired for disease detection, diagnosis, prognosis, and development of preventive screening methods. Over the last several decades, the field of metabolomics has developed as a result of significant technological advances for measuring and interpreting metabolic changes. As a result, applications in a growing number of areas have been reported, including, but not limited to, toxicology, pharmacology, early disease diagnosis, drug target identification and development, environmental studies, as well as the study of food and nutrition [2,3,5]. The perturbed metabolites can be localized to specific pathways that may be related to protein or gene (dis)function as well as to various disease states. Thus, metabolomics can reveal significant information that is closely related to existent diseases or health disorders, or even to therapeutic status. All of these aspects and opportunities have made the metabolomics field a vibrant area of research.

The wide range of applications resulting from metabolomics-based research arises from the ability to detect up to many hundreds of metabolites and their concentration and flux changes in a variety of biological specimens. More than 30,000 endogenous human body metabolites have been identified thus far, with a majority belonging to various lipid classes [6]. Plants are known to have secondary metabolites that increase this number to over 200,000; however, many of these exist at very low concentrations. Therefore, advanced analytical methods are required to profile a broad range of metabolites that constitute the "metabolome." By using highly sensitive mass spectrometry (MS) techniques, up to a few thousand metabolites can be routinely detected by global analysis; however, less than one-third of these are identified in practice with a vast majority of the signals remaining unidentified. Other methods, such as nuclear magnetic resonance (NMR), or more targeted MS approaches detect a small fraction of the metabolome as discussed below, leaving reliable detection and identification of the complete metabolome as one of the major challenges in the field of analytical chemistry. Nevertheless, significant technological advances in the last decade have pushed metabolomics methods and applications to new heights.

A Brief History

Although metabolomics is considered a relatively new field, as early as 500 BC Hippocrates was one of the first physicians to interpret the functions of the human body based on urine characteristics; further, some accounts indicate that urine-based diagnosis even predates Hippocrates [7]. As early as 4000 BC, one of the earliest

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00005-9

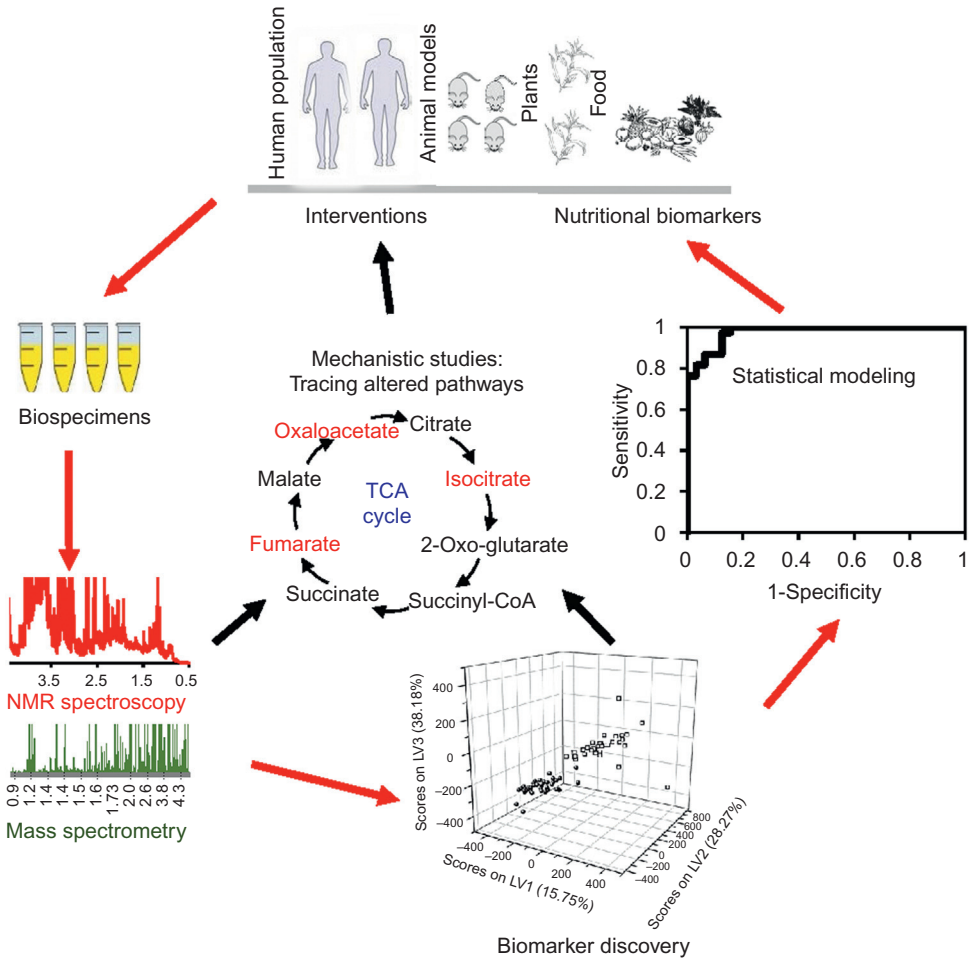

FIGURE 5.1 Schematic diagram depicting the application of NMR and MS-based metabolic profiling for early disease diagnosis, systems biology research, and discovery of dietary and nutritional biomarkers and drug targets.

civilizations is believed to have recognized altered characteristics of urine in different diseases [8]. It is also known in Hindu culture that some people's urine tasted sweet, and that black ants were attracted to this sweet urine, which is now known to be a symptom of the widespread disease "diabetes" [9]. In ancient China, it was known that ants could be used to detect diabetes based on urine samples [10]. In the Middle Ages, "urine charts" that correlated smell, taste, and color of urine were employed to diagnose various medical conditions now known to be of metabolic in origin [11]. Distinctive "metabolic patterns" that could be "finger-printed" by studying biological fluids was proposed in late 1940s [12]. In these investigations, paper chromatography was utilized to demonstrate significant variations of metabolic patterns among different subjects including alcoholics and schizophrenics.

The growth of metabolomics technologies benefited by the detection of inborn errors of metabolism (IEM). Specifically, from 1950s to 1970s the field witnessed explosive growth in the number of IEMs detected [13]. A factor that contributed to modern metabolomics is the metabolic-control analysis developed in the 1960s for modeling metabolism in cells, which used metabolite concentrations derived often using gas chromatography (GC) or GC coupled to MS [11]. Another contributing factor was the development of NMR spectroscopy methods, which in the 1980s were able to identify metabolites in intact biological fluids. The technological advances in GC, liquid chromatography (LC), and MS in the 1960s and 1970s enabled quantitative metabolic profiling studies. In 1971, Horning and coworkers used gas chromatography–mass spectrometry (GC-MS) to measure metabolites in human urine and tissue extracts [14,15]. Horning, along with Pauling and Robinson, led the development of GC-MS-based techniques focused on the measurements of metabolites in biological mixtures through the 1970s to early 1980s [16]. Subsequent developments

of high-resolution and high-sensitivity MS and NMR instrumentation in combination with multivariate statistical analysis set the stage for metabolomics to become one of the fast-growing fields in systems biology.

B Relevance to Nutrition

Metabolomics is widely used to investigate numerous aspects of nutrition using a variety of samples ranging from plants and foods to human and animal tissues and biofluids. Plant metabolomics is increasingly realized as an important tool for investigations of systems biology [17]. Metabolic profiling of plants has been applied to numerous key areas, including growth, development, and stress responses, the discovery of phenotypic differences induced by genetic variations or environmental perturbations, in environmental studies for monitoring the response of wild species to changes such as temperature, human activities, diseases, and pollutants, as well as many other areas [17–20].

The application of metabolomics in food science has also seen significant advances. Owing to its direct relation to nutrition and human health, food metabolomics is witnessing increased interest in the recent years. To date, a variety of foods including fruits, vegetables, beer, and meats have been subjected to metabolomics investigations [21]. One area of food metabolomics evaluates food quality, since metabolite fingerprints provide information on the composition of foods and allow characterization and authentication of foods [22,23]. Numerous studies have focused on understanding the importance of food for health for reducing (or increasing) the risk of diseases. Diet is known to significantly impact human health and hence there is an important need for comprehensive understanding of metabolites present in foods. Such understanding will positively influence food production by enabling efforts to favorably modulate the food metabolome. Thus, numerous metabolomics studies have focused on understanding the impact of agricultural practices, processing, and storage on the metabolite composition of food; studies have also focused on identification of novel bioactive compounds and determination of their regions of origin [21].

II SPECIMENS

A variety of biological samples are investigated by metabolomics due to the significant amount of information that can be extracted, from each type of sample, on metabolic changes and their connections with biological perturbations. Blood (serum or plasma) and urine top the list owing to their high information content combined with the ability to obtain these biofluids with noninvasive or minimally invasive methods. Analyses of tissue and cell samples have also gained strong interest for understanding cellular function and for the identification of potential drug targets. Moreover, fecal samples are being used to investigate the gut microbial community. The analysis of plant and food samples forms a major basis for the development of nutritional metabolomics. Environmental samples as well as many other sample types are also among those widely investigated.

A Blood Serum and Plasma Samples

Among the biological fluids commonly studied in metabolomics, blood serum and plasma are most often used due to the fact that they are rich in metabolites that are capable of providing information on disease, toxicity, and pathophysiological changes. Due to the compositional complexity of blood, which is sensitive to many factors relevant to health and diseases, extensive efforts in sample selection, collection, preparation, and metabolite extraction have been made [24]. As an easily accessible and important biological fluid, blood has been the subject of comprehensive studies over decades and is used for many clinical metabolic determinations [25].

Blood serum and plasma are metabolite-rich biological media but they also contain a large concentration of macromolecules such as proteins and lipids. Macromolecules pose challenges particularly for analysis using MS. Therefore, blood serum/plasma are generally deproteinized by the addition of organic solvents such as methanol or acetonitrile, as a necessary step during sample preparation [26,27]. Blood treatment conditions such as clotting time and temperature, centrifugation speed and time, the type of vials used during sample collection and preparation, and sample storage are important parameters that need to be carefully controlled in order to obtain reliable and reproducible results.

B Urine Samples

Urine contains a wide variety of metabolites, which are generated by a large range of cellular metabolism. It is particularly advantageous to study urine samples due to their ready accessibility owing to the noninvasive collection. While water-soluble metabolites are the primary components of urine, many other components such as inorganic ions and non-polar organic solutes including trace levels of enzymes and fatty acids are present. Variations in urine content can be seen between individuals depending on food intake, urine concentration, and other environmental and physiological factors, which can complicate data analysis. Therefore, a systematic sample collection, storage, and preparation protocol needs to be performed in order to obtain stable and reliable results, although careful normalization procedures (see below)

can counteract the deleterious effect of dilution. Due to the relatively low abundance of high molecular weight compounds in urine, minimal sample preparation is required for high quality measurements, especially for NMR analysis. For NMR experiments, peak position (i.e., chemical shift) variations due to different salt concentrations can be observed, while for MS, high salt concentrations can lead to adduct formation and signal suppression, and can negatively affect the performance of chromatography coupled-MS instruments. The above-mentioned effects can be minimized by sample pretreatment (including desalting) prior to data acquisition analysis [28].

C Cell Samples

Metabolomics studies of cell samples have revealed a number of new mechanistic insights and even drug targets in cancer and other diseases [29,30]. In the area of methods development, advances in sample preparation, treatment, and other protocols allow the discrimination of intracellular and extracellular metabolites and the measurements of metabolic fluxes using isotope tracers [31]. Careful treatment procedures must be followed when dealing with cell samples as several types of cells are known to be highly sensitive to osmotic changes of their surrounding medium, while the effects of different solvents can have a profound effect on metabolite recovery and even stability. NMR and matrix/assisted laser-desorption ionization time-of-flight MS (MALDI-TOF-MS) analyses have been performed on intact cell samples, while extraction methods usually using organic solvents are very popular for liquid chromatography−mass spectrometry (LC-MS), GC-MS, and also NMR analyses.

D Tissue Samples

A variety of tissue samples have been investigated using a broad range of analytical techniques in metabolomics, driven by the fact that the analysis of tissue metabolites potentially provides insights into the molecular basis of a variety of diseases, especially carcinogenic tumors [32]. High-resolution magic angle spinning NMR spectroscopy has often been employed in metabolomics analysis of intact tissue samples when minimal sample preparation is desired. Using this approach, several malignancy markers have been reported in a variety of cancer types [32,33]. Advancements in MS ionization methods such as DESI (desorption electrospray ionization) have made it possible to analyze tissue samples directly, including during surgery [34,35]. While analysis of tissue biopsies represents a direct examination to better understand altered metabolism, it is a less popular approach due to the invasive nature required to obtain the samples.

E Plant and Food Samples

Metabolomics is also applied to other complex biological mixtures such as plants and food samples. Broadly, the metabolomics analysis of plants involves collecting metabolite data of unpurified plant extracts and then analyzing the data using multivariate statistical methods, as will be described below briefly, as they have been provided previously in significant detail [36]. Plant extraction procedures must recognize the potential for degradation or modification of metabolites by enzymes released as well as other factors during extraction and sample preparation. Therefore, one should first rapidly cool the plant tissue to extremely low temperature to restrict enzyme activity and, subsequently, disrupt the tissue and inactivate enzymes by denaturation with acid or organic solvents [37]. A number of factors affect the reproducibility and it is important to consider each factor carefully to obtain reliable results. Important factors include, among others, the position of the leaf, its age, exposure to sunlight and rain as well as the time of collection, and the weather [36]. For analysis of food samples, metabolites extraction is required prior to analysis using NMR or MS method. Different solvent systems with various polarities, including methanol, acetonitrile, ether, acetone, hexane, or cyclohexane can be used, each of which provides complimentary information on the metabolome [38]. However, in case of liquid samples such as wine and beer, intact samples are generally used especially for analysis using NMR [39,40].

F General Study Design

Prior to the collection of samples it is very important that the study be well designed. For example, variations such as age, gender, race, weight, life style, medication use, and underlying diseases can alter the metabolic profiles, and as such, it is important to minimize unwanted sources of variation when designing metabolomics studies. Accordingly, the study design of metabolomics must be well-planned and carefully performed using sufficient numbers of reliably matched samples so that the investigation can use its full analytical capabilities. The inclusion of good quality control samples and standards/calibrants is also part of good analytical method protocols for reliable data acquisition [41,42]. A number of resources exist that describe the process for biomarker discovery in general, under the heading Quality Control [43,44].

A good study design should also incorporate proper validation protocols. One aspect of validation is to make

the samples blinded to the analyst; another is to use different analytical platforms to analyze the same samples. Further, most biomarker discovery efforts in the metabolomics field rely on relatively small numbers of samples owing to the cost and effort required to acquire such samples. Information derived from small sets of samples runs the risk of overriding confounding effects or false discoveries. Generally, validation involves dividing samples into two groups, training and validation sets. While a prediction model is developed using the training sample set, the validation set is used to evaluate model performance. Independent sample sets for validation help reduce confounding factors that arise in the analysis stage. Good study design should incorporate steps to account for both biological and technical variance, and provide important information on biomarker performance including sensitivity and specificity.

G Sample Preparation

Sample preparation—prior to data acquisition—is a critical step in all metabolic profiling studies. A typical procedure consists of biological sample collection (which may have its own detailed protocols including amounts, timing, collection tubes, etc.), storage, and typically, metabolite extraction prior to analyzing the samples. Given the complexity of biological samples, metabolite extraction is often a key step in performing metabolic profiling. Blood serum and plasma specimens contain a wide variety of proteins such as lipoproteins; on the other hand, urine contains high concentrations of urea and salts that can interfere with the low molecular weight compounds of interest. The ideal extraction procedure should remove interferences while being simple to carry out, and provide the maximum recovery of a broad range of metabolites (or analytes, more generally) as possible. Numerous extraction procedures have been utilized in the sample preparation of a variety of studies; some of these have been optimized to obtain the highest reproducible results possible [45], whereas others focus on the largest number of features or alternatively a more limited class of metabolites.

For MS analysis, generally, samples are extracted with an appropriate solvent, depending on the compounds of interest (such as just aqueous or lipid metabolites); otherwise, multiple extraction procedures can be applied for more global profiling approaches. For serum and plasma samples, organic solvents such as methanol or acetonitrile are added, which force the precipitation of proteins and many lipids. In contrast, chloroform or other nonpolar solvents can be used to extract lipid species. Urine samples are usually treated with urease to eliminate urea, and most importantly to avoid column overloading and potential ion suppression [46]. Using GC-MS, several biological fluids can be directly analyzed after extraction procedures; however, the low volatility of numerous metabolites make a chemical derivatization step important for broadening the metabolite coverage of the method [47].

Sample preparation for NMR-based analysis is somewhat simplified, and ranges from none to limited, depending on the type of biological specimen being analyzed. Several studies reported comprehensive procedures on sample collection, storage, and preparation for NMR-based metabolic profiling investigations [45,48]. NMR chemical shifts are well documented for common metabolites and are quite reliable. However, they can show some small dependencies on a number of factors such as pH, concentration, ionic strength, and temperature [49]. A phosphate buffer solution made up in D_2O is often used to reduce pH effects, while sodium azide (NaN_3) is commonly added to prevent bacterial growth in intact urine specimens.

III METABOLOMICS ANALYTICAL TOOLS

Among the analytical techniques that have been employed in metabolic profiling studies, MS and NMR are the most commonly utilized due to their ability to analyze a large number of metabolites in a single measurement with high throughput [50–52]. Moreover, the two methods possess unique characteristics; NMR is highly reproducible and quantitative, while MS is intrinsically highly sensitive, which makes it an important method for measuring metabolites present at even very low concentrations in complex biological samples. While NMR generally does not use chromatography, MS methods are most often combined with a separation technique such as LC, GC or capillary electrophoresis (CE) in numerous metabolomics investigations [50]. Some important characteristics of NMR and MS in relation to metabolomics studies are provided in Table 5.1.

A Mass Spectrometry

The use of MS-based techniques in metabolomics has continuously increased over the past decade, with an ever growing number of applications being investigated [28,53]. One of the major advantages of MS is that it offers quantitative analysis with high sensitivity and selectivity, which allows the use of relatively small amounts of sample [54,55]. The chromatographic separation techniques (LC, GC, or CE) normally associated with MS analysis reduce the complexity of the individual mass spectra. This effect, in turn, offers better opportunities for compound identification which can be achieved utilizing metabolite databases and libraries [56,57]. The high sensitivity (picogram level) of MS detectors makes MS a

TABLE 5.1 Characteristics of MS and NMR Spectroscopy Methods Used in Metabolomics Applications

	Strength	Weakness
MS	• Highly sensitive • Detects up to thousands of metabolites in a single measurement • Tandem mass analysis enables reliable metabolite identification • Highly quantitative using internal standards (one per metabolite) • Accurate mass can be used to derive empirical formulas • Enables high-throughput measurements • Wide range of instruments enables detection of different types of metabolites • Instrument cost can be relatively low	• Chromatographic separation is generally required before detection • Often, expensive internal standard is required for each metabolite for absolute quantitation • Salty samples are hard to analyze • Identities for a major fraction of detected metabolites are not known • Destructive to samples • High-end instruments are expensive
NMR	• Highly quantitative • Highly reproducible • Detects up to hundreds of metabolites in a single measurement • Generally no chromatographic separation is involved • Single internal reference is sufficient for absolute quantitation of all detected metabolites • Enables unknown metabolite identification de novo • Enables high-throughput measurements • Nondestructive to samples	• Relatively less sensitive (Limit of Detection $\sim 1\ \mu M$) • Limited spectral resolution • Detects fewer metabolites compared to MS • Difficulty measuring individual lipids • High cost for high field instruments

highly suitable analytical platform to investigate complex pathophysiological disorders in biological samples.

B Liquid Chromatography Resolved Mass Spectrometry

Due to its characteristics of high metabolome coverage and relatively simple sample preparation, LC-MS has become the most popular technology for metabolite profiling over the past five years. The intrinsic high sensitivity of MS enables detection of several hundred to over a thousand small molecules (along with thousands of unidentified spectral features) from a single experiment. The unique characteristics of LC-MS allow the direct detection of metabolites from biological mixtures with no requirement for chemical modification such as derivatization. Robust step-by-step protocols are available for LC-MS analysis of a variety of biological mixtures including serum [58], urine [59], as well as for animal and human tissue analysis [60]. More recently, detailed protocols for characterization of unknown peaks using tandem mass spectra along with a large database of over 50,000 metabolites (METLIN database) have been compiled [61].

A variety of LC columns are used to separate metabolites prior to mass analysis, depending on the nature of metabolites of interest. Reversed phase (RP) LC is primarily used for broad-based global metabolic profiling [62]. Although both polar and nonpolar metabolites can be separated by RPLC, highly polar metabolites are not well retained (separated) on common RP stationary phases. Instead, hydrophilic interaction chromatography MS is commonly used to analyze highly polar metabolites [63]. The development and use of ultrahigh pressure liquid chromatography has significantly improved the peak capacity and chromatographic resolution, and in so doing, lowered the limit of detection for metabolite profiling [64].

Postseparation by chromatography, metabolites are ionized in the MS ion source. The ionization source most commonly used for LC-MS-based metabolic profiling methods is electrospray ionization (ESI), which is operated in either positive or negative mode to ionize a broad range of metabolites. ESI is known as a "soft" ionization technique in that it typically does not result in a significant amount of molecular ion fragmentation. ESI alone does not allow for easy metabolite identification based on the MS fragmentation patterns. Therefore, ESI is very often coupled with detection with part per million mass resolution, to allow metabolite identification. Alternatively, tandem mass spectrometry (MS/MS), which includes an ion fragmentation step that produces additional molecular information, can assist in metabolite identification [65].

A variety of mass spectrometers are available for LC-MS analysis. High mass resolution instruments include Fourier transform ion cyclotron resonance, Orbitraps, and TOF instruments. Low (i.e., unit) mass resolution instruments include ion traps, Qtrap, and standard triple quadrupoles. High-resolution MS instruments provide important routes to detect different coeluting species and for unknown identification. A recent book describes different configurations and performance of these types of instruments along with their applications to metabolomics [50]. A significant challenge for LC-MS, however, is ion suppression in which coeluting compounds alter the degree of ionization of a particular analyte and cause serious signal attenuation or even signal loss.

C Gas Chromatography Resolved Mass Spectrometry

GC-MS is widely used in metabolomics due to numerous factors including its reliability and relatively low instrument cost and maintenance [57,66]. The high separation efficiency, resolution, and high reproducibility achieved through retention time markers represent important characteristics for GC-MS-based metabolite profiling. However, GC-MS is limited to the use of volatile and thermally stable compounds; those which are not volatile are often subjected to chemical derivatization to make them volatile and compatible with the GC interface [67]. As a result, GC-MS can be applied to the analysis of a large range of metabolite classes, including lipids, peptides, alcohols, organic acids, amino acids, ketones, aldehydes, esters, sulfides, sugars, sugar-phosphates, sugar-alcohols, alkaloids, amines, and amides. Due to the use of a gaseous mobile phase and the high energy nature of its ionization source (typically 70 eV), GC-MS analysis generally avoids the interfering effects of ion suppression on metabolite signal intensities, which is a major challenge faced by LC-MS. The detection of 150−200 identified metabolites along with a few hundred unknown metabolites and spectral features is typically achieved using GC-MS analysis of biofluid or tissue extract samples.

GC-MS analysis normally requires somewhat extensive sample preparation including chemical derivatization to increase thermal stability and volatility [68]. Metabolites with active hydrogens from the functional groups such as −COOH, −NH, −SH, and −OH can be derivatized by alkylation, acylation, or silylation. However, silylation is the most commonly used derivatization method, in which an active hydrogen atom is replaced by a silyl group. A number of silylation reagents are used, each of which has its own advantages and disadvantages. Depending on the experimental design and research interest, a two-step derivatization procedure is generally used, which includes methoximation to help derivatize keto- groups to prevent enolyzation, followed by silylation to cover a broad range of metabolites [69].

The ion source primarily used in GC-MS platforms is electron impact ionization (EI), which provides good, reliable, and reproducible metabolite fragmentation patterns for compound identification when used in conjunction with large and commercially available MS libraries. Some instruments are equipped instead or additionally with chemical ionization (CI). CI is generally considered to be a softer ionization source and usually gives the M^+ peak, instead of only molecular fragments commonly observed in EI. Most metabolomics-based investigations that use GC-MS instruments are equipped with either quadrupole or TOF mass analyzers [57]. TOF analyzers offer higher mass resolution and rapid metabolite detection, which is useful when dealing with narrow, unknown peaks in the chromatogram [70,71].

In order to improve and increase metabolite separation, the use of comprehensive, two-dimensional (2D) GC coupled to a mass spectrometer (GC × GC-MS) has also been developed and applied to metabolomics analysis [72]. Compared to GC-MS, the second chromatographic dimension in GC × GC-MS provides improved resolution and high sensitivity which is very advantageous for metabolomics applications. However, the data sets obtained from this platform are large (typically 100 MB per sample) and quite complex; improved solutions for peak deconvolution and data processing are only now becoming available [73].

D Other MS-Based Techniques

Additional MS-based techniques have been employed to analyze the metabolome, and numerous applications have been investigated. Among them, capillary electrophoresis-mass spectrometry (CE-MS) is a rapidly growing field in metabolomics that has already demonstrated great potential [74]. However, CE is limited to the analysis of charged molecules, and lower sensitivities are often obtained as compared with GC-MS or LC-MS. The application of MALDI, laser desorption ionization, and new atmospheric ionization methods, such as DESI [75], direct analysis in real time [76], and nano-ESI [77], have been investigated for application in metabolomics; these methods have potential for providing much simpler, less time consuming analytical approaches than LC-MS or GC-MS. However, these methods do suffer from a variety of challenges, such as reduced reproducibility, difficulty in standardization, and spectral overlap. Nevertheless, new applications of these approaches continue to be developed. For example, the utility of the DESI approach has recently been demonstrated in the surgical room. This approach, known as iKnife, can detect volatized metabolites from a special

surgical knife that can be analyzed to indicate the presence of cancer or healthy tissue essentially in real time [34]. Although a single analytical platform can be suitable for performing metabolite profiling studies, the use of multiple-platform approaches has gained much interest over the past decade, as a wider range of metabolites can be analyzed using this approach [52,78,79].

E NMR Spectroscopy

High-resolution NMR spectroscopy has proven to be a powerful and very reliable technique for metabolite profiling [51,52]. A growing number of metabolomics studies have demonstrated the capabilities of NMR in a variety of fields including toxicology, drug discovery, disease diagnostics, environmental studies, energy, and foods and nutrition. NMR spectroscopy exhibits numerous unique and favorable characteristics that are very beneficial to the field of metabolomics [52]. Importantly, (1) NMR is highly reproducible and quantitative; a single internal reference is sufficient for absolute metabolite quantitation over an incredible dynamic range since signals in NMR have the same sensitivity, independent of the properties of the metabolite; (2) a combination of NMR techniques enables the unambiguous identification of structures for unknown metabolites, which is important considering that a majority of the detected metabolites in complex biological mixtures is unknown; (3) NMR enables analysis of intact biofluids and tissues with minimal or no need for sample separation or preparation, which is important considering that factors associated with sample preparation and separation contribute to analytical variability and represent a major bottleneck; (4) NMR is nondestructive, which means the sample remains intact after the analysis and can be used for reanalysis at a later time period or analysis using other methods such as MS; (5) NMR possesses unsurpassed capability to trace metabolic pathways and measure metabolic fluxes utilizing isotope-labeled substrates; (6) NMR provides unique opportunities to translate in vitro findings to clinical applications in vivo; and, finally, (7) metabolite profiles obtained by NMR are virtually independent of the operator and instrument used, which provides a high degree of reliability to the derived results. A variety of procedures have been reported for sample preparation depending on the type of the study. Sample requirements are typically 100−200 μL for biofluids and 5−10 mg for tissue, which are much higher than for MS analysis. With advanced high-throughput NMR methodology, up to ∼200 samples can be measured within a day with the assistance of flow-injection probes and automated liquid handlers [80,81].

^{1}H signals from water protons are very large and thus require suppression, which is typically performed by the application of an appropriate water suppression pulse sequence such as presaturation (PRESAT) [82] or other sequences. Once the water signal has been suppressed, a significant number of metabolites can then be detected in the biological samples. However, the NMR data from biological specimens contain a large number of peaks which often overlap. As a result, metabolites of lower concentration are frequently overshadowed by larger peaks, thereby limiting the detection capabilities of the instrument. Typically, 50−200 metabolites can be detected, depending on the type of sample, with urine providing the highest number. In order to reduce problems with signal overlap that are encountered in 1D NMR experiments, 2D NMR spectroscopy can be used to assist in the identification of putative metabolites found in the 1D NMR spectrum. 2D NMR spectroscopy is less commonly employed in metabolic profiling approaches due to its longer acquisition time and more involved data analysis requirements. The high reproducibility and quantitative abilities of NMR, its use in combination with multivariate statistical methods, make it a very powerful approach to identifying putative metabolites from a complex spectrum. NMR continues to witness widespread use in metabolomics.

NMR's ability to analyze intact samples is fully exploited for the analysis of samples such as urine and saliva that are usually devoid of large amount of interfering proteins. Traditionally, even widely used samples such as serum/plasma are analyzed using intact samples by suppressing protein signals using the Carr−Purcell−Mieboom−Gill NMR sequence [45]. However, it is increasingly realized that analysis of blood serum/plasma by NMR is improved by physically removing serum/plasma proteins before the analysis. Broadly, two approaches are used for removal of proteins: one is ultrafiltration and the other, protein precipitation using an organic solvent such as methanol, acetonitrile, or others [48,83]. More recently, it was shown that protein precipitation using methanol (2:1 v/v) provides an efficient route to remove proteins and recover metabolites quantitatively for improved metabolomics analysis of serum/plasma by NMR [84,85].

F Global Versus Targeted Metabolic Profiling

Metabolomics-based studies can be divided into two main categories: targeted and nontargeted metabolic profiling approaches [86]. Untargeted, or "global," metabolic profiling studies are "hypothesis generating" and have mostly focused on the discovery of new metabolite biomarkers or new alterations in metabolism caused by biological stresses. Targeted approaches have focused more on metabolite-specific studies, as well as for the validation of putative biomarkers.

While it is likely impossible to completely profile all metabolites in a complex biological sample, current analytical methods are quite capable of measuring hundreds to a few thousand metabolites, especially when several platforms are combined. Initially, metabolomics investigations primarily used global metabolic profiling methods involving the analysis of all detectable signals, including both known and unidentified metabolite peaks. Very often, metabolites are not identified prior to analysis. Instead, the complex data are subjected to statistical analysis (discussed later), after a preprocessing step. For NMR, preprocessing includes apodization and zero-filling, Fourier transformation, phase and baseline correction, peak alignment, solvent peak removal, and (optionally) data binning [87]. For MS, spectral peak quantitation and alignment are typically followed by metabolite identification, wherever possible. Typically, only one-third of metabolite identities are assigned with confidence in global profiling studies. For LC-MS, preprocessing also includes the removal of isotope and adduct peaks resulting in simplified and better quantified spectra. Subsequently, metabolite features that distinguish sample classes are identified and then the structures of distinguishing metabolic features are established wherever possible.

In targeted metabolite profiling, a set of known metabolites are quantitated. The identities of metabolites are established a priori based on available databases and using standard compounds; the identified metabolite peaks are then quantified relatively, or sometimes absolutely based on the inclusion of internal or external reference compounds. The resulting data can then be used for pathway analysis to prove or disprove biological hypotheses, or as input variables for statistical analysis. Because of the reliable peak identification and measurement of metabolite intensities or even concentrations, targeted metabolomics provides greater insights into the dynamics and fluxes of metabolites and promises more robust statistical models for distinguishing sample classes with better classification accuracy. As NMR spectroscopy already provides highly reproducible results with a coefficient of variation (CV) of 2−3%, targeted metabolomics can be performed easily using NMR [52]. Targeted metabolomics using tandem mass spectrometry (LC-MS/MS) enables fast MS data acquisition resulting in quantitative data with reasonably good reproducibility (5−10% average CV) [88,89]. A variety of internal standardization methods using isotope-labeled compounds (^{2}H, ^{13}C, ^{15}N) as well as external standardization methods are also available to provide much better reproducibility. The inclusion of internal standards reduces these CVs to $<5\%$.

Targeted metabolomics analysis encompasses the measurement and identification of a specific list of metabolites from selected pathways of interest [90]. This approach can be used for pharmacokinetic studies, drug metabolism, and for the validation of putative markers in numerous disorders [2,91,92]. The main strengths of this approach are its quantitative capabilities and reliability. However, one limitation is that it requires knowledge of the metabolite's identity, and as a result novel biological markers can be difficult to discover.

While multiple MS techniques can be applied, the use of triple quadrupole MS coupled with chromatographic techniques has become the standard approach used for targeted metabolomics analyses of a number of compound classes including amino acids, organic acids, carbohydrates, amines, and nucleotides [86]. Currently, the detection of 100−300 targeted metabolites is possible using multiple reaction monitoring [80,86].

IV DATA ANALYSIS

In addition to the analytical methods, advanced statistical and typically multivariate methods play an essential role in metabolite profiling [93,94]. While univariate methods such as the Student's *t*-test or *p*-value calculations are extremely useful in identifying individual metabolite changes or biomarker candidates, it has been recognized for some time that *individually* almost all metabolite biomarkers are likely to be insufficient in terms of performance. Thus, in order to build predictive models based on multiple biomarkers that can improve performance, multivariate statistical methods are employed. Multivariate methods are also very useful for reducing the dimensionality of the NMR/MS data, and to extract the maximum information. Multivariate methods are generally capable of processing several thousand inputs or "variables" and their corresponding intensities; however, most practical applications typically involve a dozen or less biomarkers because of the increased effort needed to develop and validate each marker individually.

A Data Pretreatment

Prior to data analysis, there are a number of data preprocessing steps that are often necessary in order to extract the optimal information from the complex biological data. These steps include normalization and scaling, along with additional preprocessing steps such as noise reduction, baseline correction, peak deconvolution, and peak alignment. These steps ensure that valuable information is derived from the acquired data with only minimal bias. The specific treatment, however, depends on the analytical platform used to acquire the data.

For NMR spectra, baseline correction is performed to reduce offsets that might introduce errors into the accurate measurements of metabolites [95]. Spectral data alignment is performed using the peak from a reference

compound such as TSP (trimethylsilyl propionate-d_4 sodium salt) or DSS (sodium 4,4-dimethyl-4-silapentane-1-sulphonate-d_6). On the other hand, mass spectra are normally aligned based on retention times (RT) or mass/charge ratios in order to counteract column or instrument drift over time. In LC-MS, Quantitative Structure−Retention Relationship modeling can be used to predict RT [96]. For GC-MS analysis, retention time locking procedures along with a library of fatty acid methyl esters (FAMEs) with different chain lengths that are added to each biological sample provide an opportunity to circumvent problems associated with column drift [97]. These procedures have also facilitated the identification of metabolites irrespective of the specific GC-MS platform used in the analysis.

Data normalization is carried out to minimize the effects of unwanted variations that arise as a result of different sample volumes, concentrations, and instrumental sensitivity changes. There are various types of normalization that are applied, such as total (spectral) sum normalization or normalization to a reference compound. Methyl succinate or d_{27}-myristic acid is used for GC-MS, TSP normalization is used for NMR studies, while more generally creatinine normalization is used for urine analysis [98]. Scaling is sometime performed in order to compare or enhance metabolites that are present at low concentrations. This is made necessary by virtue of the fact that, when performing multivariate data analysis, low abundance metabolites can be misinterpreted or even excluded. A number of different scaling methods are used in metabolomics including variance scaling, autoscaling, and Pareto scaling. In addition, log transformation of the data can be used to reduce data skew and outliers.

B Univariate Analysis

One of the simplest forms of statistical analysis employed in metabolic profiling studies, univariate analysis involves a single variable at a time, and is quite commonly used in the first stages of systems biology research and biomarker discovery. Univariate analysis is also used to further validate the performance of single putative metabolite biomarkers. There are various univariate statistical methods that are commonly used in metabolomics, including the Student's *t*-test, the Mann−Whitney U-test, and the receiver operating characteristic (ROC) curve [99]. The Student's *t*-test is widely used since it gives the probability that two sample sets are distinguishable for a particular variable (metabolite). However, it does assume that the data are normally distributed, which may not always be the case in metabolomics data sets. Alternatively, the U-test does not require normally distributed data.

ROC curves are often used to evaluate the performance of a diagnostic test or the potential of putative biomarkers [100]. As shown in Fig. 5.2A, the ROC curve is a plot of sensitivity (true positive rate) versus 1-specificity (false positive rate). In an ROC curve at the (0,0) coordinate, all test results are negative while at the (1,1) coordinate all results are positive. The diagonal line connecting the two coordinates indicates that the diagnostic test results are purely by chance (random prediction) and, therefore, that the test lacks diagnostic capabilities. The overall utility of a diagnostic test is often assessed by calculating the area under the ROC (AUROC) curve. In these cases, an area of 1 represents a perfect test while an AUROC of 0.5 corresponds to the diagonal line indicating a random prediction. A main advantage of the ROC curve is the ability to see the trade-off between decreasing the sensitivity and increasing the specificity and vice versa, which is crucial when performing clinical studies.

C Multivariate Statistical Analysis

In general, multivariate statistical approaches are broadly classified into two categories: "unsupervised" and "supervised" methods. In unsupervised analysis, the sample status (e.g., "case" or "control") is not known or used during the statistical analysis, whereas in supervised methods this information is part of the analysis.

D Unsupervised Statistical Methods

Several different types of unsupervised methods are used in metabolomics, including principal component analysis (PCA), hierarchical cluster analysis (HCA), k-nearest neighbor, and factor analysis [102]. Many of these methods are used in exploratory data analysis for hypothesis generation.

PCA (see Fig. 5.2B) is the most commonly used unsupervised method in metabolomics [99]. It is a powerful data reduction method and also serves as a useful starting point in multivariate statistical data analysis. PCA is commonly applied to detect possible outliers and clusters present in the sample set. PCA is a mathematical procedure that transforms the data set into a set of ranked principal components (PCs) that explain the variance in the data. As a result, the transformed data matrix is described as the product of a set of "scores" based on the PCs and corresponding "loadings" which give the contribution of each metabolite to that particular PC. The first PC explains the direction that describes the largest variance in the metabolite signals; this is followed by the second and subsequent PCs, which explain successively lower variance. The loadings provide information on the variables (metabolite signals) that account for separation of the data clusters in the scores plot. Since no prior knowledge of the sample class (control,

Anal. Chim. Acta. 686 (2011) 57–63.*

disease, etc.) is utilized, the variables identified from the corresponding loading plots may serve as potential biomarkers for further (confirmatory) analysis [103]. However, cluster separation may also result from confounding effects (age, gender, BMI, etc.) unrelated to the condition under study.

HCA seeks to define natural clusters based on comparing distances between pairs of samples or variables within the data set. It is most useful when the intention is to cluster a small number of variables. The distances between all samples are calculated, and the smallest distances between samples imply that this subset of samples share similar metabolite levels, thereby representing similar physiological properties or disease states or stages for example. The process is repeated until all samples in the data set are grouped. HCA is often used in combination with heat maps to help visualize patterns in the data (see Fig. 5.2C). In biomarker discovery, HCA is usually used as a supporting method for more commonly used unsupervised methods such as PCA [104].

E Supervised Statistical Methods

Most predictive models in metabolomics currently rely on supervised statistical analysis in order to reduce the effects of confounding factors such as age, diet, race, gender, etc., which can affect the performance of the model. Supervised methods require a training data set, in which the outcome (i.e., disease or healthy) is known, to build a predictive model. Typically, sample data sets

are split into training and test sets, although some practitioners utilize an intermediate set of data that is used to improve the modeling. After training, the model's accuracy is evaluated by classifying samples in the test set of samples. Typically, cross-validation [94] is used to test the robustness of putative biomarker candidates during the training process as well as to identify the best model, given the training set of sample data.

Two of the most popular methods for supervised pattern recognition include partial least squares discriminant analysis (PLS-DA) [105] (which is often combined with orthogonal signal correction [106]) and logistic regression (LR). Other, often used, methods include soft independent modeling of class analogies, genetic programming, and neural networks.

PLS is a regression algorithm that predicts a vector Y, the dependent variable(s) from the independent data in matrix X, which is typically the NMR or MS data. PLS finds a combination of the X data that explains the maximum variance in the Y data. In PLS-DA, the Y-matrix contains categorical class variables, for example, 1 = cancer; 0 = control [107]. Similar to PCA, where the PCs describe the variance, each orthogonal axis in PLS-DA is referred to as a latent variable (LV). The LVs contain the weight of each variable (metabolite signal). By maximizing the differences between two selected classes, putative biomarkers can be identified from PLS-DA from the weights of the LV. While PLS-DA statistical models can establish the difference between preassigned sample groups, they can often over-fit the data. One must, therefore, carefully validate the results of the model established during training, and use prudence when applying the results of PLS-DA to new data sets [108].

LR is a commonly used method to predict the probability of an event (toxicity, disease, effect of a drug) from a set of predictor variables that can be a variety of inputs, either numerical or categorical. The output, or dependent variable, itself is categorical (i.e., cancer vs normal). In LR, the occurrence of an event is mathematically evaluated in terms of its probability, which can be summarized in the equation below:

$$\text{Logit}\,(p) = \ln(p_i/1-p) = \beta_0 + \beta_1 x_1 + \cdots + \beta_k x_k$$

where p is the probability of an event, x_i are input variables, β_0 is the intercept of the regression line, and β_k are fit parameters. The output of LR analysis is a set of predictors indicated by the nonzero β coefficients, which can be useful in determining the most important variable(s) for statistical modeling. In metabolomics, LR is most often used to combine a limited number of biomarker candidates as a predictive algorithm for diagnostic, prognostic, or other purposes.

In general, it is extremely important to validate the findings of any of these multivariate methods (including unsupervised methods) using extensive cross-validation [109] and, in particular, additional sets of samples (preferably blinded and from other locations) and which are sufficiently large to yield statistically significant results. Beyond the statistical aspects of validation, ultimately, biological validation, such as involving a disease hypothesis specifically related to the discovered biomarkers, may be required before acceptance by the medical and scientific communities can be anticipated.

F Correlation and Other Associative Approaches

In addition to regression and clustering analyses, correlation approaches have attracted major interest in metabolomics for their ability to identify relationships among different metabolites and/or pathways, to reduce spectral complexity and help identify unknown metabolite structures. In addition to standard correlation calculations such as the Pearson correlation between two metabolites, several new and alternative approaches have been introduced. For example, STOCSY (statistical total correlation spectroscopy) is a method applied to 1D NMR spectra to generate correlation coefficients between every pair of 1D NMR peaks across multiple spectra. Peaks showing high correlations provide clues to unknown metabolite identification [110]. A large number of variants of STOCSY have been developed, such as subset optimization by reference matching, which improves data quality and peak alignment using correlations across subsets of samples [111], or statistical heterospectroscopy, which correlates peaks in MS with NMR for improved unknown identification and biomarker discovery [112].

A novel statistical approach based on peak ratios was introduced for the analysis of NMR and mass spectral data: RANSY (Ratio Analysis of NMR Spectroscopy) was demonstrated to isolate peaks from metabolites in complex mixtures based on the principle that the peak intensity or integral ratios between peaks from the same metabolite are fixed [113]. The RANSY spectrum for individual metabolite is obtained by generating peak ratios that are divided by the ratios' standard deviation σ across a set of small number (viz., 8−10) of spectra. NMR peaks arising from the same molecule exhibit fixed ratios, which leads to small σ and thus provides large RANSY values. This ratio analysis approach was extended to identify metabolites using mass spectral data [114], in a method called RAMSY (Ratio Analysis of Mass Spectrometry) that efficiently isolates mass fragment peaks for the same metabolite using a single mass chromatogram.

G Major Challenge: Unknown Metabolite Identification

The powerful methods of NMR and MS provide capabilities to measure hundreds of metabolites. However, the current peak identification capabilities in MS are limited to approximately one-third of globally detected metabolite features, which are typically assigned based on databases of spectra for authentic compounds. Identifying unknown metabolites is thus a challenging endeavor and a major focus in the metabolomics field. MS methodologies to identify unknown metabolites mostly rely on combinations of high-resolution MS to determine the chemical formula along with MS/MS experiments to determine fragmentation patterns, along with general rules of chemical bonding [115]. NMR analysis using an array of 1D/2D experiments represents a powerful approach for unknown identification de novo. Using this approach, nearly 70 metabolites have been identified and quantified in the NMR spectra of blood [84]. However, unambiguous assignment of peaks for many metabolites with low (less than or equal to few micromolar) concentrations is especially challenging, since many of these peaks are often overlapped with abundant metabolite signals.

Unknown metabolite identification in the spectra of human urine is generally more challenging than other biological mixtures. The significant amount of salt present in urine makes it less attractive for analysis using LC-MS, and GC-MS is more often used for analysis. Urine spectra generally provide significantly higher numbers of signals compared to serum/plasma, and hence urine is a rich source of information specifically for investigations of biomarkers of food and nutrition. Unlike serum/plasma, urine metabolic profiles are sensitive to contributions from numerous factors including diet, medications, personal habits such as physical activity or smoking, gender, age, gut microbe diversity, and genetics [49]. Because of these factors, urine from even the same individual exhibits significant variability depending on the time of the day the urine was collected [116]. Urine pH also varies significantly (from $\sim$5 to 8), which together with the high salt concentration causes significant peak shifts for many metabolites when analyzing by NMR. Nevertheless, significant improvements in the identification of unknown metabolites in urine have been recently achieved based on comprehensive analysis using new database software and spiking with authentic compounds [117]. Interestingly, the number of urine metabolites identified by NMR is higher than that obtained from the more highly sensitive GC-MS.

H Mechanistic Studies—Flux Analysis

Most metabolomics analyses measure relative changes in abundance or concentrations for different sample groups. However, a limitation of the analysis of metabolites at steady state is that their concentrations may lack sufficiently specific information to obtain an unambiguous understanding of the biosynthesis of metabolites. This situation occurs because many metabolites are associated with multiple metabolic pathways. Additionally, in cells and tissues many metabolic levels are controlled by regulation through homeostasis. Hence, the contribution of each metabolite to a specific pathway is masked. Thus it has been increasingly realized that a metabolic pathway-focused, hypothesis testing approach is desirable to further understand pathogenesis and potentially to discover additional disease biomarkers. An approach that promises more specific information on metabolic pathways involves the incorporation of stable isotopes into the downstream metabolites using precursors enriched with stable isotopes such as ^{2}H, ^{13}C, or ^{15}N. This approach provides vital clues regarding biological mechanisms by tracing isotope-enriched metabolite products and long-lived intermediates that are produced. Flux analysis allows a better understanding of the dynamics of metabolic pathways and enables better modeling of intracellular metabolite levels and determination of the rates at which metabolites are produced or consumed. More specifically, metabolite profiling of cells supplied with ^{13}C-labeled glucose, for example, facilitates the determination of the glucose consumption rate as well as the rates at which the downstream metabolic products of glycolysis are produced. As an example, ^{13}C-labeled lactate produced from the glycolysis of ^{13}C-glucose in cancer cells can be distinguished from the same lactate produced from other pathways based on the presence or absence of the embedded ^{13}C isotope [118]. Advances in targeted metabolic profiling methods have improved the accuracy of metabolite quantitation and facilitated increased interest in understanding diseases based on altered metabolic pathways. Both NMR and MS methods are used in stable isotope-based flux analysis using labeled precursors.

V APPLICATIONS TO FOOD AND NUTRITION

It is well known that foods and nutrients as well as dietary patterns interact with metabolic processes and contribute to a reduction or an increase in the risk of a number of important diseases [119]. Thus, diet plays a major role in human health and also constitutes an important risk factor for many diseases. A large number of metabolomics investigations are therefore focused on understating the composition of foods as well as diet-induced metabolic changes in biological specimens such as urine and blood [120].

Most foods are essentially mixtures of metabolites and other compounds in solid or liquid forms that are similar

to biofluids in complexity. Metabolomics provides a powerful means for investigations of foods; nevertheless, the comprehensive analysis including quantitative measurements of ingredient micronutrients is still lacking for many foods. To date, studies on numerous fruits, spices, oils, and beverages have been reported, with NMR as the major method for quantitative characterization of polar metabolites with relatively high abundances [121]. As an example, metabolomics is used to characterize wine to prevent adulteration, classify wines according to variety, region, and vintage, and to understand the fermentation behavior, using NMR spectroscopy [122–124]. Metabolite profiles of beers from different sites, including different countries, produced under various fermentation conditions, have also been compared. Significant differences in metabolite composition observed among the various types suggest the utility of the approach for controlling the quality and identifying fermentation conditions [125–127]. A study focused on the analysis of honey using an advanced approach to identify low concentration metabolites that differentiated the honey's origin by reducing the effect of large, uninteresting sugar signals [128]. Metabolomics methods have also been applied to coffee produced by different manufacturers [129]. Based on multivariate analysis of the ^{1}H NMR data, 99% of the samples were correctly attributed to their manufacturers. Investigations of tea have also been made to discriminate different teas according to the country of origin or to various quality factors. By comparing teas from different countries, it was shown that the concentration of metabolites such as catechin and theanine can be used to classify fermentation and processing of tea [130,131]. Numerous components of tea including theogallin (5-galloyl quinic acid), theobromine, 2-*O*-(beta-L-arabinopyranosyl)-myo-inositol, fatty acids, sucrose, and some minor sugar-containing compounds have also been shown to distinguish different tea types [131].

Identification of dietary biomarkers is also of significant interest to evaluate their impact on nutritional value and adverse effects on health. Broadly, dietary biomarkers are grouped under two major categories: recovery biomarkers and concentration biomarkers. Recovery biomarkers signify absolute dietary intake over a certain period of time; the amount of nitrogen in 24-hour urine is an example of a recovery biomarker. On the other hand, concentration biomarkers that correlate with diet do not represent the absolute level of dietary intake; vitamin E in plasma, for example, represents a concentration biomarker [132]. Current methods that use food frequency questionnaires (FFQs) with 24-hour recalls and weights of the food are often prone to errors. Therefore, the biomarker studies are challenged by the insufficient precision associated with the detection of diet–disease associations based on FFQs.

Metabolomics promises numerous potential benefits to alleviate some of the challenges in conventional methods of dietary assessment through the identification of nutritional biomarkers. Dietary effects are reflected in variations of metabolite profiles and specific effects can be detected by measuring metabolites in biofluids [133]. An advantage of metabolomics for nutritional studies is that a large number of dietary markers can be investigated in a single measurement. Owing to these potential benefits, the field has witnessed a large increase in applications over the last five years. Currently, three different approaches are used for the discovery of dietary biomarkers: (a) intervention studies, where participants are made to consume a specific food, (b) cohort studies, where groups of consumers and nonconsumers of a specific food are compared, and (c) dietary pattern studies, where the analysis focuses on certain dietary patterns. A recent article has reviewed these approaches in greater detail [120].

Intervention studies have resulted in the identification of a number of potential dietary biomarkers. Among them, identification of proline betaine from citrus fruit intake is an important finding [134]. A number of independent studies have validated this biomarker [135,136]. Many studies have focused on the identification of food sources of various biomarkers found in complex meals and representative dietary patterns. Using sensitivity and specificity analyses many conjugated isothiocyanates have been identified as biomarkers of brassica intake [137]; however, only 23% of these biomarkers could be validated, which highlights the need to use proper study protocols for reliable identification and validation [138]. Other intervention studies have identified biomarkers for meat and fish [139–141]. Different effects of meat and fish on the plasma metabolome have also been investigated. For example, a beef meal showed higher concentrations of 2-aminoadipic acid, β-alanine, and 4-hydroxyproline compared with a baked herring meal [142]. Other studies have shown that a daily consumption of 40 g of dark chocolate for 2 weeks altered the metabolic profile involving lactate, citrate, succinate, *trans*-aconitate, urea, proline, adrenaline, 3,4-dihydroxyphenylalanine (DOPA), 3-methoxy-tyrosine, methylamines, *p*-cresol sulfate, and hippurate in healthy subjects [143].

Many cohort studies have also been focused on the identification of putative biomarkers. Unlike intervention studies, cohort studies make use of self-reported dietary data for searching biomarkers. A study of prostate, lung, colorectal, and ovarian cancer screening compared the serum metabolite profile with dietary data collected using FFQ and detected 39 metabolites that were correlated with 13 dietary groups [144]. Notable among these were correlations of citrus intake with stachydrine, chiro-inositol, scyllo-inositol, and *N*-methyl proline; fish intake with 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid,

docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA); peanut intake with tryptophan betaine and 4-vinylphenol sulfate, and coffee intake with trigonelline-*N*-methylnicotinate and quinate. However, a number of metabolites were not specific to food; for example, DHA correlated with fish and rice. Hence, validation and additional studies based on intervention are required for more insights into these biomarkers. Separately, a large cohort study ($n = 2047$) identified ferritin, glycine, 4 diacyl phosphatidylcholines, 11 acylalkyl phosphatidylcholines, 2 lysophosphatidylcholines, and 2 sphingomyelins in serum as associated with red meat consumption; six of these were found to be associated with diabetes risk [145]. A downside of this interesting study, however, is that the dietary information relied on the estimates of meat consumption by FFQ and that no distinction was made between processed and unprocessed meat. Another cohort study based on metabolic profiling of urine identified higher concentrations of benzoxazinoids and alkylresorcinol metabolites as well as many gut microbial metabolites, such as enterolactones, hydroxybenzoic and dihydroferulic acid in bread consumers. In whole-grain bread consumers, 2,8-dihydroxyquinoline glucuronide was found to be higher [146].

Numerous studies report the discovery of dietary biomarkers based on dietary patterns [120]. For example, based on statistical analysis of three dietary patterns and self-reported data, a number of metabolites that are reflective of specific food intake were identified [147]. Another study identified lipid patterns that are predictive of dietary fat intake, alcohol intake, or fish intake [148]; this study identified lysophosphatidylcholine as a potential biomarker of alcohol consumption and lysophosphatidylethanolamine and phosphatidylethanolamine diacyl of fish intake. More recently, a study was made using urine metabolomics for the development of a model for compliance measures using two dietary patterns, a Nordic diet or an average Danish diet. This study provided a robust model with a misclassification rate of 19%, which highlights the utility of this approach to evaluate the compliance measures [149]. The application of metabolomics to nutrition studies continues to advance at a fast pace.

VI SUMMARY

Through its ability to simultaneously analyze hundreds of metabolites, metabolomics approaches promise numerous avenues for the establishment of multiple biomarkers that correlate with food and nutrition as well as to provide detailed information on biological states, diseases, and health risks. The discovery of dietary biomarkers offers new avenues for establishing beneficial or deleterious effects of various diets on human health. In view of its importance in these areas, the metabolomics field is witnessing an exponential growth of applications to food and nutrition. As a consequence, an increasing number of biomarkers have been detected based on metabolomics studies of dietary interventions, cohorts as well as dietary patterns. These identified biomarkers, however, need proper validation before they can be considered for translational investigations. Validation is critical and also challenging due to numerous factors that confound the metabolite data. On the metabolomics technology side, the unsolved challenge is the lack of knowledge of identities for a large fraction of the detected metabolites. Further, continuously increasing advances in analytical technologies have enabled detection of an increasing number of metabolites from the same biological samples; thus, the advances in analytical techniques also continuously increase the fraction of unidentified metabolites. In view of this, a major focus in the metabolomics field is on developing methods for unknown metabolite identification and expanding pool of quantifiable metabolites. Such advances combined with improvements to study protocols that eliminate confounding effects are anticipated to impact immensely the discovery and validation of dietary biomarkers and their use in nutritional intervention.

Chapter 6

Translational Research: Concepts and Methods in Dissemination and Implementation Research

Jamie M. Zoellner and Kathleen J. Porter
University of Virginia, Charlottesville, VA, United States

I INTRODUCTION

Scientific discoveries are not efficiently translated into everyday practice to benefit patient and population health. The lag time for scientific discoveries to be integrated into clinical and community practices has been estimated to take about 17 years [1]. Of further concern, it is estimated that only about 14% of research discoveries are translated to benefit patient care in this timeframe. Additionally, due to the complexities of moving scientific discoveries along the research pipeline to establish widespread clinical and population impact, others argue that this lag time is much longer [2]. Despite lack of clear consensus on the number of years, there is broad agreement that the research pipeline process is entirely too long [3]. As a result, translational research and translation science have emerged as a key research paradigm for accelerating scientific discovery into patient and population benefit.

Translation is the process of turning observations in the laboratory, clinic, and community into interventions that improve the health of individuals and the public [4]. Translational science is the field of investigation focused on understanding the scientific and operational principles underlying each step of the translational process [4]. Therefore, research within translational science involves a bidirectional process that moves among basic, clinical, practice, population, and policy-based research and requires multidisciplinary team. Across different fields, there are a variety of models that depict the phases of the translational research process, ranging from two to five stages [5,6]. For example, the National Institutes of Health (NIH) describes translational research in two defined stages, defining T1 as "*the process of applying discoveries generated during research in the laboratory, and in preclinical studies, to the development of trials and studies in humans*" and T2 as "*the research aimed at enhancing the adoption of best practices in the community*." Others have described the translation spectrum in more distinct phases, including T1−T3 [6,7], T1−T4 [8], and T0−T4 [9,10] descriptions of translation. Table 6.1 provides an overview of the T0−T4 translational research phases along with examples of nutrition research associated with each phase. In this five-stage model, T0−T2 involves the translation of basic science to human studies while T3−T4 addresses the translation of new information into the clinic and community. Regardless of operationalization challenges related to defining the stages of translational research process, there is broad acceptance and agreement on the importance of translational research. Furthermore, the overarching concept of translational research is consistent.

Being aware of differences in taxonomy across prominent models of translation research is key to promoting effective communication of translation research concepts within a multidisciplinary team. In this chapter, the T0−T4 descriptors and research phases, as illustrated in Table 6.1, will be used.

This chapter provides an overview of key concepts, methods, and trial types in translational research. The primary purpose of this chapter is to focus on the later phases of translational research, or the translation of research aimed at the promotion and the adoption of the

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00006-0

TABLE 6.1 Translational Research Phases, Example Types of Research, and Sample Research Questions

Research Phase	Example Types of Research	Sample Research Question
T0: Basic and applied science research	Defining mechanisms and targets: basic research, animal research, preclinical and preintervention studies	What are the mechanistic actions of carbohydrate sources on liver and pancreatic tissues in an experimental rat model?
T1: Translation to humans	Discovery of application to human health: proof of concept, early stage human clinical trials	What are the mechanistic actions of ingested carbohydrate sources on liver and pancreatic tissues in humans?
T2: Translational to patients	Discovery of application to clinical settings: later stage human clinical trials, efficacy studies, controlled observational studies, clinical guidelines	What is the effect of regulating the amount of carbohydrate sources among prediabetic subjects in a highly controlled clinical research setting?
T3: Translation to practice	Health application of evidence-based practice guidelines and practice guidelines to health practice: effectiveness research, CER, D&I research, health services research	What is the relative effect on diabetic risk factors (e.g., A1c, fasting glucose, weight) among prediabetic patients in free-living conditions when randomized to a 6-month diet which regulates carbohydrates versus a 6-month usual diet comparison condition?
T4: Translation to community	Health application of practice to population health impact: D&I research, scale-up and spread research, population health impact	What is the degree to which nutrition professionals in community health clinics can adopt, implement, and maintain an evidence-based program to encourage healthy carbohydrate modifications among at-risk clients?

best evidence-based practices into real-world clinical and community settings. Specifically, this chapter concentrates on concepts and application of dissemination and implementation (D&I), an emerging and critical field of research [3]. Dissemination research is defined as an active research approach of spreading evidence-based interventions to a targeted audience via determined channels using planned strategies and examining the success of this dissemination. Implementation research is the process of putting to use or integrating evidence-based interventions within a setting and examining whether the interventions are put into place as designed and thus focusing on the adoption or uptake of clinical interventions by providers and/or systems of care. This chapter will emphasize methodological considerations and illustrates common models and measures used in D&I research. Illustrated research concepts and resources are relevant for nutrition researchers and practitioners.

II KEY CONCEPTS IN TRANSLATIONAL RESEARCH

An overview of key terms and definitions relevant to translational research is presented in Table 6.2. First, it is important to define and understand internal and external validities. Internal validity refers to the degree to which study bias is minimized and a causal relationship of the treatment/clinical intervention within a study sample can be estimated [11]. When considering internal validity, the focus is on eliminating confounding variables so that a cause and effect relationship can be established between independent and dependent variables. Alternatively, external validity refers to the degree to which research findings from a study can be generalized to other populations and settings [11]. External validity is focused on conducting the research with a study population that represents the target audience and in more realistic settings where control variables are not artificially contrived. While both forms of validity are important throughout the spectrum of translational research process, more emphasis is generally placed on internal validity in the earlier stages and on external validity in the later phases. Notably, these forms of validity are not all-or-none or black-and-white, and they can vary widely along the research continuum. Researchers and practitioners need to carefully consider and be transparent in reporting the methodological factors that influence both the internal and external validity of research findings.

Second, application of translational research concepts demands awareness of the types of research associated with the different stages in translation research process. Across the T0–T4 spectrum, there are distinct types of research at each stage: preintervention research (T0/T1); efficacy research (T2); effectiveness research (T3); D&I research (T3/T4) [3]; and scale-up and spread research (T4) [3,12].

TABLE 6.2 Key Concepts, Methods, and Trial Types in Translational Research

Term	Definition
Internal validity [11]	The degree to which study bias is minimized and a causal relationship of the treatment/clinical intervention within a study sample can be estimated.
	Example: *Can effect sizes from a randomized-controlled weight loss study (e.g., magnitude of weight change between a treatment group and control group) be determined, while minimizing confounding variable?*
External validity [11]	The degree to which research findings from a study can be generalized to other populations and settings.
	Example: *Can the effects from a weight loss study be generalized to real-world practice settings (e.g., health care clinic, community center), and diverse participants (e.g., minorities, low health literate)?*
Preintervention research	Research that is done in a controlled laboratory setting, typically using nonhuman subjects. The focus is on understanding the cellular and molecular mechanisms that underlie a disease or disease process.
	Example: *Is there an observed relationship between variables?* (T0/T1)
Efficacy research	Highly controlled clinical research that is primarily concerned with internal validity. Threats to causal inference are typically reduced by using homogeneous samples/settings and controlling intervention parameters. The primary outcome measures target individuals and are usually symptom specific.
	Example: *Does the treatment work under optimal conditions?* (T2)
Effectiveness research	Clinical or community research that is primarily concerned with external validity. Threats to generalizability are typically reduced by using heterogeneous samples in "real-world" and diverse study locations. The main outcomes can be broad, ranging from clinical to other individual and organizational-level outcomes (e.g., quality of life, costs).
	Example: *Does the treatment work under real-world conditions?* (T3)
Dissemination research [3]	An active research approach of spreading evidence-based interventions to a targeted audience via determined channels using planned strategies and examining the success of this dissemination. The main outcomes may target individuals and/or organizations, such as awareness, receipt, acceptance, and use of information.
	Example: *Can the treatment be diffused to and engage the targeted users?* (T3/T4)
Implementation research [3]	The process of putting to use or integrating evidence-based interventions within a setting and examining whether the interventions are put into place as designed. Implementation research is focused on the adoption or uptake of clinical interventions by providers and/or systems of care, with primary outcomes such as levels and rates of adoption, fidelity, implementation costs, and sustainability.
	Example: *Can the treatment be adopted by providers and systems?* (T3/T4)
Scale-up and spread research [3,12]	"Deliberate efforts to increase the impact of health service innovations successfully tested in pilot or experimental projects so as to benefit more people and to foster policy and program development on a lasting basis." The main outcomes are similar to D&I outcomes, but typically at national and international levels.
	Example: *Can the treatment be adopted and maintained by a practice-based reach network, for long-term, lasting impact?* (T4)
Hybrid type trial [13]	A study design that takes an a priori focus in the dual assessment of clinical effectiveness and implementation. Hybrid designs can typically take one of three approaches: (1) testing effects of a clinical intervention on relevant outcomes while observing and gathering information on implementation; (2) dual testing of clinical and implementation interventions/strategies; (3) testing of an implementation strategy while observing and gathering information on the clinical intervention's impact on relevant outcomes.
PCTs [3,14,15]	Clinical trials for which the hypothesis and study design are developed specifically to answer the questions faced by decision-makers are called PCTs. The characteristic features of PCTs include: (a) select clinically relevant alternative interventions to compare, (b) include a diverse population of study participants, (c) recruit participants from heterogeneous practice settings, and (d) collect data on a broad range of health outcomes.
CER [16–19]	The conduct and synthesis of research comparing the benefits and harms of different interventions and strategies to prevent, diagnose, treat, and monitor health conditions in real-world settings.

Source: Reprinted from J. Zoellner, L. VanHorn, P. Gleason, C.J. Boushey, What is translational research? Concepts and application in nutrition and dietetics, J. Acad. Nutr. Diet., 115 (7) (2015) 1057–1071, with permission from Elsevier.

This progression is shown through the advancement of the sample questions in Tables 6.1 and 6.2: "*Is there an observed relationship between variables?*" (T0/T1) to "*Can the treatment be adopted and maintained by a practice-based reach network, for long-term, lasting impact?*" (T4). These questions illustrate the progression of research inquiry, as well as diversity of trial types and outcomes demanded in translational research.

Third, and of particular relevance to the T3−T4 phases of translational research, recent emphasis has been placed on hybrid type trials [13], pragmatic or practical clinical trials (PCTs) [3,14,15], and comparative effectiveness research (CER) [16−19]. With a focus on efficiency, the primary intent of hybrid type trials is to accelerate the timeline from efficacy trials to public health practices and impact [13]. Hybrid designs blend the study design and methodological elements to dually consider components of both clinical effectiveness and implementation research. There are several contrasting design features between clinical effectiveness and implementation research studies. For example, clinical effectiveness trials typically test the clinical intervention with the unit of randomization and unit of analysis at the patient or clinical unit level. The primary focus is usually on health outcomes with intermediate measures related to process/quality measures typically considered as intermediate. In contrast, implementation trials test an implementation intervention strategy with the unit of randomization and unit of analysis at the provider, clinical unit, or system level. Primary outcomes are usually focused on both the adoption and uptake of the clinical intervention as well as process/quality measures. To address challenges in linking clinical and implementation research designs, Curran and colleagues provide detail of three different hybrid designs [13]. The first design, a hybrid trial type 1, has a primary aim of testing clinical effectiveness on relevant patient-level outcomes and secondary aim relevant to understanding the intervention context and to gathering information about factors that influence implementation processes. The second design, a hybrid trial type 2, equally weights effectiveness and implementation; therefore, there are coprimary aims of simultaneously testing effects of a clinical intervention and feasibility testing of implementation strategies. Finally, a hybrid trial type 3 has a primary aim of testing an implementation strategy and secondary aim of examining the relevant clinical outcomes associated with the implementation trial. Applying hybrid designs require attention to the complexities and balance of internal and external validities and collaboration among a multidisciplinary team [13]. Hybrid designs have been used in nutrition-related studies; notable examples include (1) a two-arm randomized-controlled trial (RCT) hybrid type 1 trial with a primary aim to examine the effects of a behavioral intervention to reduce sugar-sweetened beverage consumption in rural Appalachia [20], (2) a three-arm RCT hybrid type 2 trial with coprimary aims to examine reach, effectiveness, adoption, and cost of the adapted Diabetes Prevention Program (DPP) in a clinical setting [21], and (3) a nonrandomized hybrid type 3 trial with a primary aim to assess implementation of the DPP in three Veterans Affairs (VA) medical centers [22]. The hybrid type 3 trial is further illustrated in Section VI, Examples from the Literature.

PCTs have also gained prominence in the research literature [3,14,15]. PCTs support the clear goal of D&I scholars to shift the research paradigm from a concentrated focus on highly controlled efficacy trials to emphasis on systems and pragmatic approaches [23]. In contrast to efficacy research aimed at testing research questions in optimal conditions, PCTs are designed to answer questions faced by stakeholders and decision-makers in real-world settings, thereby maximizing the external validity of research findings [3,14,15]. By designing research trials with practice needs in mind, PCTs can speed up the translational research findings and accelerate integration into practice and policy [14]. As detailed in Table 6.2, there are a number of notable characteristics and design features of PCTs, including selection of a clinically relevant comparison intervention, inclusion of diverse study participants selected from a variety of practice settings, and assessment measures across a broad range of outcomes. These outcomes should include traditional outcomes, such as changes in patient-level health outcome (e.g., clinical end point, patient reported health behavior and/or psychosocial issue, mortality, and morbidity) as well as outcomes related to quality of life, implementation factors (e.g., costs, fidelity, characteristics of delivery agents, needs of health-care delivery system), and satisfaction (e.g., patient, staff/clinician, organizational decision-makers).

Many of the methodological concepts of PCTs are also relevant when considering CER. While there are a variety of definitions of CER [16−19], one of the most widely accepted is "the conduct and synthesis of research comparing the benefits and harms of different interventions and strategies to prevent, diagnose, treat and monitor health conditions in real-world conditions" [19]. Although CER has historically dominated the biomedical and pharmacological research (i.e., comparison of two different therapeutic options), there has been more recent emphasis on expanding CER to clinical preventative services, behavioral interventions, and public health services delivery systems. One key element of a PCT is selection of a clinically relevant comparison intervention. Historically, when studying research questions related to the efficacy and effectiveness of treatment and intervention options, a placebo, usual care, or noncontact control is used. However, these comparisons are rarely relevant for practice. By definition, CER refers to research that

compares the outcomes of two or more real-world health-care strategies or intervention options that have already been shown to be efficacious. Like PCTs, the intent of CER is to assist patients and community members, clinicians, and stakeholders to make shared decisions on treatment options. A key element of CER is that results inform real-world decision and that they are practical or pragmatic [24]. CER has been used to assess nutrition-related research, including (1) comparison of a counselor-delivered versus web-based-delivered coronary heart disease lifestyle and medication intervention [25,26] and (2) a retrospective cohort study to compare the effectiveness of laparoscopic Roux-en-Y gastric bypass and laparoscopic adjustable gastric banding on weight, adverse health outcomes, and subsequent intervention [27].

Distinguishing among these key concepts, methods, and trial types in translational research is a prerequisite for choosing and applying an appropriate D&I framework. Fortunately, there are a variety of available frameworks to guide the D&I research of nutrition professionals [28].

III COMMON FRAMEWORKS IN D&I RESEARCH

The translation of a discovery into clinical and/or community settings requires that organizations and/or systems change their behaviors by engaging in new organizational practices that permit the adoption, execution, and maintenance of the innovation. Therefore, as with research targeting individual behaviors, there are theories, frameworks, and models. The term "frameworks" will be used in the remainder of this chapter when talking about theories, frameworks, and models that provide researchers and practitioners with theoretical guidance when conducting translational research. These frameworks are most notable in D&I research and attend to the development of motivations and skills needed to adopt, execute, and maintain the innovation at staff and organizational levels. These frameworks guide the development, execution, evaluation, and synthesis of D&I research.

There are numerous D&I frameworks available from which nutrition researchers and practitioners can select; Tabak and colleagues identified 61 different frameworks [28]. While many of these frameworks consist of overlapping constructs, each posits different views of how health-related innovations are disseminated and implemented; focuses on a specific aspect of D&I research; and/or views different potential end goals of D&I research. To add to this complexity, due to these frameworks developing within specific fields, there is a lack of standardized terminology within the frameworks [29], which means that a single construct may have different names across theories. To make the landscape less complicated, D&I scholars have compiled terminology [29] and constructs [30] across frameworks to help standardize language. Other D&I scholars have compiled, organized, and compared frameworks [28,31] to aid nutrition and health professionals and researchers in identifying the framework that is best suited for a given project or research study. Table 6.3 provides a description of six commonly used D&I frameworks and the following section describes their development, focus, and key constructs [29]. Examples of nutrition-related studies that have applied the different frameworks are also included.

A Diffusion of Innovations

Developed by Rogers in the early 1960s as a way to describe how new agricultural innovations spread, Diffusion of Innovations focuses solely on constructs related to dissemination and addresses both individual and organizational levels [28]. Specifically, it provides a framework for understanding how an innovation (i.e., "an idea practice or object that is perceived as new by an individual or other unit of adoption" [32]) is diffused, or "communicated through certain channels over among the members of a social system" [32]. Diffusion of Innovation's constructs are broad, which allow nutrition researchers and practitioners more flexibility when applying the framework [28]. This framework consists of four overarching elements: *attributes of the innovation*, *communication*, *time*, and *social systems*. *Attributes of the innovation* are its perceived characteristics relating to relative advantage (i.e., how much better is the innovation to what it would replace); compatibility (i.e., how consistent the innovation is with experiences and needs of the potential adopters); complexity (i.e., the perception of how difficult the intervention is to understand and use); trialability (i.e., the "degree to which the innovation may be experimented with on a limited basis" [32] before deciding to fully commit to the innovation); and observability (i.e., how visible the results are to others). The *communication* element is concerned with the communication channels, particularly whether the traits of the individuals or organizations communicating are homophilic (similar) or heterophilic (different). The element of *time* addresses the decision-adoption process and rate of adoption. This element provides a way to describe the different groups of adopters. Finally, the *social system* is concerned with how the different members and structures within the system work to influence the innovation adoption. Within the field of nutrition, Diffusion of Innovations has been used to describe the dissemination and/or the use of nutrition education curricula in New York state's secondary schools [37] and Vermont elementary schools [38].

TABLE 6.3 Descriptions of Example D&I Frameworks

Framework	Year Developed	Field of Origin	D&I Focus[a]	Key Constructs
Diffusion of Innovations [32]	1960s	Rural sociology	D	Attributes of the innovation
				Communication
				Time
				Social systems
RE-AIM [33]	1999	Health promotion	D = I	Reach
				Effectiveness
				Adoption
				Implementation
				Maintenance
PARIHS [34]	2004	Nursing	I	Evidence
				Context
				Facilitation
PRISM [35]	2008	Health care	I > D	Perspectives of the intervention
				Characteristics of the recipients
				Implementation and sustainability infrastructure
				External environment
ISF [36]	2008	Violence prevention	D = I	Prevention synthesis and translation system
				Prevention support system
				Prevention delivery system
CFIR [30]	2009	Health promotion	I	Intervention characteristics
				Inner setting
				Outer setting
				Characteristics of individuals
				Process of implementation

[a]*Focus on D&I spectrum based on Tabak and colleagues' rating [28].*
D, dissemination only; *D = I*, equal focus on D&I; *I > D*, greater focus on implementation; *I*, implementation only.

B RE-AIM Framework

The RE-AIM framework, developed by Glasgow and colleagues [33], was specifically designed to provide a structure to develop, conduct, and report on studies of health innovations that address both internal (related to efficacy) and external (related to generalizability) validities. As such, RE-AIM seeks to move beyond the pervading efficacy-based research evaluation paradigm toward a research paradigm that provides better evidence to assess the population-level impact of health-related innovations in real-world settings. Equally focusing on D&I, RE-AIM can be used at the individual, community, and organizational levels of the socioecological model [28]. RE-AIM gets its name from its five well-defined and readily operationalizable constructs:

- *Reach*: the proportion of the target population that participates in the assessment of the innovation and how that population reflects the local population;
- *Effectiveness*: ability of the innovation to change behaviors, mediators, and anthropometrics in the desired direction;
- *Adoption*: where and who take on the program;
- *Implementation*: how the intervention is delivered, including proportion of activities completed, fidelity, and cost;
- *Maintenance*: extent to which the program and its effects are maintained over time.

The RE-AIM framework is widely used in nutrition and other health fields. A total of 370 articles that have used the framework have been identified, including 8 nutrition interventions and 58 physical activity interventions [39]. Nutrition interventions that have used RE-AIM to guide their evaluation and reporting include Huye and colleagues' nutrition intervention for adults in the lower Mississippi Delta [40] and Toobert and colleagues' clinical trial exploring the impacts of the Mediterranean Lifestyle Program on Type 2 Diabetes [41].

C Promoting Action on Research Implementation in Health Services

Developed by researchers and practitioners at the Royal College of Nursing to provide a framework to support the delivery of evidence-based nursing practices, promoting action on research implementation in health services (PARIHS) posits that the dynamic relationships among *evidence*, *context*, and *facilitation* drive the successful implementation of effective, evidence-based practices [34]. When all these factors are "high," implementation success is theorized to be more likely. *Evidence* involves data from multiple sources, including effectiveness research, clinical experience, and patient satisfaction. Evidence is high when the data from the various sources are aligned (i.e., effective program, positive clinical experiences, and high patient satisfaction). *Context*—described as the environment in which the innovation will be received or implemented—impacts whether or not the environment is supportive of the innovation and includes three themes: culture, leadership, and evaluation. *Facilitation* is the process that makes implementing the innovation easier and involves a facilitator with a purpose, role, and skills/attributes. PARIHS can be used at the individual, organizational, and community levels of the socioecological model [28]. Relevant to nutrition research, Perry and colleagues [42] applied PARIHS in their qualitative examination of factors needed to improve nutrition and hydration practices within a residential care center.

D Practical, Robust Implementation, and Sustainability Model

Practical, Robust Implementation, and Sustainability Model (PRISM), which has a larger emphasis on implementation than dissemination [28], was developed to provide both a practical and robust conceptual framework to improve the translation of innovations within health-care settings into practice [35]. This framework builds from four existing and well-tested frameworks, including Diffusion of Innovations [32] and RE-AIM [33]. This model posits that *perspectives of the intervention* interact with the *characteristics of the recipients* at both the organizational and patient levels. This interaction is then influenced by the *implementation and sustainability infrastructure* and *external environment*. Taken together these four domains (and their subelements) impact outcomes related to adoption, implementation, and maintenance at organizational level, and reach and effectiveness at the patient-level. The model proposes these domains as "leverage points" that can be acted on to support or improve implementation. PRISM is often used within health-care settings, and an example of its application relevant to nutrition is Liles and colleagues' [43] qualitative exploration of the facilitators and barriers to the implementation of a colorectal screening outreach program within a large health-care organization.

E Interactive Systems Framework

With roots in the violence prevention field, Interactive Systems Framework (ISF) was developed to address the "how to" gap that prevents effective innovations tested in research trials from being well-implemented in real-world settings and having a greater population health impact [36,44]. This framework—which equally focuses on D&I and can be applied to the individual, organization, community, and systems levels of the socioecological model [28]—presents an approach to address key challenges that prevent evidence-based programs from being implemented by building capacity at two levels: specific (e.g., directly related to the delivery of the program) and general (e.g., more transferable) [36]. To do this, ISF posits that three systems must act together to allow an evidence-based program to be successfully disseminated and implemented into a real-world setting. The *Prevention Synthesis and Translation System* synthesizes and translates information about innovations and distills it into understandable and actionable information that can be used by (potential) delivery agents. The *Prevention Support System* builds specific and general capacity (i.e., the ability, skills, and motivations to conduct and sustain prevention work at the individual, organization, and systems level) to conduct the prevention activities. The *Prevention Delivery System* facilitates the actual delivery activities necessary to implement the innovation (e.g., recruiting participants, conducting education sessions). ISF rejects a top-down approach and requires stakeholders across levels (e.g., researchers, managers, delivery agents) to be involved in each of the three systems. Leading D&I scholars view the ISF framework as integrating many of the concepts found across other D&I frameworks [45]. While ISF has been used to support and/or explore the D&I of health innovations, there are no known published studies using the framework in the context of nutrition (as of mid-2016). However, there are a few relevant

studies that are currently ongoing, such as Zoellner and colleagues' use of ISF to support the D&I of an effective intervention to reduce sugar-sweetened beverage intake into Appalachian communities through the Virginia Department of Health [46].

F The Consolidated Framework for Dissemination Research

Developed by US Veteran Health Administration researchers [30], Consolidated Framework for Implementation Research (CFIR) is a meta-theoretical framework that brings together constructs from the 19 established implementation frameworks. CFIR does not depict relationships between constructs; it provides an overarching typography that allows researchers and practitioners to identify relevant constructs. CFIR—which addresses only implementation and provides constructs that can be readily operationalized at the organizational and community levels of the socioecological model [28]—consists of 37 constructs that are organized into five domains. Constructs within the first domain, *intervention characteristics*, address the core and peripheral attributes of the innovation, including intervention source, complexity, design quality and packaging, and cost. Constructs relevant to the context that surrounds the innovation's implementation are found in two domains: *inner setting* (i.e., the immediate organization context) and *outer setting* (i.e., the external economic, political, and cultural contexts). The line between these domains is dynamic and may not always be clear. The domain *characteristics of individuals* houses five constructs related to traits of the agents within the implementation process. The fifth domain focuses on constructs that relate to the *processes* of implementation, including planning, engagement, execution, and evaluation; processes "may be formally planned or spontaneous, conscious or subconscious; linear or non-linear" [30]. While CFIR is relatively new, it has been used in 359 studies looking at health innovations [47]. Related to nutrition, CFIR has been applied in research to define next steps for nutrition research at the molecular to population levels [48]; to develop a web-based clinical decision-support system for dental hygienists that would allow for chairside primary care screening, including screening for dietary risk factors for dental caries risk [49]; and to understand stakeholder experiences implementing a weight management program for veterans [50].

Identifying a D&I framework, along with the identification of the appropriate trial type for the stage of translational research, forms the foundation for the conduct of translational research. While these six D&I frameworks are not an exhaustive reflection of those available [28], they provide indication of construct overlap and differences across frameworks. Consideration of the trial type and framework will guide the selection of D&I research methodology, including the study design.

IV COMMON STUDY DESIGNS AND APPROACHES IN D&I RESEARCH

Previous chapters in this book detail important concepts and methodology related to the design and evaluation of nutrition interventions. These prior chapters primarily focus on the opportunities and challenges when evaluating efficacy and effectiveness, focus on internal validity, and highlight the value of RCTs. Indeed, the hierarchy of research evidence clearly posits RCTs as the most robust and strongest level of evidence in efficacy and effectiveness research trials [51]. However, as described in Tables 6.1 and 6.2, research questions in translational research often move beyond by only evaluating effectiveness. Therefore, an RCT design may not always be the most appropriate design, nor the design that can provide the best evidence to address the important questions posed by organizational- and systems-level stakeholders [52,53]. Likewise, D&I research addressing complex public health problems may not be suited to RCT, due to less-controlled settings and demand for pragmatic approaches [54]. This challenge is evidenced in the D&I field, as the emerging frameworks demand new perspectives for study designs that are both appropriate and rigorous to address D&I research questions. As such, several D&I scholars have challenged the notion that RCTs are the gold standard of D&I research and have encouraged broader use and acceptance of novel randomization techniques, quasi-experimental studies, and natural experiments. Table 6.4 illustrates several research designs that are valued in the D&I field and have also been shown to provide compelling evidence in the translational research process.

Stepped-wedge design and randomized encouragement trials are two examples of novel randomized designs that offer alternatives to the traditional parallel RCT [55,56]. In both of these designs, randomization can occur at the individual level, but is often used when individual randomization is not desired or possible. As such, randomization typically occurs at the group or setting level (i.e., cluster). In the stepped-wedge design, an intervention is rolled-out sequentially to the participants (either as individuals or clusters) over several time periods or "steps," and the order in which they receive the intervention is random [55]. In this design, more clusters receive the intervention toward the end of the study, relative to the earlier stages. By the end of the study all individuals will

TABLE 6.4 Examples of Research Study Designs for the D&I Phases of Translational Research

Study Design	Design Features
Randomized Designs	
Stepped-wedged design [55,56]	The intervention is rolled-out sequentially to the participants over several time periods. Individuals are randomized to the order in which they receive the intervention. By the end of the study, all individuals will have received the intervention. Data collection points are incorporated each time period where a new group (step) gets the intervention. Intervention effects are assessed by comparing data points of participants in the control section of the wedge with participants in the intervention section. This design can also be applied to clusters of individuals.
Randomized encouragement trial [56]	This design encourages study participants randomized to the intervention condition to participate in the intervention or to choose among specifically defined intervention components from a menu of options. Control participants are not offered the intervention nor encouraged to participate. This design can include randomization at individual level or higher, and is often used to mimic the delivery of preventive services in real-world settings.
Quasi-Experimental Designs or Nonrandomized Design With or Without Controls	
Pre–post [11,56]	Measures variables at a single point before the intervention begins and at a single point after the intervention. In this design, there may or may not be a control or comparison group.
Interrupted time series [11,56,57]	Consecutive observations are measured and interrupted at a specific point in which the intervention, service, or policy will occur. These consecutive observations are made before, during, and after implementation of the intervention. Effects are assessed by examining fluctuations in the slope or level of the series following the intervention implementation.
Multiple baseline [56]	This design is a form of an interrupted time series design. Numerous intervention components can be initiated at the onset of the study, and then components are selectively removed to understand which ones are most effective. Alternatively, components can be consecutively added until the intervention has achieved the desired effect. This design provides the ability to study different components of the intervention, in contrast to designs that only allow evaluation of a whole intervention package.
Regression discontinuity design [12,56]	Rather than random assignment, this design involves assigning individuals to the intervention and comparison conditions based on cut-point scores for the targeted variable. This design can be applied to groups, and can also include two or more intervention conditions. Intervention effects are assessed by studying the regression line, and examining if the intervention groups' regression line is discontinuous from the comparison group.
Natural Experiments [52,53]	
	Natural experiments typically involve situations where an intervention cannot be manipulated by the researcher. This can involve the study of existing or newly developing programs or policies in naturally occurring situations. Nonexperimental and quasi-experimental designs can both be used to study natural experiments.

Source: Reprinted from J. Zoellner, L. VanHorn, P. Gleason, C.J. Boushey, What is translational research? Concepts and application in nutrition and dietetics, J. Acad. Nutr. Diet., 115 (7) (2015) 1057–1071, with permission from Elsevier.

have been exposed to the intervention. Data collection points are incorporated in each time period where a new group or "step" gets the intervention. Reviews on stepped-wedge designs illustrate the breadth of these studies across diverse disease conditions, health service delivery, social policy, and criminal justice areas [55,58,59]. Two examples of a stepped-wedge randomized-controlled design include a multiple behavior healthy lifestyle intervention for clients attending a residential substance abuse treatment [60] and an intervention to improve cardiovascular disease prevention and care for high-risk patients in primary care settings [61]. While randomized encouragement trials are distinct from stepped-wedge design, they are also often used to mimic the delivery of preventive services in real-world settings [56].

A quasi-experimental study lacks random assignment. With respect to internal validity, quasi-experimental studies are often viewed as inferior to randomized experiments. However, quasi-experimental designs have obvious value when conducting research in the context of real-world practice- and community-based settings, where external validity is equally valued. While not an exhaustive list, features of four quasi-experimental designs including pre–post [11,56], interrupted time series [11,56,57], multiple baseline [56], and regression discontinuity [12,56] designs are illustrated in Table 6.4.

To further illustrate the interrupted time series, consecutive observations are measured and interrupted at a specific point in which the intervention, service, or policy will occur. These observations are made before, during, and after implementation and effects are assessed by examining fluctuations in the slope or level of the series following implementation. A few examples of interrupted time series designs include nutrition labeling provided at the point of selection [62] and pay for performance incentives on the quality of primary care and outcomes among hypertensive patients [63].

Additionally, the value of natural experiment cannot be discounted when conducting D&I research [52,53]. Natural experiments involve situations where exposure to the experimental and control condition are determined by factors outside the control of the researchers. When examining existing or newly developing programs or policies in naturally occurring situations, natural experiments can be of immense value and can include both nonexperimental and quasi-experimental designs. A recent systematic review of natural experiments in the context of obesity-related outcomes highlight the strengths and limitations of policy and built environmental changes on body mass index, diet, and physical activity outcomes [64]. The demand and value of rigorously evaluated natural experiments are increasingly being recognized among policy makers, D&I scholars, and funding agencies.

In addition to considering the study designs illustrated in Table 6.4, the use of participatory research approaches are often necessitated when conducting D&I research [65–67]. Given that stakeholder involvement is at the core of translational research efforts [68], participatory research tactics are needed to engage and promote trusted collaboration among diverse stakeholders, health-care professionals, and multidisciplinary academic researchers. Community-based participatory research (CBPR) [65], practice-based research networks (PBRNs) [66], and systems science methods [67] are all examples of participatory research approaches. CBPR is an important approach to develop and execute health interventions among marginalized populations, and a key strategy to translate research into practice to help reduce health disparities [69–71]. Effective CBPR initiatives use the collective knowledge, expertise, and resources gained through community-academic partnerships to develop and execute culturally-effective interventions, as prioritized by the community [72–74]. The CBPR approach is designed to ensure community participation in all aspects of the research process and build equitable community-academic partnerships [69]. Gaining trust in vulnerable communities and promoting intervention program sustainability have been noted as essential elements of CBPR [65]. PBRN refer to the collaboration of a group of clinicians and/or practices to address practice- and community-based health-care questions. A primary goal of PBRNs is to provide capacity building activities and to engage clinicians in the translation of evidence-based findings into primary care practices. These PBRNs can be at the regional, state, local, or national levels. Examples of collaborating institutions can include, but are not limited to, academic medical centers, individual group practices, Federally Qualified Health Center, local or regional hospitals, and community health centers [66]. Systems science methods take into account the complex and dynamic nature of public health relevant to D&I research because interactions are occurring among multiple levels within a system and across systems [67]. One description of systems science within health-care or public health settings describes vertical and horizontal components that may interact to translate an evidence-based intervention into practice [75]. Vertical components of a systems-based approach can be operationalized from a municipal, regional, state, and federal level, and can also include the involvement of both the staff and organizational decision-makers in the development, implementation, and testing processes. Horizontal components of a systems-based approach include the engagement of several sectors within a local region that can aid in the implementation and maintenance of evidence-based interventions [75]. Systems science approaches typically include social network analysis, agent-based modeling, and systems dynamics [3,67].

Similar to the use of participatory research approaches, mixed-methods research designs are common in D&I research [76,77]. Mixed-methods research designs combine the strengths of both quantitative and qualitative methods in a single inquiry, to gain a more complete perspective [76,77]. While a complete description of mixed-methods research designs are beyond the scope of this chapter, there are a variety of mixed-methods research designs (e.g., convergent parallel, explanatory sequential, exploratory sequential, embedded, transformative, multiphase) that have relevance to answering research questions that examine the translation of evidence-based practices in real-world clinical and community settings. Conducting complex and multilevel D&I interventions and evaluations requires close considerations for the trade-offs in study designs and must be considered concurrently when selecting appropriate D&I measures.

V MEASURES IN D&I

As D&I research simultaneously assesses different types of outcomes that address aspects of the D&I process and of the innovation's effectiveness [78], there is a diversity of quantitative and qualitative measures to assess D&I outcomes. Related to the D&I process, dissemination (e.g., reach) [78] and implementation

(e.g., fidelity, acceptability, penetration, cost) [78,79] outcomes are assessed as well as characteristics of the service system through which the innovation is being disseminated and implemented (e.g., organizational capacity, organizational behavior, policy adoption) [80]. Table 6.5 highlights how constructs within different D&I-focused outcomes have been measured. Related to intervention effectiveness, D&I outcomes relate to an individual (e.g., behavior change, anthropometrics) [79] and/or population (e.g., population-wide consumption patterns, disease incidence) health. Additionally, D&I researchers are often interested in interrelationships between D&I and effectiveness outcomes (e.g., *how does implementation impact individual outcomes?* and *what is the cost-effectiveness of the intervention?*) [78]. To measure these outcomes, D&I researchers use quantitative and/or qualitative approaches.

Quantitative measures produce numerical data about the outcome or framework construct in question. Records of material, personnel, and travel expenses may be kept to determine implementation costs. To assess reach, tallies of the numbers and characteristics of potential participants approached may be kept and compared to those joined the intervention. Checklists, including items such as proportion of material delivered, concepts covered, and rating of delivery, are often used to measure implementation fidelity. Surveys and questionnaires can be used to assess well-defined constructs, such as organizational climate.

Within D&I research, qualitative measures are used both to assess outcomes and to inform the development or

TABLE 6.5 Example Measures by General Constructs Across D&I Outcome Levels

Outcome	Sample Construct Measured	Construct Description	Types of Measures	Example of Construct Assessment in Literature
Dissemination	Reach	Total number, proportion, and representativeness of individuals who participate in a given initiative	Tracking forms	Determining the reach of a multilevel community intervention with a media component to reduce childhood obesity [81]
Implementation	Fidelity	Integrity of how the initiative was delivered, e.g., delivered as intended, adherence to protocols	Checklists, observations	Using a fidelity checklist to completion of a nutrition education curriculum delivered by teachers [82,83]
	Acceptability	Perceptions of participants that the initiative met their needs and/or perceptions of organizational stakeholders that the initiative fits within their system	Surveys, interviews	Determining participant satisfaction with a community-based intervention to reduce sugary beverage intake [84]
	Penetration	Who participates and how often, at the participant and/or provider levels	Tracking forms, surveys, interviews	Assessing the uptake of standard terminology and definitions for texture modified foods and fluids [85]
	Cost	Financial resources needed to deliver the intervention, including recruitment, implementation, and maintenance and how those costs are reflected in changes in other outcomes, such as health	Tracking forms	Determining the cost-effectiveness of a physical activity intervention for older adults [86]
Service system	Organizational capacity	Existing knowledge, skills, and infrastructure within an organization that gives it the ability to deliver services	Surveys, observations, focus groups, interviews	Assessing the organizational capacity of public health organizations to deliver chronic disease prevention programs [87]
	Organizational behavior	How an organization responds to a specific initiative	Record reviews, surveys, observations, interviews	Tracking changes in school cafeteria food purchasing following an intervention [88]

refinement (e.g., cultural adaptations) of D&I strategies. Qualitative measures are able to explore aspects of D&I constructs that may not be directly captured through quantitative measures. Additionally, qualitative measures can elucidate information that might not be readily known or previously considered by a researcher (e.g., specific organizational norms). Focus group and interview protocols, observation notes, and analysis of process artifacts (e.g., meeting minutes, brainstorming sheets) are commonly used qualitative measures. As one example, the CFIR guide provides a list of possible interview or focus group questions for all constructs within the framework as well as templates for observations and meeting notes [47]. Often, qualitative measures are used in tandem with quantitative measures to provide more robust data [76,77].

Unfortunately, the progress of D&I research is being somewhat slowed by conceptual and practical barriers to measuring outcomes that extend beyond the innate complexity of the field [89]. Martinez and colleagues have identified six instrumentation issues: (1) growing number of frameworks and lack of standardization of constructs among frameworks; (2) lack of reporting of measuring of psychometric properties; (3) use of home-grown and adapted instruments; (4) not choosing the most appropriate evaluation method and framework; (5) lack of pragmatic measures; and (6) few decision-making tools [89]. These issues have arisen due to some of the characteristics of D&I research. First, D&I research is relatively new and is spread across specific content fields (e.g., violence prevention, nursing, health care). As researchers within and across fields arrive at solutions to address gaps in knowledge, this knowledge is not always efficiently shared within and across fields. Next, there is often a need for measures, such as fidelity checklists and satisfaction surveys, to reflect specific content of a D&I project. Lastly, existing measures may need to be practically adapted to meet the needs of the target population (e.g., translation for non-English speaking populations) and the needs of the organization providing the intervention (e.g., adapting measures to be conducted over the phone or via the Internet instead of in-person when the population to be served is highly spread out, such as in a rural area) [14].

The measurement challenges, mentioned previously, should not deter interested nutrition researchers and practitioners from engaging in translational and D&I research. Rather, they provide opportunity for interested stakeholders to thoughtfully approach the selection and measurement of D&I outcomes. Notably, the field is undertaking many of the recommendations laid out by Martinez and colleagues [89] as ways to address these measurement issues and make them available to others researchers and stakeholders. For example, in efforts to harmonize framework constructs, D&I scholars are cross referencing theory constructs related to diffusion [90], adoption [80,91], and implementation [30,31]. Additionally, efforts are ongoing to consolidate the measures. A working group of 23 leading D&I researchers, practitioners, and decision-makers identified at least 17 (13 of which are from the health field) living repositories (e.g., Society for Implementation Research Collaboration (SIRC) instrument review project [92]) and static reviews (e.g., systematic reviews published in scholarly journals [93,94]) of constructs from frameworks and relevant measures [95]. Finally, and of particular importance, D&I scholars from SIRC were awarded a 3-year NIH grant (2015–18) to establish a battery of reliable, valid, and pragmatic measures that can be used to advance D&I research [92,96].

D&I research inherently straddles a line between scientific rigor and pragmatism [14]. When done well, D&I research appropriately balances internal and external validity factors and produces outcomes that increase the opportunity to efficiently translate scientific discoveries to improve population health. The concepts presented in this chapter have provided an overview of concepts, challenges, and opportunities to be considered when conducting D&I projects and research. The remainder of this chapter presents two translational research studies of the DPP and shares resources to allow nutrition researchers and practitioners to further expand their knowledge and skills about D&I and translational research.

VI EXAMPLES FROM THE LITERATURE

To further illustrate several translational research concepts presented in this chapter, examples from the literature focused on the DPP are presented. The DPP is an effective lifestyle intervention designed to reduce diabetes incidence among prediabetic adults. Between 1996 and 2001, 3234 nondiabetic persons with elevated fasting blood glucose were randomized into one of three arms of an RCT: (1) lifestyle modification program which focused on diet, physical activity, and weight loss/maintenance (DPP); (2) metformin medication; or (3) placebo. In brief, the study showed that the incidence of type 2 diabetes could be reduced by 58% through participation in the lifestyle modification program (DPP) [97]. Importantly, the positive effects achieved by the diabetes lifestyle intervention exceeded the effects achieved by metformin medication. Findings were so strong that the blinded treatment phase was stopped a year early. Based on these results, there have been numerous efforts to disseminate the DPP into routine practice to improve individual- and population-level health. The DPP has been adapted and translated into a variety of populations (e.g., gender, race) and real-world, practice-based settings (e.g., out-patient

clinics, primary care, YMCAs, churches, work places, online platforms) both in the United States and abroad [98–101]. Likewise, these efforts have utilized an assortment of translational strategies, cultural adaptations, frameworks, study designs, and evaluation of individual- and organization-level outcomes [98–101]. Translation of the DPP in two different settings, including a hybrid effectiveness–implementation type 3 trial and a quasi-experimental comparative effectiveness trial, are further critiqued here.

The first example is a clinical demonstration project of the DPP being conducted by Damschroder and colleagues [22]. In this hybrid effectiveness–implementation type 3 trial, the primary aim is focused on the implementation of the DPP in three VA medical centers. Secondary aims are focused on participant effectiveness outcomes including weight and hemoglobin A1c. Additional aims include cost-effectiveness and budget impacts from the VA health systems' perspective. For the primary aim, development and evaluation of the implementation strategy is being guided by Simpson and colleagues' theoretical model for translating research into practice [102]. Implementation phases pertain to training, leadership decision, exploratory use, and routine use. This is a nonrandomized trial, as neither the VA sites nor VA staff delivery agent will be randomized. However, the goal is to systematically assign about 720 VA participants into the DPP program or the established VA Move! Program [103]. This pragmatic trial is guided by integrating both the RE-AIM [33] and CFIR [30] frameworks. The study protocol includes specific quantitative and qualitative research questions across each of the RE-AIM dimension. A few key sample research questions include: (1) What are the characteristics of eligible patients that enroll (in VA DPP and VA MOVE!) as compared to eligible patients who don't enroll (reach); (2) What are the changes in weight and A1c at 6 months (effectiveness) and 12 months (individual-level maintenance); (3) How many sites agree to implement the VA DPP (adoption); (4) To what extent are the VA DPP and VA MOVE! delivered as intended; and (5) What are the prospects of continuing or restarting a VA DPP (organizational-level maintenance). The CFIR framework will be used to thoroughly understand the barriers and facilitators that influence adoption and implementation of the DPP, assessing constructs across the five major CFIR domains including intervention characteristics, outer and inner setting, characteristics of individuals, and implementation process. Mixed method sources of data include staff interviews, fidelity assessments, cost tracking, and patient-level measures including anthropometrics, clinical outcomes, and patient surveys (e.g., quality of life, interviews). This trial is an exemplary representation of a rigorous, mixed-method, D&I research study. By using sound D&I frameworks, a type 3 hybrid trial design, and carefully selected mixed-methods measures, findings from this research will answer important practice-based questions pertaining to implementation, effectiveness, and cost-effectiveness [22].

The second example is a quasi-experimental, multisite study that examines four 12-week comprehensive lifestyle behavior-change programs adapted from the DPP [104]. In this comparative effectiveness trial, the four groups include face-to-face, DVD, Internet modalities, as well as a self-selection group that choses their own intervention modality. The primary aim of this study was to determine the comparative effectiveness of these modalities in influencing individual-level diabetes risk factors including weight and clinical cardiovascular risk factors (e.g., blood pressure, glucose, lipids, waist circumference) at 3 and 6 months. Neither participants nor communities were randomized. Rather communities were allocated to one of the four intervention conditions based on community characteristics and the community's capacity to deliver the intervention. For example, communities that did not have adequate high-speed Internet infrastructure where not allocated to the intervention group. The research team trained and certified community sites' registered nurses, dietitians, and lay health coaches on the study protocol including screening and measurement techniques as well as content and support for the interventions. In total, 555 overweight participants from 26 intervention sites and 8 rural underserved communities were assigned to an intervention group. At 3 and 6 months, all intervention groups had significant decreases in body weight and significant improvements in the proportion of participants with cardiovascular risk factors. However, statistical difference among groups was noted at both 3 and 6 months. Compared to other groups, participants in the self-selection group experienced the largest average weight loss at 3 months, and participants in the face-to-face group experienced the largest weight loss at 6 months. This study illustrates the pragmatic decisions demanded when conducting CER in real-world and underserved community settings. However, there is no D&I framework identified in this study and no reported dissemination, implementation, or qualitative outcomes. The external validity would be enhanced by assessing and reporting barriers and facilitators that influenced adoption, implementation, and site- and/or community-level maintenance of the interventions. As one example, evaluation of intervention fidelity among the community sites and staff would inform the potential to translate the programs into other communities.

Limited focus on D&I outcomes is not isolated to the aforementioned comparative effectiveness trial of four DPP intervention modalities [104]. In a recent systematic review of 44 studies conducted to characterize the literature on the DPP translation from 2004 to 2013, 15 studies

described cultural adaptations and 38 studies reported on implementation [98]. Of these 38 studies that reported on implementation, only 11 (28%) described the use of an implementation framework. The most common frameworks include the following: CBPR (5 studies), Diffusion of Innovation (3 studies), and RE-AIM (2 studies). At the organizational level, the most common type of implementation outcome assessed was feasibility ($n = 32$ studies; 84%), such as cost, staffing, and space. Other types of organizational-level outcomes and the proportion of studies that were reported included appropriateness (53%), sustainability (39%), acceptability (37%), adoption (37%), fidelity (34%), and penetration (24%). Findings from this review also highlight shortcomings with insufficient detail provided on the measurement and evaluation of these organizational-level outcomes [98].

While substantial effort has been invested in translating the DPP into numerous real-world, practice-based settings and for diverse populations, concerted effort is still needed to elevate the focus on D&I frameworks, methods, and measures. The translational research on evidence-based practices into real-world clinical and community settings demands heightened attention and prioritization on organizational- and systems-level outcomes. The additional resources provided later are intended to assist nutrition researchers and practitioners in obtaining additional information on advanced D&I topics and staying abreast of the rapidly expanding field of translational research.

VII ADDITIONAL RESOURCES

A Leading D&I Centers and Agencies

In the past several years, there have been notable investments to speed up the translation of scientific discovery into patient and community benefit more quickly. One key example is efforts led by the NIH and the establishment of the *National Center for Advancing Translational Science (NCATS)* in 2012 [105]. The mission of the NCATS is "to transform the translation of scientific discoveries so that new treatments and cures for disease can be delivered to patients faster." The NCATS is responsible for administering the *Clinical and Translational Science Award program*. This program supports a national network of over 50 medical research centers that are collaborating to develop and disseminate innovative methods and technologies that improve the efficiencies of turning scientific discoveries in clinical advances. Another example is the *Implementation Science team lead by the Division of Cancer Control and Population Sciences within the National Cancer Institute* [106]. This team is addressing the degree to which health interventions can fit within real-world public health and clinical services systems. Additional illustrations are two federal groups that have emerged as leaders in the area of CER, including the *Agency for Healthcare Research and Quality* and the *Patient-Centered Outcomes Research Institute*. While these examples are clearly not an exhaustive list, they provide an indication of investments into accelerating the translational research process and provide a hub of supplementary resources to this chapter. Many of these leading centers and agencies also offer advance training and seminars in translational and D&I science, host annual research conferences, and have free Listserv subscriptions.

B Research Tools for Identifying and Reporting Diverse Trial Types

Two additional resources for understanding the conduct and reporting of diverse trial types include extensions of the *Consolidated Standards of Reporting Trials* (CONSORT) statement and the *Pragmatic-Explanatory Continuum Indicator Summary* (PRECIS). The main CONSORT statement is a 22-item checklist to improve the reporting of an RCT, based on the "standard" two-group parallel design [107]. To improve the reporting of my diverse trial types, including many of those used in D&I research, several modifications are now available including extensions for cluster trials [108], noninferiority and equivalence trials [109], and pragmatic trials [110]. For example, the PCT extension adds specific guidance of good reporting for 8 of the 22 checklist items, including background, participants, interventions, outcomes, sample size, blinding, participant flow, and generalizability [110]. The PRECIS provides 10 domains to identify the extent to which a trial is pragmatic [111]. The PRECIS domains illustrate aspects such as eligibility criteria for trial participants, flexibility with experimental intervention, flexibility of comparison intervention, intensity of follow-up of trial participants, intensity of measuring participants' compliance with the prescribed intervention, degree of practitioner expertise, intensity of measuring practitioners' adherence to the study protocol, and the nature and scope of the trial's primary outcome. The intent of the PRECIS tool is to assist researchers and practitioners in designing and characterizing trials and to help highlight the multidimensional nature of the pragmatic-explanatory continuum [111]. The PRECIS criteria have been applied in several studies relevant to nutrition outcomes including weight loss trials in obese patients with comorbid conditions [112] and eHealth cancer prevention and control interventions [113].

C Resources for Selecting D&I Frameworks and Measures

Rabin and colleagues' glossary of D&I terminology provides researchers and practitioners seeking to conduct

translational resource within nutrition and other health fields to navigate the often conflicting terminology needed to identify the focus of a D&I study and to select the proper framework. This resource was first published in the *Journal of Public Health Management and Practice* [114] and updated in 2012 for the *Dissemination and Implementation Research in Health: Translation Science to Practice* textbook [29].

Regarding the selection of frameworks, Tabak and colleagues' 2012 review of D&I frameworks published as an open access article in the *American Journal of Preventive Medicine* provides a synthesis of 61 D&I frameworks [28]. To aid researchers and other stakeholders in selecting the framework that best fits their needs, frameworks are organized by D&I focus as well as construct flexibility. Levels of the socioecological framework are also presented. Additionally, some of the research teams host their own websites that provide greater detail about constructs and highlight articles that have used the frameworks. Two notable website examples are the *CFIR technical assistance* [47] and the *RE-AIM working group* [39].

There are also a number of measurement resources. Notably, Rabin and colleagues present a compilation of 17 such resources identified by a working group of leading D&I scholars, practitioners, and decision-makers [95]. Two of the publicly available resources are (1) the *CFIR technical assistance website*, which includes relevant quantitative and qualitative measures [47] and (2) the National Cancer Institute's *Grid-Enabled Measures (GEM)* portal, which allows D&I stakeholders to add evidence about relevant constructs and measures and share data sets [115,116]. As of mid-2012, there were 1202 measures assessing 357 constructs compiled in GEM. Additionally, there is the *SIRC* website which hosts a repository of 450 measurement instruments that have been collected through the ongoing Instrument Review Project. Measures are organized by CFIR constructs and have been rated based on their empirical validation [92]. This resource is available to SIRC members.

D Books and Journals

The *Dissemination and Implementation Research in Health: Translation Science to Practice* textbook is one of the most comprehensive textbook on the theory, frameworks, methodology, and analysis of setting- and population-specific D&I research [3]. Another relevant textbook is *Improving Patient Care: The Implementation of Change in Health Care* [117]. Finally, while D&I research is featured across numerous scientific journals, a few journals dedicated to this research paradigm include: *Implementation Science* published by BioMed Central and *Translational Behavioral Medicine* published by Springer. These books and journals are recommended for nutrition scholars wishing to advance their proficiencies in translational and D&I research.

VIII CONCLUSIONS

Since several definitions and models of translational research exist in the literature, it can hold diverse meanings across individuals and disciplines. Despite variances in terminology of translational research phases, the need to accelerate the lag time from scientific discoveries to widespread clinical and population health impact is well-recognized. This chapter focused on the D&I research concepts, processes, and factors that influence the successful integration of evidence-based interventions into real-world clinical and community settings. Fortunately, there are numerous D&I frameworks, study designs, and measures to select from. Exploring how D&I concepts have been used in other health and nutrition-relevant studies, as well as using the resources provided in this chapter, can aid nutrition researchers and practitioners in the critical evaluation and careful application of D&I methodology that best meets the needs of their projects.

I INTRODUCTION

Epidemiology is the science of public health whose laboratory setting is human populations. Specifically, epidemiology is the study of the distribution and determinant of disease frequency in human populations [1]. Epidemiology addresses such questions as who gets a disease, when, and why; this information is then used to create strategies for prevention or treatment. Nutritional epidemiology is the study of how dietary factors relate to the occurrence of disease in human populations [2]. For example, observations that persons who consumed fish at least twice a week had a lower risk of incident cardiovascular disease (CVD) and stroke as well as lower risk of sudden cardiac death than persons who ate no fish [3,4] led to widespread recommendations to include fish in the diet for CVD prevention. Similarly, population-based studies demonstrating that consumption of trans-fatty acids may be associated with unfavorable blood lipid profiles have led to the decline in use of these fats by food manufacturers and outright bans by some local health departments [5–8]. Another finding by nutritional epidemiologists that has had major public health policy implications was the observation that use of multivitamins containing folic acid during pregnancy reduced the risk of neural tube defects in the fetus. Consistent evidence from numerous epidemiologic studies led to the fortification of the US food supply with folic acid as a primary prevention strategy in 1998 [9,10]. Thus, some of the major nutrition-related public health contributions of the past 50 years have been made possible by nutritional epidemiology.

One factor that distinguishes the discipline of nutritional epidemiology is the extraordinary challenge of accurately assessing exposure [11]. In epidemiology, exposure is defined as participant characteristics, lifestyle behaviors, or agents (e.g., food, medications such as hormone replacement therapy, tobacco, and sun) with which a participant comes into contact that may be related to disease risk (Table 7.1) [12]. Measuring dietary intake is particularly complex for many reasons. For purposes of illustration, we can compare the assessment challenges for two common exposures: cigarette smoking and diet. Smoking is a simple (yes/no) activity, so individuals can accurately report whether or not they smoke. Because smoking is addictive, it tends to be a consistent long-term behavior. Furthermore, because smoking is a habit, most people smoke roughly the same number of cigarettes per day (i.e., one or two packs per day). In contrast, during the course of even 1 week, an individual can consume hundreds, even thousands, of distinct food items in various combinations, making it cognitively challenging for respondents to accurately report their intake. Meals can be prepared by others (e.g., in a restaurant, by a spouse, and as prepackaged food) so that the respondent may not be cognizant of preparation details such as fat or salt used in cooking or portion size. Food choices typically vary with seasons and other life activities (e.g., weekends, holidays, and vacations). In fact, the day-to-day variability in food intake can be so large that it is not possible to identify any underlying consistent dietary pattern. In addition, foods are often a surrogate for the exposure of interest (e.g., dietary fat or fiber), which means that investigators must rely on food composition databases to calculate the exposure variable. Given the problems inherent in assessing dietary intake, it is not surprising that despite some of the important contributions noted previously, it has been difficult to obtain consistent and strong evidence regarding how diet affects disease risk.

The vast majority of nutritional epidemiologic research in the past 25 years has focused on the identification of foods and/or specific nutrients in foods that prevent or promote the occurrence of chronic diseases, such

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00007-2

TABLE 7.1 Examples of Exposures Relevant to Nutritional Epidemiologic Studies

Exposure	Diet-Related Example	Other Example
Agent that may cause or protect from disease	Vegetable consumption may be protective for colon cancer	Physical activity may be protective for colon cancer
Constitutional host factors	Genetic predisposition to nutrition-related disease	Older adults are more predisposed to chronic disease
Other host factors	Food preferences that determine food choices	More educated adults may have better disease screening
Agents that may confound the association between another agent and disease	Correlation between dietary constituents (e.g., a diet high in fruits and vegetables is usually low in fat)	Smokers are less likely to engage in physical activity
Agents that may modify effects of other agents	Fruits and vegetables may protect against lung cancer among smokers	Alcohol results in increased risk of lung cancer from smoking
Agents that may determine outcome of disease	Malnutrition	Medical treatment

as cancer, diabetes, and CVD. Therefore, the tools and methods of nutritional epidemiology were developed to address scientific issues unique to the biology of chronic disease, including the extensive time for disease development and the multifactorial nature of these diseases. Furthermore, epidemiologic research is generally conducted in free-living humans, which establishes associations only and precludes direct tests of cause and effect. Each of these challenges is discussed here.

A Extensive Time for Disease Development

Chronic diseases develop over years and even decades, which has important implications for the field of nutritional epidemiology. For example, the currently accepted model of colon cancer assumes that it is a multistep pathogenic pathway beginning with mutations (germ line or somatic) leading to growth of polyps (preneoplastic growths), which become adenomas and progress to carcinoma [149]. Even after an adenoma has developed, many years may elapse before it is clinically detected. Upon clinical detection of colon cancer, it is clear that a meal consumed that day, or the month before, could have no significant effect on the disease for two reasons. First, the critical period of cancer initiation and promotion likely occurred many years prior to disease diagnosis. Second, the biologically relevant exposure is the long-term or usual diet, rather than any single eating occasion. Therefore, the exposure of interest in the development of cancer occurred throughout the previous 10–20 years and perhaps the previous 5 years for CVD and diabetes.

This time lag between dietary exposure and disease occurrence presents considerable difficulties in the study of diet and chronic disease. These difficulties have been addressed in two major ways. First, dietary assessment instruments for epidemiology were developed to capture information on usual, long-term dietary intake [13]. The most common is the food frequency questionnaire (FFQ). Second, study designs developed in other areas of epidemiology were applied to studies of diet–disease risk: case–control and cohort studies. These designs were already being used to gather data on remote exposures (i.e., use of oral contraceptives and age at menarche) or life events (i.e., age at first pregnancy and number of full-term pregnancies), which proved to be useful for establishing associations of various risk factors with disease risk [1]. For example, asking detailed questions about reproductive history to women with and without breast cancer has provided useful and reliable data about breast cancer risk factors. Using the same approach, nutritional epidemiologists have asked people about retrospective diet in case–control studies or assessed current diet in cohort studies and followed participants over time to monitor incidence of disease. The difficulty with the latter approach is that it often takes years or decades for a disease to develop, and during that time, study participants may markedly alter their usual dietary habits.

B Multifactorial Nature of Chronic Diseases

Chronic diseases such as cancer and CVD have complex etiologies that are multifactorial in nature. In addition to diet, other determinants of chronic diseases include host factors (e.g., genetic susceptibility) and other lifestyle habits (e.g., cigarette smoking, physical activity, and alcohol intake). These other factors may confound our ability to find an association of dietary intake with disease risk. For example, individuals with an interest in health may eat a low-fat diet high in fruits and vegetables and have high physical activity levels. If vegetable intake is found to be associated with reduced risk of colon cancer, it can be difficult to disentangle whether it is the high vegetable intake or the low fat intake that affects disease risk. It is also possible that diet is not related to disease

risk but is merely serving as a marker for some other healthful behavior, such as physical activity or adherence to cancer screening guidelines [14].

Another illustration of the multifactorial nature of chronic disease is the complex relationship between dietary factors and a person's genetic constitution. For example, the phase II enzymes glutathione-*S*-transferases (GSTs) are upregulated by vegetables from the *Brassica* family (broccoli, Brussels sprouts, and cauliflower) such that compounds in these vegetables increase the activity of this family of enzymes [15–17]. There is also evidence that the health benefits of *Brassica* vegetables may vary depending on whether a person has any of the common genetic variations in these enzymes. Humans with GSTM1 null (approximately 50% of US Caucasians and 35% of African Americans) or GSTT1 null (approximately 15% of US Caucasians and 25% of African Americans) have greatly reduced (heterozygote) or no (homozygote) enzyme activity [16]. Among those with the null variants, compounds in the *Brassica* vegetable, such as isothiocyanates, may be metabolized and eliminated more slowly, so they may be available for a longer period of time in target tissues and organs [18]. Several studies have found stronger associations of *Brassica* vegetables with reduced risks of lung [19], breast [20], and colon cancer [21] among persons GSTM1 and/or GSTT1 null. This example of a diet–gene interaction illustrates the complexity and multifactorial nature of diet-related chronic disease development.

C Research in Human Beings

There are several important considerations with regard to conducting research in humans. Notably, population-based nutrition research or nutritional epidemiology is often conducted among healthy persons, at least at the time of initial assessment. For studies that involve dietary interventions, federal guidelines for the protection of human subjects dictate that study participants (both healthy and diseased) cannot (knowingly) be exposed to potentially dangerous dietary regimes that restrict essential nutrients or introduce known carcinogens at high levels over long periods of time. However, short-term controlled feeding studies can reasonably test the effect of potentially harmful food constituents for the purpose of learning about nutrient metabolism and disease mechanisms in relation to food intake [22]. For example, participants can be fed charred meat containing nitrosamines to learn how humans metabolize or eliminate such potential carcinogens [23,24], or they can be fed restricted diets devoid of certain nutrients to learn about nutrient absorption, metabolism, and excretion [25,26]. Indeed, such information is critical for public health recommendations regarding nutrient requirements. These tightly controlled human feeding or intervention studies are expensive and laborious and therefore are not feasible to conduct in a large-scale manner, especially when studying general population risk. For these reasons, nutritional epidemiology is primarily an observational discipline that consists largely of (1) measuring an exposure (e.g., usual dietary intake), (2) measuring an outcome (e.g., disease occurrence), and (3) using statistical techniques to quantify the magnitude of the association between these two observations and adjust for potential confounders.

II PRINCIPLES OF EXPOSURE MEASUREMENT IN NUTRITIONAL EPIDEMIOLOGY

A variety of dietary assessment methods are used in nutritional epidemiology. The choice of instrument used depends on the hypothesis being tested, the population being studied, and cost considerations. The three primary tools are FFQs, 24-hour dietary recalls, and food diaries or records. Here, we briefly describe these instruments and discuss the issues of error and bias associated with self-reported dietary intake.

A Food Frequency Questionnaire

Chronic disease risk develops over many years. As such, the biologically relevant exposure is usual or long-term diet, consumed many years prior to the appearance of clinical symptoms and disease diagnosis. Therefore, assessment instruments that only capture data on recent dietary intake (e.g., food records or recall) may not be as useful for studies examining chronic diseases that evolve over years or decades. For these reasons, FFQs have been regarded as the dietary assessment instrument best suited for most epidemiologic applications [13]. Although the design of FFQs can deviate somewhat, they typically contain the following sections: (1) adjustment questions, (2) the food checklist, and (3) summary questions.

FFQ adjustment questions permit more refined analyses of fat intake by asking about food preparation practices (e.g., removing fat from red meat) and types of added fats (e.g., use of butter vs margarine on bread). The main section consists of a food or food group checklist, with questions on usual frequency of intake and portion size. The foods are selected to capture data on (1) major sources of energy and nutrients for most people, (2) between-person variability in food intake, and (3) major hypotheses regarding diet and disease. Portion sizes are often assessed by asking respondents to mark "small," "medium," or "large" in comparison to a given medium portion size. Summary questions ask about usual intake of fruits and vegetables because the long lists of these foods

(needed to capture micronutrient intake) lead to overreporting of intake [27,28]. Since an FFQ asks about usual intake over many months, these questionnaires provide no information on dietary behaviors such as eating breakfast, snacking, or meal timing.

Note that development of an FFQ is a daunting, complex task requiring considerable understanding of exposure measurement in nutritional epidemiology, food composition knowledge, formatting and questionnaire design expertise, and computer programming resources [29–31]. A limitation of FFQs is that they may be fraught with both random measurement error and bias, which limits their usefulness [32,33]. See Section V for details regarding error in FFQs.

B Measures of Short-Term Dietary Intake: Food Recalls and Records

Food records and 24-hour dietary recalls are the other common tools used in nutritional epidemiology [13]. Food records or diaries require individuals to record all foods and beverages consumed during a specified period of time, usually 3–7 days. Participants are asked to carry the record with them and to record foods as eaten in real time. Some protocols require participants to weigh and/or measure foods before eating and review the record with a registered dietitian, whereas less stringent protocols use food models or other aids to instruct respondents on estimating serving sizes and do not engage in extensive review or documentation [34]. To obtain nutrient estimates, the food consumption information from records/diaries must be entered into a specialized software program. This data-entry step is a time-consuming task and requires trained data technicians or registered dietitians. Food records are burdensome for study participants and, due to the staff time required, are expensive to administer. Therefore, for large epidemiologic studies with tens of thousands of study participants, food records are cost prohibitive.

Some of the participant's burden can be alleviated by the use of innovative technologies such as personal digital assistants, mobile telephones, digital cameras, and other electronic devices both to record and to transmit food record data [35]. As with a paper-and-pencil food record, participants carry the electronic device with them during the assessment period. They are either asked to record each food and beverage as it is consumed or prompted every few hours to enter recently eaten foods. Electronic food records can produce intake estimates comparable to those from traditional food records or recalls [36,37]. Alternatively, mobile phones or digital cameras may be used to photograph each meal, snack, or beverage [38]. In these studies, a fiducial marker (an object of known dimensions) is often placed next to the food to provide a reference point for size. The foods are then identified and quantified either automatically using specialized software or manually by a trained technician. The participant may be asked to take both a "before" and an "after" photograph so that the amount consumed can be estimated. A third approach is the use of websites or a mobile phone application (app) which participants can use to enter their intake. These apps offer a large database of prepared and packaged foods, eliminating the need to enter caloric and macronutrient data. Users can also contribute to this database by entering packaged foods or restaurant items not already included and can also create custom meals, food combinations, or recipes to facilitate efficient entry of home-cooked dishes that they consume frequently. Advantages of app-based dietary assessment include convenience, reduced burden, and potential use in dietary change interventions [39]. Limitations include technological barriers (particularly for segments of the population where mobile phone penetrance and familiarity with app-based programs may be limited) and the potential for misinterpretation of dietary information on the part of patients and study participants [40].

Electronic approaches allow for more comprehensive recording than a paper-and-pencil survey and are particularly appealing for certain populations, such as school-aged children and adolescents [41]. Conversely, these techniques may not be suitable for individuals who are unfamiliar or uncomfortable using technology. Photograph-based methods are convenient for participants, but are limited by the lack of descriptive information about the foods and beverages in the photographs; even a highly trained dietitian can only guess at the ingredients or preparation method used. The cost of technology-based approaches compared to paper-based recalls is variable, depending on the method used for intake quantification (automated/computerized vs manual). Furthermore, the need to purchase, distribute, and recover the electronic devices limits the feasibility of this approach for large studies.

Twenty-four-hour dietary recalls are frequently used in population-based studies, such as the National Health and Nutrition Examination Survey (NHANES) [42]. Data from these recalls provide snapshots of US eating patterns and are used for formulations of dietary recommendations. A 24-hour dietary recall is a 20- to 30-minute interview in which the respondent is asked to recall all foods and beverages consumed during the previous 24 hours. Ideally, the interview is conducted with real-time direct data entry into a software program for analysis. It is important that the interviewer be well trained; tone of voice, body posture (when in-person), and reactions to participant descriptions of foods consumed can influence the quality of the data.

A single recall is considered suitable for characterizing mean intakes of groups, such as the US Department of

Agriculture (USDA) survey titled *What We Eat in America* [42]. However, for individual assessment, day-to-day variability of food intake is so high that for both records and recalls, several days of data are required to characterize usual intake for an individual. Using data on variability in intake from food records completed by 194 participants in the Nurses' Health Study [13], the number of days needed to estimate the mean intakes for individuals within 10% of "true" means would be 57 days for fat, 117 days for vitamin C, and 67 days for calcium. Unfortunately, research has shown decreases in reported energy intake, nutrient intake, and recorded number of foods with as few as 4 days of recording dietary intake [43]. These decreases in reported intake may reflect either (1) reduced accuracy and completeness of recording intake or (2) actual changes in dietary intake to reduce the burden of recording intake. Because of the participant burden, dietary recalls or records are generally only kept for 3 or 4 days. Most protocols require that one of these days be a weekend day. Although a random selection of days would be ideal, food records are generally kept for 4 days in a row to improve response rates.

In 2009, the National Cancer Institute released a web-based 24-hour dietary recall instrument, the Automated Self-Administered 24-Hour Recall (ASA24) [44–46]. The ASA24 uses a modified version of the USDA's Automated Multiple-Pass Approach, which aims to improve recall quality by giving participants several opportunities at which to recall a food item. During the first step of the recall, the participant identifies foods and beverages eaten at each meal or snack. The web-based program then asks the participant whether anything was consumed during each of the gaps between meals/snacks, offering a second chance to add forgotten items. Participants are then asked about the details of each food/beverage item, such as the serving size, container type (for beverages), amount of serving consumed, and any condiments or toppings. Pictures are used to help participants select the appropriate responses. The program then asks the participant to review a list of foods and beverages that are commonly forgotten by respondents, such as water or candy. After a final review, participants are offered one additional opportunity to report items. The last item asks the participant whether the reported consumption is representative of his or her usual daily intake. Supplement information may also be collected if specified by the investigator. The ASA24 instrument is offered in both English and Spanish. The most recent versions of the ASA24 system have been adapted for use with adults living in Canada (ASA24-Canada), with school-aged children (ASA24-Kids), and can also be used as a food record in order to allow for real-time data collection and for promoting dietary change. Efforts are underway to adapt the ASA24 for use with adults living in Australia [46].

In theory, the ASA24 offers the benefits of traditional telephone-based or in-person recalls while removing much of the expense. The ASA24 is available at no cost to researchers and is intended for self-administration by participants, eliminating the need for data entry or computation by trained dietitians. Some participant populations, however, may find it difficult to report their diet accurately using the system. This is particularly likely for individuals who are not accustomed to using a computer, are low in literacy, or who eat a lot of home-prepared dishes with many ingredients. The lack of a human interviewer to answer questions and probe for clarification may exacerbate these issues. Finally, more research is needed to document its measurement characteristics. Other web-based recall approaches include the Oxford WebQ [47], DietDay [48], and the National Cancer Institute's targeted instruments (the Fruit and Vegetable Scan and Block Fat Screener) [49].

A major advantage of food records and recalls is that they include a time stamp for every eating occasion. Therefore, these data can be used to construct dietary behavior variables such as number of meals and snacks per day, breakfast skipping, and the nightly fasting interval. Research in rodents [50,51] and sparse human data suggest that meal timing may be an important factor in human health [27]. For example, a recent (2016) analysis of 2413 breast cancer survivors found that women who fasted <13 hours per night had a 36% increased risk of breast cancer recurrence compared to women who fasted ≥ 13 hours (hazard ratio: 1.36; 95% confidence interval, $1.05-1.76$) [52]. Women who had longer nightly fasting duration also reported more sleep and had lower concentrations of hemoglobin A1c. Large cohorts that only have FFQ dietary data are not able to investigate these types of hypotheses.

C Dietary Indices

In the last few decades, the use of indices to capture overall dietary patterns has gained popularity [13,53]. A dietary index is based on either current nutritional knowledge (i.e., dietary guidelines/recommendation) or existing dietary patterns with some cultural aspects (i.e., the Mediterranean dietary pattern) and can be used to describe adherence to a specific overall dietary pattern. Some commonly used dietary indices include the Healthy Eating Index [54,55], the Diet Quality Index (DQI) [56], or for instance, on Mediterranean dietary pattern, such as the MedDietScore [57]. Typically, the assessment tool is a score based on the degree of adherence to the dietary pattern. The score is calculated by assigning a value to variables representing low (or high) intake of specific food items associated with the dietary pattern of interest [13]. The score is then used to examine the relationship between

the risk of a cause-specific morbidity or mortality and adherence to the dietary pattern. There is documentation on the reproducibility and validity of dietary patterns [54,58].

The use of dietary indices reflects a movement toward testing dietary interventions that focus on eating patterns rather than a single nutrient or type of food. A good example is the PREDIMED study that examined the health impacts of the Mediterranean diet (MeDiet), defined as the traditional dietary pattern found in the early 1960s in Greece, Southern Italy, Spain, and other olive-growing countries of the Mediterranean basin. Specifically, this study randomized 7447 men and women at high CVD risk into three diets: MeDiet supplemented with extra-virgin olive oil, MeDiet supplemented with nuts, and control diet (advice on a low-fat diet). During a median time of 4.8 years, both MeDiet dietary patterns showed significant reductions in the CVD and incident diabetes in relation to the control group [59]. In summary, the utilization of dietary indices will complement analyses of nutrients or food, and maximize the value of dietary pattern assessment in nutritional epidemiology [13].

D Vitamin/Mineral Supplement Assessment

Historically, less attention has been paid to measuring vitamin/mineral supplement use compared to food intake. However, assessing vitamin/mineral supplement use is important because supplement use per se is an exposure of interest for the risk of several chronic diseases [60–64]. In addition, supplements are used by approximately half of all Americans, so they contribute a large proportion of total (diet plus supplement) micronutrient intake [29,65–67]. Epidemiologic studies typically use personal interviews or self-administered questionnaires to obtain information on three to five general classes of multiple vitamins (multivitamins with or without minerals, stress supplements, antioxidant mixtures, and other mixtures, including multivitamins with herbals), single supplements, the dose of single supplements, and sometimes frequency and/or duration of use [68].

In a validity study comparing a self-administered assessment method to label transcription among 104 supplement users, we found correlation coefficients ranging from 0.1 for iron to 0.8 for vitamin C [68]. The principal sources of error were investigator error in assigning the micronutrient composition of multiple vitamins and respondent confusion regarding the distinction between multiple vitamins and single supplements. These results suggest that commonly used epidemiologic methods of assessing supplement use may incorporate significant amounts of error in estimates of some nutrients. In a subsequent study, we found that a similar inventory reporting system captured supplement use when compared to blood, toenail, and urine biomarkers [66,69]. In a marketplace that is becoming rapidly more complex, with vitamins, minerals, and botanical compounds combined in unusual mixtures at highly variable doses, the association of dietary supplements with disease risk is becoming increasingly difficult, but important, to assess [70].

E Use of Biomarkers in Nutritional Epidemiology

Dietary biomarkers have been critical to the advancement of nutritional epidemiology and have led to huge advances in our understanding of errors in self-reported dietary intake [32,71]. Biomarkers from blood, urine, stool specimens, or toenails can provide objective estimates of dietary intake and therefore circumvent problems associated with self-reported diet such as underreporting. Two major drawbacks of biomarkers are that (1) biological specimens are expensive to collect, store, and analyze in large studies and (2) suitable biomarkers have not been identified for all foods or nutrients. For example, there is no established biomarker for total fat or carbohydrate intake.

Dietary biomarkers fall into one of two general categories: recovery biomarkers and concentration biomarkers. Recovery biomarkers are those that have a known quantitative time-associated relationship between dietary intake and excretion or recovery in human waste (e.g., urine or feces) [72,73]. Concentration biomarkers (e.g., serum β-carotene for total fruits and vegetables) are responsive to diet and generally have a linear association with dietary intake [74,75]. However, these qualitative biomarkers are of limited usefulness in assessing overall or person-specific biases in self-report and cannot be used to estimate absolute intake in the same manner as recovery biomarkers [72,73].

Urinary nitrogen is an example of a recovery biomarker and is used to estimate protein intake. The measure is based on the following equation [76]:

$$\text{Reported protein intake (g)} = (\text{24-hour urinary nitrogen} + 2) \times 6.25\text{(g)}$$

Similar to a single 24-hour dietary recall, a single 24-hour urine collection does not reflect usual intake, but nitrogen intake has been shown to be less variable than protein intake such that only 8 days of collection are required compared to 16 days of dietary intake data to assess habitual protein intake. Although the collection of 24-hour urine is a tedious procedure, the method is readily accessible and comparatively inexpensive. In addition, other markers of dietary intake and intermediate risk markers may also be measured in the 24-hour urine that is obtained.

The "gold standard" for assessing energy intake is the use of doubly labeled water. Although this method actually measures energy expenditure (carbon dioxide output), it can be used as a measure of energy intake because energy intake and expenditure are approximately equivalent in weight-stable individuals. Doubly labeled water is water that has been "tagged" by replacing some of the hydrogen and oxygen with heavy isotopes (deuterium and oxygen-18). The participant ingests a dose of the doubly labeled water, and after a delay of a few hours, urine samples are collected to obtain a measure of the markers once they have reached equilibration with water in the body. As time continues, the deuterium will be eliminated as water and the oxygen-18 will be eliminated as water plus carbon dioxide. Thus, the rate of carbon dioxide production can be deduced by comparing the elimination of the two markers. Only one follow-up urine sample is required, and it can be collected up to a few weeks after baseline. Although it is expensive, this method has a relatively low participant burden and can accurately estimate energy intake and expenditure.

Energy expenditure can also be estimated using other methods, such as indirect calorimetry or accelerometers. In indirect calorimetry, a metabolic chart is used to measure the participant's oxygen intake and carbon dioxide output, which are then used to calculate the resting metabolic rate. A major disadvantage of this method is that it does not capture energy expended by movement or physical activity and is therefore inappropriate if free-living energy expenditure is of interest.

Accelerometers (e.g., the ActiGraph) are small electronic meters typically used to provide an objective measurement of physical activity. Worn on the hip during all waking hours over several days, these devices record movements during daily activity. Accelerometers can also be worn on the wrist, which can increase compliance, allows for 24-hour wear, and provide an objective assessment of sleep duration and quality [77]. By entering data for sex, age, and weight, investigators can apply algorithms to estimate the energy expended during each day or for the entire wear period [78].

The primary advantage of accelerometry is the objectivity of the data. Limitations to this approach include the pragmatic considerations involved in distributing and retrieving the monitors, the short assessment period (typically 1 week), the inability to discern type of activity being performed, and, to some extent, the cost of the devices. Recently, consumer-based trackers such as the Fitbit, Jawbone Up, and others have also been used by researchers to assess physical activity and energy expenditure. Validation studies indicate that fitness trackers can accurately measure steps but may be only moderately accurate for estimation of total daily energy expenditure [79–81]. Even so, the lower cost of these trackers, combined with their ability to provide continuous monitoring over weeks or months, supports their use in certain research contexts.

III STUDY DESIGNS USED IN NUTRITIONAL EPIDEMIOLOGY

Epidemiologic studies can be divided into two general types: observational and experimental. The three primary observational study designs are ecologic, case–control, and cohort studies. In human studies, the main experimental study designs are intervention trials or randomized controlled trials. An overview of these study designs in relation to nutritional epidemiology is given here.

A Observational Studies

1 Ecologic and Migrant Studies

Important hypothesis-generating studies have examined the relationship of national estimates of per capita supply of foods (e.g., dietary fat) with time-lagged rates of cancer or heart disease incidence or mortality [82–85]. These analyses strongly suggest that dietary fat intake increases risk while plant foods decrease risk of these major diseases. However, there are numerous problems with country-specific measures of dietary intake. First, estimates of per capita intake from food disappearance data are extremely imprecise and include nonhuman consumption uses such as livestock feed and manufacturing use of food or food end products (e.g., corn biofuel and soybean-based inks used in newsprint). Second, it is generally not feasible to control for other differences between countries (e.g., differences in physical activity levels or smoking prevalence). Finally, it is unknown whether the individuals within the countries that are exposed to specific dietary factors are the same individuals experiencing the disease.

Migrant studies have often shown that with a single move from less developed to Westernized countries, large and significant increases occur in risk of several chronic diseases such as breast cancer [86,87]. These changes occur rapidly, often after just one generation, as immigrants become acculturated to the diet and other habits of their new country [88]. Migrant studies offer strong evidence to support a major role for lifestyle and environment exposures as disease risk factors; however, few such studies have included pertinent dietary assessment to be able to properly address these questions [88].

2 Case–Control Studies

In a case–control study, individuals are identified and studied according to a single disease outcome. Specifically, individuals who have recently been diagnosed with a disease (e.g., colon cancer) are asked about their past

exposure to diet and other risk factors and often provide a blood sample. A comparable set of control individuals, usually drawn from the same population, are also enrolled in the study and are asked about their past exposures. The two groups (those with and those without the disease) are then compared for differences in dietary intake and other exposures. The major advantage of this design is that an entire study can be completed in just a few years with a smaller sample size than is needed for other study designs (it could be as small as 200 cases and controls). However, this study design can only answer questions about a single disease outcome.

In addition, these studies can introduce potentially serious biases. Two major concerns with case–control studies are recall bias and selection bias. In studies of chronic disease, investigators typically ask participants to recall behavior and other exposures (e.g., dietary intake) from the past 5–10 years, or even earlier. Bias can occur when cases recall exposure to potential risk factors differently than do controls. For example, past consumption of fatty foods might be more salient and easier to recall for individuals diagnosed with CVD than for healthy individuals. Selection bias occurs when controls agree to join the study because of an interest in health and are therefore more likely to exhibit healthy behavior (e.g., eat healthful diets and be physically active). The higher prevalence of healthy behavior in the controls appears to be associated with reduced risk of disease when actually it is associated with willingness to participate in a research study on health. Thus, control selection is an extremely important part of study design [1,89]. Furthermore, because cases are usually recruited relatively soon after diagnosis, unless remote diet is assessed, the dietary habits reported during the previous year (or a more recent time frame) represent dietary intake in the preclinical phase of the disease. Inferences from such data are not clear with respect to understanding diet–disease relationships.

Another problem with case–control studies is that biomarkers of diet (e.g., serum micronutrient concentrations) are potentially affected by the disease process and therefore may not be reliable indicators of long-term status (e.g., risk) in cases. As described in the following section, this problem is partially overcome in nested case–control studies.

3 Cohort Studies

The cohort study typically enrolls people who are free of disease, assesses baseline risk factors, and then follows the participants over time to monitor disease occurrence. The major advantage of cohort studies is that exposure to potential risk factors is assessed before the development of disease [1,89]. Therefore, exposures such as self-reported dietary intake or nutritional biomarkers from blood samples cannot be influenced by the disease process. In addition, cohort studies can examine many different exposures in relation to several different disease outcomes. A cohort study is generally a large enterprise because most diseases affect only a small proportion of a population, even if the population is followed for many years. These studies typically have sample sizes exceeding 50,000, can have a total cost in excess of $100 million, and require that the cohort be followed for 10 or more years [1,89]. Despite the cost and logistics, cohort studies have been useful in identifying diet–disease risk factors with ensuing recommendations for public health [90–95].

Because of the large size of these studies, the analysis of biologic markers (e.g., serum micronutrient concentrations) for all participants is prohibitively expensive. Therefore, cohort studies often archive (e.g., store) serum or plasma, white blood cells, toenails, DNA, or other biologic specimens for the purpose of conducting nested case–control studies in the future [96–98]. In a nested case–control study, a sample of cohort participants who developed a disease such as breast cancer (e.g., cases) is matched with other individuals in the cohort who did not develop the disease (e.g., controls). Cases and controls may be matched with respect to age, gender, and/or other important characteristics. This ensures that the sample of cases is comparable to the sample of controls with respect to potential confounding factors. Once cases and controls have been selected, biologic samples from these individuals are retrieved and analyzed to determine whether there are differences in prevalence of exposures (e.g., diet) between the two groups [99,100]. This can be an efficient and powerful study design that avoids many of the pitfalls of the classic case–control studies.

B Intervention Trials

Intervention trials prospectively examine the effect of an exposure randomly assigned by the investigators, such as a low-fat diet or a dietary supplement, on an outcome such as disease occurrence, risk factor for a disease, or a biomarker. An important consideration when designing these studies is the degree of dietary control needed. For example, depending on the hypothesis, the dietary intervention could be a controlled diet provided by the investigators, a vitamin supplement, or dietary counseling. The stringency of dietary control is determined partially by the expected size of the response (e.g., change in disease risk) and the length of the treatment period required. If the required dietary treatment period exceeds several months, a controlled feeding study is usually not logistically or financially viable.

It is also important to note that with the exception of dietary supplement intervention trials, most dietary

interventions are not double-blinded. If the study compares a low-fat eating pattern to usual diet, for example, participants will know to which arm they have been randomized because they are being asked to make specific dietary changes. Furthermore, as with any intervention trial, one must account for "drop-in" and "dropout" rates. Some study participants may find the required intervention activities too burdensome, so they may drop out or be less than 100% adherent to study activities [101,102]. Control participants, on the other hand, even if they are asked not to change their diet or take any new dietary supplements, may begin new dietary patterns that could be similar to the intervention. Both drop-in and dropout phenomena can diminish the amount of contrast between the intervention and comparison groups, thereby attenuating any effects of the intervention.

In an intervention trial, the random assignment of participants to the control versus the intervention group means that participants with predisposing conditions or unmeasured factors that might influence the outcome are equally likely to be randomized into the intervention or the control group. Therefore, there is little or no confounding in randomized intervention studies [89]. In addition, random allocation of the exposure eliminates the potential for selection bias and recall bias. However, such trials are generally expensive and labor intensive. Therefore, randomized trials are only conducted for important public health questions where the observational data are suggestive but a controlled experiment is needed prior to issuing public health recommendations. Randomized trials are the only epidemiologic study design in which cause and effect may be concluded [1,89].

IV INTERPRETATION OF CAUSE AND EFFECT IN NUTRITIONAL EPIDEMIOLOGY

Given that nutritional epidemiology is the study of dietary intake and its association with disease risk, we must use careful scientific judgment in determining when the strength of the evidence supports a causal link between the exposure and the outcome. When assessing causality, important considerations include: (1) the main measure of association used in epidemiologic studies; (2) the major alternative explanation for an observed association in observational studies, which is confounding; and (3) methods for assessing causality in studies of associations. Other important considerations include: (1) biological plausibility, (2) temporal association, (3) the strength of the association, (4) dose−response relationship, and (5) consistency with other studies [1,89].

A Measures of Association

The most commonly used measure of association between dietary intake and disease risk is relative risk (RR). The RR estimates the magnitude of an association between the dietary exposure and disease and indicates the probability of developing the disease in the exposed group relative to those who are not exposed [1,89]. For example, an RR of 1.0 indicates that the incidence of disease in both exposed and unexposed groups is the same. An RR greater than 1.0 indicates a positive association. For example, an RR of 2.0 between dietary fat and colon cancer indicates that individuals eating a high-fat diet are twice as likely to develop colon cancer as those eating a low-fat diet. RRs less than 1.0 are typically considered protective. An RR of 0.5 for the association of vegetable intake with colon cancer risk indicates that among individuals with diets high in vegetables, the risk of colon cancer is approximately half compared to those with diets low in vegetables. Often, RRs are given for the highest category of intake (e.g., highest quartile of fat or vegetable intake) in comparison to the lowest category of intake.

Given the degree of measurement error in dietary intake estimates, RRs in nutritional epidemiology rarely exceed 3.0. RRs are typically presented with their associated CI (e.g., RR 2.0, 95% CI of 1.3−2.9), which provides information on the precision of the point estimate (e.g., the RR). Specifically, it is the range within which the true point estimates lie with a certain degree of assurance. Typically, 95% CIs are given, which correspond to the traditional test of statistical significance, $p < 0.05$, meaning that there is less than a 5% probability that the findings occurred by chance. A 95% CI that does not include the null value (1.0) is, by definition, statistically significant at the $p = 0.05$ level. The width of the CI also provides information about the variability in the point estimate, which is primarily a function of sample size. Therefore, the wider the CI, the more variability in the measure, the smaller the sample size, and the less confidence we can have that the observed point estimate is the true point estimate.

It is important to separate the strength of an RR from its public health relevance. For example, a large RR (e.g., RR = 5.0) might be observed between a specific food and a risk of disease. However, if consumption of that food is rare, then its overall influence on the population's total morbidity or mortality will be minimal. Conversely, an RR of 1.5 might be very important from a public health perspective if the dietary exposure is common. Once RR estimates are used to determine the strength of association, then projections of the consequence of an exposure on public health (termed population attributable risk) become important in the development of policy and allocation of resources. For example, the consistent observations from observational studies that trans-fats were associated with unfavorable serum lipid profiles and CVD led to new food labeling laws requiring that trans-fats be listed among the "Nutrition Facts" [8].

B Confounding

Confounding occurs when an observed association between dietary intake and disease is actually due to another factor (e.g., physical activity) that is highly correlated with dietary intake and disease risk [1,89]. Confounding is a critical concept in nutritional epidemiology because it is plausible that people who have healthful diets are likely to differ from those who did not choose healthful diets with regard to other exposures (e.g., physical activity) [13].

For example, a population-based study among 1449 adults observed that those who used vitamin/mineral supplements were more likely to be female, older, better educated, nonsmokers, regular exercisers, and to consume diets higher in fruits and vegetables and lower in fat [14]. We also found previously unreported associations of supplement use with cancer screening, use of other chemopreventive agents (e.g., aspirin), and a psychosocial factor (belief in a diet−cancer connection). These relationships could confound studies of supplement use and cancer risk in complex ways. For example, male supplement users were more likely to have had a prostate-specific antigen test, which is associated with increased diagnosis of prostate cancer [103]. Therefore, supplement use could spuriously appear to be associated with increased incidence of prostate cancer.

The observed relationship between supplement use and belief in a connection between diet and cancer is especially interesting. Health beliefs influence cancer risk through behavior such as diet and exercise. For example, in a previous prospective study, we found that belief in a connection between diet and cancer was a statistically significant predictor of changes to more healthful diets over time [104]. In cohort studies, the increasing healthfulness of supplement users' diets and other health practices over time could result in a spurious positive association between supplement use and chronic disease risk.

It is important to note that in studies in which nutrient intake is summed from foods and supplements, the intake of micronutrients in the highest exposure category is often too high to be obtained from food and reflects supplement use. Therefore, studies of nutrient intake may also be confounded by the relationship between supplement use and healthful lifestyle. In these studies, consistency of findings for the nutrient from foods and vitamin supplements separately would increase confidence that an observed association was not confounded by supplement users' healthful lifestyles.

In theory, statistical adjustment in analyses for participant characteristics and major health-related behavior controls for the effects of confounding factors are important. However, the absence of residual confounding cannot be ensured, especially if other important confounding factors are unknown, not assessed, assessed with error, or not included in the analyses.

C Evidence of Causality

Epidemiology is the study of associations, and statistical methods provide the means to conduct hypothesis testing to quantify the association. However, it is important to note that the existence of a statistically significant association does not indicate that the observed relationship is one of cause and effect. For any observed association, the following questions should be considered:

- How likely is it that the observed association is due to chance?
- Could this association be the result of poor study design, poor implementation, or inappropriate analysis?
- How well do these results meet other criteria of causality, as given in Table 7.2 [1]? Specifically, is the association weak or strong? Is there a plausible biologic mechanism? Did the exposure precede the outcome? Is there a dose−response relationship?
- How well do these results fit in the context of all available evidence on this association? Causality is supported when a number of studies, conducted at different times, using different methods, among different populations, show similar results. Note that true causality can only be inferred within the context of an experimental study, a randomized controlled trial.

In a field characterized by as much uncertainty as nutritional epidemiology, it is rare for a cause-and-effect relationship to be considered unequivocal. However, lack of complete certainty does not mean that we should ignore the information that we have or postpone the action that appears needed at a given time [1,105,106]. It merely means that we exercise prudence and thoughtful consideration before acting on epidemiologic evidence.

V OBSTACLES TO FINDING ASSOCIATIONS OF DIETARY INTAKE AND DISEASE RISK

Here, we review the major obstacles to epidemiologic research, including error in exposure assessment and limitations of study designs.

A Assessing the Reliability and Validity of Measures of Dietary Intake

Reliability is generally used to refer to reproducibility, or whether an instrument will measure an exposure (e.g., nutrient intake) in the same way twice on the same respondents.

TABLE 7.2 Criteria for Judging Whether Observed Associations Between Diet and Disease Risk are Causal

Criteria	
Strength of the association	The stronger the association, the less likely that it is due to the effect of an unsuspected or uncontrolled confounding variable.
Biological credibility	A known or postulated biologic mechanism supports causality. However, an association that does not appear biologically credible at one time may eventually prove to be so. Implausible associations may be the beginning of the advancement of knowledge regarding mechanisms.
Consistency	This criterion requires that the association be observed in several types of studies—e.g., in more than one population and using different study methods.
Specificity	This is the degree to which one factor predicts the frequency or magnitude of a single disease.
Time sequence	The exposure of interest must precede the disease outcome by a time span consistent with known biologic mechanisms.
Dose–response	Evidence for a dose–response relationship (i.e., increased risk associated with increased exposure) is considered supportive of causality.

Source: Adapted from C.H. Hennekens, J.E. Buring, Epidemiology in Medicine, Little Brown, Boston, MA, 1987 and M.L. Neuhouser, B. Thompson, C.C. Solomon, Higher fat intake and lower fruit and vegetables intakes are associated with greater acculturation among Mexicans living in Washington state. J. Am. Diet. Assoc. 104 (2004) 51–57.

Validity, which refers to the accuracy of an instrument, is a considerably higher standard. Generally, a validity study compares a practical, low-cost measurement method (e.g., an FFQ) with a more accurate but more burdensome or expensive method (e.g., food records). Reliability and validity are typically investigated by means of statistical measures of bias and precision [12].

In a reliability study, reproducibility is assessed by comparing mean intake estimates from two administrations of the instrument in the same group of respondents. If an instrument is reliable, the mean intake estimates should not vary substantially between the two administrations. In a validity study, bias is generally assessed by comparing the mean estimates from the instrument of interest to those from a criterion measure (e.g., a "gold standard" instrument) in the same respondents. This comparison allows us to determine whether nutrient intake estimates from the first instrument appear to be generally under- or overreported in comparison to the criterion measure [12,13]. Bias is particularly important when the objective is to measure absolute intakes for comparison to dietary recommendations or some other objective criteria. For example, bias is critical when estimating how close Americans are to meeting the dietary recommendation to eat five servings of fruits and vegetables per day.

Precision is concerned with whether an instrument accurately ranks individuals from low to high nutrient intakes, which is typically the analytic approach used to assess associations of dietary intake with risk of disease [13]. In this situation, bias in the estimate of absolute intake is not important as long as precision is good. In a validity study, precision is the correlation coefficient between nutrient intake estimates from the instrument of interest in comparison to a criterion measure. Often, dietary assessment studies also assess validity by ranking nutrient intake estimates, dividing them into categories (e.g., quartiles), and comparing these to similar categories calculated from another instrument. However, classifying a continuous exposure into a small number of categories does not reduce the effects of measurement error [12] and, therefore, this analysis does not yield additional information beyond that provided by correlation coefficients.

It is important to know that an instrument can be reliable without being accurate. That is, it can yield the same nutrient estimates two times and be wrong (e.g., biased upward or downward) both times. Alternatively, an instrument can be very reliable and can consistently yield an accurate group mean (e.g., unbiased) but have poor precision such that it does not accurately rank individuals in the group from low to high in nutrient intake. Reliability is easy to measure, and nutrient correlation coefficients between two administrations of the same FFQ are generally in the range of 0.5–0.8 [13]. Estimates of reliability give an upper boundary to the accuracy of an instrument. Although a high reliability coefficient does not imply a high validity coefficient, a low reliability coefficient clearly means poor validity.

1 Sources of Error Associated With Self-Reported Dietary Intake

Regardless of the approach used, self-reported dietary intake is inherently subject to several sources of error (Table 7.3). Sources of random error that are common across dietary assessment methodologies include error in estimation of portion sizes, forgetting to report foods or beverages, and mistakes in reporting. Bias can occur when under- or overreporting of intake is related to some characteristic of the participants. For example, obese

TABLE 7.3 Sources of Error and/or Bias in Dietary Intake Estimates

Source of Error	Type of Error	Reason for Error	FFQ	Food Record	Food Recall
Participant	Memory	Unable to recall food consumption. This error increases with interval of memory required.	X		X
	Frequency judgments	Respondent has cognitive difficulty accurately providing this information. May be a particular problem in low-literacy respondents.	X		
	Question comprehension	Respondent may not understand what foods are being asked about, understand the frequency categories, or be able to estimate portion sizes.	X		
	Response errors	Respondent mistakenly codes incorrect frequency or skips questions.	X		
	Portion size errors	Respondent cannot conceptualize reference portion size or his or her own portion sizes.	X	X	X
	Social desirability bias	Respondent unintentionally (or intentionally) misrepresents dietary intake in order to please investigators. For example, obese participants may underestimate intake.	X	X	X
	Fatigue/burden	Respondent alters normal food choices or omits some items to simplify record keeping.		X	
Investigator/ tool	Food list	Food list is too short or not appropriate for population being studied and therefore dietary intake data are incomplete.	X		
	Food groups	Food groups may not appropriately group foods by nutrient composition.	X		
	Portion sizes	The reference portion size may be too large or too small for a population such that it consistently over- or underestimates amounts of food consumed.	X		
	Categorization of frequencies	Loss of information by using close-ended categories (e.g., 2−4 times/week) instead of using an open-ended format.	X		
	Poor form design	Font is too small, skip patterns are not clear, or instructions are unclear.	X		
	Data collection errors	Scanning errors may occur. Data from incomplete FFQs are used in analysis.	X		
	Database	Database may have incorrect nutrient values, incomplete nutrient values, or be missing important exposures altogether (e.g., isoflavones).	X	X	X
	Programming errors	Nutrient analysis program may contain errors.	X	X	X
	Estimation	Investigator relies on estimates to quantify nutritional intake. With food records, there is no opportunity to probe participant for additional information.		X	X
Other	Seasonal variation	It may not be possible to adequately report average intake of foods where intake varies markedly over seasons.	X		
	Unusual dietary patterns	Respondents with unusual eating patterns (e.g., liquid diets) may not be able to accurately report dietary patterns.	X		
	Short time period	Short duration of reference period results in a "snapshot" that may not be representative of respondent's usual intake.		X	X
	Intervention-associated bias	Respondents in an intervention are more likely to report socially desirable responses.	X	X	X

individuals tend to underreport their energy intake to a greater degree than normal-weight individuals [107]. Another concern is social desirability bias, which is the tendency to respond in a pleasing way. For example, participants enrolled in a program to increase fruit and vegetable intake may consciously or subconsciously overreport their intake of these foods. Susceptibility to social desirability bias varies among individuals and has been associated with differential error in the reporting of energy intake [108]. Furthermore, research indicates that dietary interventions introduce reporting bias toward the more desirable responses [109]. Finally, food records, food recalls, and FFQs are all subject to limitations in the food database and errors in the programming used to quantify nutrient intake.

2 Measurement Error Specific to FFQs

The FFQ form is a major source of error due in part to the limitations inherent in the following commonly used components: closed-ended scannable response options, limited food list (generally approximately 100 items), inadequate food composition information, and instructions for respondents to report their average intake over long periods of time, such as one year.

Studies comparing FFQs with records or recalls are often called validation studies. The theory behind this type of study is that the major sources of error associated with FFQs are independent of those associated with short-term dietary recall and recording methods, which avoids spuriously high estimates of validity resulting from correlated errors. As summarized by Willett [13], errors unique to the FFQs include the restrictions imposed by a fixed list of foods, perception of portion sizes, and the cognitive challenge of assessing frequency of food consumption over a broad time frame. However, it is clear that many sources of error (e.g., underestimating portion sizes) are common to all self-report assessment instruments.

3 Measurement Error Specific to Food Records/Recalls

Unlike FFQs, food records and recalls are open-ended, do not depend on long-term memory, and allow for measurement of portion sizes. In addition to the sources of error that are common across self-reported dietary assessment methods, food records are also prone to bias that results when participants change their eating habits during the assessment period. This may occur as the result of social desirability bias (e.g., respondent decreases intake of unhealthy foods to avoid having to report these items) or due to burden and fatigue (e.g., respondent begins eating fewer foods or more simply prepared dishes to make it easier to record intake). Like food records, food recalls are typically open-ended. However, recalls are usually collected without advance notification. Therefore, participants cannot change what they eat retroactively and the instrument itself should not affect food intake, although misreporting due to social desirability bias is still possible. Both recalls and records are subject to coding errors because scannable forms are not typically used.

4 Comparison of Self-Reported Diet to Objective Biomarkers

Validity studies that compare self-report dietary instruments against one another are subject to certain limitations. They rely on the assumption that there will be little overlap between the sources of error and bias on the two instruments. This is unlikely to be fully true because some sources of error are common to all self-report assessments. For this reason, recent validity studies have focused on comparing self-reported diet to objective biomarkers, such as doubly labeled water. As described previously, the doubly labeled water method is a gold standard method that provides an accurate assessment of total energy expenditure (essentially equivalent to energy intake). A 2014 paper reported on pooled data from five large validation studies of dietary self-report instruments that used recovery biomarkers as references to clarify the measurement properties of FFQs and 24-hour recalls. Using an FFQ, the average correlation coefficients for reported versus true intakes for energy, protein, and protein density were 0.21, 0.29, and 0.41, respectively. Using a single 24-hour recall, the coefficients were 0.26, 0.40, and 0.36, respectively, for the same nutrients and rose to 0.31, 0.49, and 0.46 when three 24-hour recalls were averaged. The average rate of underreporting of energy intake was 28% with an FFQ and 15% with a single 24-hour recall, but the percentages were lower for protein. Personal characteristics related to underreporting were body mass index (BMI), educational level, and age. This project established that their self-reported energy and protein intake are poorly correlated with truth, the use of multiple 24-hour recalls substantially increases the correlations when compared with a single 24-hour recall, and BMI strongly predicts underreporting of energy and protein intakes [110].

5 Effects of Error in Dietary Intake Estimation and Measures of Disease Association

Error in dietary assessment can be of two types, with markedly different consequences. Random error refers to mistakes such as inadvertently marking the wrong frequency column, skipping questions, and lapses in judgment. These errors introduce noise into nutrient estimates such that our ability to find the "signal" (e.g., an association of dietary fat and breast cancer) is masked or attenuated (biased toward no association).

Systematic error refers to under- or overreporting of intake across the population (e.g., bias) as well as to person-specific sources of bias. For example, studies indicate that obese women are more likely to underestimate dietary intake than are normal-weight women [108,111,112]. Systematic error may result in either null associations or spurious associations. In one report, Prentice used data from FFQs collected in a low-fat dietary intervention trial to simulate the effects of random and systematic errors on an association of dietary fat and breast cancer, where the true RR was assumed to be 4.0 [113]. Assuming only random error exists in the estimate of fat intake, the projected (i.e., observed) RR for fat and breast cancer would be 1.4. Assuming both random and systematic errors exist, the projected RR would be 1.1, similar to that reported in a pooled analysis of cohort studies [114]. These results indicate that FFQs may not be adequate to detect many associations of diet with disease, even if a strong relationship exists [115,116]. In view of the error in dietary self-report, it is not surprising that results from diet–disease studies are often null or conflicting [113,117–120]. Because of cost or practical considerations, the use of objective biomarkers is not feasible in epidemiologic studies. One approach for large studies using self-reported diet assessment is to collect biomarker data on a subset of participants and use that data to develop calibration equations that reduce the "noise" component of dietary measurement error [117,119] and correct for subject-specific error in reporting that can reduce bias in diet–disease association studies [121].

B Limitations in Research Designs

1 Observational Studies

In studies of nutritional epidemiology, unique obstacles exist in finding clear and interpretable relationships between dietary intake and disease risk [106,118]. In roughly increasing order of importance, these obstacles include the following:

- Current or recent dietary intake may differ from intake over the time frame relevant to the development of disease, which will reduce our ability to find associations between diet and disease.
- Certain nutrient intakes within a population may not be highly variable. For example, energy from dietary fat in a population of postmenopausal women may only vary from 25% to 40%, resulting in inadequate range of disease risk to find an association with breast cancer. This situation is akin to assessing whether smoking causes cancer by studying men who smoke one pack per day in comparison to men who smoke one and a half packs per day. Minimal heterogeneity in exposures provides insufficient contrasts.
- Diet is a complex mixture of foods and nutrients, including many highly correlated compounds, making it difficult to separate the effects of any one compound from other dietary factors.
- Dietary intake may relate in a complicated manner to other risk factors such as hormonal status, obesity, or hypertension. These relationships (some of which may be in the causal pathway) make it difficult to appropriately control for confounding factors.
- Existing dietary self-report instruments include many sources of random and systematic error, both of which obscure our ability to find associations between dietary intake and disease risk.

An important point to consider is that most of the obstacles listed previously will limit or attenuate our ability to find associations between dietary intake and disease. For example, as shown in Table 7.4, an observed association of dietary fat intake with BMI might appear too small to be clinically important. However, if we assume that significant measurement error exists in our estimate of fat intake (e.g., a correlation of 0.30 between our measure and "true" intake), then the real association would be 4.0 BMI points per 10 g of fat intake, which is considerably more important. Therefore, studies showing weak or no associations between dietary intake and disease (e.g., null results) need to be interpreted cautiously.

Observational studies are frequently referred to as hypothesis-generating studies, which set the stage for testing in a large randomized trial with disease outcomes. However, many hypotheses that were well supported by

TABLE 7.4 Estimates of the Observed Association[a] Between Dietary Fat Intake (per 10 g of Fat) and BMI After Adjustment for Random Measurement Error in the Measure of Dietary Fat

Correlation Coefficient[b] Between the FFQ Estimate and "True" Fat Intake	Observed Increase in BMI for Every 10 g of Fat Consumed[c]
1.00 (FFQ is a perfect measure of fat intake)	4.0
0.70 (FFQ is a good measure of fat intake)	2.8
0.50 (FFQ is a weak measure of fat intake)	2.0
0.30 (FFQ is a poor measure of fat intake)	1.2

[a] $\beta_{observed} = \beta_{true} \times$ validity coefficient.
[b] Correlation coefficient from validity study comparing FFQ to multiple 24-hour recalls.
[c] Assume true regression coefficient from a multivariate model predicting BMI = 4.0.

laboratory and observational epidemiologic research have proven to be null when tested in a trial:

- Experimental and epidemiological data suggested that vitamin E supplementation prevents cancer and cardiovascular events. In a trial of 7030 patients with vascular disease or diabetes mellitus, long-term vitamin E supplementation did not prevent cancer or major cardiovascular events and resulted in some increase in the risk for heart failure [122].
- β-Carotene was hypothesized to reduce tumor incidence. However, two large trials to test the effect of β-carotene supplements on lung cancer incidence in smokers found that β-carotene supplementation increased the incidence of lung cancers as well as cardiovascular and all-cause mortality [123,124].
- B vitamins were believed to lower the risk of CVD. However, after 38 months of treatment and follow-up, supplementation with folic acid, B_{12}, and B_6 did not reduce total cardiovascular events among 3096 patients with coronary artery disease or aortic valve stenosis [125]. An analysis with long-term follow-up found that treatment with folic acid plus vitamin B_{12} was associated with increased cancer outcomes and all-cause mortality [126].
- A healthy diet, characterized to be low in fat and high in vegetables, fruits, and fiber, is hypothesized to reduce disease risk and disease progression in at-risk populations, such as postmenopausal women and breast cancer survivors. However, a trial of 48,835 postmenopausal women found that adoption of a diet high in vegetables, fruits, and whole grain and low in fat did not reduce the risk of CVD or risk of colorectal cancer over an 8-year follow-up period [127,128]. In a separate trial of 3088 breast cancer survivors, the adoption of a similar dietary pattern did not reduce additional breast cancer events or mortality during a 7.3-year follow-up period [129].
- Vitamin E and selenium were thought to reduce the risk of prostate cancer. Unexpectedly, a trial of 35,533 men found that dietary supplementation with vitamin E significantly increased the risk of prostate cancer among healthy men [130,131].

Although this list of null or negative trials is in no way comprehensive, it clearly illustrates that regardless of their size or duration, observational epidemiologic studies alone may not provide reliable information on the associations of dietary intake and disease.

2 Limitations of Clinical Trials of Dietary Intake and Disease Risk

Despite the many desirable features of dietary intervention trials, unique obstacles are present in these types of studies, as summarized here.

The costs of a long-term dietary intervention trial can be formidable. For example, the National Institutes of Health-sponsored Women's Health Initiative tested whether "low-fat eating pattern" would reduce the incidence of breast cancer, colorectal cancer, and coronary heart disease among 48,837 postmenopausal women in the United States [127,128,132]. The dietary intervention required participants to attend monthly sessions (run by specially trained nutritionists) for the first 18 months followed by quarterly classes for the remainder of the trial—approximately 8.5 years [133]. In addition, new intervention components were added to the trial to encourage adherence. The costs of implementing this type of intervention far exceed those required for comparatively simple pill−placebo trials or observational studies.

Maintenance of dietary adherence for a sufficient period of time to be able to ascertain clinical outcomes (e.g., disease risk) can be a formidable task. On the one hand, the greater the contrast in dietary intake between the intervention and control groups, the more likely the study will be able to detect an effect on the outcome. On the other hand, it is clearly more difficult to get participants to adhere to very strict or limited regimes, which can result in such poor adherence that the trial becomes futile [134]. Monitoring of dietary adherence typically requires use of self-reported dietary instruments, with their attendant weaknesses (discussed previously).

VI FUTURE RESEARCH DIRECTIONS

As is apparent from this overview of nutritional epidemiology, the major challenge is that of addressing random, systematic, and person-specific sources of error in dietary assessment. Only when well-designed validity studies clarify these sources of error we will be able to markedly improve our ability to draw valid inferences from epidemiologic studies of diet and disease.

A growing area of research concerns diet−gene and diet−environment interactions in the etiology and pathogenesis of chronic diseases. Despite the vigorous investigation of environmental causes of disease, it has long been recognized that not all persons exposed to the same risk factors will develop the associated disease [135,136]. For example, although it is well accepted that smoking will cause lung cancer, only 10−15% of smokers will be diagnosed with the disease in their lifetime. We are only beginning to understand the complexity of genetic susceptibility in the etiology and pathogenesis of common diseases such as coronary heart disease and cancer. If only a subgroup of individuals is sensitive to certain dietary exposures, the effect will be diluted and the association will be undetectable when the entire population is the focus of study. On January 20, 2015, President Obama announced the Precision Medicine Initiative (PMI) in his State of the Union address. The PMI Cohort Program

seeks to extend precision medicine to all diseases by building a national research cohort of one million or more US participants who contribute genetic, environmental, and lifestyle information over a long period of time [137]. This initiative has the potential to improve our understanding of individual susceptibilities and lifestyle factors. A second part of the PMI will advance the field of precision oncology by discovering unique therapies that treat an individual's cancer based on the specific abnormalities of their tumor [138]. Although focused on targeted therapies, this initiative offers considerable potential to expand this knowledge to nutrition. For example, a nested, case−control study of 265 postmenopausal breast cancer survivors found that among women whose tumor tissue was positive for insulin-like growth factor 1 (IGF1) receptor, stable or increased carbohydrate intake postdiagnosis was associated with a fivefold increased risk of recurrence [139]. This is the first study to suggest that it may be possible to personalize dietary recommendations for breast cancer survivors based on molecular characteristics of their primary tumor tissue.

Another exciting area is the use of new technologies to assess the influence of diet on the various "omics," such as proteomics and metabolomics [140−142]. These small molecules may prove to be more informative biomarkers of diet and diet−disease relationships than simple assessment of blood nutrients. For instance, recent evidence has implicated the gut microbiota, several distinct microbial ecosystems found within the gastrointestinal tracts of humans, to contribute in important ways to human health and disease. The "thrifty microbiome hypothesis" theorizes that the gut microbiota, specifically the relative proportions of two phyla (i.e., Bacteroidetes and Firmicutes), plays a key role in human energy homeostasis and impact the obesity epidemic [143−145]. This particular phenotype may introduce a survival advantage to its host in times of nutrient scarcity, promoting positive energy balance by improving metabolic efficiency and energy storage, and increasing efficiency of nutrient absorption [146]. However, in the presence of excess nutrients, obesity and obesity-related conditions may result [144,147]. Furthermore, potential factors that modify the relationship between the microbiota and risk of obesity are the host's external environment, geographic location, and behavioral factors (sedentary behavior and dietary patterns) [148].

In summary, despite the challenges in nutritional epidemiology and the measurement error issues that have impeded progress in the field, nutritional epidemiology studies have made important scientific contributions that have shaped public health policy and practice. To better understand the influence of diet on obesity-related health outcomes, efforts to reduce dietary measurement error through improved collection, evaluation, and analysis of consumption data are still urgently needed [11]. In addition, future research on diet and disease should focus on study designs that do not rely on self-reported diet as a measure of intervention adherence or an outcome. These research approaches include the use of randomized trial designs, the inclusion of dietary biomarkers, and the use of disease biomarkers such as insulin resistance. The challenge for the future is to decide which epidemiologic methods and study designs are most useful in studying chronic disease, determine which associations and the hypotheses derived from them are especially strong and worthy of pursuit, and finally to design randomized studies that are feasible, affordable, and likely to result in confirmation or refutation of these hypotheses [2].

Chapter 8

Analysis, Presentation, and Interpretation of Dietary Data

I INTRODUCTION

Nutritional epidemiological studies play a critical role in relating dietary intake to risk of disease. These investigations often require gathering dietary intake data from large cohorts of people, which must then be translated into a usable format for analysis. This chapter focuses on research applications for the analysis, the examination of dietary data to determine the nutritional composition of participants' diets; presentation, the communication of the data and results in a logical format, such as comparing the results to a standard; and interpretation, the translation of the data and results—what do the data really tell us? The first step in planning a research study is to define the research question. The dietary assessment method and the type of analysis undertaken will be largely determined by the research question being addressed and the dietary assessment method that is best suited to the research question. How best to minimize measurement error through data collection and analysis should be one of a researcher's key considerations. In Chapter 1, Dietary Assessment Methodology, the advantages and disadvantages of dietary assessment instruments were outlined in detail. While ideally, the research question will drive the choice of method, but constraints of funding, research staff availability, and participant burden also influence choices in methods. With future advances in technology, it may be possible to overcome some of these limitations to dietary assessment so that more detailed methods can be undertaken without being limited by cost and participant burden [1].

II ANALYSIS OF DIETARY DATA

The methods most often used to obtain dietary intake information for research investigations include 24-hour dietary recalls, dietary records or diaries, and food frequency questionnaires (FFQs). The 24-hour dietary recalls and dietary records provide detailed descriptions of the types and amounts of foods and beverages consumed throughout a specified period of time, normally 1−7 days. The FFQ provides a less detailed list of selected foods and the frequency of their consumption in the past. See Chapter 1, Dietary Assessment Methodology, for further description of these methods. The data received must then be analyzed to determine the total intake of nutrients or food components consumed by each study participant.

A Preparation for Analysis

Prior to data analysis, the data need to be checked for missing data and data entry errors. Technology has helped a great deal with reducing data entry errors and ensuring there are no missing data (e.g., forcing a response on an electronic FFQ), but there are still areas where the researcher must make decisions on what to enter for analysis and ensure data cleaning has occurred before the analysis is undertaken.

The first step in this process is to check the participants' data for completeness. For interviewer-administered 24-hour dietary recalls, self-administered 24-hour recalls such as the ASA24, or computer-based FFQs, data may be coded as complete or incomplete. Thus making it simple for research staff to identify and exclude incomplete data. Food records, both digital and paper-based FFQs require thorough review to identify missing data.

Food records should be verified for missing data and research staff may contact participants to ask for details on food types and amounts in effort to improve the quality of the data [2]. Ideally, record checking should be done in-person with the participant so that portion size aids

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00008-4

may be shown. Alternatively, contacting the person by telephone may also be done to verify items recorded. Image-based methods also require confirmation to ensure the participant has not missed taking images of any food or beverage during the recording period and to verify the content of the images. Research staff who are familiar with food composition, age-specific foods (e.g., foods commonly consumed by toddlers), ethnic or regionally specific foods, and the food database system being used for analysis, as well as the format in which foods need to be entered are critical for this review and verification step. This requires knowledge of the brand names along with the generic equivalent the food may be listed as in the food composition database [3]. In addition, with technology-based dietary assessment methods becoming more available, training in technology is becoming increasingly important. Ideally, the research staff should have qualifications in nutrition and dietetics and have undergone advanced training in dietary assessment. It is recognized, however, that not all graduates may have training in this important competency for dietetic professionals [4]. Although complete checking of records is ideal, there may be situations in which some details are missed or the participant is unable to provide the level of detail the researcher would like.

The task of undertaking 24-hour recalls or food records can become tedious for participants. When the researcher probes for more details, some participants may become concerned that they have not done a good job, whereas others may become bored and lose interest in the task [1]. The researcher must to be able to balance the need for detail with the burden placed on the participant, particularly when working with adolescents and young adults who may have a low tolerance to some methods [5,6]. In addition, with food records, there may be incomplete days of recording or participants may have been unwell and not eaten. For some participants, no amount of probing will result in a quality record due to a consistent lack of detail of the foods consumed. The researcher should make a decision if he or she considers the record suitable for analysis.

B Rules for Data Entry

When entering data, rules for data entry should be set up to ensure a consistent approach is applied to all records. This is particularly important when a team of researchers is entering the data. The researcher needs to be able to translate the food or drink reported to the best match in the food database. These decisions need to be recorded along with what to do about missing data so that a standardized approach is used across all data collected. In some situations, participants may not know the composition of the food or drink consumed. This commonly occurs with meals eaten outside the home or where they have not been involved in the food preparation. In this case, it is important to standardize the rules and decision making on what food is considered the best match for a food selected from the food database. For databases such as the Food and Nutrient Database for Dietary Studies used in the "What We Eat in America" (WWEIA) 24-hour recalls, for most foods there is an option to select a food code "not (further) specified" (NFS or NS) when the participant is unable to provide details of the food eaten. If the quantity of food eaten is not known, then "quantity not specified" may be chosen. These are known as defaults used for coding. Because these are based on usual consumption patterns from survey data, the use of default codes introduces more error; thus, their use should be minimized [7].

C Choosing a Nutrient Composition Database

A variety of computer-based food composition databases and nutrient computation systems are available in which the foods can be entered directly by name and computation of nutrient values is automated. The food composition databases are referred to as either the reference or user database. Selection of the correct food composition database is critical because the foods in the database must be appropriate to the geographical location and the ethnicity of the population being studied. Stumbo [3] and Buzzard and colleagues [8] summarize key points for selecting dietary assessment systems; e.g.: (1) Does the databases contain all the foods and nutrients of interest? (2) Is the database complete for nutrients of interest? (3) Do the food descriptions included in the database provide adequate specificity to accurately assess food components of interest? and (4) What quality control procedures are used to ensure the accuracy of the database? The accuracy of the data obtained from these systems will differ, depending on the following factors:

Updating of the database. New foods are constantly being introduced in the market, so the best databases are updated often to keep up with these changes. Virtually all databases use the US Department of Agriculture (USDA) Nutrient Database for Standard Reference (SR) as their primary source of nutrient data. The 2010 version, Release 28 (SR28), contains data on 8789 food items and up to 150 food components [9]. Nutrient profiles were added for new foods and existing nutrient profiles were updated in this release. A focus was to monitor those foods which are major contributors of sodium to the diet. Although the database may not include information on all food products currently in the marketplace, specific criteria

have been established for evaluating foods to ensure the data are as accurate as possible [10,11]. Many databases also add information from specific food manufacturers to provide information on name-brand foods not available in the SR.

The numbers and types of food items available. This is particularly important for recalls and dietary records or for FFQs containing write-in sections in which all foods must be assigned nutrient values. In regions with ethnocultural diversity, special care must be taken when selecting databases [12,13]. The databases that contain a variety of ethnic foods will provide greater accuracy and will require less manual entry of nutrient values for foods. The researcher must have knowledge of the naming convention and the search strategy required when using food composition databases [3]. Many food names can be ambiguous or spelled in a number of different ways—e.g., in the United States, ketchup versus catsup versus tomato sauce in England and Australia [3]. Pennington [14] summarized a number of useful examples of food items with more than one meaning and food synonyms.

The ability to add foods or nutrients. This is most important for those investigations in cohorts with multiethnicity [12,15,16] or when there is a high tendency for the participants to include restaurant foods that may not be included in the database. The trend is for greater consumption of food away from home [17], especially for teenagers and young adults [18]. This has implications for the accuracy of dietary assessment because when a restaurant-specific food is not available in a database, it may be difficult in some situations for participants to identify the contents and amount of food they have consumed. The ability to adapt or add recipe information should also be available. For example, if a participant reports homemade beef stew for lunch, the database should allow the coder to either add or delete ingredients from an existing recipe or add a new recipe to the file. The decision as to what foods to add to the database may depend on the research question and how important the composition of these foods may be to the study outcomes. Otherwise, choosing a similar food or an NFS item may be appropriate. There are increasing numbers of functional foods that may not appear in the database. Again, it depends on the study objectives as to how critical it is to add these foods or adjust the composition of existing foods.

The ease of data entry and analysis. Systems should be easy to use to avoid unnecessary coding errors. Entry of products by name, particularly brand names, should be available. Some databases, such as the Food Intake Analysis System [19], which is a nutrient analysis software program, offer default options. These choices provide average estimations of foods for which exact information is not known. For example, if a subject had chicken breast but was not sure of the cooking method or the serving size, the coder can choose the default option instead of making guesses. These options can help decrease differences in nutrient intake values caused by multiple coders or data entry technicians.

The nutrients available. Not every database contains all nutrients. A database may be limited to those nutrients available on the Nutrition Facts Panel or have as many as 65 nutrients/food components such as in the USDA Food and Nutrient Database for Dietary Studies. Some contain more accurate data for particular nutrients using analytically derived values while others may impute nutrient values. Systems should be evaluated for the accuracy of the nutrient values that are being studied.

The handling of missing nutrient values. Missing values exist if the food has not been analyzed for all food components [4]. If a specific nutrient value is unknown for a particular food, the way the database handles the missing information may affect the accuracy of the nutrient information. Some systems impute values, whereas others simply use a value of zero. An imputed value is almost always a better estimation [20]. However, imputing nutrient values is a labor-intensive task and requires nutritionists with knowledge of data evaluation and imputing procedures. Therefore, caution must be taken when using databases with imputed values.

The handling of dietary supplements. In studies where total nutrient intake is of interest, a database that includes dietary supplements will be needed. For example, in a study examining the relationship between calcium intake and bone health, total calcium intake from all sources including dietary supplements and calcium-fortified foods will be necessary. Merging data from a dietary supplement database with data from the food nutrient database may be necessary. The assessment of dietary supplement use is presented in detail in Chapter 2, Assessment of Dietary Supplement Use.

Standardizing dietary assessment. The emergence of large multicenter trials that may span across countries has presented challenges for nutrient analysis of dietary data. Because food composition may differ markedly, how best to pool nutrient databases must be addressed. The European Prospective Investigation into Cancer and Nutrition (EPIC) nutrient database project is an example of how researchers have attempted to standardize nutrient databases across 10 European countries [21]. A total of 26 priority nutrients were identified by the researchers along with procedures for food matching across counties.

D Statistical Approaches to Data Checking

Statistical packages such as IBM SPSS Statistics [22] and SAS [23] are useful for checking nutrient data for errors prior to undertaking analysis. Once data entry is completed, various tests should be undertaken to ensure data entry errors have not occurred. Some laboratories will perform "double entry" by two researchers of all records as a way to minimize data entry errors. Once this is complete, using the compare function in statistics packages, such as SAS, can be useful to identify where data entry errors have occurred. Additionally the explore function in SPSS or PROC UNIVARIATE in SAS checks for outliers or extreme values in the data. In general, results that fall well outside the mean should be further explored to determine if they are true outliers or a data entry error. It is recommended that all nutrients be examined for outliers because some data entry errors may be nutrient specific. For example, an outlier in β-carotene may have occurred if the serving size of carrots was entered incorrectly, but this may have little impact on energy (calorie) intake. Some researchers omit data from records with implausible energy intakes but this must be approached carefully as the application of arbitrary cutoffs may result in the loss of a substantial number of subjects [24]. Researchers may establish a priori high and low sex-specific cutoff points for energy intake and exclude data outside of the cutoff point. For example, in one study of pregnant women the researchers excluded reports with a calculated daily energy intake of <1000 and >5000 calories/day [25].

E Factors Affecting Food Composition Databases

When computing nutrient intake from food consumption data, it is assumed that the nutrient quality and content of certain foods are virtually constant and that what is consumed is available for use. However, we know that this assumption is not totally correct. There are various reasons why the actual value of a consumed nutrient may differ from the calculated value. The level of certain nutrients in foods may be affected by differences in growing and harvesting conditions (e.g., selenium [26,27]), storage, processing, and cooking (e.g., vitamin C [28]). Databases attempt to account for some of the differences by increasing the data banks to include preparation methods, cuts of meat, and specific manufacturers for processed food. For example, if chicken is entered into the database, the coder may have approximately 455 items to choose from. This large number includes name brand foods, particular pieces of chicken available (e.g., breast or thigh), and cooking methods (e.g., baked or fried, cooked with skin on or off, and skin eaten or not). Because so many choices are offered, recalls and records should be as detailed as possible to provide enough information to make an accurate selection.

The use of controlled feeding trials in a study, such as the Dietary Approaches to Stop Hypertension (DASH) trial [29], can help alleviate some of the differences between the calculated and the actual nutrient values of food. The DASH trial was a multicenter study designed to compare the effects of dietary patterns on blood pressure. The subjects were asked to consume only foods prepared by the research centers. Food procurement, production, and distribution guidelines were set and strictly adhered to at all sites to ensure that menus consistently met nutrient goals. For example, food items were given specific purchasing sizes, detailed descriptions, or defined brand names to ensure that all site recipes were of uniform composition [30]. Menu items were analyzed in a laboratory to obtain nutrient content values [31]. When possible, foods can be obtained from central suppliers to further eliminate any differences in nutritional content of foods due to regional variations in a study of this type.

The diet as a whole can also affect the availability of some nutrients. For example, phytic acid may decrease the availability of iron [32]. Computer-based analysis programs do not generally examine the overall diet and cannot determine how nutrient−nutrient interactions may affect availability. For example, iron is a mineral for which intake is not a good marker for availability. The absorption of iron is influenced by the following components: (1) the source of iron (more heme iron is absorbed than nonheme iron), (2) the iron status of the individual (decreased iron stores increase absorption), and (3) the overall composition of the meal. These components play a role in determining how much of the iron consumed is available to the body [33,34]. In turn, iron consumption can also affect the absorption of other nutrients, such as zinc. Nutrient−nutrient interactions can greatly determine how well a calculated nutrient value represents the actual available amount of a nutrient.

Other factors that should be taken into account are drug−nutrient interactions and those people who may be malnourished or suffer from malabsorption. For example, the elderly are more likely to have a decreased ability to absorb vitamin B_{12} than are younger adults. The elderly population is also at higher risk for drug−nutrient interactions because they are often prescribed many medications. Researchers must be aware of any illnesses or medications taken by subjects that could interfere with nutrient absorption.

Although food composition databases are increasingly becoming more accurate and may be closer to actual values of energy intake than laboratory analysis [31], they cannot provide exact measurements for all nutrient intakes. Furthermore, even if these values are determined to be

accurate, intake does not necessarily mean the nutrient is available for use. To obtain more accurate information on nutrient status, other methods, such as external reference biomarkers, should be employed. Also, familiarity with the participants' diets is essential for more accurate calculations. This includes, but is not limited to, factors such as dietary supplement use, medications used, the presence of diseases or illness, as well as special diets that participants may be following (e.g., vegetarian or weight loss). The decision to include or exclude individual dietary data will depend on how these factors may affect the study outcomes.

F Dietary Pattern Analysis

There is increasing interest by researchers in examining whole foods and dietary patterns rather than only single nutrients [35,36]. Many countries use a food-based approach to dietary guidelines, so examining how the diet compares to dietary guidelines may be of interest to researchers and nutrition policy makers. Diet quality indexes (DQIs) are also widely used and are able to quantify the risk of some nutrition-related health outcomes [37].

In reviewing the indexes of overall diet quality, Kant [38] found that there were three major approaches to the development of indexes: (1) derived from nutrients only, (2) based on foods or food groups, and (3) based on a combination of nutrients and foods. The definition of "diet quality" differs based on the attributes chosen by the investigators of each index [38], so the index chosen will depend on the needs of the study. The indexes based on nutrients only tend to consider consumption as a percentage of one of the nutrient-based reference values of the dietary reference intakes (DRIs), such as the recommended dietary allowance (RDA), as a marker for diet quality. Those based on food groups and dietary patterns examine the intake patterns of foods to identify patterns associated with adequacy and positive health outcomes [38].

Although numerous tools are available for examining overall diet quality and dietary patterns, those most commonly applied are based on the combination of nutrients and foods. These indexes, including the Healthy Eating Index−2010 (HEI-2010) [39], the DQI [40,41], the Diet Quality Index−International (DQI-I) [42], the alternate Mediterranean diet (aMED) score, and the DASH [43−46], use dietary guidelines [47] and food selection guides to score the overall diet. An update of the HEI to align it with the 2015−2020 Dietary Guidelines for Americans can be expected. Patterson et al. [41] were among the first to relate diet quality to the Dietary Guidelines for Americans. The DQI was based on dietary recommendations from the 1989 National Academy of Sciences publication *Diet and Health*, in which intakes were stratified into three levels for scoring. These points were summed across eight diet variables to score the index from zero (excellent diet) to 16 (poor diet). Haines et al. [40] revised the index in 1999, now called the Dietary Quality Index−Revised (DQI-R) [40], to reflect the updated guidelines.

The DQI-R incorporates both nutrients and food components to determine diet quality. It is based on 10 components, with a 100-point scale; each component is worth 10 points (Table 8.1). Components are based on total fat and saturated fat as a percentage of energy; milligrams of

TABLE 8.1 Diet Quality Index−Revised

Component	Maximum Score Criteria[a]	Minimum Score Criteria[a]
Total fat (% of energy intake)	≤ 30%	>40%
Saturated fat (% of energy intake)	≤ 10%	>13%
Dietary cholesterol	≤ 300 mg	>400 mg
% Recommended servings of fruit per day (2−4 based on energy intake)	≥ 100%	<50%
% Recommended servings of vegetables/day (3−5 based on energy intake)	≥ 100%	<50%
% Recommended servings of bread per day (6−11 based on energy intake)	≥ 100%	<50%
Calcium (% AI for age)	≥ 100%	<50%
Iron intake (% 1989 RDA for age)	≥ 100%	<50%
Dietary diversity score	≥ 6	<3
Dietary moderation score	≥ 7	<4

[a]*Scoring range for each component is 0 (minimum) to 10 (maximum).*

cholesterol consumed; recommended servings for fruit, vegetables, and grains; adequacy of calcium and iron intake; dietary diversity; and dietary moderation. The dietary diversity score was developed to show differences in intake across 23 broad food group categories, including 7 grain-based products, 7 vegetable components, 2 fruit and juice categories, and 7 animal-based products [40]. Dietary moderation scores added sugars, discretionary fat, sodium intake, and alcohol intake. The DQI-R was designed to monitor dietary changes in populations but can provide an estimate of diet quality for an individual relative to the national guidelines and can note improvement or decline of diet quality with multiple calculations [40].

The HEI [39,48] was first developed in 1995 by the USDA Center for Nutrition Policy and Promotion to assess and monitor the dietary status of Americans [48]. It has undergone several revisions to use a density-based scoring metric and reflect updated Dietary Guidelines for Americans, including a revision known as HEI-2010 [39]. The HEI-2010 captures the key recommendations of the 2010 Dietary Guidelines and, like earlier versions, is used to assess the diet quality of the US population and subpopulations, in evaluating interventions, in dietary patterns research, and to evaluate various aspects of the food environment. The HEI-2010 contains 12 components, including 9 adequacy and 3 moderation components; it uses a density approach to set standards expressed as a percent of calories or per 1000 calories; and it employs least restrictive standards, i.e., those that are the easiest to achieve among recommendations that vary by energy level, sex, and/or age (Table 8.2) [48].

The Dietary Patterns Methods Project (DPMP) was initiated in 2012 to strengthen the research evidence on dietary indices and dietary patterns [49]. The HEI-2010, Alternative HEI-2010 (AHEI-2010), aMED, and DASH scores showed a high degree of correlation and consistent

TABLE 8.2 Healthy Eating Index, 2010—Components and Standards for Scoring[a]

Component	Maximum Points	Standard for Maximum Score	Standard for Minimum Score (0)
Total fruit[b] (includes 100% juice)	5	≥0.8 cup equiv. per 1000 kcal	No fruit
Whole fruit[c] (includes all forms except juice)	5	≥0.4 cup equiv. per 1000 kcal	No whole fruit
Total vegetables[d]	5	≥1.1 cup per 1000 kcal	No vegetables
Greens and beans[d]	5	≥0.2 cup equiv. per 1000 kcal	No dark green vegetables or beans and peas
Whole grains	10	≥1.5 oz. equiv. per 1000 kcal	No whole grains
Dairy[e]	10	≥1.3 cup equiv. per 1000 kcal	No dairy
Total protein foods[f]	5	≥2.5 oz. equiv. per 1000 kcal	No protein foods
Seafood and plant proteins[f,g]	5	≥0.8 oz. equiv. per 1000 kcal	No seafood or plant proteins
Fatty acids[h]	10	(PUFAs + MUFAs)/SFAs > 2.5	(PUFAs + MUFAs)/SFAs < 1.2
Moderation			
Refined grains		<1.8 oz. equiv. per 1000 kcal	4.3 oz equiv. per 1000 kcal
Sodium	10	≤1.1 g per 1000 kcal	≥2.0 g per 1000 kcal
Empty calories[i]	20	≤19% of energy	≥50% of energy

[a] *Intakes between the minimum and maximum standards are scored proportionately.*
[b] *Includes fruit juice.*
[c] *Includes all forms except juice.*
[d] *Includes any beans and peas (called legumes in HEI-2005) not counted as total protein foods (called meat and beans in HEI 2005).*
[e] *Includes all milk products, such as fluid milk, yogurt, and cheese, and fortified soy beverages.*
[f] *Beans and peas are included here (and not with vegetables) when the total protein foods (called meat and beans in HEI-2005) standard is otherwise not met.*
[g] *Includes seafood, nuts, seeds, soy products (other than beverages) as well as beans and peas counted as total protein foods.*
[h] *Ratio of poly- and monounsaturated fatty acids to saturated fatty acids.*
[i] *Calories from solid fats, alcohol, and added sugars; threshold for counting alcohol is >13 g/1000 kcal.*

classifications among participants in three large, diverse cohorts (the AARP Diet and Health Study, the Multiethnic Cohort, and the Women's Health Initiative Observational Study—WHI-OS). It is encouraging that the DPMP researchers concluded that all four indices captured the essential components of a healthy diet [49].

Categorizing foods into appropriate groups, particularly combination foods, can be a challenge when using these analysis techniques. Guidelines are available to help overcome two major obstacles when assessing food intake with respect to the dietary guidelines—which are dealing with food mixtures and the differing units of measurement used. Because many foods are eaten as mixtures and are difficult to categorize into food groups, Cleveland et al. [50] developed a recipe file that helps break down food mixtures into ingredients so they can be assigned to their respective groups more easily. Standard serving sizes were assigned gram weights to help to overcome the unit problem, allowing for the use of only one unit of measure. The USDA Food Patterns Equivalents Database allows researchers to easily disaggregate combination foods into simple food group components using standardized cup- and ounce-equivalent units.

III PRESENTATION OF DATA

The presentation of data depends on the research questions for each study. For example, for a cross-sectional dietary assessment of an ethnic population, it may be useful to compare the data against population standards. These standards may include the DRI or comparison to a national average, such as the National Health and Nutrition Examination Survey (NHANES). Batis et al. [51] demonstrate how dietary differences among ethnic populations may be presented. Researchers may also wish to evaluate menus in comparison to dietary intakes. In a study involving 40 New York child care centers, researchers compared the dietary intakes of children to the dietary recommendations and found that less than 50% of children ate at least half of the daily recommended intake for each of the five food groups [52]. When comparing data for analyses, researchers must take into account differences that may exist among survey methods, questionnaire wording, data processing, and databases that could impact comparisons.

The DRIs are a set of nutrient-based reference values that include an estimated average requirement (EAR), an RDA, and an adequate intake (AI), which are defined by nutrient adequacy and may relate to the reduction of the risk of chronic disease [53]. Once the EARs have been established, they are used to set the RDAs, which should be used as a daily intake goal by healthy individuals and should be sufficient to meet the needs of 97% or 98% of all healthy people. If there is not sufficient evidence to determine an EAR, then an AI is set, once again based on groups of healthy people. A tolerable upper intake level (UL) is set when information is available as an indicator of excess for nutrients [53]. Each value has a specific goal and use [53] (Table 8.3). For example, the EAR is the estimate that is believed to meet the nutrient needs of half of the healthy people in a gender or life-stage group. When assessing nutrient intake of healthy groups, the EAR should be used instead of the RDA [53].

DRIs are set for specific subgroups based on age and sex. They are to be applied to healthy populations and may not be adequate for those who are or have been malnourished or have certain diseases or conditions that increase nutrient requirements. For individuals, the RDA and AI can serve as a goal for nutrient intake. A more complete description of the DRIs can be found in a later chapter.

TABLE 8.3 Uses of DRIs for Healthy Individuals and Groups

Type of Use	For the Individual	For a Group
Planning	RDA: Aim for this intake.	EAR: Use in conjunction with a measure of variability of the group's mean intake of a specific population.
AI: Aim for this intake.		
UL: Use as a guide to limit intake; chronic intake of higher amounts may increase risk of adverse effects.		
Assessment[a]	EAR: Use to examine the possibility of inadequacy; evaluation of true status requires clinical, biochemical, or anthropometric data.	EAR: Use in assessment of the prevalence of inadequate intakes within a group.

[a]*Requires statistically valid approximation of usual intake.*
AI, adequate intake; *EAR*, estimated average requirement; *RDA*, recommended dietary allowance; *UL*, tolerable upper intake level.

TABLE 8.4 Overview of WWEIA

Five-step USDA AMPM used for collecting interviewer-administered 24-hour dietary recalls	Day 1: Day 1 in-person at the Mobile Exam Center
Day 2: Day 2 from central NHANES telephone center	
For each food and beverage, including water, consumed by a survey participant	• Name, identified by a USDA food code and description • Amount consumed, in grams • Amounts of food energy and 64 nutrients/food components provided by each food/beverage • Identification of items eaten in combination (e.g., cereal with milk added) • Separate ingredients coded for many salads and sandwiches • Day of week • Eating occasion—name (breakfast, lunch, etc.) • Time when each item was consumed • Source of food/beverage (where obtained) • Whether the food/beverage was eaten at home or not
For each survey participant	• Daily aggregates of energy and 64 nutrients/food components • Whether the day's intake was usual, much more than usual, or much less than usual • Salt type and use in food preparation and at the table • Whether on a special diet and type of diet • Frequency of fish/shellfish consumption in past 30 days (participants' age 1 year or older)

Some researchers use national survey data as a standard when presenting dietary data. WWEIA is the dietary intake component of NHANES. This survey is a joint effort between the USDA and the US Department of Health and Human Services, with data released in 2-yearly intervals. NHANES provides medical history, physical measurements, biochemical evaluation, physical signs and symptoms, and diet information from two 24-hour recalls using USDA's Automated Multiple-Pass Method (AMPM) [54]. Table 8.4 provides an overview of the dietary information collected. Researchers may wish to compare results of the information obtained from these surveys to determine how their study sample compares to the national average. Although the data from these surveys may be applied to certain subgroups, such as specific age groups, sex, socioeconomic levels, education levels, and some ethnic groups, they cannot be used as guides for others, such as malnourished or specific disease states.

IV INTERPRETATION OF DATA

Once the dietary intake data have been checked for errors, analyzed, and compared to a standard, researchers must then examine the results to determine what the data really mean. How the data are interpreted can depend on the research questions, the dietary assessment method used and the nutrient being studied, the study type, and the accuracy of participants' responses.

A Assessment Methods

The assessment method chosen for use in a study can determine how the data collected can be interpreted. Recalls and records gather present intake data, whereas FFQs provide data based on past intake. It is known that a person's nutrient and energy intake varies not only from day to day but also from season to season. Thus, if past intake is needed, FFQs may be the better choice.

The number of days of food intake records or recalls available can also affect the interpretation of the data. If high levels of accuracy are needed for a person's nutrient intake, a greater number of days will be required than if a group average could be used. Care must be taken when determining the number of days to use in a study. For example, researchers using data from a single 24-hour recall from 832 men found that saturated fat intake was inversely associated with stroke [55]. Because of the day-to-day variability, dietary changes or recommendations for an individual should not be based on a single day's intake. Basiotis et al. [56] determined the number of days of food intake data needed to estimate individual intake as well as group intake for food energy and 18 nutrients. They found that for females, an average of 35 days were needed to determine a true average of energy intake for each women, whereas 3 days of food records from each subject were required to determine a group average. A minimum of 6 days of food records were needed to

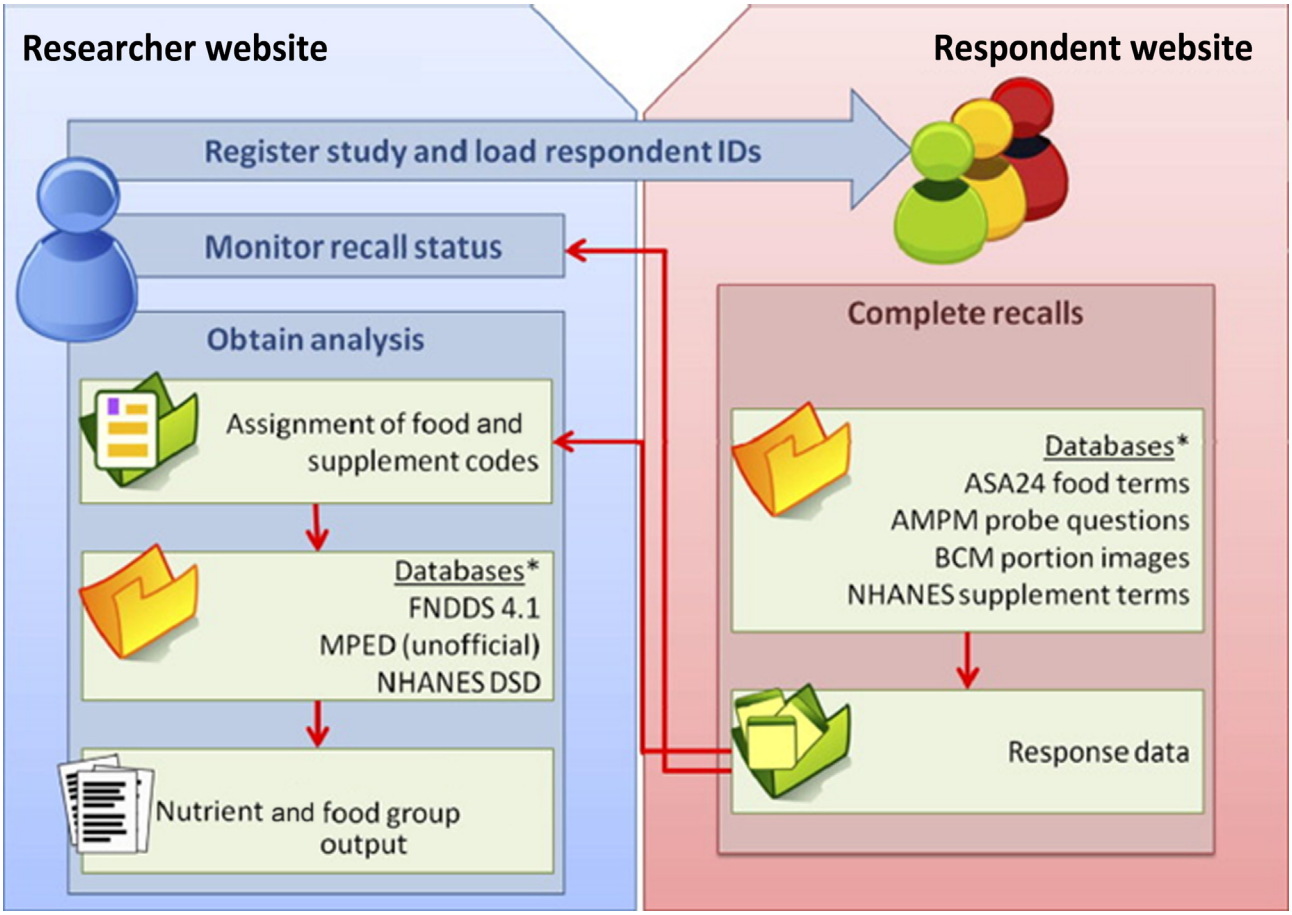

FIGURE 8.1 ASA24— *Taken from J. Acad. Nutr. Diet. 112(8) (2012) 1134–1137, doi:10.1016/j.jand.2012.04.016. Copyright © 2012 Academy of Nutrition and Dietetics.*

assess vitamin K in an elderly population [57]. However, participant burden also needs to be considered because longer recording periods may result in lower quality records as the number of days of recording increases [58].

It is also important that data obtained from dietary assessment methods be used properly. The FFQ was developed to rank nutrient intakes from low to high. It was not intended to be used to determine and develop levels of nutrient intake to prevent disease. However, many researchers have chosen to use the FFQ for this purpose. For example, studies based on FFQ data have recommended levels of vitamin E intake to reduce risk for heart disease [59,60]. However, other studies have concluded that these levels may not have the effect on the development of heart disease that was previously suggested [61–63]. When choosing a method for dietary assessment, care must be taken to ensure that the data are properly interpreted.

The Automated Self-Administered 24-hour Recall (ASA24) is a Web-based tool that was developed by researchers with the National Institutes of Health/National Cancer Institute to improve the feasibility of collecting high-quality dietary intake data from large samples [64]. See Fig. 8.1. Research demonstrates that the ASA24 performs well and offers substantial cost savings over interview-administered recall methods. Detailed information about the ASA24 including instructions to register and to use it free of charge is available at http://epi.grants.cancer.gov/asa24/.

B Data Validity

One major concern when interpreting dietary data is the accuracy of the information reported. Because most of the information gathered is self-reported, the reliability and validity of the data depend on the reporter's motivation, memory, ability to communicate, and awareness of the foods consumed. Most methods have been proven to be generally reliable; i.e., they will provide the same estimate on different occasions. However, do the techniques gather

true and accurate measurements, or valid measurements, of what people are really eating? In the past, assumptions were made that the information was indeed valid. The validity of the techniques was often verified by comparing the different methods to each other. This technique has been referred to as calibration [65]. For example, the results of an FFQ are compared with results obtained using a food record or repeated 24-hour recalls. The estimates by the different methods will differ for a number of reasons. The FFQs rely on the participant's memory to recall foods eaten over a specified period of time. Some participants may have difficulty in remembering this level of detail. Alternatively, food records rely on participants' willingness to record in great detail all food items and beverages consumed. The burden of this task is known to lead to participants changing their intake. It is important to be aware that all self-report methods will have measurement error. This presents a major issue for data interpretation because imprecise methods may obscure the diet–disease relationship. This issue is discussed in detail by Freedman and colleagues [66]. A way to address measurement error in dietary assessment methods is by use of external recovery biomarkers [65,67]. Doubly labeled water (DLW) is the most widely used biomarker for energy intake. Other biomarkers that have been used to validate nutrient intake include fatty acid patterns in blood to reflect fatty acid intake [68], urinary nitrogen to validate protein intake [69,70], serum carotenoids and vitamin C concentrations as markers of fruit and vegetable consumption [71,72], as well as urinary sucrose and fructose as a marker of total sugar intakes [73]. With the increased use of these biomarkers, particularly DLW, to determine the accuracy of dietary intake data in a variety of subjects, reporting errors will be better defined. The use of dietary biomarkers may even help to compensate for reporting errors related to some nutrients—e.g., urinary sucrose and fructose as a biomarker for total sugar intakes. Misreporting of food intake—over- or underreporting—occurs with all self-report methods of dietary assessment [67].

A concerted effort is being made to develop and identify objective dietary biomarkers to aid in defining dietary exposures. Dietary biomarkers are objective biochemical indicators of dietary intake or nutritional status that accommodate the error in self-report methods and thus shed light on the diet–disease relationship [74]. Biomarkers may also be defined as a biochemical indicator of dietary intake/nutritional status, an index of nutrient metabolism, or a marker of the biological consequences of dietary intake [75]. There are three classes of nutritional biomarkers: recovery, concentration/replacement, and predictive biomarkers [75]. In order to obtain independent observations, epidemiologists have utilized concentration biomarkers assessed in biological samples as predictors of disease risk. High-density lipoprotein cholesterol and low-density lipoprotein cholesterol are examples of well-known biomarkers that are strongly associated with risk for cardiovascular disease. One of the main uses of dietary biomarkers is as a reference measurement to assess the validity and accuracy of dietary assessment methods. Recovery biomarkers are based on the concept of metabolic balance between intake and excretion over a fixed period of time [75]. Recovery biomarkers such as DLW and urinary nitrogen help to quantify errors in self-report of energy and protein intake, respectively. The concept of predictive biomarkers is relatively new. These biomarkers are sensitive, time dependent, and show a dose–response relationship with intake levels [73]. Although the correlation to intake is high, the actual recovery of the marker is quite low. Urinary fructose and sucrose concentrations represent predictive biomarkers that have been shown to significantly correlate with sugar intake and provide a useful, independent qualitative index of sugar consumption [73]. Urinary sucrose and fructose have been used in the Observing Protein and Energy Nutrition (OPEN) study to assess for error in self-reported intake of total sugars [76]. Researchers propose that predictive biomarkers, like recovery biomarkers, may be useful for validation and calibration studies to estimate the error in self-reported dietary intakes. Predictive biomarkers may also be used independently of self-report to categorize people by their level of nutrient intake. Inherent errors (e.g., underreporting and undereating) in self-report of dietary intake may be difficult to eliminate. However, the use of dietary biomarkers will accommodate for the errors in self-report methods and thus shed light on the diet–disease relationship. For the researcher, the issue is how best to deal with implausible records as well as continuing to try to identify those participants most likely to overreport and why.

1 Overreporting

Overreporting occurs when reported intakes are higher than the measured energy expenditure levels. Overreporting has not been found to be as large of a problem with regard to reported energy intakes as underreporting, but it still has the potential to interfere with results and conclusions. This occurs particularly if the overreported foods are low in energy but high in nutrients such as many vegetables. Johansson et al. [77] found that people who overreport tend to be younger and, with lower body mass indexes (BMIs), and are often considered lean. The highest proportion of overreporters was found among those subjects who wanted to increase their body weight. A study of the elderly population found that overreporting was higher in men [78]. Although overreporters are not common, care should be taken when obtaining data from participants who have characteristics related to risk of overreporting.

2 Underreporting

Underreporting occurs when reported intakes are lower than measured energy expenditure levels or estimated energy requirements. These reports are often so low that basal metabolic needs could not be met, and they are not biologically plausible. Depending on the age, gender, and body composition of a given sample, underreporters may comprise 2–85% of the total sample [79]. It is now understood that underreporting tends to be associated with certain groups. Prevalence of underreporting also increases as BMI increases. Many studies have shown that the obese underreport more often and to a greater degree (30–47%) than the lean [80–84]. Women have also been found to underreport more often than men [82,85–90]. The EPIC 24-hour recall data indicated that BMI and age were consistently related to underreporting among 35,955 men and women aged 35–74 years [90]. The researchers note, however, that the association observed may simply be due to the common source of variability between EI (energy intake)/basal metabolic rate (BMR) and its components and not to a true causal relationship between BMI, age, and underreporting. Table 8.5 provides a summary of groups most likely to be underreporters. These factors are further complicated by the possibility that they are risk factors for many chronic diseases.

TABLE 8.5 Summary of Underreporting

Populations Most Likely to Underreport	
Women [77,90]	Smokers [77,86]
Higher BMI [77,83,84,89–91]	Lower education [82]
Low socioeconomic status, lower income [83,86,89]	Ethnicity [83]
Psychosocial Characteristics Associated With Underreporting	
High scorers on restrained eating scales [92]	A history of dieting behavior [84,92]
Body dissatisfaction [89,93]	Social desirability [84,89]
Fear of negative evaluation [84]	
Foods Most Likely to Be Underreported	
US survey [94]	
Cake/pie	Meat, fish, poultry, egg sandwiches, or mixtures
Savory snacks: chips, popcorn, pretzels	Regular soft drinks
Cheese	Fat-type spreads
White potatoes	Condiments
British survey [93]	
Cake	Breakfast cereal
Sugars	Milk
Fats	

3 The Problem with Underreporting

A major problem with underreporting occurs when researchers begin to classify dietary intake information to determine diet and disease associations. This is often done by ranking nutrient intakes from low to high and then searching for any associations between nutrient intake and the occurrence of disease. There is a danger of misclassification of subjects if this ranking is based on false or underreported intakes. As noted previously, those who tend to be at higher risk for underreporting are also those who are at greater risk for many chronic diseases. For example, obesity is a known risk factor for coronary heart disease as well as underreporting. Because bias in measuring dietary intake has the potential of removing as well as creating associations, it can generate misleading conclusions about the impact of diet and disease [73,74]. Underreporting is a potentially misleading problem in nutrition research. The use of biomarkers can help to validate and objectively interpret dietary intake data and, ideally, should become routine in nutritional epidemiology. However, the cost of some biomarkers such as DLW may make it impractical for routine use for researchers.

4 Reasons for Underreporting

With the aid of biomarkers for dietary intake, reporting error has been defined. Researchers continue to search for reasons why people underreport. We know that being obese is not the cause of underreporting, but it is most likely the psychological and behavioral characteristics associated with obesity that lead to underreporting [79,95]. Social desirability and self-monitoring are contributors to reporting errors [84,92]. A need for social acceptance, a desire to be liked or accepted by the interviewer, may cause the subject to underreport "sinful" foods or report "healthy" foods that were not actually consumed. A high level of body dissatisfaction—i.e., if a person sees a leaner physique as being healthier or more desirable than his or her own—may cause the person to misreport foods [93]. Also, researchers found that women who scored higher on restrained eating scales, those who believe they are making a conscious effort to avoid certain foods, tend to underreport as well [79,92,95]. For some people, the act of recording dietary intake may lead to changes in eating behaviors. Thus, a person may be reporting actual, but not usual, intakes.

Another explanation for underreporting may be related more to meal size than body size. Wansink and Chandon [96] asked overweight and normal-weight adults to estimate the calories in both small and large fast-food meals.

They found that both groups underestimated the number of calories in the larger meals. Therefore, greater underestimation of energy by obese individuals may be, in part, a result of their tendency to consume larger meals.

5 Foods Most Often Underreported

Underreporting does not occur for all foods and nutrients to the same degree. Foods that are perceived as unhealthy are reported less frequently and in smaller portions among low energy reporters. In a US survey of 8334 adults, 1224 were found to be low energy reporters [94]. Foods that were found to be most often underreported included cakes/pies, savory snacks, cheese, white potatoes, meats, regular soft drinks, fat-type spreads, and condiments [94]. British researchers found little difference between underreporters and plausible energy reporters with regard to bread, potatoes, meat, vegetables, or fruit, but a significant difference was seen with cakes, sugars, fat, and breakfast cereal [97]. Participants completing a 24-hour dietary recall after being observed for 24 hours in a metabolic unit frequently did not report between-meal eating events [98]. This may further contribute to the most often underreported foods. Table 8.5 gives a summary of underreported foods. Some researchers have found that underreporters tend to report lower intakes of fat and higher intakes of protein and carbohydrates as a percentage of total energy [98,99], whereas others show that reports of added sugars intake are significantly lower [98]. The OPEN study used DLW to identify low energy reporters [100] and found they were more likely to report smaller portions, and female low energy reporters reported less soft drink consumption. No agreement has been reached as to how much, if at all, specific macronutrients are misreported.

TABLE 8.6 Principles of the Goldberg Cutoff

Principle	Equations and Comments
Principle 1: Validation of reported energy intake rests on the following:	Energy intake (EI) = energy expenditure (EE) − changes in body stores
Principle 2: Assumes that subjects are weight stable and therefore are in energy balance:	EI = EE
Principle 3: Express energy requirements as multiples of BMR.	EE = physical activity level (PAL) × BMR
Principle 4: Since EI = EE and EE = PAL × BMR, then the following can be assumed:	EI = PAL × BMR or EI: BMR = PAL
Principle 5: Reported energy intake expressed as:	EI_{rep}: BMR can be compared with expected PAL
Principle 6: Since error exists in all the measured elements of the equation, absolute agreement cannot be expected.	
Principle 7: Confidence limits (cutoffs) of the agreement between:	EI_{rep}: BMR and PAL must be determined to establish if reported values within the subjects are acceptable. (For cutoff equations, see Black et al. [93].)

Source: Data from A.E. Black, Critical evaluation of energy intake using the Goldberg cut-off for energy intake:basal metabolic rate: a practical guide to its calculation, use and limitations. Int. J. Obes. Relat. Metab. Disord. 24 (2000) 1119–1130.

6 Identifying Underreporters

To help identify underreporters, researchers can apply methods such as the Goldberg cutoff, extensively described by Goldberg and colleagues [101] and Black and colleagues [102,103]. The Goldberg cutoff identifies the most obvious implausible intake values by evaluating the energy intake against estimated energy requirements. BMR can be measured using methods described elsewhere, or height and weight measurements can be used to predict BMR from a standard formula (the Schofield equation is recommended by Goldberg et al. [101]). A ratio of the estimated EI to measured or predicted BMR is calculated as EI/BMR. This ratio can then be compared with a study-specific cutoff value (see Black [102] for a practical guide to using the Goldberg cutoff). This cutoff represents the lowest value of EI/BMR that could reasonably reflect the energy expenditure based on the physical activity level if the information is available or assuming a sedentary lifestyle if no activity information is gathered. A summary of the principles of the cutoffs can be found in Table 8.6. Studies using the Goldberg cutoff classified 28–39% of the women and 18–27% of the men as low energy reporters [86,94].

The Goldberg cutoff has several limitations [102]. It has poor sensitivity for defining invalid reports at the individual level because it identifies only the extreme underreporters. It also does not distinguish between varying degrees of underreporting. The major limitation is that the cutoff depends on knowledge of energy requirements or energy expenditure. If no physical activity information is available, the cutoff assumes a sedentary lifestyle and will therefore underestimate the underreporters and may lead to misclassification of energy reporting. If researchers can gather information on lifestyle, occupation, leisure time activities, and particularly information regarding physical activity of the participants, calculations can be more specific and improve the classification of energy reporting (i.e., plausible, underreporting, or overreporting).

To compensate for the physical activity level limitations, McCrory et al. [104,105] proposed a method based on the

principles of the Goldberg cutoff to screen for implausible reports by comparing reported energy intake with predicted total energy expenditure [104,106]. Researchers offer that because total energy expenditures are predicted, not just BMR, this new method eliminates the potential error caused by assigning inaccurate physical activity levels when there is limited or no information on activity levels available [104]. With the Goldberg method, only those participants who report ± 2 standard deviation cutoffs are considered underreporters. However, McCrory et al. [104] suggest that in some studies, particularly those in which relationships between habitual intakes and disease outcomes are examined, using a 1 standard deviation cutoff may help to identify those reporters who report actual but not habitual diet. Using this method to analyze CSFII 1994–1996 data, Huang et al. [104] found that implausible reported energy intakes reduced the overall validity of the sample and including misreporters could lead to inappropriate conclusions about the impact of diet on health outcomes. Thus, in the absence of objective measures of total energy expenditure (TEE) or physical activity, the Goldberg method is a reasonable approach to characterize underreporting [107].

7 Handling Underreporting in Dietary Data

Researchers are still not sure how to handle data sets containing large numbers of underreporters. Several approaches have been suggested, but none are ideal. One technique is to exclude anyone who is found to report implausible energy intakes. The problem with this method is that the underreporters tend to fall into specific subgroups (i.e., obese and smokers) and, as stated previously, eliminating them will alter the sample. Some investigators have analyzed their data with all the subjects and then again after the underreporters were removed [108]. Among adults from Pacific Northwest tribal nations, plausible reporters completing dietary records were found to have higher estimates of vitamins A, C, and E, magnesium, and sodium [109]. For the plausible reporters in this population, the association between reported energy intakes (from dietary records and from FFQs) and weight was significant [110]. However, when the sample was not limited to plausible reporters, the association between reported energy intakes and weight was not significant.

Other researchers have suggested adjusting nutrient intakes for energy intake using the regression of nutrient versus energy [111]. This would be feasible only if portion sizes were underestimated but the actual foods were all reported accurately. Otherwise, this method could make the reports worse [112]. As noted previously, it is most likely that foods are systematically omitted from recalls. Thus, if, e.g., fat-containing foods (e.g., desserts) are often underreported, whereas vitamin A-containing foods (e.g., cantaloupe) are not, energy adjustments would provide lower than actual measures of fat intake but a higher measure of vitamin A intake. Many researchers have recognized that adjustments cannot eliminate the bias caused by selective underreporting [113].

Recently authors claimed that, because of energy intake underreporting, measurement error from self-reported dietary intake data is so great that findings that rely on them are of no value [114]. In response, a writing group of esteemed nutritional epidemiologists countered that the amassed evidence shows the self-reported dietary intake data can successfully be used to inform dietary guidance and public health policy [115]. These scientists published seven specific recommendations for collecting, analyzing, and interpreting self-reported dietary intake data [115]. See Table 8.7.

8 Improving Dietary Assessment with Technology

Variations on the 24-hour dietary recall, food records, and FFQs have been carefully developed and improved

TABLE 8.7 Recommendations for Collecting, Analyzing, and Interpreting Self-Reported Dietary Intake Data

1. Continue to collect self-report dietary intake data because they contain valuable, rich, and critical information about foods and beverages consumed by populations that can be used to inform nutrition policy and assess diet–disease associations.
2. Do not use self-reported energy intake as a measure of true energy intake.
3. Do use self-reported energy intake for energy adjustment of other self-reported dietary constituents to improve risk estimation in studies of diet–health associations.
4. Acknowledge the limitations of self-report dietary data and analyze and interpret them appropriately.
5. Design studies and conduct analyses that allow adjustment for measurement error.
6. Design new epidemiologic studies to collect dietary data from both short-term (recalls or food records) and long-term (FFQs) instruments on the entire study population to allow for maximizing the strengths of each instrument.
7. Continue to develop, evaluate, and further expand methods of dietary assessment, including dietary biomarkers and methods using new technologies.

Source: Data from A.F. Subar, L.S. Freedman, J.A. Tooze, S.I. Kirkpatrick, C. Boushey, M.L. Neuhouser, et al., Addressing current criticism regarding the value of self-report dietary data, J. Nutr. 145 (12) (2015) 2639–2645, doi:10.3945/jn.115.219634.

upon throughout the years; however, the errors discussed previously still remain. Technological advances have prompted researchers to investigate the use of technology to improve diet assessment methods. Efforts to use available technology include applications for personal computers and mobile devices, as well as the development of objective biomarkers for dietary intakes [116]. Technology-based dietary assessment holds promise for engaging participants and reducing participant burden, as well as alleviating many researcher burdens (e.g., data entry and interview staff), thus improving cooperation and accuracy [116,117]. Objective biomarkers hold promise for improving associations between dietary intakes and disease outcomes in tandem with or independent of dietary assessment methods.

As technology has rapidly evolved and become more widely adopted by the general public, applications for mobile devices with integrated digital cameras have become desirable tools for use in the research community. Applications in which a participant or "user" takes images of foods and beverages consumed have become of increasing interest. Mobile applications are also viewed favorably by adolescent and adult study participants who report a preference for technology-based dietary assessment over pen-and-paper methods [1,118]. Proposed image-based dietary assessment methods can be categorized as follows: Images are reviewed by the participant/user, images are reviewed by a trained analyst, or automated systems review the images. One proposed use of digital images is to supplement a 24-hour dietary recall—in other words, an image-assisted dietary recall. Arab and Winter [119] proposed a method in which a user wears a mobile device that hangs around his or her neck for a 24-hour period. During this time, intermittent images are automatically taken. The images containing food and beverages are presented to the user to help him or her remember all foods and beverages during the 24-hour dietary recall [119]. In another study the use of wearable cameras by participants reduced the magnitude of underreporting by 8% for men and 7% for women compared with the 24 hour recall alone [120]. Although the digital images of foods reviewed by the user reduce the memory-related burden, issues related to portion size estimation still exist. Applications in which images taken by a participant are reviewed by a trained analyst to remove the portion size estimation burden from the user. In one example, the remote food photography method, analyst estimates range from approximately −5% to 7% of actual energy intake [118]. Another study used digital imaging to measure elementary school children's fruit and vegetable intake. The researchers found that mean fruit and vegetable consumption using digital imaging was not significantly different from the gold standard of weighed plate waste and was within 1.0 g of weighed plate waste (about the weight of one pea pod) [121].

Although accuracy of energy intakes would be improved with this method, there remains a burden on research staff to visually analyze the images. To further remove burden from the user as well as the researcher in an effort to improve the accuracy of dietary intakes, nutrition researchers are teaming with electrical engineers to develop an application in which the images are primarily analyzed using an automated system [122−124]. The Technology Assisted Dietary Assessment (TADA) mobile telephone food record (mpFR) application has been developed for mobile devices with the goal of providing a more accurate method for dietary assessment. The researchers believe they have developed a tool that will be useful for replacing the traditional food record methods currently used and they continue to refine and develop the system to increase its accuracy and usability [124].

As technology continues to evolve, we can expect that image-based dietary assessment will become more mainstream as a means for ameliorating self-reporting errors currently seen in diet assessment methods.

CONCLUSION

Dietary assessment methods provide valuable data to measure dietary exposure in nutritional epidemiology. When undertaking dietary assessment, attention should be given to ways in which error can be minimized throughout the data gathering and analysis process. Identifying underreporters and improving dietary database validity through analytical approaches should remain in the forefront of dietary assessment until methodology improvements can be found. Improving dietary intake methodology is critical to the credibility of nutrition research, and improvements in technology may be a way forward to achieving this goal.

I INTRODUCTION

Dietary interventions are a central component of disease prevention and management. Health professionals' roles in dietary interventions are pivotal because of their centrality in health care and their credibility as patient educators [1−4]. The most recently published evidence-based recommendations in the United States advice to include intensive behavioral dietary counseling for adults with known risk factors for chronic disease, noting that this counseling can be provided by physicians or other clinicians such as dietitians [5,6]. Although a recent report from the US Preventive Services Task Force stated that there is inadequate direct evidence that intensive behavioral counseling interventions lead to decreases in cardiovascular morbidity or mortality in adults with cardiovascular disease risk factors [5], earlier reports noted that people who report receiving advice or counseling recommending dietary change report more health-enhancing diet changes and weight loss than do those who received no such advice [7,8]. Furthermore, nonclinical community sites such as worksites, churches, schools, and community centers are becoming increasingly important as settings for nutritional information and dietary interventions, especially with the epidemic rates of obesity and diabetes among US children, adolescents, and adults [9−11].

II THE IMPORTANCE OF UNDERSTANDING INFLUENCES ON DIETARY BEHAVIOR

Successful dietary interventions take many forms. Interventions to yield desirable changes in eating patterns can be best designed with an understanding of relevant theories of diet-related behavior change and the ability to use them skillfully [12]. Although earlier reports of dietary interventions did not cite a particular theory or model as the basis for the strategies they employed [13,14], the application of sound behavioral science theory in dietary interventions has become more the norm today [15]. Also, emerging evidence suggests that interventions developed with an explicit theoretical foundation are more effective than those lacking a theoretical base [16,17] and that combining multiple theories may lead to better outcomes (e.g., social cognitive theory (SCT) and the transtheoretical model (TTM)) [18,19]. In recent years, empirical evidence demonstrates that mobile health (mHealth) interventions can achieve significant improvement in dietary intake [20]; in particular, the studies using health behavior theories to guide mHealth interventions showed improvements of behavior changes in dietary intake [21,22].

Six theoretical models have been used often in studies targeting dietary change and thus have been demonstrated to be useful for understanding the processes of changing eating habits in clinical and community settings as well as guiding the development of dietary interventions: SCT, which includes self-efficacy and self-regulation—constructs that have been used extensively in diet and weight loss studies; the stages of change construct from the TTM; consumer information processing; the theory of planned behavior (TPB); multiattribute utility theory (MAU); and the social ecological model [12,23,24]. This chapter describes the central elements of each theory and how the theories can be used to guide the development of interventions and provide a framework for the interpretation of outcomes.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00009-6

A Multiple Determinants of Food Choice

Many social, cultural, and economic factors contribute to the development, maintenance, and change of dietary habits. No single factor or set of factors has been found to adequately account for why people eat as they do. Physiologic and psychological factors, acquired food preferences, and knowledge about foods are important individual determinants of food intake. Families, social relationships, socioeconomic status, culture, geography, and access to food are also important influences on food choices. A broad understanding of some of the key factors and models for understanding food choice can provide a foundation for well-informed clinical dietary interventions, help identify the most influential factors for a particular patient, and enable clinicians to focus on issues that are most salient for their patients.

B Multiple Levels of Influence

Common wisdom holds that nutrition interventions are most likely to be effective if they embrace an ecological perspective for health promotion [25,26]. That is, they should not only target individuals but also affect interpersonal, organizational, and environmental factors influencing diet-related behaviors [27,28]. This is most clearly illustrated when one thinks of the context of selecting and purchasing food. Consumers learn about foods through advertising and promotion via multimedia, labels on food packages, and through product information in grocery stores, cafeterias, and restaurants [29]. Their actual purchases are influenced by personal preferences, family habits, medical advice, availability, cost, packaging, placement, and intentional meal planning. The foods they consume may be further changed in the preparation process, either at home or while eating out. The process is complex and clearly determined not only by multiple factors but also by factors at multiple levels. Still, much food choice can be represented by routines and simple, internalized rules. Even though multilevel interventions proceed organically from socio-ecological theory by virtue of addressing various personal and environmental factors, actual multilevel interventions remain scarce [26].

Traditionally, health/patient educators focus on intraindividual factors such as a person's beliefs, knowledge, and skills. Contemporary thinking suggests that thinking beyond the individual to the social milieu and environment can enhance the chance of successful health promotion and patient education [25,30]. Health providers can and should work toward understanding the various levels of influence that affect the patient's behavior and health status. This is discussed and illustrated with examples later on in this chapter.

III WHAT IS THEORY?

A theory is a set of interrelated concepts, definitions, and propositions that present a systematic view of events or situations by specifying relations among variables in order to explain and predict the events or situations. The notion of generality, or broad application, is important [12]. Although various theoretical models of health behavior may reflect the same general ideas, each theory employs a unique vocabulary to articulate the specific factors considered to be important. Theories vary in the extent to which they have been conceptually developed and empirically tested.

Theory can be helpful during the various stages of planning, implementing, and evaluating interventions [12]. Theories can be used to guide the search for reasons why people are or are not consuming a healthful diet or adhering to a therapeutic dietary regimen. They can help pinpoint what you need to know before working effectively with a client, group, or patient. They also help to identify what should be monitored, measured, and/or compared in evaluating the efficacy of nutrition intervention.

IV EXPLANATORY AND CHANGE THEORIES

Theories can guide the search to understand why people do or do not follow health-related or therapeutic advice, help identify what information is needed to design an effective intervention strategy, and provide insight into how to design an educational program so it is successful [12]. Thus, theories and models help explain behaviors as well as suggest how to develop more effective ways to influence and change behaviors. These types of theory often have different emphases but are quite complementary [12]. For example, understanding why someone chooses the foods he or she eats is one step toward successful dietary management, but even the best explanations are insufficient by themselves to fully guide change to improve health. Some type of change model will also be needed. All of the theories and models described here have some potential as both explanatory and change models, although they might be better for one or the other purpose. For example, the TPB was originally developed as an explanatory model, whereas the stages of change construct was conceived to help guide planned change efforts.

V UNIQUE FEATURES OF DIET-RELATED BEHAVIOR TO CONSIDER WHEN USING THEORY

Diet-related behavior changes are most likely to be effective for preventing or managing disease when they are

sustained over the long-term and in people's natural environments, outside the clinical setting. To be effective in dietary interventions, health care providers need to understand both the principles of clinical dietary management and a variety of behavioral and educational issues [31].

There are several core issues about diet and eating-related changes that should be recognized. First, most diet-related risk factors are asymptomatic and do not present immediate or dramatic symptoms. Moreover, by the time symptoms are recognized, the changes needed are often very challenging—e.g., sodium restriction in the patient with congestive heart failure. Furthermore, health-enhancing dietary changes require qualitative change, not just modification of the amount of food consumed, and eating cessation is not a viable option (as with smoking or other addictive behaviors). Finally, both the act of making changes and self-monitoring require accurate knowledge about the nutrient composition of foods or a convenient, practical reference source, as well as a commitment to make change by the individual. Thus, information acquisition and processing may be more complex for dietary change than for changes in some other health behaviors, such as smoking and exercise. As such, consumer information processing models (described later) are more important for dietary interventions than for other types of health-related behaviors. Other important issues include long-term maintenance, the format and medium for providing dietary advice, nutritional adequacy, and options for initiating the change process, the ubiquitous availability of food, the ever-changing food supply, fad diets, and special populations.

A Long-Term Dietary Change

Because dietary intervention leads to meaningful improvements in health only when long-term change is achieved, both providers and patients need to "look down the road" when formulating expectations and setting goals [32]. For example, for most patients without other major risk factors or a familial disorder who follow recommended dietary changes for cholesterol reduction, significant reductions are seen within 4–6 weeks, and cholesterol reduction goals can be reached within 4–6 months [33]. Even after goals are achieved, new dietary habits must be maintained. Thus, if it takes several weeks or even months to adjust to the new dietary regimen, patience and persistence by both physician (dietitian, or clinician) and patient may be worthwhile in the long-term [34,35]. Maintenance of new eating habits occurs mainly outside any clinical or therapeutic setting. Also, different skills are required to make initial changes and to maintain them over the long-term, so follow-up consultations and advice should address new issues, not merely repeat or rehash old information. Reinforcement of the behavior changes that have occurred is paramount [36].

B Restrictive and Additive Recommendations: Typical Reactions

Traditionally, dietary intervention has focused on advice to restrict intake of certain foods or nutrients—e.g., reducing fat and saturated fat intake, limiting calorie intake, and limiting sodium/salt. Yet the most often mentioned obstacle to achieving a healthful diet is not wanting to give up the foods we like [37]. Basic psychological principles hold that when people are faced with a restriction or loss of a choice, that choice or commodity becomes more attractive. In other words, focusing mainly on what not to eat, or on eating less of some types of foods, may evoke conscious or unconscious negativism in some people. In contrast, counseling rather than advising the individual about making behavior changes and emphasizing additive recommendations, such as increasing intake of fruits and vegetables or eating more fiber-rich foods, often appeals to people because it sanctions their doing more of something and guides them in how to do it. The challenge is to make these recommendations attractive to individuals and to ensure that they are presented in the context of an overall healthful diet.

C Implications of Counseling for Gradual Change or Very Strict Diets

A generally held view is that the chances of long-term dietary change are greater when efforts to change occur in a gradual, stepwise manner and are viewed in the context of a lifestyle change rather than a diet. This might involve setting small goals for attempting changes within specific food groups one at a time, until the total diet comes close to recommendations. A basic principle involved is that small successes (i.e., recognition of each successful behavioral change) increase confidence and motivation for each successive change. Although this is effective for many people, others become impatient or even lose their enthusiasm for changes that are minimally recognizable. An alternative is to begin with a highly restrictive diet such as a very low-calorie weight loss diet, a very low-fat diet for prevention of cardiovascular disease, or a very low-sodium diet for an individual with kidney disease. These types of programs, with very strict dietary regimens, may be useful for patients who are highly motivated (e.g., postsurgically, after a coronary incident, or newly diagnosed) or for those who have not been successful in making gradual changes. In some cases, a strict diet for an initial short period will yield visible and/or clinical changes that help motivate patients to continue adhering

to a less extreme regimen; however, such diets may require careful supervision. Moreover, diets that require extreme calorie restriction for weight loss often result in a rapid weight regain after the diet is discontinued [34,35]. For these reasons, these markedly restricted diets are not recommended for most individuals.

D Special Populations

Ideally, each patient should be treated as an individual with unique circumstances and health history. Still, epidemiological research indicates that certain demographic subgroups differ in terms of both risk factors and diet. Understanding these population differences can help prepare a provider to work with various types of patients. Minority and lower socioeconomic status individuals are disproportionately affected by obesity [38] and related risk factors. Targeted interventions are needed for disadvantaged groups [39]. Age may also make a difference: younger persons may feel invulnerable to coronary events, and older adults may be managing multiple chronic conditions and using both prescribed and over-the-counter medications that could interact with foods. These are just a few examples of how population subgroups may differ, and they serve as a reminder to be sensitive to group patterns but to avoid stereotyping in the absence of firsthand evidence about an individual.

VI IMPORTANT THEORIES, THEIR KEY CONSTRUCTS, AND APPLICATION

Several available and widely used models and theories of behavior change can guide dietary interventions. This section describes the following six models and their constructs: SCT, including self-efficacy and self-regulation; stages of change from the TTM; consumer information processing; the TPB; multiattributed utility theory; and the social ecological model [12]. The central elements of each theory and how they can be used to help formulate and guide dietary interventions are described. Table 9.1 provides illustrative statements demonstrating the application of each theory. Following a review of theory constructs, we will discuss findings related to the application of each theory for dietary intervention.

A Social Cognitive Theory

SCT, the cognitive formulation of social learning theory that has been best articulated by Bandura [40,41], explains human behavior in terms of a three-way, dynamic, reciprocal model in which personal factors, environmental influences, and behavior continually interact. SCT synthesizes concepts and processes from cognitive, behavioral, and emotional models of behavior change, so it can be readily applied to dietary interventions that target behavior change for disease prevention and management. A basic premise

TABLE 9.1 Statements Representing Theoretical Approaches to Understanding and Changing Dietary Behavior

Theory	Statements
Social cognitive theory	Overeating at holidays is triggered by food advertisements, store displays, and party buffets that people encounter. Work with individual to set realistic, specific, and proximal goals; e.g., at holiday parties, have just one dessert.
Stages of change	The intervention should match the stage of readiness of the client. If someone believes that the time is right and is "ready to change," he or she will probably be more successful with a nutrition intervention. For the person who is in a contemplative stage, provide attractive literature that is appropriate for the individual to read to possibly motivate the person to move forward.
Consumer information processing	The information on nutrition labels sometimes "overloads" consumers. Consumers who are concerned about nutrition tend to look at nutrient labels before deciding which food to buy.
Theory of planned behavior	An individual who plans to change how he or she eats and specifies what, when, how, and where the changes will happen is more likely to follow through than someone with a more general plan. Furthermore, if the person thinks that his or her spouse will be supportive, motivation will be higher.
Multiattribute utility theory	If taste and convenience are foremost in someone's mind when deciding what to eat, a nutrition intervention that zeroes in on these factors has the greatest promise of success.
Social ecological model	If healthful food is easily available and low in cost, and there are good facilities for cooking and food preparation, individuals will be more likely to follow healthy eating patterns.

Viswanath (Eds.), Health Behavior and Health Education: Theory, Research, and Practice, Jossey-Bass, San Francisco, CA, 2008, pp. 169–185 and J. Rudd, K. Glanz, How consumers use information for health action: consumer information processing, in: K. Glanz, F.M. Lewis, B.K. Rimer (Eds.), Health Behavior and Health Education: Theory, Research, and Practice, Jossey-Bass, San Francisco, CA, 1990, pp. 115–139.

of SCT is that people learn not only through their own experiences but also by observing the actions of others, particularly role models who seem credible, and the results of those actions [12]. Key constructs of SCT that are relevant to dietary intervention include observational learning, self-regulation [42], reinforcement, self-control, and self-efficacy [41,43].

Principles of behavior modification, which have often been used to promote dietary change, are derived from SCT. Elements of behavioral dietary interventions based on SCT constructs of self-control, self-regulation, reinforcement, and self-efficacy include goal-setting, self-monitoring, self-evaluation, feedback, and behavioral contracting [31,44]. As discussed later, goal-setting and self-monitoring are key behavioral strategies to support behavior change [45,46].

1 Self-Efficacy

Self-efficacy is a person's perception of how capable he or she is to perform a specific behavior or take action and persist in that action despite obstacles or challenges. Self-efficacy is behavior specific; e.g., a person may have high self-efficacy for initiating a physical activity program but low self-efficacy for changing dietary habits [41]. Health providers can make deliberate efforts to increase patients' self-efficacy using three types of strategies: (1) setting small, incremental, and achievable goals; (2) using formalized behavioral contracting to establish goals and specify rewards; and (3) monitoring and reinforcement, including having the patient self-monitor by keeping records and providing feedback and reinforcement to the individual on the changes and progress [12,47]. Using specific, proximal goals that are achievable fosters mastery performance—the most powerful source of enhancing self-efficacy. The use of credible models to demonstrate behaviors (e.g., how to modify a recipe or cook low-fat) is another important source for self-efficacy enhancement. A setting in which this is easily implemented is group sessions for cooking demonstrations. Research has provided evidence across multiple behavior domains that increased self-efficacy is associated with improved outcomes—e.g., making healthy food choices [48], developing healthier eating habits such as reducing fat and sodium intake [49], increasing fruit and vegetable consumption [50], improving health-related behavior outcomes such as glucose control in type 2 diabetes [51], and sustaining weight loss maintenance [52,53].

The key SCT construct of reciprocal determinism means that a person can be both an agent for change and a responder to change [41]. Thus, changes in the environment, the examples of role models, and reinforcements can be used to promote healthier behavior. For example, Gase and colleagues reported that self-efficacy was a mediator of the association between perceived food environment and healthy eating in low-income population [54]. Others have reported that self-efficacy is a mediator of the relationship between adherence to dietary self-monitoring and weight loss outcomes [53]. This core construct is also central to the social ecological model, which is discussed later.

2 Self-Regulation

Self-regulation, part of SCT, posits that individuals seek control over important events in their lives by self-regulating their thoughts, behaviors, and environment to achieve their defined goals [40]. According to this theory, reciprocal interactions are assumed to occur among behaviors, environment, and personal factors [41]. Kanfer [55] noted that the major self-regulative mechanism operates through three main functions: self-monitoring, self-evaluation, and self-reinforcement. The key to this process is the behavioral strategy of self-monitoring. Individuals cannot influence their motivation and actions well unless they pay deliberate attention to their own performance, as well as the conditions under which they occur and their immediate and long-term effects [43]. Thus, success in self-regulation depends in part on the fidelity, consistency, and temporal proximity of self-monitoring [43].

Studies based on self-regulation showed positive effects on dietary behavior change, e.g., reductions in energy and saturated fat intake [56], increases in fruit consumption [57], and better fruit and vegetable intake [58]. Several large worksite nutrition programs have applied the constructs of SCT [59,60]. A multisite study, the Working Well Trial, used an intervention rooted in SCT, consumer information processing, and the stages of change [61].

In SCT, self-regulation-based interventions focused on improving eating habits and achieving and/or maintaining a healthy weight and lifestyle have emphasized the role of self-monitoring as a key behavior (e.g., food intake, physical activity, and weight) [62]. A systematic review of the self-monitoring literature found that there was a consistent significant association between dietary self-monitoring and weight loss [46]. A self-regulation intervention focused on daily self-weighing and monitoring of weight with set goals for weight loss maintenance demonstrated efficacy in a clinical trial [63–65].

The use of new technologies for self-monitoring diet, although more expensive than traditional pen-and-paper methods, may reduce the burden of recording [66]. Studies using personal digital assistants for self-monitoring demonstrated greater reduced energy, saturated fat intake, and weight change [56], increased vegetable and whole-grain intake in middle-aged and older adults [67], and reduced sodium intake in hemodialysis patients [68]. A behavioral weight loss trial that provided daily feedback to those using an electronic diary to self-monitor their diet showed

improved self-monitoring adherence and a higher proportion losing 5% of their baseline weight compared to those who did not receive the daily feedback message [56]. Recently developed diet-related application (apps) for use in self-monitoring on mobile devices integrate the constructs of self-regulation theory, which are helpful to promote healthy dietary behaviors, particularly regarding emphasis on goal-setting for limiting calories or for food group or nutrient intake [20,69]. Additionally, researchers are developing apps for mobile devices for self-monitoring of diet to promote dietary behavior changes. For example, a wearable computer, eButton, is able to capture digital pictures of food and estimate portion size [70,71]. A mobile phone-captured food image to identify food and volume can be analyzed to estimate portion size, energy, and nutrients consumed in real time [72]. Compared to traditional methods, children and adolescents have a strong preference for capturing food images with the use of technology, which has demonstrated improved cooperation and increased accuracy in reporting diet [73].

B Stages of Change

Long-term dietary change for disease prevention or risk reduction involves multiple actions and adaptations over time. Some people may not be ready to attempt changes, whereas others may have already begun to change their diet and eating habits. The construct of "stage of change" is a key element of the TTM of behavior change, and it proposes that people are at different stages of readiness to adopt healthful behaviors [74–76]. The construct of readiness to change, or stage of change, has been examined in dietary behavior research and found useful in explaining and predicting the adoption of dietary change [76–78], and has also been applied in the treatment of childhood obesity [78,79].

Stages of change is a heuristic model that describes a sequence of steps in successful behavior change: precontemplation (no recognition of need for or interest in change), contemplation (thinking about changing), preparation (planning for change), action (adopting new habits), and maintenance (ongoing practice of new, healthier behavior) [77]. People do not always move through the stages of change in a linear manner. They often recycle and repeat certain stages: e.g., individuals may relapse and go back to an earlier stage depending on their level of motivation and self-efficacy.

The stages of change model can be used both to help understand why individuals might not be ready to undertake dietary change and to improve the success of dietary interventions [31]. During the past two decades, there has been a substantial increase in research applying the stages of change model to dietary behavior [80–83]. Prospective intervention research examining employees' readiness to change their eating patterns has revealed "forward movement" across the stage continuum in worksite nutrition studies and has shown that changes in stage of change for healthy eating are significantly associated with dietary improvements [59].

Multiple validated tools are available to assess readiness to change [79,84]. Prior to development of these tools, patients were classified according to their stage of change by asking a few simple questions: are they interested in trying to change their eating habits, thinking about changing their diet, ready to begin a new eating plan, already making dietary changes, or trying to sustain changes they have been following for some time? By knowing their current stage, clinicians can help to determine the best approach to intervening—e.g., how much time to spend with the patient, whether to provide informational material or dramatic relief for the person to consider during the contemplative stage, whether to wait until the person is more ready to attempt making changes, or whether referral for in-depth dietary counseling when preparation and action is warranted.

Assessing the patient's current stage of change can lead to appropriate follow-up questions about past efforts to change, obstacles and challenges, and available resources for overcoming barriers. Evidence has suggested that interventions at different stages have different results and implications for care, and these may be gender specific [85]. People's initial stage of change may influence their participation in dietary interventions. Individuals who are initially in the later stages of change (preparation, action, and maintenance) tend to spend more time on complex behaviors such as dietary change [86,87]; they also report making more healthful food choices. A study that assessed readiness for change in adapting a plant-based diet found the majority of the participants identified themselves to be in the precontemplation stage, recognizing fewer benefits and more barriers to adopting a plant-based diet. Evidence demonstrated that the states of action and maintenance were associated with more positive changes in individuals with type 2 diabetes and parents of children with obesity [88,89]. Other reports using this theory revealed that individuals in the intervention group who were in the precontemplation or maintenance stage were more likely to achieve improved adherence to goal-setting compared to those in similar stages in the control group [81,90]. However, not all evidence supported the use of the TTM. Systematic reviews of stage-based interventions have questioned the effectiveness of TTM, providing important critiques and noting the limitations of the theory [91,92]. Some argue that the theory draws arbitrary lines differentiating stages, categorizing individuals to stable coherent plans in periods of instability and mixtures of constructs, while focusing change on conscious decision making and planning, which diverts attention away from human motivation [93].

Evidence supports limited long-term effects for dietary change under stages of change interventions because these behaviors are more complex and require a number of specific actions to influence self-efficacy and lifestyle change [91,94,95]. In addition, two systematic reviews of behavioral techniques for weight loss failed to identify stages of change strategies as a key intervention in either impaired mobility subjects [96] or in the elderly [97]. Thus, while Prochaska's theory is well known, and there is some evidence of effectiveness of its use with behavior change as related to weight management, it is neither extensive nor overwhelming. This may be due in part to the complexity of dietary behavior change and attributing change to a singular feature.

C Consumer Information Processing

People require information about how to choose nutritious foods in order to follow guidelines for healthy eating. A central premise of consumer information processing theory is that individuals can process only a limited amount of information at one-time [98]. People tend to seek only enough information to make a satisfactory choice. They develop heuristics, or rules of thumb, to help them make choices quickly within their limited information processing capacity. The nutrition information environment is often complex and confusing; especially when programs rely heavily on print nutrition educational materials that may be written at a level higher than the audience can comprehend.

Several elements of consumer information processing theory can be applied in dietary interventions. Seemingly unrelated aspects have influence: in a survey, consumers reported associating yellow, blue, green, and red colored labels to be healthy foods and heather, pink, and celadon suggesting something artificial and seemingly unhealthy [99]. Front of package messages may be attended to by consumers more than Nutrition Facts Panels when signage drew attention to them [100]. Messages that are food focused rather than nutrient focused may be particularly helpful [101,102]. Nutrition information is most helpful when it is tailored to the comprehension level of the audience, matched to their lifestyles and experience, and is either portable or available at or near the point of food selection [102–104]. Nutrition labeling had an impact with evidence of interpretive labeling like "traffic light" design endorsed by multiple researchers as most effective [105–110]. Other data suggested other simplistic interventions were useful: simple happy versus sad emoticons on products reduced ambiguity for consumers [111].

An analysis of the National Health and Nutrition Examination Survey 2005 data revealed that four out of five Americans, age 16 years or older, were aware of one of the three federal dietary guidance efforts—the Food Guide Pyramid, 5 A Day Program, and Dietary Guidelines for Americans (DGAs); however, there were significant differences when comparing race and ethnic groups (non-Hispanic white Americans were more familiar), as well as among the different levels of education and income groups. MyPlate introduced by USDA in 2011 has had modest acceptance. Nestle USA partnered with Harris Interactive to conduct a survey in 2013 to gage consumer knowledge of MyPlate and the Dietary Guidelines. Their data showed 41% of consumers were aware of MyPlate or ChooseMyPlate.gov, 92% of consumers had not visited ChooseMyPlate.gov, and 87% of consumers indicated interest in learning about simple ways to follow the DGA [112]. Thus while 59% were unaware of MyPlate, most indicated interest in eating more healthfully. Cluss et al. [113] assessed understanding of the Food Guide Pyramid of parents with children in an obesity treatment program from a large urban pediatric care setting and found "black race and lower education within a low-income sample were independently related to misidentification of low nutrition and high caloric content foods" [113]. Better results of consumer awareness of MyPlate were found in a smaller sample, with 40% reporting that it had influenced their choices [114]. In a review of interventions targeting at young adults in educational institutions, information such as nutrition messages and labeling resulted in positive behavior change [115].

These reports in summation indicate nutrition education via MyPlate can be effective but there is a continued need to educate all individuals on eating a better quality diet, including those in minority groups, those with lower socioeconomic status and low literacy levels about nutrition and how to read dietary information.

The Patient Protection and Affordable Care Act of 2010 mandated menu labeling to disclose nutrient information for standard menu items for chain restaurants or similar retail food establishments that are part of a chain with 20 or more locations [116]. The objective of this initiative was to improve access to consumer information so that individuals can make informed decisions and select more healthful menu options [117,118]. The Federal Register notes some studies have shown that individuals consume fewer calories when menus have information about calories on the menus, critical for Americans who now consume 30% of meals outside the home. Two meta-analyses of the effects of nutrition labeling on menus reported similar results: labeling had a modest effect on calorie consumption but remained a low-cost strategy which needed further study to understand what is most effective [119,120].

Knowledge about which foods to choose, and how much to consume, on a therapeutic diet, are the *sine qua non* of dietary adherence. However, knowledge of how to use nutrition information and the skills to choose or prepare healthful foods are insufficient for behavior change without motivation and support. Furthermore, patients

with low literacy skills and language barriers may require more explanations and fewer printed materials, thus posing important challenges [121]; those with better education or motivation for health concerns may increase likelihood of using nutrition labels. Community studies involving participants with low literacy levels and multicultural backgrounds demonstrated successful dietary changes by administering the intervention through mixed multimedia and audiovisuals [122]. Those successfully conveying education through print materials suggest using simple messages, one- or two-syllable words, large print, and, when necessary, the participant's first language [121–124]. It appears as interpretive labels, most commonly the traffic light system, whose colors are universally recognized, are consistent in showing better effectiveness in changing consumer behavior.

D Theory of Planned Behavior

Often people's food choices are influenced by how they view the actions they are considering and whether they believe important others such as family members or peers would approve or disapprove of their behavior. The TPB, which evolved from its predecessor, the theory of reasoned action, focuses on the relationships between behavior and beliefs, attitudes, subjective norms, and intentions [80]. The concept of perceived behavioral control involves the belief about whether one can control his or her performance of a behavior [125]; i.e., people may feel motivated if they believe they "can do it." A central assumption of TPB is that "behavioral intentions" are the most important determinants of behavior [126].

TPB has been applied widely to help understand and explain many types of behaviors, including eating behavior [127]. The core constructs of TPB have been found to explain fast-food consumption behaviors among middle-school students whose behaviors were mostly influenced by subjective norms [128] and saturated fat intake among adults affected by habit strength and behavior intention [129]. The TPB has also been found to predict intention to dietary change [130] and healthy eating such as fruit and vegetable intake [46], eating breakfast, cooking homemade meals, and eating together [131] and to be more effective in predicting expectation than intention or desire for controlling weight [132]. Behavioral intentions are important and central to TPB; however, there has been some concern that they are still too far removed to be good predictors of actual behavior. The concept of *implementation intentions* involves encouraging individuals receiving an intervention to be specific about how they would change. One study found that providing implementation intention prompts led to greater weight reduction in a commercial weight loss program [133]. Overall, while the TPB has been the focus on limited study for more than 30 years, recent reviews note that "the potential of the TPB as a model either to understand 'food choice' behaviors or serve as a basis for intervention development, appears limited" [130]. The authors emphasize the complexity of determinants of eating behaviors and the importance of considering alternate behavioral models when planning interventions.

E Multiattribute Utility Theory

Both health professionals and marketers recognize that people seek the things they like and that give them pleasure, and that they take action to obtain these things. Identifying those concerns that are most important to a person's decision about performing a specific behavior can lead to the development of effective interventions and decision aides to promote desirable behaviors [12]. MAU is a form of value expectancy theory that aims to specify how people define and evaluate the elements of decision-making about performing a specific behavior. Key elements of value expectancy theory are the valence, or importance, of a particular feature of a behavior or product and the expectancy, or subjective probability that a given consequence will occur if the behavior is performed [134].

MAU is a form of value expectancy theory with particular relevance to understand influences on food choice and changes in eating habits. MAU posits that people evaluate decisions based on multiple attributes and somehow consciously or unconsciously weigh the alternatives before deciding what actions to take. A widely cited report used MAU as the framework for analyzing surveys of a national sample of 2967 adults. The study identified several key factors that appear to be important in food selection: taste, nutrition, cost, convenience, and weight control [23]. For the general public, taste has been reported to be the most important influence on food choice, followed by cost [23]. Understanding the relative importance of various concerns to individuals can guide the design of nutrition counseling and nutrition education programs. For example, by designing and promoting a nutritious diet as tasty, an intervention might be more successful than if it is presented primarily as nutritious or inexpensive. No published reports have explicitly applied MAU to design a dietary intervention, but a project that used tailored messages based on alternative food choices and the attributes among them was found to be effective for increasing dietary fiber consumption; it was based on the behavioral alternatives model, which has many similar features to MAU [135].

F Social Ecological Model

The social ecological model helps researchers understand factors affecting behavior and also provides guidance for

developing successful programs through social environments. The social ecological model emphasizes multiple levels of influence (e.g., individual or intrapersonal, interpersonal, organizational, community, and public policy) and the idea that behaviors both shape and are shaped by the social environment [24,25].

The principles of the social ecological model are consistent with SCT concepts that suggest creating an environment conducive to change is important to making it easier to adopt healthy behaviors [40]. Given the widespread problems of over nutrition in developed countries, more attention is being focused on increasing the health-promoting features of communities and neighborhoods, reducing the ubiquity of high-calorie, high-fat food choices [30,136] as well as promoting high fruit and vegetable intake [137].

The social ecological model is useful to guide intervention research related to changing dietary habits because of its focus on multilevel linkages [17]. This model is often discussed in the context of the obesity epidemic [30]. Also, it has been endorsed as a foundation for diet-related behavior interventions in children considering the contextual influences on childhood obesity, and its focus on prevention is embedded in the home, school/community, and society at large [138–140]. Health promotion programs that include a focus on home [141], worksite [142,143], and church [144] environments can improve eating habits and weight management of adults. Studies have found that socio-ecological resources mediated the lifestyle intervention effects on saturated fat consumption among postmenopausal women with type 2 diabetes [145,146]. The literature also suggests that this model can provide guidance for intervention development for pregnant women [147], low-income African Americans to support healthy eating habits [148], and childhood obesity [149].

Overall, in the past two decades, there has been an increase in published research applying theoretical models to longitudinal studies and clinical trials testing interventions for diet-related behavior change, particularly applying SCT, stages of change, and the social ecological model [130,150,151]. Numerous studies have examined the determinants of eating behavior using coherent theoretical frameworks and constructs. There continues to be a need for more studies using longitudinal designs studying families, the changing food roles in families as well as the changing food environment.

G Selecting an Appropriate Theoretical Model or Models

Effective nutrition intervention depends on marshaling the most appropriate theory and practice strategies for a given situation [152]. Different theories are best suited to different individuals and situations. For example, when attempting to overcome a patient's personal barriers to changing his or her diet to reduce his or her cholesterol level, TPB may be useful. The stages of change model may be especially useful in developing diabetes education interventions. When trying to teach low literacy patients how to choose and prepare healthy foods, consumer information processing may be more suitable. The choice of the most fitting theory or theories should begin with identifying the problem, goal, and units of practice [12,152], not with simply selecting a theoretical framework because it is intriguing or familiar.

With regard to practical application, theories are often judged in the context of activities of fellow practitioners. To apply the criterion of usefulness to a theory, most providers are concerned with whether it is consistent with everyday observations [12,152]. In contrast, researchers usually make scientific judgments of how well a theory conforms to observable reality when empirically tested. Patient educators should review the research literature periodically to supplement their firsthand experience and that of their colleagues.

A central premise in understanding the influences on health behavior and applying them to patient education is that one can gain an understanding of a patient through an interview or written assessment and better focus on the individual's readiness, self-efficacy, knowledge level, and so on. Clearly, it is necessary to select a "short list" of factors to evaluate, and this may differ depending on clinical risk factors or a patient's history. Once there is a good understanding of that person's cognitive and/or behavioral situation, the intervention can be personalized or tailored. Tailored messages and feedback or delivering these messages and feedback through mHealth [47,153,154] have been found to be promising strategies for encouraging healthful behavior changes in primary care, community, and home-based settings [155]. The challenge of successfully applying theoretical frameworks in nutrition programs involves evaluating the frameworks and their key concepts in terms of both conceptual relevance and practical value [14]. In recent years, the focus on home self-management of chronic disease such as diabetes and cardiovascular disease has increased. Nutrition professionals can assist in the development of these comprehensive approaches to patient care. The integration of multiple theories into a comprehensive model tailored for a given individual by frequent assessments can guide the implementation of best-practice interventions, and improve patient outcomes [156]. Psychosocial issues to consider during program development and implementation include social/cultural factors, socioeconomic status, access to community/health care resources, literacy level, personal experience, available support systems, and the

individual's knowledge and skills to manage the condition for which treatment is designed [157].

VII CONSTRUCTS AND ISSUES ACROSS THEORIES

It is important to bear in mind that the various theories that can be used for dietary interventions are not mutually exclusive. Not surprisingly, they share several constructs and common issues. It is often challenging to sort out the key issues in various models. This section focuses on important issues and constructs across models, the first of which is that successful dietary behavior change depends on a sound understanding of the patient's, or consumer's, view of the world.

A The Patient's View of the World: Perceptions, Cognitions, Emotions, and Habits

For health professionals who work with patients and provide them with advice on health and lifestyle, adherence to treatment is often disappointingly poor, even in response to relatively simple medical advice. Such poor adherence often arises because patients do not have the necessary behavioral skills to make changes to their diet. Following a heart attack, e.g., patients might well understand the importance of changing their lifestyle but are unable to make the suggested changes. There will be other circumstances in which patients might not understand the importance of suggested changes and may even believe that the recommended changes pose an additional risk to their health. Indeed, motivational interviewing seeks to elicit the ambivalence patients have about making changes, the source of which may be inaccurate or emotionally based perceptions. In still other circumstances, patients might be experiencing depression or anxiety, such that emotional dysfunction will be a major barrier to adherence. In addition, a longitudinal study demonstrated that adherence to the dietary intervention protocol declined steadily even during the intervention period as the frequency of contact declined, which suggests that it is difficult for participants to sustain the behavior changes without ongoing reinforcement [158].

Traditionally, it has been assumed that the relationship between knowledge, attitudes, and behavior is a simple and direct one. Indeed, throughout the years, many prevention and patient education programs have been based on the premise that if people understand the health consequences of a particular behavior, they will modify it accordingly. Moreover, the argument goes, if people have a negative attitude toward an existing lifestyle practice and a positive attitude toward change, they will make healthful changes. However, it is now known from research conducted during approximately the past 30 years that the relationships among knowledge, awareness of the need to change, intention to change, and an actual change in behavior are very complex.

Ideally, each patient should be treated as an individual with unique circumstances and health history. Still, epidemiological research and clinical trials indicate that certain demographic subgroups differ in terms of risk factors, eating behaviors, and dietary patterns [159,160]. Understanding these population trends can help prepare a provider to work with various types of patients. For example, younger persons may feel invulnerable to coronary events, and older adults may be managing multiple chronic conditions. An active middle-aged professional may place returning to his previous level of activity above important health protective actions. These examples serve as a reminder to be sensitive to group patterns but to avoid stereotyping in the absence of firsthand evidence about an individual. Within this general context, various theories and models can guide the search for effective ways to reach and positively motivate individuals.

B Behavior Change as a Process

Sustained health behavior change involves multiple actions and adaptations over time. Some people may not be ready to attempt changes, some may be thinking about attempting change, and others may have already begun implementing behavioral modifications. One central issue that has gained wide acceptance in recent years is the simple notion that behavior change is a process, not an event. Rather, it is important to think of the change process as one that occurs in stages. It is not a question of someone deciding one day to change his or her diet and the next day becoming a low-fat eater for life. Likewise, most people will not be able to dramatically change their eating habits all at once. The idea that behavior change occurs in a number of steps is not particularly new, but it has gained wider recognition in recent years. Indeed, various multistage theories of behavior change date back more than 50 years to the work of Lewin, McGuire, Weinstein, Marlatt and Gordon, and others [12,161,162].

The notion of readiness to change, or stage of change, has been examined in health behavior research and found to be useful in explaining and predicting a variety of behaviors. Prochaska, Velicer, DiClemente, and colleagues have been leaders in beginning to formally identify the dynamics and structure of change that underlie both self-mediated and clinically facilitated health behavior change. The construct of stage of change (described previously) is a key element of their TTM of behavior change, and it proposes that people are at different stages of readiness to adopt healthful behaviors [163,164].

Although the stages of change construct cuts across various circumstances of individuals who need to change or want to change, other theories also address these processes. Here, we discuss various models to illustrate four key concerns in understanding the process of behavior change: (1) motivation versus intention, (2) intention versus action, (3) changing behavior versus maintaining behavior change, and (4) the role of bio-behavioral factors.

1 Motivation Versus Intention

Behavior change is challenging for most people even if they are highly motivated to change. As previously noted, the set of relationships between knowledge, awareness of the need to change, intention to change, and an actual change in behavior are very complex. For individuals who are coping with disease and illness, and who are often having to make very significant changes to their lifestyle and other aspects of their lives, this challenge is even greater. According to the TTM, people in precontemplation are neither motivated nor planning to change, those in contemplation intend to change, and those in preparation are acting on their intentions by taking specific steps toward the action of change [164].

2 Intention Versus Action

The TTM makes a clear distinction between the stages of contemplation and preparation and overt action [163,164]. A further application of this distinction comes from the TPB [128], which proposes that intentions are the best predictor of behavior [125,165]. However, researchers are increasingly focusing attention on "implementation intentions" as being more proximal and even better predictors of behavior and behavior change [133].

3 Changing Behaviors Versus Maintaining Behavior Change

Even when there is good initial adherence to a lifestyle change program, such as changing diet or eating habits, maintenance of long-term behavior changes is challenging [158,159]. Thus, it has become clear to researchers and clinicians that undertaking initial behavior change and maintaining behavior change require different types of strategies. The TTM distinction between "action" and "maintenance" stages implicitly addresses this phenomenon [164]. Another model that is not described in detail here, Marlatt and Gordon's relapse prevention model, specifically focuses on strategies for dealing with maintenance of a recently changed behavior [161]. It involves developing self-management, coping strategies and establishing new behavior patterns that emphasize perceived control and environmental management as well as improve self-efficacy. These strategies are an eclectic mix drawn from SCT [40], the TPB [125], and applied behavioral analysis—the forerunners of the stages of change model.

C Bio-behavioral Factors

The behavioral and social theories described thus far have some important limitations, many of which are only now beginning to be understood. Notably, for some health behaviors, especially addictive or addiction-like behaviors, there are other important determinants of behavior, which may be physiological and/or metabolic. Among the best known are the addictive effects of nicotine, alcohol, and some drugs. Physiologic factors increase psychological cravings and create withdrawal syndromes that may impede even highly motivated persons from changing their behaviors (e.g., quitting smoking and not consuming alcoholic beverages). Some behavior changes, such as weight loss, also affect energy metabolism and make long-term risk factor reduction an even greater challenge than it would be if it depended on cognitive−behavioral factors alone. Research on the psychobiology of appetite offers intriguing possibilities for understanding bio-behavioral models of food intake, including food addiction.

D Barriers to Actions, Pros and Cons, and Decisional Balance

According to SCT [40], a central determinant of behavior involves the interaction between individuals and their environments. Behavior and environment are said to continuously interact and influence one another, which is known as the principle of reciprocal determinism. The concept of barriers to action, or perceived barriers, can be found in several theories of health behavior, either explicitly or as an application. It is part of SCT [40] and the TPB [125]. In the TTM, there are parallel constructs labeled as the "pros" (the benefits of change) and "cons" (the costs of change) [164]. Taken together, these constructs are known as "decisional balance."

The idea that individuals engage in relative weighing of the pros and cons has its origins in Janis and Mann's model of decision-making, published in their seminal book more than 40 years ago [166], although the idea had emerged much earlier in social psychological discourse. Lewin's idea of force field analysis [167] and other work on persuasion and decision counseling by Janis and Mann predated that important work. Indeed, this notion is basic to models of rational decision-making, in which people intellectually consider the advantages and disadvantages, obstacles and facilitators, barriers and benefits, or pros and cons of engaging in a particular action.

E Control over Behavior and Health: Control Beliefs and Self-Efficacy

Sometimes, "control beliefs" and self-efficacy prevent people from achieving better health. These deterrents to positive health behavior change are common, and they can be found in several models of health behavior, including SCT, TPB, and relapse prevention. One of the most important challenges for these models—and ultimately for health professionals who apply them—is to enhance perceived behavioral control and increase self-efficacy, thereby improving patients' motivation and persistence in the face of obstacles.

VIII IMPLICATIONS AND OPPORTUNITIES

Theory and research suggest that the most effective dietary interventions are those that use multiple strategies and aim to achieve multiple goals of awareness, information transmission, skill development, and supportive environments and policies [81]. The range of dietary intervention tools and techniques is extensive and varied. Programs will differ based on their goals and objectives, the needs of clients, and the available resources, staff, and expertise. Dietary interventions can stand alone or be part of broader, multicomponent, and multiple-focus health promotion and patient education programs.

What can be expected? Program design relates closely to what one can expect in terms of results. In general, minimally intensive intervention efforts such as one-time group education sessions can reach large audiences but seldom lead to behavior changes. More intensive programs typically appeal to at-risk or motivated groups; cost more to offer; and can achieve relatively greater changes in knowledge, attitudes, and eating habits [168].

Dietary interventions must be sensitive to audience and contextual factors. Food selection decisions are made for many reasons other than just nutrition: taste, cost, convenience, and cultural factors all play significant roles [23]. Dietary change strategies must take these issues into consideration. The health promotion motto "know your audience" has a true and valuable meaning. Planning processes can consider multiple theories in a systematic way through approaches such as intervention mapping [169]. Intervention programs should be developed on the basis of the needs, behaviors, motivations, and desires of target audience [170,171].

Furthermore, change is incremental. Many people have practiced a lifetime of less than optimal diet-related behaviors. It is unreasonable to expect that significant and lasting changes will occur during the course of a program that lasts only a few months. Programs need to nudge participants along the continuum of change, being sure to be just in front of those most ready to change with attractive, innovative offerings.

In population-focused programs, it appears to be of limited value to adopt a program solely oriented toward modifying individual choice (e.g., teaching and persuading individuals to choose low-fat dairy products). A more productive strategy that supports and facilitates healthy behavior changes would also include environmental change efforts, such as expanding the availability of more nutritious food choices [2,24,25,136]. When this is done, along with individual skill training, long-lasting and meaningful changes can be achieved.

Finally, when planning interventions, we need to strive to be creative. Dietary interventions should be as entertaining and engaging as the other activities with which they are competing. People will want to participate if they can have fun with the nutrition programs. Communication technologies have opened up many new channels for engaging people's interest in better nutrition. The communication of nutrition information, no matter how important it is to good health, is secondary to attracting and retaining the interest and enthusiasm of the audience. The mHealth interventions which incorporate constructs of different *theoretical* models need to be further studied and evaluated for treatment efficacy [154,172].

Chapter 10

Nutrition Intervention: Lessons From Clinical Trials

Linda G. Snetselaar[1] and Linda M. Delahanty[2]
[1]University of Iowa, Iowa City, IA, United States, [2]Harvard Medical School, Boston, MA, United States

I INTRODUCTION

The modification of dietary patterns to prevent and optimize the management of chronic disease has been traditionally perceived as a difficult and challenging task. However, much has been learned since the 1980s about how to successfully modify eating patterns. For example, in clinical trials, several diet intervention studies that focused on the prevention of cancer or cardiovascular disease have demonstrated the feasibility of reducing dietary fat intake in targeted groups. In addition, complex dietary modifications testing the effect of diet on the progression of renal disease have also been successfully achieved.

II COMMON COMPONENTS OF DIETARY INTERVENTIONS IN CLINICAL TRIALS

A Study Design

A frequently used research design is the randomized control trial (RCT) in which the study begins by screening those study participants who meet the eligibility criteria. Often, very large numbers of participants are screened to arrive at the final number of participants who meet these criteria. For those who are screened into the study, each participant is randomly assigned to either dietary intervention or control, sometimes labeled the usual care group.

B Recruitment

Recruitment for an RCT can involve a variety of strategies, including newspaper advertisements, posters at pharmacies and in doctors' offices, booths at county and state fairs, mass mailings, and presentations to appropriate groups who may become study participants. It is wise to have a number of recruitment strategies. If one fails, others can be initiated to achieve the targeted sample size goal. Although recruiting the number of study participants needed for optimum sample size is an important element of an RCT, recruiting participants into a study who will remain with the study for the entire dietary intervention is equally important. Carefully reviewing the required internal review board-approved study participant consent is crucial. If a potential study participant has the following responses when the study is described, he or she may not be an appropriate candidate for the study:

- Hesitant about being willing to be a part of either the control (usual care) or the intervention group and voices that only the intervention group is best for him or her;
- Concerned about the time that the study intervention group will require;
- Unsure about getting supervisor-approved time off to participate in the mandatory intervention group activities;
- Adamant to be a part of the study when the study has another objective that is counter to this rationale for study participation;
- Concerned about being able to continue the study for the entire time it is scheduled to run;
- Unsure about spouse or significant other support for study activities;
- Unwilling to comply with required activities explicitly stated in the consent form;
- Concerned about travel time needed to participate in the study.

Placing a study participant in a study when these criteria exist may mean that the number of dropouts

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00010-2

in the study increases. Losing a study participant following randomization reduces the sample size and compromises study power to show a difference between the intervention and the control group. When randomized study participants drop out of a study, this is equivalent to under-recruiting and not meeting required study sample numbers. Study participants who drop out of a study cannot be replaced.

C Intervention Design

Study interventions begin with an initial hypothesis. The following are two examples:

- This study will compare the dietary intervention and control groups using data on the number of study participants who have a change in waist circumference of 4 or 5 inches over a 2-year intervention period.
- Following a 3-year dietary intervention study, participants will have a change in hemoglobin A1c that is double that of the control group.

These hypotheses are designed to provide a comparison of the intervention and control groups. Note that each hypothesis has a numeric difference. Without this difference, the study will not show that the dietary intervention did make a difference.

The strategy for the dietary intervention should have a basis in other studies that may have had smaller numbers and short periods of intervention time compared to those of the RCT. In addition, the RCT should be backed by a pilot study to show the ability to achieve the numeric changes that the original hypothesis indicates.

A more recent study design that can benefit from the older RCT studies is the community-based participatory research study. This more community-focused study requires that community participants who will be involved in implementing the study have a voice in its design. For this study, participants will need to be involved in the beginning phases of the study design and the development of implementation strategies. Without their involvement, the study will not be truly participatory. Whereas RCTs are more structured and have many checks and balances, this more formalized method of data collection can be more difficult in a community setting. For example, absentee data collection in a school setting may be very unstructured, with different personnel collecting the data and little standardization in the recording of the reasons for a student being absent. To mimic a more structured RCT, rules and guidelines that will allow for consistent categorization of absenteeism are required. This means working with school personnel—those collecting the data and those eventually entering data—to ensure that everyone is of equal understanding with a new policy or procedure for data collection.

III CONCEPTUAL MODELS OF MOTIVATION

Interventions are developed around models to provide conceptual designs for motivation for positive directions in dietary adherence. Theories for behavior change are extensive, and some offer techniques that are practical for use in nutrition counseling. This section discusses theories that describe models of motivation.

A Self-Regulation Theory

This theory, originally described by Kanfer, states that behavior is regulated by cycles that involve self-monitoring, comparing goal achievement with expectations, and correcting the course of action when the goal is not met [1,2]. To change dietary behavior, a person seeks to increase knowledge of the discrepancy between current status and the identified goal. Two ways to accomplish this are: (1) to increase the awareness of current status (e.g., through feedback such as dietary self-monitoring) or (2) to change the goal to make it more attainable. In conflict situations, when a goal is desired and yet not seen as important enough to strive to attain, ambivalence (feeling at least two different ways about something) is a normal, key obstacle to dietary change.

An example might be used of the double-sided reflection as described in this example.

Client: I know that I should be doing a better job of exercising and reducing my carbohydrate intake, but I love the foods that are high in carbohydrate and just cannot give them up.

Dietitian: You know that exercising and reducing carbohydrate loaded foods would be good for you, but you have great difficulty giving them up.

B Rokeach's Value Theory

Studies in persons who have undergone sudden transformation shifts in behavior show that personality is organized around concentric layers [3]. An individual's attitudes, numbering in the thousands, represent an organizational series of steps inward. More central are our beliefs, and even more central are our core personal values. The most central is the sense of personal identity. The more central the shift, the more likely the resulting behavior change will be maintained over time. In order to move forward with change often discovering what a person values can be a step in a positive direction. An example follows:

Client: I love playing with my grandchildren and do not want to have complications due to poor diabetes control making that impossible.

Counselor: Playing with your grandchildren is something that you value greatly.

C Health Belief Model

The health belief model attempts to explain and predict health behaviors by focusing on the attitudes and beliefs of individuals. The key variables of the health belief model are as follows [4]:

Degree of perceived risk of a disease. This variable includes perceived susceptibility of contracting a health condition associated with lack of a healthy diet and its perceived severity once the disease is contracted.

Perceived benefits of diet adherence. A second benefit is the believed effectiveness of dietary strategies designed to help reduce the threat of disease.

Perceived barriers to diet adherence. This variable includes potential negative consequences that may result from changing dietary patterns, including physical (weight gain or loss), psychological (lack of spontaneity in food selection), and financial demands (cost of new foods).

Cues to action. Events that motivate people to take action in changing their dietary habits are crucial determinants of change.

Self-efficacy. A very important variable is the belief in being able to successfully execute the dietary behavior required to produce the desired outcomes [5–7].

Other variables. Demographic, sociopsychological, and structural variables affect an individual's perceptions of dietary change and thus indirectly influence his or her ability to sustain new eating behaviors.

Motivation for change depends on the presence of a sufficient degree of perceived risk in combination with sufficient self-efficacy relative to achieving dietary change. Perceived risk without self-efficacy tends to result in defensive cognitive coping, such as denial and rationalization, rather than behavior change.

D Decisional Balance

The classic Janis and Mann decisional balance model [8] was a rational view, describing a decision as a process of weighing cognitively the pros and cons of change. Change depends on the pros of change outweighing the cons. The counselor who is adept at reflective listening skills, designed to assist the client in reviewing those ideas that result in an optimum final choice, can facilitate determining the strengths and weaknesses of a decision.

E Transtheoretical Model

This model indicates that individuals change depending on where they are in conceptual readiness to modify their behavior. Prochaska and DiClemente were the forerunners of this theory that focuses on the concept that behavioral change happens in stages of motivation as clients move to a more healthful lifestyle.

The model postulates that both cessation of high-risk behaviors and the acquisition of healthy behaviors involve progression through five stages of change: precontemplation, contemplation, preparation, action, and maintenance [9]. The precontemplation stage is characterized by having no intention of changing the behavior in question in the foreseeable future. People in this stage tend to be unaware that they have a problem and are resistant to efforts to modify the behavior in question. Contemplation is characterized by awareness that the particular behavior is a problem and requires serious consideration about resolving the problem but having no commitment to take action in the near future. The preparation stage is the stage of decision making. The person has made a commitment to take action within the next 30 days and is already making small behavioral changes. In the action stage, clients make notable overt efforts to change. Maintenance involves working to stabilize the particular behavior change and avoid relapse for the next 6 months. People do not simply progress through the stages in a straight line; they may recycle by relapsing and repeating stage progressions, and they can enter or exit at any point [10,11]. This transtheoretical model has been shown to generalize across a broad range of problem behaviors (including diet, exercise, and weight control) and populations [10].

Integral to the stages of change model is a "standard" or goal for the behavior that has been proven to produce results. For example, the goal of the national cholesterol education program (NCEP) therapeutic lifestyle changes (TLC) diet for a dietary saturated fat intake of less than 7% of energy and less than 200 mg cholesterol per day was established based on research showing associated reduction in serum low-density lipoprotein cholesterol concentration. Stages of change techniques help individuals evaluate current behaviors against a defined standard and then assess their readiness to change. The objective is to help patients achieve the standard for the behavior; however, incremental goals are often required. Fortunately, many nutrition interventions in clinical nutrition show benefits associated with stepwise progression to the goal.

If dietitians use the stages of change model as a basic technique for approaching nutrition counseling sessions in a research study, it often requires a modification in their

teaching and counseling style [12]. The focus of attention shifts from establishing an agenda to merely educate the individual and shifts toward an approach that assesses the status of the individual as a basis for tailoring the counseling session. For example, instructing a client with hypercholesterolemia who is clearly in the precontemplation stage on an NCEP TLC diet will be less effective than discussing the risks associated with high cholesterol levels and the benefits of reducing the saturated fat content of the diet. Although the counselor may feel an obligation to impart specific information, mismatching stages and interventions could break rapport and may lead the client to avoid further follow-up sessions.

F Self-Determination Theory

The self-determination theory is based on the concept that humans have an innate tendency for personal growth. The idea behind the self-determination theory is the question of how people internalize and integrate external factors that affect their motivation to change. Eventually, they will come to self-regulate their behaviors moving toward autonomy in actions in their daily lives. The use of reflections and affirmations can be helpful in achieving this autonomy in behavior change. Motivational interviewing (MI), although not considered a theory but rather a communications style, has been connected to this self-determination theory and uses reflections and affirmations as tools to achieve this autonomy.

This theory can be used when it seems that the client is not ready to make a change (precontemplation). Using MI can result in movement toward change talk and the eventual contemplation of behavior change followed by action in making a change.

MI is a client-centered communication style designed to build commitment and reach a decision to change [13]. It focuses on increasing the clients intrinsic motivation to change and self-confidence in their ability to do so. Results from several studies support the use of MI to improve glycemic control and enhance weight loss, particularly for those who are struggling with weight loss or have hit a weight loss plateau. The increased weight loss with MI appears to be mediated by enhanced treatment engagement and program adherence [14].

MI involves an interview process that elicits "change talk" or personally relevant reasons that support movement in the direction of healthful behavior change. "Change talk" may include expression of a concern, recognition of a problem, optimism about change, or an intention to change [14].

The goal of MI is to increase the frequency, range, and strength of client "change talk" and to minimize "sustained" talk where the focus is on maintaining current unhealthy behaviors. Although MI acknowledges that ambivalence is normal and exists among most people considering a behavior change, it does not seek to pull for or emphasize the reasons to stay the same (the disadvantages). This is because people who talk more about reasons not to change, do not change, whereas, those who express more "change talk" have a greater likelihood of making targeted behavior changes [15]. When clients hear themselves articulate why they want to change, it has a motivating effect.

Thus, rather than actively eliciting the advantages and disadvantages of behavior change, MI focuses on (1) asking strategic open-ended questions:

> What might a benefit of dietary change be to you?
> How do you think you would feel when you reach your goal?
> What do you see as the next step?

and (2) responding by spending a short time recognizing and acknowledging a client's reasons for staying the same but spending the most of the time emphasizing personalized reasons for change. Dietitians can use the OARS approach to increase the proportion of "change talk" that a client offers [14].

1 The OARS Approach

The OARS approach is described below:

> O: *Open questions*: Ask for more detail about the personal reasons for change (advantages of behavior change). Use the questions "how" and "what" or the statement "Tell me more. . .."
> A: *Affirmation*: Comment positively on the client's "change talk" statements.
> R: *Reflection*: Use reflective statements to further strengthen client's "change talk."
> S: *Strategic summary*: Collect a bouquet of all the "change talk," put it together, and give it back to the client. When all of the personal reasons are grouped together and reflected back to the client in a succinct summary, it can be powerfully motivating [14].
> *Dietitian*: "What makes you want to _____ (reduce fat intake, lose weight, lower blood sugars) right now?" (O)
> *Client*: "I'd really like to be on less medications and I know if I lose weight and increase my activity, then I might be able to reduce or get off of some of these medications." "I've had a hard time focusing because of other family stresses. I tend to eat when I am worried but I am trying to walk to help my stress."
> *Dietitian*: "You have done a wonderful job of taking all of your medications (A), but it concerns you that you are on so many different pills." (R)
> *Client*: "The more medications that I take, the less healthy I feel. All of these medications have side effects."

Dietitian: "So for you, a major benefit of losing weight and increasing your activity is to reduce the amount of medications that you take and to feel healthier as well." (R)
Client: "Yes that is right!"
Dietitian: "The fact that you've started walking to relieve stress instead of eating for stress is a very positive step that you have made toward your goal." (A)
Client: "Yes, I want to keep that up. I noticed that my energy level is better after I walk."
Dietitian: "You seem pleased that you have been able to fit walking into your schedule and that it is a constructive way to deal with your stress. It also seems to energize you." (R)
Client: "Yes I really want to try to do more."
Dietitian: "That sounds good. What are you ready to work on?" (O)
Client: "I would like to start using frozen proportioned meals for dinner 4 times per week. This will save me some time and help me eat less at dinner."
Dietitian: "That sounds like a really good idea because it will save you time, help you lose weight and get closer to your goal of being on less medication (A). Out of 100% confidence, how confident are you that you will be able to eat frozen dinners 4 days per week?" (O)
Client: "80% confident. I can do it."
Dietitian: "So, you definitely would like to be on less medication and you believe that losing weight and increasing your activity level is the key (A). It is clear that the walking that you have been doing energizes you and helps manage your stress. You feel that the next step is to use frozen dinners 4 times per week and that this is doable and will help you lose weight." (S)
Client: "I definitely feel I can do this. I can pick up the frozen dinners on the way home."

2 Elicit-Provide-Elicit to Provide Information and Advice

In addition to OARS, Miller and Rollnick identify the process of informing and advising. This process involves the concept of elicit-provide-elicit [16]. Often it can be used when a client has a mistaken idea about diet and disease.

Dietitian: What do you know or have heard about carbohydrates in food and their effect on diabetes control? (E)

Client: I try to eat very few foods with high carbs because I know that all carb is bad for you.

Dietitian: This is probably different from what you have heard but some carbs are fine for you to eat even though you have diabetes. (P)

Client: Oh, really.

Dietitian: What might this information do to alter what you do in selecting carbohydrate containing foods? (E)

Client: I will pay attention to the types of carbohydrate foods I select, but not try to avoid them completely.

3 FRAMES Strategy

Miller and Rollnick [17] suggested that the following specific motivational techniques can be combined to achieve an effective MI strategy (FRAMES):

Feedback: Clearly discuss the client's current health situation and risks and explain results of objective tests; share observations based on food records and weight trends. Clarify goals by comparing feedback on the client's current situation to some standard, and set goals toward that standard that are realistic and attainable.
Responsibility: Emphasize that it is the client's responsibility to change.
Advice: Clearly identify the problem or risk area, explain why change is important, and advocate specific change.
Menu: Offer the client a menu of alternative strategies for changing eating habits. Offering each client a range of options allows the individual to select strategies that match his or her particular situation and enhance the sense of perceived personal choice.
Empathy: Show warmth, respect, support, caring, concern, understanding, commitment, and active interest through attentive listening skills.
Self-efficacy: Reinforce the client's self-efficacy via competency-based questions and statements. Research has shown that the counselor's belief in the client's ability to change can be a significant determinant of outcome [17].

The dietitian's responsibility in counseling clients is to help reduce the barriers to making changes, focus more on the benefits, recognize and elicit "change talk," simplify the "to do" steps, and enhance self-efficacy. Some questions that might elicit change talk are as follows:

What do you think that you would like to do?
What options would you consider trying?
What would you say is the first step that you would like to take?

Once the dietitian has completed this process, it is the client's responsibility and choice to make a decision about changing eating habits.

According to Miller and Rollnick [17], motivation can be thought of not as a client's trait but as an interpersonal process between nutrition counselor and participant. Rather than seeing motivational change as something the

client achieves, this process is one that the nutrition counselor and the client experience in tandem. Use of this interactive process is of great value in achieving maintenance to goals in clinical trial research.

IV THEORIES USED IN ACHIEVING DIETARY BEHAVIOR CHANGE IN CLINICAL TRIALS

The nutrition components of clinical trials require skills in long-term dietary maintenance. These skills go beyond educating participants and instead involve strategies designed to reinitiate participants who no longer comply with the recommended eating plan. The studies described here provide research data collected when the theories presented previously are initiated in a clinical trial setting.

A Women's Health Initiative

The Women's Health Initiative (WHI) [18–20] is a randomized controlled clinical trial designed to look at prevention of breast and colorectal cancer. The dietary arm of this study focused on a diet with 20% energy from fat plus five servings of fruits and vegetables and six servings of grain products per day.

To accomplish this change in dietary habits, nutritionists in the study used a variety of behavior change techniques based on the models discussed here. The stages of change model drove efforts to increase compliance in the WHI. The Prochaska–DiClemente model includes six designated stages of change: precontemplation, contemplation, determination, action, maintenance, and relapse [21]. In an effort to simplify and accommodate different levels of adherence, WHI investigators chose to use only three levels of readiness to change: ready to change, unsure, and not ready to change. The decision to simplify levels is based on work with study participants showing that strategies to modify behavior fall within these three categories.

To test the effectiveness of using motivational strategies targeted at these three levels of change, a small research study was devised. Results of that study showed a positive change in dietary behavior following its implementation [22]. In this pilot study, researchers evaluated an intensive intervention program with diet. The basis of the program was the use of MI with participants in the WHI. The goal was to meet the study nutrition goal of 20% energy from fat.

WHI dietary intervention participants ($n = 175$) from three clinical centers were randomized to intervention or control status. Those randomized to the intensive intervention program participated in three individual MI contacts from a nutritionist, plus the usual WHI dietary intervention. Those randomized to the control group continued with the usual WHI dietary management intervention. Percentage energy from fat was estimated at intensive intervention program baseline and intensive intervention program follow-up (1 year later) using the WHI food frequency questionnaire (FFQ).

The change in percentage energy from fat between the intensive intervention program and the control group at baseline and 1-year follow-up was −1.2% points from the total fat for intensive intervention program participants and +1.4% points for control participants. The result was an overall difference of 2.6% points ($p < 0.001$).

Table 10.1 presents summary statistics on the intensive intervention program effects comparing baseline levels of fat consumption. The changes in fat consumed varied by intensive intervention program baseline fat intake as a percentage of energy intake. Participants having the highest intensive intervention program baseline fat intake (>30% energy) showed the largest overall change in percentage energy from fat between intensive intervention program baseline and intensive intervention program follow-up. As might be expected, the smallest change was found in participants who consumed between 25% and 30% of energy from fat at intensive intervention program baseline. These participants were closer to their goal of 20% energy from fat at baseline, allowing for less overall change.

The results of this study show that a protocol based on MI and delivered through contacts with trained dietitians is effective. Those subjects who participated in the intervention arm of the study further lowered their dietary fat intake to achieve study goals.

B The Diet Intervention Study in Children

A similar protocol was used in the Diet Intervention Study in Children (DISC) [23]. DISC was a randomized, multicenter clinical trial assessing the efficacy and safety of lowering dietary fat to decrease low-density lipoprotein cholesterol in children at high risk for cardiovascular disease [24,25]. Children began this study between ages 7 and 10 years and participated in group dietary intervention programs. As they moved into adolescence (ages 13–17 years) and encountered added obstacles to dietary adherence and retention, researchers in the study designed and implemented an individual-level motivational intervention. The diet prescription in the DISC study required providing 28% energy from total fat, less than 8% energy from saturated fat, up to 9% energy from polyunsaturated fat, and less than 75 mg/day of cholesterol. The diet met the age- and sex-specific Recommended Dietary Allowance for energy, protein, and micronutrients.

Researchers used a pre- to postintervention design among a subset of the total intervention cohort ($n = 334$).

TABLE 10.1 Effect of WHI (Pilot) Intervention on FFQ Percentage Energy from Fat Stratified by Baseline Percentage Energy from Fat[a]

	n	Baseline X (SD)	Follow-up X (SD)	Difference
% Energy from Fat <20.0				
Intervention control	23	17.75 (1.8)	17.86 (3.9)	0.1
	25	17.35 (2.3)	19.70 (4.5)	2.3
Difference[b]		−0.4	1.8	2.2
% Energy from Fat = 20.0 and <25.0				
Intervention control	25	22.72 (1.4)	21.68 (4.6)	−1.0
	26	23.17 (1.7)	25.29 (4.8)	2.1
Difference[b]		0.5	3.6	3.1
% Energy from Fat = 25.0 and <30.0				
Intervention control	21	27.42 (1.6)	26.3 (4.6)	−1.1
	15	26.94 (1.2)	26.89 (4.6)	0.0
Difference[b]		−0.5	0.6	1.1
% Energy from Fat = 30.0				
Intervention control	13	34.24 (2.5)	30.11 (6.5)	−4.1
	16	33.81 (3.1)	33.82 (5.0)	0.0
Difference[b]		−0.4	3.7	4.1

Source: Modified from D. Bowen, C. Ehret, M. Pedersen, L. Snetselaar, M. Johnson, Results of an adjunct dietary intervention program in the Women's Health Initiative, J. Am. Diet. Assoc. 102 (2002) 1631–1637.

The first 127 participants who appeared for regularly scheduled intervention visits after the implementation of the new intervention method were considered part of the study. These participants ranged from 13 to 17 years of age, with equal number of boys and girls. Nutrition interventionists asked all of the 127 participants to return in 4–8 weeks for a follow-up session. Initial sessions were conducted in person, and follow-up sessions were conducted either in person or by telephone.

Three 24-hour dietary recalls were collected within 2 weeks after the follow-up session. These dietary data were compared to three baseline 24-hour dietary recalls collected in the year preceding initial exposure to the motivational intervention method.

Self-reported data were also collected. At initial and follow-up intervention sessions, participants were shown "assessment rulers" (Fig. 10.1) numbered 1–12 and asked to rate their adherence to dietary guidelines and their readiness to make new or additional dietary changes.

Results from the study show that the mean energy from total fat decreased from 27.7% to 25.6% ($p < .001$) (Table 10.2) and the mean energy from saturated fat decreased from 9.5% to 8.6% of the total energy intake ($p < .001$). In addition, dietary cholesterol decreased from 182.9 to 157.3 mg ($p < .003$). A comparison of males and females showed no differences in gender relative to study results. Note that for this preliminary test, no control group was randomly assigned or examined. Therefore, the researchers cannot predict if significant reductions in consumption of dietary fat and cholesterol are attributable to the intervention.

The self-reported adherence rating score and readiness to change score increased by approximately 1 point on a scale from 1 to 12 (both $p < .001$). To help accomplish goals, action plans were also made. The study results show that 94% of the participants made action plans and 89% successfully implemented them.

This study also examined dietitian's satisfaction. The results showed that nearly three-fourths of the dietitians were satisfied or very satisfied with using the stages of change methods (Table 10.3).

C Motivational Intervention Method

DISC focused on the stages of change method with elements of MI. Fig. 10.2 provides a method for establishing

rapport before tailoring the intervention to the readiness to change level: ready to change, unsure, and not ready to change. Fig. 10.3 provides specific strategies for each level of change.

1 First Level: Not Ready to Change

The main goal for this level of intervention is to raise awareness of the need to continue meeting goals (e.g., fat grams, carbohydrate grams, and energy intake). In addition, to achieve this goal, it is necessary to reduce resistance and barriers to meeting goals (e.g., decreasing cues to eat high-fat foods). Also, importantly, focus is placed on increasing interest in considering behavioral steps toward meeting the goals noted previously.

Throughout the initial interview, when working with a patient in this level, it is important to ask open-ended questions, listen reflectively, affirm, summarize, and elicit self-motivational statements. Fig. 10.3 provides examples of questions designed to facilitate the participant's ability to make motivational statements.

a Ask Open-Ended Questions

Initially for a participant at this level, it is important to ask questions that require explaining or discussing. Questions focus on requiring more than one-word answers.

The goal is to guide the participants to talk about their dietary change progress and difficulties. Fig. 10.2 provides some opening questions. Other questions and statements are presented here:

> "Let's discuss your experience with diet up to now."
> "Tell me how changing your diet has been for you."
> "What things would you like to discuss about your experiences with dietary change and your progress with changes? What do you like about these changes? What don't you like about these changes?"

b Listen Reflectively

Listening goes beyond hearing what a person has said and acknowledging those words. Crucial in responding to a patient or participant is the understanding of what is meant beyond the words. Reflective listening involves a guess at what the person feels and is phrased as a statement rather than a question. Stating the feeling behind the statement serves two purposes. It allows the participant to tell you if your judgment of the feeling is on target. It also shows that you really are trying to understand more than just words and do care about feelings also. The following are some participant–nutritionist interactions that illustrate reflective listening:

Scenario 1

Participant: "There are times when I do a wonderful job of meeting my fat gram goal, but sometimes I don't do so well. I keep trying though."

Dietitian: "You seem to feel badly that you don't always meet your fat gram goal."

Scenario 2

Participant: "I am so tired of trying to follow this diet. It seems that I have put hours into following it, and I have little to show for it. I certainly have not lost weight."

Dietitian: "You feel frustrated and angry about trying so hard and still getting nowhere."

Scenario 3

Participant: "When I don't fill in a food diary, I am not sure that I am doing well or not."

Dietitian: "You are worried on days when you do not fill in a food diary."

Scenario 4

Participant: "I really don't want to continue following this diet. I have other things that are more of a priority now."

Dietitian: "You seem hassled by these other competing desires and feel that following a new eating pattern is getting in the way."

c Affirm

Communicating support to participants is an excellent way of letting them know that you appreciate what they are doing. Affirmations are statements that indicate alignment and normalization of the participant's issues. Alignment means telling participants that you understand them and are with them in their difficulties. Normalization means telling the participants that they are perfectly within reason and "normal" to have such reactions and feelings. Examples of affirmations include the following:

"It is very hard to struggle with competing priorities. You've done amazingly well."

"That is an insightful idea."

"Thank you for telling me that. It must have been hard for you to tell me."

"I can see why you would have this difficulty. Many people have the same problem."

d Summarize

Periodically, and at the point when you begin to elicit self-motivational statements, summarize the content of what the participant has said. Cover key points even if they involve negative feelings. You can discuss conflicting ideas that the participant has brought up by using the strategy "on the one hand, you … and on the other hand, you …." This reminds both of you about the issues and ensures clarity.

e Elicit Change Statements

The most important part of self-motivational statements is that they help participants realize that a problem exists, that they are concerned about the problem, that they intend to correct the problem, and that they think they can do better in the future. Fig. 10.4 provides questions to

1. **Problem Recognition**
   - What things make you think that this is a problem?
   - What difficulties have you had in relation to your diet?
   - In what ways do you think you or other people have been inconvenienced by your diet?
   - In what ways has this been a problem for you?
   - How has your diet stopped you from doing what you want to do?

2. **Concern**
   - What is there about your diet that you or other people might see as reasons for concern?
   - What worries you about your diet?
   - How do you feel about your dietary problems?
   - How much does that concern you?
   - In what ways does this concern you?
   - What do you think will happen if you don't make a change?

3. **Intention to Change**
   - The fact that you're here indicates that at least a part of you thinks it's time to do something. What are the reasons you see for making a change?
   - What makes you think that you need to make a change?
   - If you were 100% successful and things worked out exactly as you would like, what would be different?
   - What things make you think that you should stop following your diet? . . . And what about the other side? What makes you think it's time for a change?
   - What are you thinking about your diet at this point?
   - What would be the advantages of making a change?
   - I can see that you're feeling stuck at the moment. What's going to have to change?

4. **Optimism**
   - What makes you think that if you decide to make a change, you could do it?
   - What encourages you that you can change if you want to?
   - What do you think would work for you, if you decided to change?

FIGURE 10.4 Examples of questions designed to elicit self-motivational statements. *Modified from D. Bowen, C. Ehret, M. Pedersen, L. Snetselaar, M. Johnson, Results of an adjunct dietary intervention program in the Women's Health Initiative, J. Am. Diet. Assoc. 102 (2002) 1631–1637.*

elicit self-motivational statements. These statements fall into four categories: problem recognition, concern, intention to change, and optimism. It is important to respectfully acknowledge decisions that participants make. These decisions may mean that a participant has decided not to make changes immediately (see Fig. 10.3). It is appropriate to offer professional advice but still leave the actual decision to make a change up to the participant. Fig. 10.3 provides some ideas on how to approach the participant. Close the discussion with another summary. Concentrate on any self-motivational statements that the participant has made. End the session with the idea that both of you should think about what has been discussed and that you can revisit the issues next time.

2 Second Level: Unsure About Change

The main goal for this intervention is to tip the balance toward working to meet the goals. Four steps are important in meeting the goals: regroup, ask key questions, negotiate a plan, and conclude the work.

a Regroup

The first step in dealing with a participant who is unsure about changing dietary habits is regrouping to focus on the transition from not being ready to deal with the problems of change to moving toward a reinitiating of behavior adjustment. This process of regrouping can serve as a reminder of what has happened in previous sessions. The following are four ways to regroup:

1. Summarize the participant's perceptions of what is going on. The summary might include self-motivational statements that the participant has made.
2. Identify ambivalence or other conflicting issues.
3. Review any self-monitoring related to dietary intake.
4. Restate intentions or plans to change or do better in the future.

b Ask Key Questions

Ask questions that focus on the participant's statements regarding future plans to make dietary changes. The goal is to ask open-ended questions that cause the participant to think about what you have just summarized and come to the conclusion that action is necessary. The goal is for the participant to provide a statement showing the desire to change. Here are some examples of questions that facilitate positive participant statements:

"How might we work together to proceed from here?"
"Hearing my summary of how things have gone in the past, what do you want to do?"
"How might you become more involved in dietary change?"
"What are the good parts and the bad parts about continuing to change?"
"You are currently unsure of what to do. How might we work together to resolve the issue?"

c Negotiate a Plan

There are three parts to the negotiation process. The first involves setting goals; the second, considering the options; and finally, arriving at a plan:

Set goals: Past wisdom dictated that setting goals meant being specific and behavioral. "I will eat candy bars only one time per week, on Sunday." MI dictates that goal setting may start out broadly at first and then move to behavioral goals that are specific. To elicit broadly stated goals, the following questions might be used:

"What about your diet would you like to change?"
"How would you like things to be different from how they are now?"

Consider options: Make a list of things that might be changed to bring the participant closer to the dietary goal. Ask the participant to choose among the options. If the first one does not work, the participant has many choices as backups.

Arrive at a plan: Ask the participant to arrive at a plan. Include in the plan the specific behavioral goals with potential problems that may serve as barriers to making these changes.

d Conclude the Work

Always end the session with an encouraging statement and a reflection on the participant's resourcefulness in identifying the plan. Follow this statement with the idea that he or she is the best expert relative to behavior change. Indicate that you will stay in touch to check on how the behavior change is going.

3 Third Level: Ready to Change

The main goal for this third intervention is to reengage the participant in meeting the dietary goals.

a Review

Cover the previous discussions with the participant. Focus on the statements the participant made that show interest and a willingness to change. Use statements that show that it was the participant's idea to meet dietary goals previously set—e.g., "You said that you were interested in trying again."

b Encourage Choices and Activities

Ask the participant what he or she would like to do to reengage. Encourage the participant to make his or her

own choice. Collaborate and negotiate short-term, easily attained goals initially, such as "I will drink 1% milk for a week in place of 2% milk and gradually reduce to fat-free milk."

c Summarize

Review the discussion, the issues, and the difficulties on both sides. Remind the participant to keep trying and to believe in himself or herself.

D The Modification of Diet and Renal Disease Study

The Modification of Diet and Renal Disease Study (MDRD) [26] used the self-management approach to modify dietary behavior. In this population of persons diagnosed with renal disease, research nutritionists counseled participants on diets low in protein and phosphorus. Although the diets were difficult to follow, the study participants showed great motivation based on their desires to avoid renal dialysis [27]. The following strategies were used successfully in the MDRD [28]:

Single-nutrient approach to dietary behavior change: The focus in this study was on reducing protein content of the diet. With this reduction, dietary phosphorus was also reduced. When other nutrients were modified, specific food groups were identified. Even with changes in other nutrients, protein was still a primary focus.

Self-monitoring: The participant's ability to self-monitor was crucial to keeping protein intake down to goal levels. Weighing and measuring was used as a means of matching dietary change on a daily basis with the biological marker of urinary nitrogen. Further study in self-monitoring matched with the biological marker showed that problems occur in knowing how to best represent dietary intake [29]. For example, it is often difficult to closely mirror the exact amount of protein in a cut of meat if that cut is not precisely specified.

Staging changes: In the MDRD, dietitians also staged changes in dietary protein by gradually reducing the dietary protein intake. This gradual change made day-to-day modifications easier.

Modeling: Dietitians modeled dietary changes by offering both recipes low in protein and taste-testing sessions. Group sessions were held at which a special meal was offered with food preparation techniques modeled.

E The Diabetes Control and Complications Trial

The Diabetes Control and Complications Trial (DCCT) [30] used techniques similar to those of the MDRD study [31]:

Single-nutrient approach: Investigators focused on carbohydrate as a single nutrient, where it was matched with insulin to achieve normalized blood glucose.

Self-monitoring: Monitoring consisted of following blood glucose concentrations and dietary intakes to verify where problems might be occurring. If dietary intake was high along with blood glucose concentrations, dietary intake or insulin was modified to achieve normal blood glucose levels.

Staging changes: Changes were staged by working on specific times of day that were most problematic. If lunchtimes were most often high, we focused on dietary intake modifications to alter blood glucose levels. Also, insulin and exercise often played a role.

Modeling: Dietary modifications were facilitated by providing recipes, modeling, and going to restaurants to identify and anticipate blood glucose levels after eating a favorite lunch or other meals out of the home.

F The Brief Motivational Intervention to Reduce Body Mass Index Study

The Brief Motivational Intervention to Reduce Body Mass Index (BMI^2) study is designed to compare three groups: pediatricians without MI training, pediatricians with MI training, and pediatricians and registered dietitians with MI training. The outcome of this study is children with elevated BMIs ranging from the 85th to the 97th percentile for their ages. Clinicians in this study will work with parents to try to modify their way of working with children to achieve dietary behavior change. The basis of this work is the self-determination theory, which serves as the underlying construct for the MI communication style. This is a 2-year intervention that is currently in its first year of data collection [32]. The study showed that the use of MI in the combined group of dietitians and pediatricians resulted in greater reductions in children's BMI toward healthy levels [33].

V SUMMARY

Considerable experience in clinical trials suggests that dietary modification requires a process of making changes on an individual basis with constant negotiation with the client or participant. Working as a team, the nutritionist and participant can achieve dietary change that alters biological markers, may reduce disease risk, and optimizes management.

I INTRODUCTION

A biomarker or biological indicator is a characteristic that is measured and evaluated as a marker of normal biological processes, pathogenic processes, or responses to an intervention. In theory, almost any measurement that reflects a change in a biochemical process, structure, or function can be used as a biomarker. In addition, an exogenous compound that, as a result of ingestion, inhalation, or absorption, can be measured in tissues or body fluids can also be considered a biomarker.

Biomarkers can be classified broadly into markers of exposure, effect, and susceptibility and have numerous applications in nutrition. They can be used to assess dietary intakes (exposure), biochemical or physiological responses to a dietary behavior or nutrition intervention (effect), a clinical end point or disease outcome (surrogate end point biomarker), and predisposition to a disease or response to treatment (genetic susceptibility).

Although clinicians have used certain biological markers, such as serum cholesterol and glucose, for generations, the use of biomarkers has taken on new importance with the dramatic advances in various fields of biology and desire for objective measures in large-scale, population-based, descriptive, and intervention nutrition research. Exquisitely sensitive laboratory techniques can detect subtle alterations in molecular processes that reflect events known or believed to occur along the continuum between health and disease.

This chapter presents the basic concepts and key issues related to the various uses of biomarkers in nutrition intervention research; it is not intended to be a comprehensive review. Identification and use of biomarkers is continuously evolving with the growing understanding of biological processes and the improved sensitivity of laboratory assays. Consequently, our examples of existing biomarkers are snapshots of the greater scheme of biomarker development and application.

II BIOMARKERS OF DIETARY INTAKE OR EXPOSURE

Biomarkers are used to monitor dietary exposure and for nutritional assessment for several reasons. One reason is to provide biochemical data on nutritional status by generating objective evidence that enables the evaluation of dietary adequacy or ranking of individuals on exposure to particular nutrients or dietary constituents. Biochemical or biological measurements may also be collected to characterize objectively a dietary pattern, such as fruit and vegetable consumption; to validate dietary assessment instruments or self-reported dietary data; or to monitor compliance to a dietary intervention. Another purpose for obtaining these biological measures is to establish the biological link between the nutritional factor and a physiological or biochemical process—often a hallmark of nutrition intervention studies—when the concentration of the micronutrient or dietary constituent is measured in a peripheral tissue.

Biomarkers of dietary intake can be classified as either recovery biomarkers, which are considered the best, or concentration biomarkers. Recovery biomarkers reflect absolute

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00011-4

intake over a defined period of time; an example is nitrogen in 24-hour urine collections as a recovery biomarker of dietary protein intake [1]. Concentration biomarkers, on the other hand, are correlated with intake but cannot be used to calculate an absolute level of intake; an example of a concentration biomarker is plasma vitamin E [2].

A Biomarkers of Energy Intake

To date, few biological measures are available that objectively monitor overall energy intake, and those that are available are cumbersome in community dwelling populations or expensive. Under steady-state conditions, indirect calorimetry provides an estimate of energy expenditure and some insight about intake. Indirect calorimetry estimates the rate of oxidation or energy expenditure from the rate of oxygen consumption (VO_2) and the rate of carbon dioxide production (VCO_2). This technique is relatively inexpensive and portable, although some participant's cooperation is required. These traits make the technique attractive primarily for clinical applications [3].

Energy expenditure can also be measured using a doubly labeled water technique [4], as discussed in detail in Chapter 4, Energy Requirement Methodology, which is an example of a recovery biomarker in which energy intake is indirectly ascertained by measuring energy expenditure. This method uses nonradioactive isotopes of hydrogen (^2H) and oxygen (^{18}O) to measure community dwelling total energy expenditure by monitoring urinary isotope excretion. Energy expenditures determined by room calorimetry, indirect calorimetry, and doubly labeled water measures are not significantly different within the calorimeter environment; however, in community dwelling individuals, doubly labeled water-derived energy expenditures are found to be 13−15% higher than those for other methods [5]. The doubly labeled water method has the distinct advantage of allowing the study participants to go about their usual activities, with energy expenditure calculated after a study period of 7−14 days. Unfortunately, the ^{18}O isotope required to conduct doubly labeled water studies is expensive and is often in short supply. Although doubly labeled water methodology is suited to nutrition research aimed at quantifying total energy expenditure for specific groups, the cost of large samples limits broad use.

B Biomarkers of Nutrient Intake

Biochemical measures of nutrients can be a valuable component of nutritional assessment and monitoring. Overall, the usefulness of biochemical indicators of nutritional status or exposure is based on knowledge of the physiological and other determinants of the measure. For several micronutrients, the concentration of the nutrient in the circulating body pool (i.e., serum) appears to be a reasonably accurate reflection of overall status for the nutrient. In contrast, the amount of some micronutrients in the circulating pool may be homeostatically regulated when the storage pool is adequate, or may be unrelated to intake, and thus has little relationship with total body reserves or overall status. Fig. 11.1 illustrates the relation between various compartments or body pools that may be sampled in the measurement of biological indicators.

Knowledge of the influencing nondietary factors is particularly important for accurate interpretation of the nutrient concentration in tissues. For example, tocopherols and carotenoids are transported in the circulation nonspecifically by the cholesterol-rich lipoproteins [6,7], so higher concentrations of these lipoproteins are predictive of higher concentrations of the associated micronutrients in the circulation, independent of dietary intake or total body pool. Smoking and alcohol consumption need to be considered in the interpretation of serum and other tissue concentrations of several micronutrients, particularly compounds that may be subject to oxidation (e.g., vitamin C, tocopherols, carotenoids, folate). Knowledge of the relationship between the indicator and the risk of nutrient depletion, in addition to the responsiveness of the indicator to interventions or change, is also necessary [8]. For some nutrients, a specific sensitive exposure marker of diet has not yet been identified.

Table 11.1 lists examples of biochemical measures of nutrients that may serve as useful biomarkers in nutritional assessment or monitoring of dietary intake; all of these are examples of concentration biomarkers and may not be proportionately related to intake because their levels are the result of other influencing factors. For more details, the reader is referred to in-depth reviews addressing the use of biomarkers for assessing nutrient exposure [9−12].

C Biomarkers of Other Dietary Exposures

Numerous dietary constituents, particularly of plant origin, although not recognized as essential for life, have demonstrated biological activity and are thought to play an important role in the prevention of chronic diseases [13,14]. These phytochemicals are absorbed to various degrees, often metabolized in the intestinal epithelium and liver, and excreted; thus, the metabolites can be monitored in serum or plasma or urine.

Some classes of compounds such as flavonoids are found in many plant foods, whereas others such as isoflavones are limited to select sources (Table 11.2). The isoflavones daidzein and genistein are highly concentrated in soybeans and soy products [15,16]. Urinary isoflavone excretion is associated strongly and directly with soy protein intake under controlled dietary conditions [17]. In intervention studies of soy foods or isoflavone supplementation,

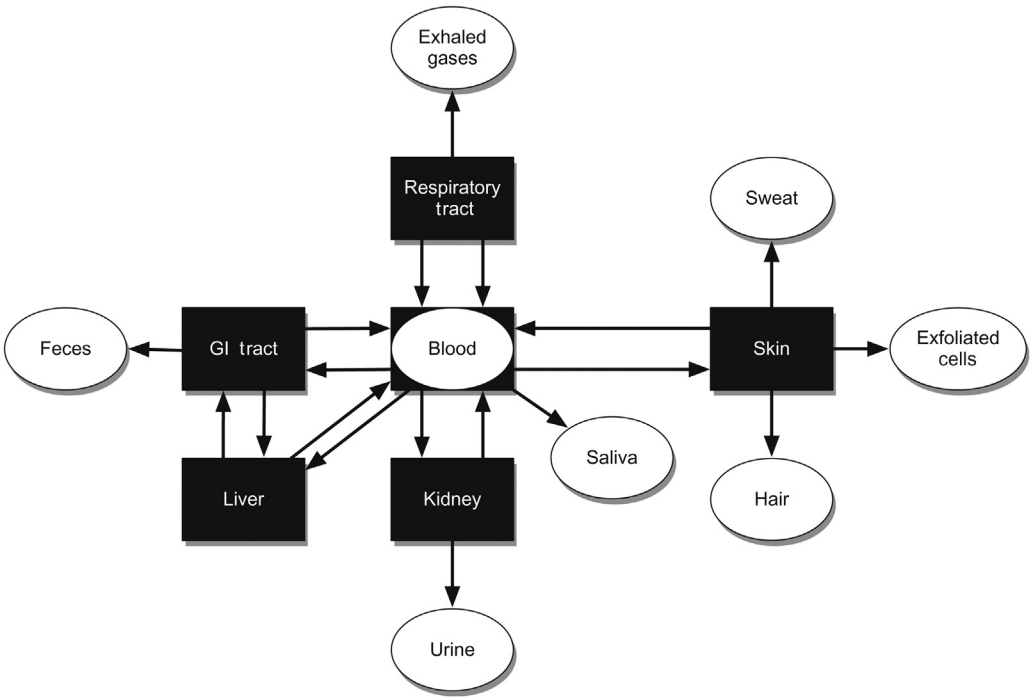

FIGURE 11.1 The relation between body compartments and biological specimens that can be assayed for dietary biomarkers.

urinary isoflavonoid excretion and serum or plasma isoflavone concentrations are useful markers of study compliance [18,19]. However, as the plasma half-lives of the isoflavones genistein and daidzein are short (6–8 hours) [20], the timing of soy consumption in relation to urine or blood sampling may under- or overestimate isoflavone exposure. Metabolism of isoflavones is also linked to the health of colonic bacterial populations, and therefore the effects of diet and drugs on the colonic environment may influence plasma and urinary levels.

Dietary exposure to flavonoids and other polyphenols can be monitored by measuring parent compounds and metabolites in urine or plasma [21,22]. Several compounds in cruciferous vegetables, such as sulforaphane and other isothiocyanates, have been of interest because of their potential chemopreventive effects. Concentrations of these compounds and their metabolic derivatives can be measured in plasma and urine by liquid chromatography–mass spectrometry (LC-MS) [23]. In addition, dithiocarbamates (conversion products of isothiocyanates and their metabolites) can be quantified readily in urine, following extraction and measurement by high-performance liquid chromatography (HPLC). Both these approaches provide a way to monitor cruciferous-vegetable exposure during an intervention [24].

Biomarkers also exist for monitoring exposure to less desirable food constituents, such as mycotoxins (e.g., aflatoxin) in mold-contaminated grain products and pyrolysis products that result from cooking meat at high temperatures (e.g., heterocyclic amines). Because of the nature of these compounds, exposure to potentially carcinogenic compounds can be determined by measuring the presence of adducts—the result of covalent binding of the chemicals to proteins or to nucleic acids in DNA. The rationale for using measurements of carcinogen–DNA adducts is based on the assumption that DNA adducts formed in vivo are responsible for genetic alterations in genes critical for carcinogenesis and that protein adducts formed through the same processes reflect the formation of DNA adducts [25]. Because adducts represent an integration of exposure and interindividual variability in carcinogen metabolism and DNA repair, they may provide a more relevant measure of exposure (i.e., a biologically effective dose [25]). Some adducts are specific for dietary exposure; aflatoxin–albumin adducts result from ingestion of aflatoxin. Other adducts, such as benzo[a]pyrene–DNA adducts, are nonspecific because benzo[a]pyrene comes from a variety of sources besides diet, including air pollution, tobacco, and occupational exposures. Adducts can be used to monitor exposure within individuals. They can also serve as early markers of the efficacy of interventions designed to prevent exposure to genotoxic agents or to modify the metabolism of procarcinogens once exposure has occurred. An example of this latter use is an intervention to reduce aflatoxin–DNA adducts using a broccoli sprout supplement [26].

TABLE 11.1 Biomarkers of Nutrient Intake

Nutrient	Biomarkers of Dietary Exposure	Possible Functional Markers
Dietary fiber, nonstarch polysaccharides	Fecal hemicellulose	Fecal weight
		Fecal short-chain fatty acids
	Urinary or plasma lignans	
	Urinary or plasma alkylresorcinols (whole grains)	
Thiamin		Erythrocyte transketolase activation
Biotin	Urinary 3-hydroxy-isovalerate with a loading dose of leucine	Erythrocyte pyruvate carboxylase activity
Riboflavin	Plasma FAD	EGRAC
	Erythrocyte FAD	
Niacin	Erythrocyte NAD	Erythrocyte nicotinate-nucleotide: pyrophosphate phosphoribosyltransferase activity (not very responsive)
	Urinary metabolites of niacin	
Vitamin B_6	Plasma pyridoxal 5-phosphate	Erythrocyte aspartate or alanine aminotransferase
	Urinary 4-pyridoxic acid	
Folate	Plasma folate	Plasma homocysteine
	Erythrocyte folate	
Vitamin B_{12}	Plasma B_{12}	
Vitamin C	Plasma vitamin C	Urinary deoxypyridinoline:total collagen cross-links
	Erythrocyte, lymphocyte, or platelet vitamin C	Urinary carnitine
Vitamin A	Plasma retinol:retinol-binding protein	
Vitamin E	α- and/or γ-tocopherol in serum or plasma, erythrocytes, lymphocytes, lipoproteins, adipose tissue, or buccal mucosal cells	LDL oxidation
		Breath pentane and ethane
		Platelet adhesion and aggregation
Vitamin D	Serum 25-hydroxyvitamin D	
Vitamin K	Plasma vitamin K	Plasma prothrombin concentrations
Phosphorus	Serum inorganic phosphate	
Magnesium	Erythrocyte or lymphocyte magnesium	
Calcium	Calcium retention	Bone mass
		Serum osteocalcin
		Serum levels of skeletal alkaline phosphatase
		Urinary and serum measures of collagen turnover
Iron		Serum ferritin[a]
		Transferrin saturation
		Erythrocyte protoporphyrin

(*Continued*)

TABLE 11.1 (Continued)

Nutrient	Biomarkers of Dietary Exposure	Possible Functional Markers
		Mean corpuscular volume
		Serum transferrin receptor
		Hemoglobin or packed cell volume
Copper	Platelet copper	Erythrocyte SOD
		Platelet cytochrome *c* oxidase activity
		Serum peptidylglycine α-aminating monooxygenase activity
		Plasma diamine oxidase
Zinc		Erythrocyte metallothionein
		Erythrocyte SOD
		Monocyte metallothionein mRNA
		Serum thymulin activity
		Plasma 5-nucleotidase activity
Manganese	Serum manganese	Lymphocyte Mn-SOD activity
		Blood arginase activity
Molybdenum		Urinary levels of sulfate, uric acid, sulfite, hypoxanthine, xanthine, and other sulfur-containing compounds
Iodine	Urinary or plasma iodine	Plasma TSH, T_4, and T_3 (total and free)
Selenium	Plasma or whole-blood selenium	Plasma GSH peroxidase activities
	Hair or toenail selenium	Erythrocyte GSH peroxidase activities
		Blood cell selenoperoxidase activities

[a]*In approximate order of increasing severity of iron shortage [109].*
EGRAC, FAD-dependent erythrocyte glutathione reductase activation coefficient; *FAD,* flavin adenine dinucleotide; *GSH,* glutathione; *LDL,* low-density lipoprotein; *NAD,* nicotinamide adenine dinucleotide; *SOD,* superoxide dismutase; *T_3,* triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone.
Direct measures of dietary exposure and nutrient-specific functional markers. This table includes both established markers and additional markers that show promise.

D Biomarkers as General Dietary Indicators

Although biomarkers of energy intake, specific nutrients, and other dietary variables can themselves be useful indicators of general diet, there are additional broad biomarkers to consider. Monitoring changes in patterns in response to dietary interventions presents additional challenges. The goal in this case is to monitor the intake of certain types of foods or food groups rather than specific nutrients; therefore, these dietary indicators should ideally be distributed within certain types of foods.

Plasma carotenoids provide a good example of the use of biomarkers as a dietary indicator when the goal is to assess and monitor dietary patterns. Vegetables and fruits contribute the vast majority of carotenoids in the diet, and plasma carotenoid concentrations have been shown to be useful biomarkers of vegetable and fruit intakes in cross-sectional descriptive studies, controlled feeding studies, and clinical trials [27–30]. The consistency of this relationship across diverse groups and involving various concurrent dietary manipulations (with differences in amounts of dietary factors that could alter carotenoid bioavailability) is notable, although considerable interindividual variation in the degree of response is typically observed. Also, nondietary factors that are among the determinants of plasma carotenoid concentrations (e.g., body mass and plasma cholesterol concentration) will influence the absolute concentration that is observed in response to dietary intake, so these characteristics must be used as adjustment factors.

Although vitamin C also is provided predominantly by fruits and vegetables in the diet, this measure is much less useful as a biomarker of this dietary pattern because the relationship between vitamin C intake and plasma

concentration is linear only up to a certain threshold [31]. The use of vitamin C supplements (which is common in the US population) often increases the intake level beyond the range in which linearity between intake and plasma concentration occurs and thus obscures the relationship between food choices and tissue concentrations.

Lignans are a group of compounds present in high-fiber foods, particularly cereals and fruits and vegetables [32]. These compounds are not found in animal products and, similar to carotenoids, may be useful markers of a plant-based diet [33]. Lignans provide an example of how using dietary constituents as biomarkers requires an understanding of the metabolism of the compounds. Lignans in plant foods are altered by intestinal microbiota so that the specific compounds, enterodiol and enterolactone, monitored in plasma or urine are actually bacterial metabolites. Because of this bacterial conversion, lignan concentrations in urine or plasma in response to a similar dietary dose vary significantly among individuals. In addition, nondietary factors (e.g., use of oral antibiotics) reduce enterolactone and enterodiol production [34].

Although whole grain foods are a source of fiber, they have independently been inversely associated with some chronic diseases, such as cardiovascular disease [35], type 2 diabetes [36], and some cancers [37,38]. The accurate assessment of whole grains from standard dietary questionnaires is challenging; therefore, a biomarker of intake is essential. Plasma concentrations and urinary excretion of alkylresorcinols and alkylresorcinol metabolites have been identified specifically as good indicators of whole grains intake[39,40].

In contrast to fiber, red and processed meats have been positively associated with stroke, cardiovascular disease, diabetes, and cancer [41–46]; these associations were identified using self-reported dietary assessment methods known to result in measurement error. Two controlled feeding studies were used to investigate potential biomarkers of meat intake by analyzing known breakdown products, including creatinine, creatine, carnitine, taurine, 1-methylhistidine, and 3-methylhistidine. Cross and colleagues reported that urinary levels of 1-methylhistidine and 3-methylhistidine dose-dependently reflected red meat intake [47]. After combining the self-reported meat intake data with the urinary data, it was found that there were no associations between 1- and 3-methylhistidine and colorectal adenoma [48]. Aside from urine analysis, hair is also a possible biomarker of meat intake. A carcinogenic substance of cooked meat, 2-amino-1-methyl-6-phenylimidizo [4,5-b]pyridine, has been shown to be measured in naturally colored hair and dyed hair [49]. However, this needs to be investigated in community dwelling individuals, in whom diet is not tightly controlled, to determine whether these can be successfully used in an epidemiologic setting as potential biomarkers of meat intake.

Investigating specific fatty acids can reveal important dietary patterns. The fatty acid composition of membrane phospholipids is in part determined by the omega-6 and omega-3 fatty acid composition of the diet. Thus, the fatty acid pattern of serum phospholipids or plasma aliquots has been used as a biomarker of compliance with omega-3 fatty acid supplementation in clinical trials [50,51]. Although enzyme selectivity and other physiological factors are also important determinants of the fatty acid composition of phospholipids, a diet high in omega-3 polyunsaturated fats will result in increased amounts of eicosapentaenoic and docosahexaenoic acids in circulating tissue pools. Specific fatty acids can also be associated with certain types of foods. Pentadecanoic acid (15:0) and heptadecanoic acid (17:0) are fatty acids produced by bacteria in the rumen of ruminant animals. These fatty acids, with uneven numbers of carbon atoms, are not synthesized by humans; therefore, their presence in human biological samples can indicate dietary exposure to milk fat. Proportions of 15:0 and 17:0 in adipose tissue and concentrations of 15:0 in serum have been found to correlate with milk fat intake in men and women [52,53].

III FUNCTIONAL BIOMARKERS AND MARKERS OF BIOLOGICAL EFFECTS

If a nutrient or dietary constituent has an identified impact on physiological, biochemical, or genetic factors, measuring markers of those effects can be extremely useful. Such indices can be classified as those that are measures of discrete functions of a nutritional factor and those that are measures of more general functions or activities [54]. A discrete functional index often relates to the first limiting biochemical system—e.g., a particular enzymatic pathway [55]. These markers can be used to identify the dosage or concentration of a nutritional factor necessary to achieve a clinically meaningful response or to define optimum nutrient status (Table 11.1). Unfortunately, for many nutritional factors, the first limiting biochemical system is unknown or not readily measured or accessible in humans. A general functional index is less specific but may be more directly linked to the pathogenesis of disease or ill health. Often, a panel of markers, rather than one specific measure, provides a better picture. Examples of general functional indices or markers are oxidative stress, immune function, bone health, and cell turnover—processes that have been shown to play roles in the risk of various diseases.

For a functional index to be an effective nutritional biomarker for intervention studies related to disease risk, a cause-and-effect relationship must be established

(1) between nutritional status and the functional index, (2) between the functional index and ill health, and (3) between nutrient status and ill health. Such an undertaking is a daunting and time-consuming task, but it is especially important if a functional biomarker is going to be used as a proxy, or surrogate, for a clinical end point or disease outcome. A clinical end point is a characteristic or variable that measures how a patient feels, functions, or survives. A surrogate end point biomarker is an index whose modulation has been shown to indicate the progression or reversal of the disease process; it is a biomarker that is intended to substitute for a clinical end point. In an intervention trial, the use of surrogate end point biomarkers (rather than the frank diagnosis of disease) requires substantially less time and fewer resources in the evaluation of efforts aimed toward reducing risk for chronic diseases such as cancer, cardiovascular disease, and osteoporosis [56].

To date, few markers have been established as true surrogate end point biomarkers (i.e., they can accurately substitute for a clinical end point [57]). The evidence supporting the linkage of a biomarker to a clinical end point may be derived from epidemiological studies, clinical trials, in vitro analyses, animal models, and simulated biological systems. Many biomarkers have been proposed as potential surrogate end points, but relatively few are likely to achieve this status because of the complexity of disease mechanisms and the limited capability of a single biomarker to reflect the collective impact of multiple therapeutic effects on ultimate outcome.

A Biomarkers of Enzyme Function

Understanding how diet influences enzyme systems is important in developing strategies for disease prevention and treatment. For example, dietary modulation of enzymes involved in carcinogen metabolism may be important in reducing cancer risk, and a dietary intervention that reduces expression of rate-limiting enzymes in cholesterol synthesis may alter cardiovascular disease risk. Enzymes that require micronutrients as cofactors are also used as biomarkers of nutritional status (Table 11.1).

Components of the diet have the capacity to modulate protein synthesis and function. An ideal discrete functional marker would be one that reflects the direct effect of a dietary constituent—e.g., mRNA amount when the dietary factor regulates gene expression or level of enzyme activity when the factor acts as a competitive inhibitor of the enzyme (Fig. 11.2). Unfortunately, monitoring at these levels in the pathway in an intact human is not always feasible. Often, we rely primarily on a downstream marker, whose measurement may be influenced by subsequent or parallel pathways and may give a diluted signal.

Often, the enzymes of interest are located primarily in tissues that are not readily accessible (e.g., liver, intestine, and lung). One approach to meeting this challenge is to measure the enzymes in more accessible tissue; e.g., enzymes that are present in high levels in the liver can often be measured in plasma or serum as a result of normal hepatocyte turnover. Enzyme activity of glutathione *S*-transferase (GST), a biotransformation enzyme

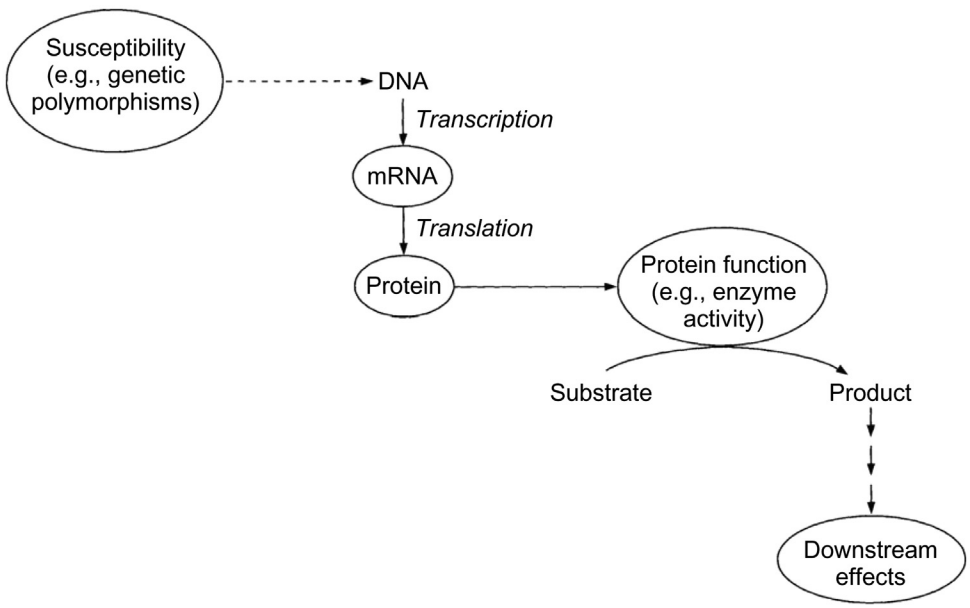

FIGURE 11.2 Direct functional markers of dietary exposure.

important in carcinogen detoxification, can be measured spectrophotometrically in serum [58] or concentrations of the enzyme can be determined in serum by immunoassay [59]. Serum concentration of the GST isoenzyme, GST-α, has been shown to increase when cruciferous vegetables are added to the diet [60]. A limitation of using serum measures of a hepatic enzyme is that the assumption is made that the liver function is normal. Thus, including other measures of liver function in the data collection is important to verify that no underlying hepatic disease is resulting in spurious GST values. In addition, some enzymes are present in isoforms in various tissues. GST-μ, another GST isoenzyme, is present in lymphocytes as well as in liver; therefore, for this isoenzyme, GST activity or protein concentration can be measured in cells extracted from blood samples [59].

Another approach to monitor enzyme activity in vivo is to use a drug probe. Many of the same xenobiotic metabolizing enzymes that metabolize carcinogens also metabolize, and are modulated, by commonly used drugs. The metabolites of these drugs can be monitored in serum, plasma, or urine and used to determine enzyme activities. For example, measuring caffeine metabolites in urine samples collected 4 hours after consumption of a defined caffeine dose allows determination of cytochrome P4501A2, *N*-acetyltransferase, and xanthine oxidase activities [60], and urinary concentrations of the glucuronide and sulfate conjugates of acetaminophen (paracetamol) are used to measure UDP-glucuronosyltransferase and sulfotransferase activities [61]. Drugs can be administered as probes during a nutrition intervention to determine the degree of change in enzyme activity in response to diet and to examine gene−diet interactions [62−64].

Measurement of arachidonic acid metabolism, which involves measuring the concentration of prostaglandins or leukotrienes (metabolic products) or enzymes in the eicosanoid metabolic pathway (i.e., cyclooxygenase), provides another example. Altered arachidonic acid metabolism is among the biochemical activities of nonsteroidal antiinflammatory agents and may also be influenced by antioxidant micronutrients such as vitamin E [65], and quantitative changes in these products or enzymes in tissues serve as biomarkers of this activity [66]. A reasonable amount of biological evidence suggests some role for this enzymatic pathway in colon carcinogenesis [67], but the overall relationship with the disease process is still under investigation.

Similarly, endogenous compounds can serve as probes to monitor enzyme activity. Serum concentrations of the amino acid homocysteine, compared to serum and red blood cell folate concentration, are a more sensitive systemic measure of cellular folate depletion [68,69]. Serum concentrations of homocysteine increase with folate inadequacy because the remethylation of homocysteine requires *N*-5-methyltetrahydrofolate as a cosubstrate [70], which therefore provides a functional marker for folate status. Nonetheless, because homocysteine is at the intersection of two metabolic pathways, remethylation and transsulfuration, deficiencies in other nutrients in these pathways—namely vitamin B_{12}, vitamin B_6, and possibly riboflavin—can contribute to elevated serum homocysteine concentrations [68].

B Biomarkers of Oxidative Stress

Oxidative stress has been suggested to play a role in the pathophysiological disease process in cancer, atherosclerotic cardiovascular disease, and many other acute and chronic conditions [71], although the specific relationship with the disease process remains to be established in most instances. Cellular damage caused by reactive oxygen species, which are generated from cellular respiration, cooxidation during metabolism, and the activity of phagocytic cells of the immune system, is controlled by antioxidant defense mechanisms that involve several micronutrients. Oxidative stress describes the condition of oxidative damage resulting when the balance between free radical generation and antioxidant defenses is unfavorable. Direct measurement of active oxygen and related species in biological samples is challenging, mainly because these compounds have short half-lives. Thus, the oxidative stress biomarkers used in human studies are typically adducts or end products that reflect reactions that have occurred between free radicals and compounds such as lipids, proteins, carbohydrates, DNA, and other molecules that are potential targets [72].

One frequently described assay used as an oxidative stress biomarker is the thiobarbituric acid reactive substances (TBARS) assay. The TBARS assay basically quantifies a product of malondialdehyde, which presumably reflects lipid hydroperoxides in the sample. Direct measurement of malondialdehyde in biological samples using HPLC has also been examined as an alternative approach, and plasma malondialdehyde concentrations have been reported to respond to alterations in antioxidant nutrient status, albeit not consistently [72].

Measurement of breath pentane is another biomarker of oxidative stress that has been utilized in human studies [73]. The approach basically involves collecting exhaled air for the measurement of the products of peroxidation of unsaturated fatty acids, a portion of which is volatile and released in the breath, using gas chromatography methods. However, the specific measurement methodologies vary a great deal and are not always reliable, and standardization of the procedure and knowledge of various influencing factors are needed to improve the usefulness of this approach [72].

Another biomarker of oxidative stress is urinary 8-hydroxydeoxyguanosine (8OHdG), which can be measured by several different methods with high sensitivity [74]. The 8-hydroxylation of the guanine base is a frequent type of oxidative DNA damage, and 8OHdG is subsequently excreted without further metabolism in the urine after repair in vivo by exonucleases. In previous studies, certain demographic factors and physiological characteristics such as gender and body mass [75] have been observed to influence urinary 8OHdG concentration, so these factors may need to be considered in interpretation. Urinary 8OHdG is increased in association with conditions known to be characterized by increased oxidative stress, such as smoking, whole-body irradiation, and cytotoxic chemotherapy [74–76]. Urinary 8OHdG (unadjusted or adjusted for urinary creatinine) has also been observed to decline in response to a high vegetable and fruit diet intervention in human subjects [77], which is particularly interesting because this type of diet has been suggested to promote reduced oxidative stress [13,77,78].

Prostaglandin-like compounds produced by nonenzymatic free radical-catalyzed peroxidation of arachidonic acid, termed F_2 isoprostanes, are currently of great interest as useful biomarkers of oxidative damage [79]. Specific gas chromatography–mass spectrometry (GC-MS) assays for the measurement of some of these compounds, such as iPF2a-III (also called 8-iso-$PGPF_2$) and iPF_2-VI, have been developed and used to quantify the compounds in urine and blood samples. These markers have been shown to be less variable than 8OHdG [80]. Elevated levels have been observed in plasma and urine samples from subjects under a wide variety of conditions of enhanced oxidative stress [81], and the measure can be altered in dietary intervention studies designed to reduce oxidative damage [82].

Another approach to measuring DNA oxidative damage that has been evaluated for use in human nutrition intervention research is the measurement of 5-hydroxymethyluracil levels in DNA in blood. 5-Hydroxymethyluracil is produced when DNA is exposed to oxidants, is relatively stable compared to other oxidation products, and can be quantified with GC-MS [83,84]. At the same time, its high intraindividual variation reduces its utility as a biomarker [85].

Oxidative damage to low-density lipoprotein (LDL) has been specifically linked to atherogenesis, and in an application of this biological activity, measurement of LDL oxidation ex vivo has been used in clinical studies as a biomarker of oxidative stress [86]. Basically, this process involves isolating the LDL fraction from a blood sample, exposing this fraction to oxidants, such as Cu^{2+}, and measuring the time lag before oxidation. Also, various specific methodologies are used across laboratories, and the lack of standardization in the approaches in use constrains the ability to make comparisons across studies.

Several other approaches to measuring biomarkers of oxidative stress have been proposed and are under study, and the reader is referred to a review of this topic [72]. Because of their inherent variability and uncertain responsiveness to dietary manipulations, clinical researchers often employ a panel of potential measures of oxidative stress rather than relying on a single indicator [77].

C Biomarkers of Immune Function

The human immune system is a complex and highly interactive network of cells and their products have a central role in protecting against various external disease-promoting factors and perhaps against malignant cells. Many of the components of the immune system can serve as biomarkers and are monitored in vivo or ex vivo [87,88]. Because of the complexity of the system, the selection of assays should be closely aligned with the research question being asked. Furthermore, multiple parameters need to be measured; one single biomarker is inadequate to monitor immune function.

Cell-mediated immune variables include the absolute amounts or ratios of various white blood cell (WBC) types (e.g., total counts, WBC differentials, T cell subsets) and measures of T cell function (e.g., lymphocyte proliferation, cytokine release from mitogen-stimulated cultures, cytotoxic capacities, and delayed-type hypersensitivity (DTH)). Both number and activity of natural killer cells (one of the cell types that play an important role in immune surveillance) are used as biomarkers in nutrition intervention trials [89,90]. Cytokines (e.g., the interleukins) are soluble factors released by immune cells, which control and direct the function of other immune effectors. Some of these have been used as markers of immune response in randomized trials of vitamin supplementation [90,91].

An in vivo functional test, the DTH skin test, is widely used to monitor the immune system in humans, including in studies of dietary modulation of immune function [92]. The test measures the capacity of an individual's immune system to mount a response to antigenic stimulation. The DTH test typically involves the simultaneous intradermal application of one or several DTH antigens. These antigens elicit an immunological reaction involving the release of lymphokines by antigen-sensitized T cells. These compounds, in turn, activate macrophages, which release inflammatory mediators, resulting in measurable skin induration.

D Biomarkers of Bone Health

Bone mass measurements and biomarkers of bone turnover are used as functional indices of bone health and, to a certain extent, can also be used as markers of the

adequacy of calcium intake. Measures of bone mass include bone mineral content (i.e., the amount of mineral at a particular skeletal site, such as the femoral neck, lumbar spine, or total body) and bone mineral density (BMD; i.e., bone mineral content divided by the area of the scanned region). Both are strong predictors of fracture risk [93–95]. Controlled calcium intervention trials that measure change in BMD provide evidence for the intake requirement of calcium [96] (see Chapter 44, Osteoporosis: The Early Years, and Chapter 45, Osteoporosis in Adults, for more details).

Biochemical markers of bone turnover predict bone mass changes and fracture risk and respond to dietary calcium intake [96]; thus, they provide some promise for a biochemical indicator of calcium status. Unlike BMD, they reflect more subtle changes in bone metabolism. Bone turnover is the cyclical process by which the skeleton undergoes renewal by a coupled, but time-separated, sequence of bone resorption and bone formation [97]. Markers of bone turnover rely on the measurement in serum or urine of enzymes or matrix proteins synthesized by osteoblasts or osteoclasts that spill over into body fluids, or of osteoclast-generated degradation products of the bone matrix [96]. Currently, serum levels of skeletal alkaline phosphatase and osteocalcin are used as markers of bone formation, and products of collagen degradation measured in urine are used to measure bone resorption. These markers exhibit substantial short-term and long-term fluctuations related to time of day, phase of menstrual cycle, and season of the year, as well as other factors that alter bone remodeling (e.g., exercise) [98].

E Biomarkers of Cell Turnover

Cellular markers of proliferation, differentiation, and apoptosis (i.e., programmed cell death) can be useful as biomarkers in research focused on nutritional factors and cancer, although the measured effect is a general indicator of an altered cell growth regulation effect. Use of such markers is severely restricted by the difficulty accessing the tissue of interest. Consequently, research in this area has been limited primarily to tissue available via endoscopic or fine-needle biopsy procedures (e.g., gastrointestinal tract, breast, and prostate).

As a general rule, increased proliferation of undifferentiated cells defines one aspect or characteristic of carcinogenesis, and in colon cancer, this relationship has been well-established. For example, cell proliferation occurs at the base of the colonic crypts, and as cells migrate from the crypts to the luminal surface, they become increasingly differentiated and mature and lose their proliferative capabilities [99]. The shift in which the proliferative zone extends to the surface so that cells on the luminal surface retain proliferative capabilities and are immature and underdifferentiated may be considered a field defect that sets the stage for current and future neoplastic changes [99–101]. Early work in this area relied on the incorporation of tritiated thymidine or bromodeoxyuridine into the DNA of dividing cells during incubation of a biopsy specimen. These methods required that the tissue be freshly obtained, so the cells were viable and replicating. Often, label incorporation was incomplete. Now, with increased sensitivity in immunohistochemical techniques, proteins present in proliferating cells (e.g., proliferating cell nuclear antigen (PCNA) and Ki67) are used more widely to quantify proliferative activity in tissue specimens. Labeling indices involving tritiated thymidine and PCNA have been used to quantify the proliferative activity in colonic mucosal samples from human subjects [102] and have been used successfully as end points in several nutrition intervention studies to prevent colon cancer [103]. These indices are being further refined by staining for proteins present during apoptosis (e.g., Bax and Bcl-2) and in differentiated cells in order to provide a more complete picture of cell dynamics.

Adoption of aberrant crypt foci (early morphological changes in colonic epithelium that are considered potential precursors of adenomatous polyps) as biomarkers in humans is an example of how improvements in technology have led to the adoption of a biomarker that until recently could only be used in animal studies. Development of magnifying endoscopes with improved resolution now allows investigators to monitor aberrant crypt foci in colon tissue samples from healthy humans [104].

IV BIOMARKERS OF GENETIC SUSCEPTIBILITY

The health of individuals and the population in general is the result of interaction between genetic and environmental factors. For the great majority of human diseases, purely genetic or purely environmental etiologies are insufficient to explain individual variability in occurrence, prognosis, or outcome [105]. This is especially the case with chronic diseases, such as heart disease and cancer. Genetically determined susceptibility factors alter disease frequency or treatment response through variations in the DNA coding sequences of genes. As a result, genetically susceptible individuals produce proteins that are structurally different from those of individuals who are not at increased risk of disease, or they produce them in greater or lesser amounts.

By genetic standards, traits with a frequency of between 1/100 and 1/10,000 in a population are considered uncommon, and rare traits are those with a frequency of less than 1/10,000 [106]. Typically, these are low-prevalence and high-penetrance genes (e.g., genes associated with familial

cancers). Common genetic traits are those in which the least common allele is present in at least 1% of the population [106]. Traits with this characteristic are known as genetic polymorphisms. They include the high-prevalence, low-penetrance genes—"susceptibility genes"—thought to contribute to disease risk.

In cases in which specific genetic mutations or variations may indicate disease risk or progression or may be modified by nutritional factors, genetic markers can also be useful biomarkers. Various molecular techniques have been developed to help characterize genetic abnormalities or differences. Genetic factors are important to consider in nutrition research for several reasons. One reason is that it is increasingly evident that genetic polymorphisms may contribute substantially to differences in the response to environmental and dietary exposures [107]. For example, genetic variations in the expression of the xenobiotic metabolizing enzymes may mediate the potentially mutagenic effect of heterocyclic amines (obtained from meat cooked at high temperature) [108] (see also Chapter 34: Nutrition and Cancers of the Breast, Endometrium, and Ovary). Also, results from laboratory animal studies suggest that dietary modifications can promote alterations in genetic factors [109] so that measuring genetic abnormalities may be considered as an approach to demonstrating a biological link between dietary factors and disease risk.

Some polymorphic traits may only be important in the presence of a particular dietary exposure. For example, carrying the 5,10-methylenetetrahydrofolate reductase thermal-labile variant has been shown to be a risk factor for colorectal adenomatous polyps, but only in the context of low-folate, vitamin B_{12}, and vitamin B_6 intake [110].

Given that a goal of nutrition research and interventions is the prevention and treatment of disease, genetic markers may aid in this effort by identifying population subgroups at high risk of disease in the presence of particular dietary exposures. Genetic susceptibility markers may also strengthen our understanding of disease by focusing attention on possible pathways of disease causation and progression. There is considerable heterogeneity in disease risk within populations; thus, markers of susceptibility may also help to clarify associations between dietary exposures and diseases within population subgroups [111].

V METABOLOMICS FOR BIOMARKER DISCOVERY

Metabolomics involves the quantitative and qualitative study of a large number (e.g., 400−800) of small molecules (typically less than 850 Da) in biological fluids, including serum or plasma and urine. Metabolomic profiles can be measured by using GC-MS, LC-MS, or nuclear magnetic resonance spectroscopy. This metabolic phenotyping integrates exposure and functional biomarkers, and it allows the investigation of biomarkers of exposures as well as disease processes. The advantage of nutritional studies is the ability to investigate an array of dietary variables rather than single exposures; furthermore, an individual's metabolic profile reflects environmental and genetic factors as well as gut microbiota, all of which play an important role in diet and metabolism.

In controlled feeding studies, metabolomics has identified metabolic signatures for consumption of diets varying in composition of fats [112], proteins [113], and phytochemicals [114,115], as well as black versus green tea [116]. According to van Duynhoven et al. 2010, intestinal microbiota in humans are responsible for biotransformation of polyphenol-rich foods into more bioavailable forms for the body to have an effect [117]. Additional focused and comprehensive efforts are underway to identify metabolites related to diet, physical activity, energy balance, and disease end points [118−122]. For example, recent studies have shown that the increased presence of branch-chained amino acids (BCAA) induces insulin resistance, possibly having to do with the signaling pathway and metabolism of BCAAs [119]. Although preliminary data suggest that only 20% of metabolites are affected when samples are nonfasting [123,124], more studies are required to investigate the sources of variation in metabolic profiles between biological fluids, as well as inter- and intraindividual variation.

VI CRITERIA FOR SELECTING AND USING BIOMARKERS

When a candidate biomarker is identified, certain basic considerations need to be addressed before it can be adopted for use in research or in a clinical setting [125]. These considerations relate to the reliability of the laboratory assay, the biological relevance of the marker, and the characteristics of the marker within a population. Whether or not a particular established marker is used also depends on the purpose the marker will serve.

Development of a biomarker usually builds on scientific knowledge from various types of laboratory studies, including tissue culture and animal studies. In the laboratory, an initial priority is to determine a marker's reliability or reproducibility. Assay performance can be evaluated using coefficients of variation (CV%; [SD/mean] × 100) to estimate within- and between-batch precision; these are measures of analytical, laboratory performance and do not reflect intra- or interindividual variation. The within-batch precision is determined by

dividing single samples into multiple aliquots and analyzing them together. Between-batch precision is determined by analyzing multiple aliquots on separate days. The acceptable numerical values for the laboratory CV% are difficult as the degree of error depends on the use of the biomarker data. For epidemiological studies, if the goal is to establish a stable estimate of the group mean, an acceptable CV% may depend on the number of samples available, the mean concentration of the biomarker, and between-individual variation [126]. Techniques of quality control [127,128] and statistical methodologies for managing quality control data [129] have been established and are used in clinical laboratories.

Biomarkers should be relatively easy to measure and require relatively noninvasive techniques of tissue sampling. This requires that the biological relevance or validity—i.e., the relationship between biomarkers in tissues readily available for human monitoring (e.g., peripheral blood) to those in target tissue (e.g., lung and liver) and the relationship between the biomarker and the disease or exposure being studied—of the measure be established. One example is the use of serum ferritin as a marker of body iron stores. Serum ferritin was validated as a measure of iron stores against bone marrow examination for stainable iron, the criterion—but very invasive—method for measuring iron stores [130]. As a result, serum ferritin has been adopted as a simple, quantitative biomarker of iron stores in otherwise healthy individuals.

If a particular biomarker is to be used as a measure of dietary exposure, it must be evaluated with respect to its sensitivity to that intake. Several approaches, both observational and interventional, can be used to define the relationship between long-term dietary intake and biological levels. Investigators can rely on geographical differences in exposure: Tissue samples from areas of known nutrient deficiency of a specific nutrient can be compared with samples from average and high-exposure areas. This approach has the advantage that it can reflect the long-term intake of a settled group of individuals; however, identifying and controlling confounding factors is a major challenge [126]. Another observational approach is to establish within individuals the relation between a dietary exposure and the biochemical marker. Participants for such a study can be selected randomly or can be selected specifically to maximize the range of intakes. Rigorous testing of the relationship between intake of the dietary factor and a biomarker under controlled dietary conditions is also valuable to establish dose−response relations; however, these trials are usually limited to weeks or months, and if they involve extensive changes to usual diet, blinding of participants may not be feasible.

Depending on the biomarker, significant variability can be seen in a biomarker. Sources of variation can be internal (e.g., age, sex, genetics, body build, and biological rhythm) or environmental (e.g., diet, season, time of day, immobilization, exercise, and drugs). These can contribute to both within- and interindividual variation. Additional external sources of variation, beyond laboratory accuracy and precision, can include an individual's posture during sample collection and sample handling and storage; protocols should be established to minimize these latter sources of variability.

Selection of a biomarker is dependent in part on its use. A biological indicator that is going to be used as a measure of a dietary exposure in an epidemiological study needs to be a valid representation of long-term intake [126]. Repeated sampling and measurement of a biomarker over time can provide some estimate of the within-individual variability and, therefore, the likelihood that the biomarker is a stable estimate of long-term intake. If repeated measures of a biochemical indicator vary substantially over time in the same individuals, then a single measure will not accurately reflect true, long-term intake [126]. This lack of consistency may occur because diet has changed over the sampling interval or because the measure is overly sensitive to short-term influences, such as recent intake. When using dietary constituents or their metabolites as biomarkers, an understanding of the metabolism and pharmacokinetics of the compound and the frequency of exposure will help to establish the utility of the measure as a biomarker of long-term intake.

A nutrition intervention study may require a biomarker that is a short-term measure of response to treatment. A biomarker that is to serve as a short-term measure of response needs to change within the time frame of the intervention. For example, serum folate provides a measure of recent folic acid exposure; however, erythrocyte concentrations are dependent on the life span of the cells and therefore will not reflect short-term changes in dietary folate. Serum folate concentrations decline within 3 weeks after the initiation of a low-folate diet, whereas erythrocyte folate concentration remains in the normal range for at least 17 weeks [131].

Additional practical considerations in the use of established biomarkers include the ability to conveniently access the body compartment for measurement, the procedures necessary to collect and process the sample, the burden to study participants or patients, and the resources for laboratory analysis. For example, multiday collections of feces or urine can be a major burden for many individuals. In addition, they can result in incomplete collections, which also compromise the final results. An accurate quantification of vitamin C or folate in a circulating body pool requires processing steps that must be conducted immediately after blood collection to preserve the sample appropriately and prevent degradation that would otherwise make the resulting measurement inaccurate. These extra steps can add time and effort to the labor

of blood processing. Furthermore, the complexity of an assay method can vary from the ability to analyze hundreds of samples a day at a cost of a few dollars per sample to a labor-intensive, week-long process that costs hundreds of dollars per sample.

The ability to measure particular biomarkers is also often linked to technological challenges and existing capabilities. For example, HPLC (developed in the 1970s) and improved separation and detection technologies that are currently emerging facilitate the quantification of many micronutrients and other dietary constituents that are present in very low concentrations in biological samples. Similarly, immunoassays allow for quantitation of phytochemicals, proteins, and so on in small volumes of serum or plasma, whereas previous methods required substantial quantities of sample. The development of microarray technology has provided the ability to analyze the expression profiles for thousands of genes in parallel [132,133]. This technique will rapidly advance knowledge regarding the mechanisms by which nutrition and diet affect disease risk; however, its application in intact humans will still be limited by access to the tissue of interest and the capacity to detect small but relevant changes in gene expression in response to diet.

A summary of the ideal characteristics of a biomarker, the assay involved, as well as study-specific questions is given in Table 11.3. Many of the prerequisites of a potential biomarker depend on the research question and study design.

TABLE 11.3 Criteria for Selecting Biomarkers

Qualities of a good biomarker
Sensitive
Specific
Biologic relevance to target tissue
Accessible in biospecimen—not invasive
Easy to measure
Applicable to many populations
Qualities of a good biomarker assay
Reliable
Reproducible
Sensitive
Identify sources of variability in the biomarker
Interindividual variation (e.g., age, sex, genetics, diet, lifestyle, season, time of day, drugs)
Intraindividual variation
The effect of sample handling and storage; e.g., is the biomarker stable during long-term storage?
Identify the type of biomarker needed
Is the biomarker applicable to the setting? For example, cohort studies usually have biospecimens from only one time point—Is a single measure representative and sufficient?
Is the assay applicable to the setting? For example, the assay would need to have relatively high throughput for cohort studies, whereas for small intervention studies this would be less important.
Does the study require a short-term or a long-term biomarker?
Does the biomarker reflect a dose–response relation?
Do the biospecimens need to be collected after fasting or should the individuals be nonfasting?

VII SUMMARY

The use of biomarkers in humans is an integral component of nutrition intervention research. Biochemical measurements of dietary constituents in blood or other tissues can provide a useful assessment of the intake of certain dietary factors. However, for some nutrients, functional markers, or direct functional indices, provide a better estimate of the significance of the true status for a nutrient. More general functional indices and indicators of biological activity relating to processes associated with disease risk are important for establishing the relationships between diet and disease prevention and response to treatment.

The development of biomarkers continues at a rapid pace. New types of markers are being proposed constantly, and analytical techniques for existing markers are improved. This advancement requires establishing the accuracy, reliability, and interpretability of the biomarkers; obtaining data on marker distributions within different age and sex groupings in normal populations; determining the extent of intraindividual variation in markers with respect to tissue localization and persistence; and assessing the contribution of genetic and acquired susceptibility factors to interindividual variability.

I INTRODUCTION AND OBJECTIVES

To promote and maintain health in the US population, and in many other parts of the world, numerous authoritative medical and public agencies have developed national health policies and expert clinical practice guidelines. All of these acknowledge that improvements in lifestyle behaviors such as healthful dietary patterns, physical activity, smoking abstinence, and alcohol moderation (if consumed, and in adults only) are the cornerstones of chronic disease prevention and health promotion.

A Importance of Nutrition Guidelines That Support Chronic Disease Reduction and Health Promotion

National nutrition guidelines are supported by a large and robust body of epidemiological and clinical research that strongly supports the importance of optimal nutrition and other healthy lifestyle behaviors in reducing risks for major chronic diseases and promoting other favorable health outcomes. This evidence base not only confirms that diet is related to the prevention and treatment of many chronic diseases, but also demonstrates the efficacy and impact of preventive nutrition and lifestyle behavioral interventions on a wide range of other health outcomes. Practicing healthy lifestyle behaviors is central to reducing chronic disease risk and improving overall health and well-being but, behavior modification is difficult. Interventions must be targeted, intensive, and multidisciplinary in nature to increase their effectiveness at addressing the complex levels of influence on diet and other lifestyle behaviors. Thus, guidelines and policies should play an important role in facilitating adherence to healthful behaviors.

In the United States, federal nutrition and health policies are designed to influence and shape nutrition, healthcare and public health systems throughout the nation as well as other sectors, such as food and agriculture. For example, the *Dietary Guidelines for Americans* (DGAs) are public policy directives that affect the nature and delivery of programs and services of the US Department of Agriculture (USDA) as well as US Department of Health and Human Services. The DGAs and other national nutrition policies and expert clinical practice guidelines affect many programs and services such as the large federal framework of food and nutrition assistance programs as well as the US healthcare and public health systems. In addition, they influence research priorities in the National Institutes of Health (NIH) and research and educational initiatives of USDA, and the Centers for Disease Control and Prevention (CDC). They can also influence regulations developed within the Food and Drug Administration.

B Public Health Approaches Can Create Environments Where Healthful Diets and Lifestyles Are Normative

Nutrition and other lifestyle behaviors are determined by multiple levels of influence. The 2015–2020 DGAs utilized the socio-ecological model [1–2] to identify the wide-ranging set of factors that affect diet and other lifestyle behaviors at individual, socio-cultural, environmental, multisectoral, and policy levels. The DGAs note that public health approaches that combine interventions aimed at

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00012-6

individual and populations will promote improvements in lifestyle behaviors. Multicomponent interventions can be guided by the current, sound research evidence base and "best practice" models, particularly those utilizing a socio-ecological approach. Most interventions will be comprehensive in nature, guided by multidisciplinary teams, and more recently, will incorporate cross-sectoral collaborations and public–private partnerships. The 2015–2020 DGAs also emphasized that interventions are most effective when they are designed to target the needs and preferences of the individuals and communities served. Of note, successful public health efforts such as those addressing automobile safety and tobacco use have used broad-based, inclusive approaches consistent with a socio-ecological model [1].

C Demographic Differences in Health Outcomes and Trajectories Support Tailored Nutrition Interventions

Increasingly, experts advocate that lifestyle interventions should be personalized to the biological and other personal needs and preferences of individuals and facilitate changes in the environments and settings in which populations work, are educated and trained, and seek recreation. Expert recommendations on personalized approaches to preventive behavioral intervention are guided by research showing that lifestyle behavior profiles and metabolic and disease-related risks vary within as well as across populations and are inextricably linked. For example, the Framingham Nutrition Studies found that adult males and females have differing patterns of lifetime weight gain and varying rates of development of overweight, obesity, and abdominal obesity in early and late adulthood [3–5]. The Framingham Nutrition Studies also found that 10 distinct, habitual dietary patterns with differing food composition and nutrient quality could be identified and were shown to be associated with metabolic risk profiles and risks for development of: overweight and obesity, abdominal obesity, metabolic syndrome, heart disease, hypertension, and stroke [3–5]. Framingham investigators interpreted these findings, combined with results from other epidemiological studies and the emerging and extensive research from randomized clinical trials (RCTs) in diverse populations, as underscoring the importance of gender-specific, individualized prevention and treatment strategies.

Consistent with this research and a large body of current, high-quality research, the 2015–2020 US DGAs and the recent American Heart Association/American College of Cardiology/The Obesity Society (ACC/ACC/TOS) Guidelines for the Management of Overweight and Obesity [6] and the ACC/ACC Guideline on Lifestyle Management to Reduce Cardiovascular Risk [7] recommend that preventive nutrition and lifestyle interventions be utilized in clinical and public health systems and other community settings. They also advocated that they be targeted to the biological needs and personal preferences of individuals and populations served.

D Chapter Objectives

This chapter is focused on nutrition guidelines to maintain and promote health. The aims are to review:

- guidelines on human nutrient requirements;
- federal nutrition-related health policies and related expert guidelines on health promotion and chronic disease prevention; and
- how nutrition policies and expert recommendations can inform professional practices to promote and maintain health.

II GUIDELINES ON HUMAN NUTRIENT REQUIREMENTS

A Dietary Reference Intakes

The Dietary Reference Intakes (DRIs) offer guidance on the level of nutrient intake that will promote health. They are comprised of four categories of values that help promote health, prevent disease, and provide guidance on consumption levels. The four categories are: the Estimated Average Requirement (EAR), the Recommended Dietary Allowance (RDA), the Adequate Intake (AI), and the Tolerable Upper Intake Level (UL).

1 Process for Establishing DRIs as Guidelines on Human Nutrient Requirements

The DRIs play a critical role in helping Americans meet their nutritional needs. To date, they have been developed by the Food and Nutrition Board of the Institute of Medicine, in conjunction with substantial input from nutrition professionals [8]. In the 1990s, the DRIs expanded and replaced the RDAs, which had been used since 1941, because of a broader evolution that was taking place in the field of nutrition science [9]. The dietary reference values were published in a series of reports titled *Dietary Reference Intakes* and were released between 1997 and 2005. The DRIs are updated, as needed, on an ongoing basis by experts at the Food and Nutrition Board of the National Academies of Medicine.

2 DRIs Serve as a Major Component of Federal Nutrition Policy

As noted above, the DRI is an umbrella term for four types of nutrient recommendations: EAR, RDA, AI, and

UL. The EAR is the intake that would be adequate to meet the nutritional requirements/needs of approximately 50% of a healthy population; the RDA is calculated from the EAR by adding two standard deviations of the requirement distribution. The RDA is thus the level of intake that would be adequate for 97.5% of the population. The AI is used when the scientific data are not sufficient to set an EAR and its associated RDA. The UL represents the upper level of intake that poses a low risk of adverse effects, and usual intakes above the UL are not recommended.

DRIs have been set for energy, 14 vitamins, 15 minerals, and 7 macronutrients. A summary of all DRI values, except EAR, is provided in the Appendix. Two reports have been released to address appropriate ways to use the DRIs—one assesses nutrient intakes [10] and the other on planning nutrient intakes at individual and programmatic levels [11]. The RDA (or the AI if an RDA is not available) is the appropriate target for guidance to consumers on healthy nutrient intakes, and the goal is to reduce to a very low level the likelihood that an individual's intake is inadequate. Thus achieving the RDA or the AI means that the risk of inadequate intake is very low. A UL should never be considered a target intake and health professionals may guide consumers in using the UL to ensure that nutrient intakes are not too high.

3 Importance of DRIs for Setting Nutrition Guidelines for Prevention and Treatment of Chronic Disease

The four primary uses of the DRIs are to assess the intakes of individuals, assess the intakes of population groups, plan diets for individuals, and plan diets for groups. They are used in planning for food assistance programs, food labeling, fortification efforts, food safety assurance, institutional food planning, military food and nutrition planning, and in developing new products or modifying existing food products.

The DRIs play a critical role in promoting and maintaining health through their link to the *DGAs* (the DGAs are discussed in greater detail below) [12]. The guidelines and the materials that support them are designed to help Americans meet the DRIs, primarily through consuming foods rather than supplements.

III FEDERAL NUTRITION-RELATED HEALTH POLICIES

A The Dietary Guidelines for Americans

Every five years, the US Departments of Health and Human Services (HHS) and Agriculture (USDA) are mandated under the 1990 National Nutrition Monitoring and Related Research Act (Public Law 101-445, 7 U.S.C. 5341 et seq) to jointly publish the DGAs [13]. The DGAs are federal policy guidelines that must be based on the preponderance of current scientific and medical knowledge and contains nutritional and dietary recommendations for the general public. The DGAs have far-reaching impact.

B Uses and Impact of the DGAs

The DGAs are used in developing federal food and nutrition programs, educational initiatives, research and programmatic priorities, and health policies and programs within the agencies that fall within the very broad jurisdictions of HHS and USDA. Among the many realms affected by the DGAs are the CDC, NIH, the US Public Health Service, the US healthcare and public health systems, the Food and Drug Administration (which regulates food labeling), the Agricultural Research Service, the Supplemental Nutrition Assistance Program (SNAP) and Nutrition Program for Women, Infants and Children (WIC), School Lunch and Breakfast Programs, Older Americans Act Nutrition Program, etc. The US military may also use the DGA to guide food and nutrition services as well as health-related programs.

The DGAs are prepared for a professional audience and are intended to guide services and interventions delivered to individuals aged 2 years and older and their families and promote consumption of a healthy, nutritionally adequate diet. Given the link between diet and physical activity and population health, the DGAs endorse healthy dietary patterns and physical activity. Additional audiences who may use *Dietary Guidelines* information to develop programs, policies, and communication for the general public include businesses (i.e., corporate wellness initiatives), schools (e.g., foodservice, curriculum, and other services), community groups (environmental and population initiatives, etc.), media, the food industry, and state and local governments.

C Overview of Process Used to Develop 2015 DGAs

The development of the 2015−2020 DGAs began with the appointment of a Dietary Guidelines Advisory Committee (DGAC) composed of nationally recognized experts in the field of nutrition and health. An external advisory committee is not mandated by law but has been appointed since the 1980s. The DGAC was charged to provide independent, science-based advice and recommendations for development of the guidelines. In so doing, the committee was asked to assess the *DGAs*, 2010, and determine where the new scientific evidence was available to inform revisions to current guidance or

suggest new guidance, in particular food-based recommendations of public health importance for Americans aged 2 years and older. The committee process was to be completed in 2 years and culminate in the submission of a report on scientific recommendations to the Secretaries of HHS and USDA. DGAC responsibilities did not include translation of the recommendations into 2015 DGAs; however, USDA and HHS are mandated to translate the DGAC recommendations into public policy in the DGAs.

The 2015 DGAC was a 14-member committee of scientists nominated through a public process and appointed by the Secretaries of HHS and USDA. DGAC members are recognized as experts in a broad range of domains, including food and nutritional sciences, medicine, epidemiology, nutrition and health policy, public health, and related areas. All DGAC members served without compensation and were fully vetted according to strict federal guidelines with regard to potential conflicts of interest pertaining to their committee responsibilities.

D Scientific Approach of the DGAC

The 2015 DGAC initially identified five major research themes: (1) food and nutrient intakes and health—current status and trends; (2) dietary patterns, foods and nutrients, and health outcomes; (3) diet and physical activity behavior change; (4) food and physical activity environments; and (5) food sustainability and food safety. Five subcommittees were then established to formulate research question priorities. In addition, three cross-cutting working groups were formed to address issues that transcended the subcommittee themes: (1) sodium, (2) saturated fatty acid (SFA), and (3) added sugars. Each 2015 DGAC member served on at least two of the subcommittees and one of the cross-cutting working groups. An oversight Science Review Subcommittee composed of the DGAC Chair, DGAC vice-chair, and two DGAC members who participated on the 2010 DGAC as well as subcommittee and working group chairs were formed to provide oversight to the process.

The procedures used to prepare the 2015 DGAC Scientific Report were systematic, transparent, and thorough and provided multiple opportunities for public input through oral testimony and website submissions. Rigorous and strict rules for DGAC meetings and communications were established and were in keeping with requirements of the Federal Advisory Committee Act [14]. All meetings of the DGAC were announced in advance in the Federal Register. At least one federal staff member representing the Designated Federal Officer was part of all subcommittee and working group meetings, conference calls, and emails. All meetings of the 2015 DGAC were made available via real-time broadcasts and, along with public comments, are archived online [15]. In February 2015, the Scientific Report of the 2015 DGAC was submitted to the Secretaries of HHS and USDA and the committee completed its assignment. The Scientific Report of the 2015 DGAC can be found online [13]. Upon completion of its report, the DGAC was disbanded as mandated by Congress. In February 2016, the 2015–2020 DGAs were published by HHS and USDA, thereby completing the mandated process of translating the DGAC Scientific Report into public policies.

E Summary of the 2015–2020 DGAs

In large part, the DGAs are consistent with the DGAC report and recommendations which underscored the importance of addressing the highly prevalent diet- and lifestyle-related diseases in the US population (including overweight and obesity, cardiovascular disease (CVD), diabetes, and diet-related cancers); improving the quality and composition of the American dietary pattern; making gradual changes in dietary patterns to be healthier and increasing physical activity; utilizing sound and effective methods of individual and population level behavior change to promote healthy dietary patterns and physical activity; and maintaining food quality and safety with best practices. There are two major areas in which the DGAC and DGAs differ. First, the 2015 DGAC recommended not to bring forward the 2010 DGAs limit on dietary cholesterol but did model healthy dietary patterns with relatively low cholesterol intake. Additionally, the Secretaries of USDA and HHS announced that the DGAC recommendations on the important topic of environmental sustainability would not be addressed in the 2015–2020 DGA. The 2015–2020 DGAs are summarized in brief below.

The *2015–2020 Dietary Guidelines* provide five overarching guidelines (Table 12.1) that encourage healthy dietary patterns, recognize that individuals will need to make shifts in their food and beverage choices to achieve a healthy pattern, and acknowledge that all segments of our society have a role to play in supporting healthy lifestyle choices, particularly dietary and physical activity. Key recommendations for healthy eating patterns are shown in Table 12.2. The 2015 DGAs indicate that the recommendations for healthy eating patterns should be applied in their entirety given the interconnected relationship of the various dietary components.

The 2015 DGAs also acknowledge that a healthy eating pattern is not a rigid prescription, but rather, an adaptable framework in which individuals can enjoy foods that meet their personal, cultural, and traditional preferences and fit within their budget. Three basic healthy dietary patterns were modeled (i.e., Healthy US Style, Healthy Vegetarian, and Healthy Mediterranean-style) in the DGAC report and are included in the 2015–2020 DGA

TABLE 12.1 Five Overarching Guidelines from the 2015–2020 US *DGAs*

1. Follow a healthy eating pattern across the lifespan. All food and beverage choices matter. Choose a healthy eating pattern at an appropriate calorie level to help achieve and maintain a healthy body weight, support nutrient adequacy, and reduce the risk of chronic disease.
2. Focus on variety, nutrient density, and amount. To meet nutrient needs within calorie limits, choose a variety of nutrient-dense foods across and within all food groups in recommended amounts.
3. Limit calories from added sugars and SFAs and reduce sodium intake. Consume an eating pattern low in added sugars, SFAs, and sodium. Cut back on foods and beverages higher in these components to amounts that fit within healthy eating patterns.
4. Shift to healthier food and beverage choices. Choose nutrient-dense foods and beverages across and within all food groups in place of less healthy choices. Consider cultural and personal preferences to make these shifts easier to accomplish and maintain.
5. Support healthy eating patterns for all. Everyone has a role in helping to create and support healthy eating patterns in multiple settings nationwide, from home to school to work to communities.

TABLE 12.2 Key Recommendations from the 2015–2020 US Dietary Guidelines[a]

Consume a healthy eating pattern that accounts for all foods and beverages within an appropriate calorie level. A healthy eating pattern includes:

- A variety of vegetables from all of the subgroups—dark green, red and orange, legumes (beans and peas), starchy, and other
- Fruits, especially whole fruits
- Grains, at least half of which are whole grains
- Fat-free or low-fat dairy, including milk, yogurt, cheese, and/or fortified soy beverages
- A variety of protein foods, including seafood, lean meats and poultry, eggs, legumes (beans and peas), and nuts, seeds, and soy products
- Oils

A healthy eating pattern limits:

- SFAs and *trans*-fats, added sugars, and sodium

Consuming the specified limits of these dietary components can help individuals achieve healthy eating patterns within calorie limits:

- Consume less than 10% of calories per day from added sugars.
- Consume less than 10% of calories per day from SFAs.
- Consume less than 2300 mg per day of sodium.
- If alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and up to two drinks per day for men—and only by adults of legal drinking age.

In tandem with the recommendations above, Americans of all ages—children, adolescents, adults, and older adults—should meet the *Physical Activity Guidelines for Americans* to help promote health and reduce the risk of chronic disease. Americans should aim to achieve and maintain a healthy body weight. The relationship between diet and physical activity contributes to calorie balance and managing body weight.

[a]*The* Dietary Guidelines*' key recommendations for healthy eating patterns should be applied in their entirety, given the interconnected relationship that each dietary component can have with others.*

(Table 12.3). The nutrient profiles of the three dietary patterns are shown in Table 12.4; each pattern is nutrient-dense and was modeled to meet the DGAs including improving intakes of "nutrients of public health concern."

The 2015–2020 guidelines make primary recommendations in relation to the use of effective interventions at individual and population levels. We will discuss in the subsequent sections of this chapter strategies for obesity prevention, lifestyle management, and methods of effective intervention at individual and population levels. The DGAC brought forward the recommendations of the physical activity, lifestyle, and obesity reports.

IV EXPERT GUIDELINES ON NUTRIENT REQUIREMENTS FOR HEALTH PROMOTION AND CHRONIC DISEASE PREVENTION

In 2005, the National Heart Lung and Blood Institute (NHLBI) of the NIH recognized the need to update their guideline reports on CVD prevention and treatment. NHLBI convened stakeholder groups to guide this process and based upon their recommendations, expert panels were assembled to update and publish guidelines on overweight/obesity, cholesterol, and blood pressure (BP).

TABLE 12.3 Food Groups in the Three Dietary Patterns (Healthy US Style, Healthy Vegetarian, and Healthy Mediterranean-Style) Modeled by the DGAC[a]

Food Group[b]	Healthy US-Style Pattern	Healthy Vegetarian Pattern	Healthy Med-Style Pattern
Fruit	2 cups per day	2 cups per day	2½ cups per day
Vegetables	2½ cups per day	2½ cups per day	2½ cups per day
Legumes	1½ cups per week	3 cups per week	1½ cups per week
Whole grains	3 oz eq per day	3 oz eq per day	3 oz eq per day
Dairy	3 cups per day	3 cups per day	2 cups per day
Protein foods	5½ oz eq per day	3½ oz eq per day	6½ oz eq per day
Meat	12½ oz eq/week	–	12½ oz eq/week
Poultry	10½ oz eq/week	–	10½ oz eq/week
Seafood	8 oz eq/week	–	15 oz eq/week
Eggs	3 oz eq/week	3 oz eq/week	3 oz eq/week
Nuts/seeds	4 oz eq/week	7 oz eq/week	4 oz eq/week
Processed soy	½ oz eq/week	8 oz eq/week	½ oz eq/week
Oils	27 g per day	27 g per day	27 g per day

Potassium—%AI	71	70	71
Sodium[a]—%UL	76	61	72

[a]*Intakes shown at the 2000 kilocalorie level as a percent of the goal or the limit for a 19- to 30-year old.*

The published reports are collaboration between the ACC, the ACC [7], as well as TOS [6]. Because of the reports, focus on nutrition, physical activity, the guidelines on overweight and obesity, and lifestyle prevention and management of CVD will be summarized in this chapter.

A 2013 ACC/ACC/TOS Guideline for the Management of Overweight and Obesity in Adults

1 Overview of Critical Questions Addressed by the Obesity Panel to Update Existing Guidelines

The Obesity Panel that was assembled in 2008 consisted of experts charged with updating existing NHLBI guidelines on overweight/obesity. Over a 5-year period, the panel reviewed and summarized high-quality, peer-reviewed published research spanning 1998 through 2011 in order to answer five critical questions (CQ1−CQ5):

- CQ1: Among overweight and obese adults, does weight loss produce CVD health benefits and what health benefits can be expected with different degrees of weight loss?
- CQ2: What are the CVD-related health risks of overweight and obesity and are the current cutpoints for overweight (BMI 25−29.9 kg/m^2), obesity (BMI >30 kg/m^2), and waist circumference (>102 cm (>40 in) in men and >88 cm (35 in) in women) appropriate for population subgroups?
- CQ3: Which dietary strategies are effective for weight loss?
- CQ4: What is the efficacy/effectiveness of a comprehensive lifestyle intervention program (i.e., diet, physical activity, and behavior therapy) in facilitating weight loss or maintaining weight loss?
- CQ5: What is the efficacy and safety of bariatric surgery? What is the profile (BMI and comorbidity type) of patients who might benefit from surgery for obesity and related conditions?

The panel summarized research studies using evidence tables that were extensively analyzed and discussed in order to guide the panel's conclusions and recommendations. Each recommendation was graded on the quality of the evidence base using standardized criteria. The Obesity Panel then created a treatment algorithm [16] which summarized its major recommendations and was intended to help direct practitioners in their assessment of patient risk and guide their management of overweight and obesity, and thereby achieve "best practices" in clinical and public health settings. Table 12.5 summarizes the major recommendations.

2 Findings and Recommendations From the Obesity Panel About Successful Weight Loss Approaches

As outlined in the treatment algorithm (ACC/ACC/TOS commentary), the Obesity Panel developed recommendations on the methods and frequency of assessing individual risk of overweight and obesity and then showed how to approach the design and implementation of effective weight loss and maintenance strategies. Their extensive literature review identified 15 distinct dietary regimens (e.g., low calorie, low-fat; low calorie higher protein; low calorie, low carbohydrate, etc.) that were shown to be sound and effective for weight loss management [16]. Of note in the panel's report is that all of the identified dietary regimens were shown to be equally effective in promoting weight loss *as long as* calories were controlled [16]. The report thus emphasizes that current research supports a wide array of effective dietary intervention options for weight loss management.

The panel recommended that weight loss be initiated in obese individuals and overweight persons with elevated CVD risk or other obesity-related comorbidities. According to the 2015−2020 DGAs, over half of adult Americans currently meet these criteria. They also recommended that patient's "readiness to change" be assessed and, as appropriate, that strategies be matched to the individual's health needs and lifestyle characteristics in order to establish a sound, *personalized* approach to weight management. It was noted that evidence-based, web and mobile tools and other technologies were emerging to enhance the effectiveness of weight loss and weight maintenance strategies.

The Obesity Panel report also points out that comprehensive lifestyle interventions, particularly approaches that incorporate dietary behavior change and physical activity, are the "gold standard" for weight loss management and weight loss maintenance. The panel used expert opinion to recommend the use of multidisciplinary teams for comprehensive lifestyle interventions, if available, or referral to nutrition professionals for dietary counseling and weight loss management.

3 Findings and Recommendations From the Obesity Panel About the Intensity and Duration of Weight Loss Approaches

The panel also examined the evidence on realistic, quantitative weight loss outcomes and made recommendations on the intensity and duration of treatment. Dietary interventions alone as well as high intensity comprehensive lifestyle programs (typically integrating diet, physical activity, and behavioral therapy) were found to result in weight losses in adult men and women at 6 months of up to 26 lb (12 kg) on average (ranging from 9 to 26 lb (4−12 kg))

TABLE 12.5 Major Recommendations for Management of Overweight and Obesity in Adults: 2013 AHA/ACC/TOS Guidelines [61]

1. *Identify Patients Who Need to Lose Weight*
   - Measure height and weight and calculate BMI at annual visits or more frequently.
   - Use the current overweight (BMI >25.0–29.9 kg/m^2) and obesity (BMI ≥30 kg/m^2) to identify adults who may be at elevated risk of CVD and the current cutpoint for obesity (BMI ≥30 kg/m^2) to identify adults who may be at elevated risk of mortality from all causes.
   - Advise overweight and obese adults that the greater the BMI, the greater the risk of CVD, type 2 diabetes, and all-cause mortality.
   - Measure waist circumference at annual visits or more frequently in overweight and obese adults. Advise adults that the greater the waist circumference, the greater the risk of CVD, type 2 diabetes, and all-cause mortality. Use the cutpoints currently in common use (from either NIH/NHLBI [>102 cm (>40 in) in men or >88 cm (>35 in) in women] or WHO/IDF [>94 cm (37 in) in men and >80 cm (31.5 in) in women]) to identify patients who may be at increased risk until further evidence becomes available.
2. *Match Treatment Benefits with Patients' Risk Profiles*
   - Counsel overweight and obese adults with CVD risk factors (high BP, hyperlipidemia or hyperglycemia) that lifestyle changes that produce even modest, sustained weight loss of 3–5% (of body weight) produce clinically meaningful health benefits, and greater weight losses produces greater benefits.
3. *Use Evidence-Based Dietary Strategies for Weight Loss*
   - Prescribe a diet to achieve reduced-calorie intake for overweight or obese individuals who would benefit from weight loss, as part of a comprehensive lifestyle intervention. Any one of the following methods can be used to reduce food and calorie intake:
     - Prescribe 1200–1500 kcal/day for women and 1500–1800 kcal/day for men (kilocalorie levels are usually adjusted for the individual's body weight);
     - Prescribe a 500 kcal/day or 750 kcal/day energy deficit; or
     - Prescribe one of the (identified 15) evidence-based diets that restrict certain food types (such as high-carbohydrate foods, low-fiber foods, or high-fat foods) in order to create an energy deficit by reduced food intake.
   - Prescribe a calorie-restricted diet, for overweight and obese individuals who would benefit from weight loss, based on the patient's preferences and health status and refer to a nutrition professional (e.g., RD) for counseling. A variety of dietary approaches can produce weight loss in overweight and obese adults.
4. *Use Evidence-Based Comprehensive Lifestyle Interventions, if Possible*
   - Advise overweight and obese individuals who wish to lose weight to participate for ≥6 months in a comprehensive lifestyle program that assists participants in adhering to a lower calorie diet and in increasing physical activity through the use of behavioral strategies. In overweight and obese individuals, in-person comprehensive lifestyle interventions consisting of diet, physical activity, and behavior therapy provided by a skilled professional team of nutritionists, exercise specialists, and behaviorists in a group or individually, have shown the highest success.
   - Prescribe on-site (face-to-face), high intensity (i.e., ≥14 sessions in 6 months) comprehensive weight loss interventions provided in individual or group sessions by a trained interventionist (e.g., RDs, psychologists, exercise specialists, health counselors, or professionals in training).
   - Recognize that electronically delivered weight loss programs (including by telephone) that include personalized feedback from a trained interventionist (e.g., RDs, psychologists, exercise specialists, health counselors, or professionals in training) can be prescribed for weight loss but may result in smaller weight loss than face-to-face interventions.
   - Utilize commercial-based programs that provide a comprehensive lifestyle intervention as an option for weight loss, provided there is peer-reviewed published evidence of their safety and efficacy.
   - Use a very low calorie diet (defined as <800 kcal/day) only in limited circumstances and only when provided by trained practitioners in a medical care setting where medical monitoring and high intensity lifestyle intervention can be provided. Medical supervision is required because of the rapid rate of weight loss and potential for health complications.
   - Advise overweight and obese individuals who have lost weight to participate, when possible, in a long-term (≥1 year) comprehensive weight loss maintenance program. For weight loss maintenance, prescribe face-to-face or telephone-delivered weight loss maintenance programs that provide regular contact (monthly or more frequent) with a trained interventionist (e.g., RDs, psychologists, exercise specialists, health counselors, or professionals in training) who help participants engage in high levels of physical activity (i.e., 200–300 minutes/week), monitor body weight regularly (i.e., weekly or more frequent), and consume a reduced-calorie diet (needed to maintain a lower body weight).
5. *Use Appropriate Methods to Selecting Patients for Bariatric Surgical Treatment for Obesity*
   - Advise adults with a BMI ≥40 or (those who present with a) BMI ≥35 (and) with obesity-related comorbid conditions who are motivated to lose weight and who have not responded to behavioral treatment with or without pharmacotherapy with sufficient weight loss to achieve targeted health outcome goals that bariatric surgery may be an appropriate option to improve health and offer referral to an experienced bariatric surgeon for consultation and evaluation.
   - Advise individuals with a BMI <35 that there is insufficient evidence to recommend for or against undergoing bariatric surgical procedures.
   - Advise patients that choice of a specific bariatric surgical procedure may be affected by patient risk factors, including age, severity of obesity/BMI, obesity-related comorbid conditions, other operative risk factors, risk of short- and long-term complications, behavioral and psychosocial factors, and patient tolerance for risk as well as provider factors (surgeon and facility).

Source: Adapted from B.E. Millen, D.M. Wolongevicz, C.A. Nonas, A.H. Lichtenstein, 2013 American Heart Association. American College of Cardiology/The Obesity Society Guidelines for the management of overweight and obesity in adults: implications and new opportunities for registered dietitian nutritionists, J. Acad. Nutr. Diet. 114 (2014) 1730–1735 [61] and B.E. Millen, D.M. Wolongevicz, J.M. De Jesus, C.A. Nonas, 2013 American Heart Association. American College of Cardiology Guideline on lifestyle management to reduce cardiovascular risk: practice opportunities for registered dietitian nutritionists, J. Acad. Nutr. Diet. 114 (2014) 1723–1729 [62].

and from 9 to 22 lb (4−10 kg) after 12 months. While weight regain occurred as treatments continued for longer duration (up to 2 years or longer), average longer-term weight losses were sufficient to recommend continued weight management treatment by qualified professionals. The panel determined that weight losses of 5−10% of body weight at 6 months are feasible with diet alone and more intensive interventions. Nonetheless, sustained weight losses of 3−5% of body weight were identified as feasible and as sufficient to improve CVD and diabetes risk factor profiles in overweight and obese adults (with and without diabetes); greater weight losses were associated with even better outcomes.

The impact of weight loss on CVD- and diabetes-related risks was also seen to be improved by medical nutrition therapy protocols that targeted risk factors (e.g., lower SFA protocols provided additional benefits on low-density lipoprotein (LDL)-cholesterol). High intensity, on-site comprehensive interventions (≥14 sessions in 6 months) were recommended for weight loss management and these recommendations align well with the most recent US Public Services Task Force [17] and Centers for Medicare and Medicaid Services recommendations [18]. The overall effectiveness of group or individual treatment regimens was similar so both are recommended as long as conducted on-site by trained interventionists (registered dietitians/registered dietitian nutritionists (RDs/RDNs), exercise specialists, and behaviorists). Web- and telephone-based interventions offered in academic and healthcare settings were considered as emerging areas with future potential but to be generally less effective than in-person treatments.

In summary, the Obesity Panel found that there is abundant current high-quality research evidence on the effectiveness of calorie-restricted dietary regimens and comprehensive lifestyle interventions for weight loss management in adult men and women. The panel provided guidelines on the assessment of risk for overweight and obesity in adults and recommended that individuals who would benefit from weight loss be referred to comprehensive lifestyle intervention implemented by trained interventionists (including RDs/RDNs, exercise specialists, and behavioral strategies) when available, and to the RD/RDN for dietary counseling for weight loss and medical nutrition therapy for CVD risk factor management. Referral to other modes of weight management including commercial programs and web and telephonic counseling by trained interventionists was recommended by expert opinion *but only if* scientific evidence of efficacy is available and with the acknowledgment that the amount of weight lost might be lower than with comprehensive lifestyle interventions implemented by trained interventionists. The 2015−2020 DGAC brought forward the recommendations of the Obesity Panel.

B 2013 ACC/AHA Guideline on Lifestyle Management to Reduce Cardiovascular Risk

1 Overview of CQs Addressed by the Lifestyle Workgroup to Develop Recommendations for CVD Risk Management Using Behavioral Intervention Strategies

Concurrent with the establishment of expert panels in 2008, the NHLBI also established a Lifestyle Workgroup to develop recommendations for CVD risk management using behavioral intervention strategies. This workgroup served alongside and complemented the ongoing guideline updates on overweight/obesity (discussed above), cholesterol, and BP. The Lifestyle Workgroup focused primarily on nutrition and physical activity, topics determined to be most relevant to the clinical practice of prevention and treatment of abnormal lipids and high BP. Over a 5-year period, the Lifestyle Workgroup set out to answer three overarching CQs:

> CQ 1: Among adults (18 years and older), what is the effect of dietary patterns and/or macronutrient composition on CVD risk factors, when compared to no treatment or to other types of interventions?
> CQ2: Among adults, what is the effect of dietary intake of sodium and potassium on CVD risk factors and outcomes, when compared to no treatment or to other types of interventions?
> CQ3: Among adults, what is the effect of physical activity on BP and lipids when compared to no treatment or to other types of interventions?

To answers these broad questions and their detailed components, the workgroup reviewed high-quality published literature consisting of systematic reviews, RCTs, and observational studies that included hard endpoints as outcomes, which spanned the time frame from 1998 through 2009. The RCTs examined by the Lifestyle Workgroup were limited to those in which research participants' body weights were kept stable so as to determine the impact of dietary patterns alone or in conjunction with physical activity on health-related risks and outcomes under participants' weight-stable conditions. The impact of change in body weight on health outcomes was a specific focus of the Overweight/Obesity Guideline that was reviewed earlier [6].

In 2012, the NHLBI partnered with the ACC and AHA to adopt and publish the 2013 Guideline on Lifestyle Management to Reduce Cardiovascular Disease Risk [7]. The guidelines are meant to provide clinicians with recommendations on the most effective diet and physical activity strategies to manage dyslipidemia and hypertension to promote cardiovascular health.

2 Scientific Approach of the Lifestyle Workgroup

The Lifestyle Workgroup specifically reviewed the effect of dietary patterns, nutrient intakes, and physical activity in modifying CVD risk [19–23] and their relationship to CVD outcomes [24–32]. RCTs were also used to assess the efficacy [33–35] and effect of dietary pattern interventions (DASH and Mediterranean-style (MED) patterns). In addition, published systematic reviews (i.e., qualitative reviews and meta-analyses) of controlled feeding studies were used to evaluate how replacement of energy from SFA and *trans*-fat with alternative energy sources (carbohydrates or monounsaturated (MUFA) or polyunsaturated (PUFA) fats) impacts levels of LDL-C and high density lipoprotein (HDL-C) cholesterol and triglycerides. The influence of dietary sodium on BP was assessed in the DASH-Sodium trial [36,37]. Observational cohort investigations were used to evaluate relationships between selected nutrients (sodium and potassium) and hard endpoints (e.g., stroke, CVD mortality) although, ultimately, potassium was omitted from the Workgroup's recommendations because evidence was insufficient to determine the effect of dietary intake of potassium on BP on CVD outcomes (including stroke). The effect of physical activity on CVD risk factors and outcomes was evaluated using systematic reviews only [38–40]. Of note in this report is that observational studies included study participants with varying health profile characteristics whereas those involved in RCTs typically were relatively "high-risk" individuals with established CVD, diabetes or hypertension, or elevated CVD risk. The reader should be aware of how this evidence-base may influence the generalizability of recommendations made by the panel.

3 Summary of Recommendations from the Lifestyle Workgroup

The Lifestyle Workgroup used a public health model and articulated recommendations at both the population and individual levels as summarized in Table 12.6. The Lifestyle Workgroup's guidelines emphasize the benefits of healthy lifestyles for CVD risk reduction and prevention in populations as well as individuals. The guidelines for individuals focus on those who would benefit from BP and LDL-C lowering. The workgroup recommended use of the 2013 ACC/AHA Blood Cholesterol Treatment Guideline [41] for further guidance identifying individuals with elevated CVD risk profiles and for information on drug treatment for cholesterol lowering. In addition, they suggested referring to the Scientific Advisory on High Blood

TABLE 12.6 Lifestyle Workgroup's Lifestyle Management Guideline Recommendations [62]

Population-Level Recommendations

The Workgroup recommended that all adult American men and women consider the following:

- Consume a heart healthy) dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils and nuts; and limits intake of sodium, sweets, sugar-sweetened beverages, and red meats.
  - Adapt this (heart healthy) dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus).
  - Achieve this (heart healthy) pattern by following plans such as the DASH dietary pattern, the USDA Food Pattern, or the AHA Diet.
- Engage in 2 h and 30 min a week of moderate-intensity, or 1 h and 15 min (75 min) a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic physical activity.
  - Aerobic activity should be performed in episodes of at least 10 min, preferably spread throughout the week.

The Workgroup recommended that all adults engage in nutrition and physical activity behaviors consistent with the DGAs (which was current at the time of the publication of their report) and the 2008 Physical Activity Guidelines for Americans.Achieve and maintain a healthy weight. Refer to the 2013 Overweight and Obesity Guideline for recommendations on weight loss and maintenance.

Individual-Level Recommendations

Advise adults who would benefit from LDL-C or BP lowering to:

- Consume a dietary pattern as described in the Population Recommendations above for heart health. The report further states "Dietary planning and nutritional counseling is often facilitated by referral to a nutrition professional," defined as a RD/RDN.

Advise adults who would benefit from LDL-C lowering to:

- Aim for a dietary pattern that achieves 5–6% of calories from SFA.
- Reduce percent of calories from SFA.
- Reduce percent of calories from *trans*-fat.

Advise adults who would benefit from BP lowering to:

- Lower sodium intake
- Consume no more than 2400 mg of sodium/day
  - Further reduction of sodium intake to 1500 mg/day is desirable since it is associated with even greater reductions in BP and
  - Even without achieving these goals, reducing sodium intake by at least 1000 mg/day lowers BP.
  - Combine the DASH dietary pattern with lower sodium intake.

In general, advise adults to engage in aerobic physical activity to reduce LDL-C, non-HDL-C, and BP: 3–4 sessions a week, lasting on average 40 min per session, and involving moderate-to-vigorous intensity physical activity.

Pressure Control from the AHA, ACC, and CDC [42] which recommends lifestyle management in the treatment of all adults with hypertension (BP: >140 mmHg/ >90 mmHg).

The Workgroup's report also provided food-based recommendations associated with the dietary patterns that reflect the highest overall benefits on CVD risk. It was noted that the recommended "heart healthy" dietary patterns can be achieved by using multiple approaches [13,43,44].

In summary, the guidelines on lifestyle management emphasize the benefits of behavior change, particularly those that facilitate healthy dietary patterns and physical activity, for population and individual CVD risk reduction and health promotion. The guidelines are largely consistent with the multiple healthy dietary patterns defined in the 2015–2020 DGAs [12] as well as the recommendations in the then current 2010 Dietary Guidelines [44] and the 2008 Physical Activity Guidelines for Americans [45]. The reader is directed to the full report [46] for further details on the studies reviewed and the expected impact of dietary pattern and physical activity interventions on BP and lipid outcomes. The 2015–2020 DGAC brought forward the recommendations of the AHA/ACC Lifestyle Workgroup.

V USING NUTRITION POLICIES AND EXPERT GUIDELINES TO INFORM THE PROFESSIONAL PRACTICE OF NUTRITION

Professional practice of nutrition is influenced in many ways by nutrition policies and expert guidelines. For example, as noted above, the *DGAs* are not only used within the agencies that fall in the very broad jurisdictions of HHS and USDA, but also to inform professional practice and can be influential in changing the food and physical activity environment. Despite the wide reach of the guidelines and the strong and growing body of literature showing that when individuals are adherent to healthy, nutrient-dense dietary patterns (and physical activity) as advocated in the DGAs, they have lower risk of overweight and obesity [47], smaller waist circumference [47,48], lower insulin resistance [49], reduced odds of carotid atherosclerosis [50], slower progression of carotid atherosclerosis [51], and lower total and CVD mortality [52], most Americans are not adherent.

Adherence to dietary guidance that promotes health has been an ongoing challenge in the United States for decades, and contributing to the prevalence of preventable diet-related conditions that have increased or plateaued at extremely high levels. To address this critical concern, multiple stakeholders such as Congress, federal agencies, and private foundations have created initiatives to promote programs and policies to achieve healthful dietary patterns in Americans. One organization that holds a unique position to address the science underlying dietary policy is the National Academies of Science, Engineering, and Medicine. It is independent from government and free from influence from political and special interest groups, and as such, the Academies can provide complementary guidance on nutrition issues. The National Academies were established by Congress, over a century ago, and incorporate four organizations: The National Academy of Sciences, the National Academy of Engineering, the Institute of Medicine (IOM), and the National Research Council. Over the past two decades, the IOM's Food and Nutrition Board and the Board on Population Health and Public Health Practice have overseen multiple consensus reports [53,54] and workshops [55–60] that address one or more aspects of the complexities of promoting adherence to *DGAs* through professional practice.

One such example is a report by the Food and Nutrition Board's committee on "*Accelerating Progress in Obesity Prevention*" [58]. It gives accessible and useful information for professional practice. The report addresses the need for improved communication of the threats of obesity and the importance of involving multiple sectors in addressing it. The report also concludes that many interest groups, including healthcare providers, policy makers, the general public, those who make decisions about food environments (including food product composition and access), businesses, private sectors, and educators, need to pool efforts and collaborate in order to address the obesity epidemic at individual and population levels. The report outlines strategies that can be used in healthcare environments that ensure incentives for, access to, coverage of routine obesity prevention, screening, diagnosis, and treatment services. Furthermore, it acknowledges that it is necessary to empower communities of individuals to work toward changes in their food environments that support efforts to achieve healthy lifestyles for healthy weight. In a workshop report from this committee in 2012, food and nutrition policies and environments were discussed [53]. The report documents several issues that may impact professional practice and adherence to the DGAs and other expert dietary guidelines. First, a key factor affecting weight and health is the availability of healthy and unhealthy foods, particularly in areas that are densely populated with fast-food outlets or have limited retail outlets with fresh and nutrient-dense food product offerings. Many communities lack nutrition policies or standards to guide what is available in neighborhoods, schools, or workplaces. Second, community-wide programs can promote healthier choices and can support changing behaviors at individual and population levels. Community environments encompass

the types and locations of restaurants and supermarkets and their accessibility within a particular community. The consumer environment is defined as what is encountered when a consumer goes out to eat or to purchase food in a restaurant, school, or elsewhere. The report also addresses factors such as the availability of healthful food choices within the environment; availability of nutrition information, pricing, and product placement; and the need to measure the food environment and policies in schools, worksites, food stores, restaurants, and local/state communities. Lastly, it summarizes the ideas shared during the workshop regarding implementing surveillance of the food environment to track nutrition-related environmental and policy changes and their effects to complement the current focus on food and obesity at the individual level.

Further support for professional practice can be found in a report by the committee on Prevention of Obesity in Children and Youth which was convened by the Food and Nutrition Board in collaboration with the IOM's Board on Health Promotion and Disease. In developing a prevention-focused action plan to decrease the prevalence of obesity in children and youth in the United States, the committee's report resonates with the DGAs and other IOM reports and addresses the importance of making changes at many levels and in numerous environments involving multiple stakeholders from diverse segments of society. The committee describes an environmental-behavioral synergy with multiple prevention strategies including improving the proportion of children meeting *DGAs* and promoting a healthy diet of appropriate quality and quantity. It also describes interim policy and system changes that are needed such as improving access to and affordability of fruits and vegetables for populations with low incomes, increased numbers of new industry products and advertising messages that promote energy balance at a healthy weight, increased availability and affordability of healthful foods and beverages at supermarkets, grocery stores, and farmers markets located within walking distance of the communities they serve; and changes in institutional and environmental policies that promote energy balance.

The IOM's Board on Population Health and Public Health Practice's committee on Public Health Priorities to Reduce and Control Hypertension in the US population reviewed available public health strategies specifically for reducing and controlling hypertension in the US population, including both science-based and practice-based knowledge. The committee concluded that a stronger focus is needed on primary prevention of hypertension and underscored the important role of nutrition-related factors in the prevention of hypertension and the reduction of risk factors for hypertension [54]. For example, the committee recommended collaboration across CDC units and their external partners to ensure that population-based lifestyle and behavioral interventions, such as promotion of consumption of a healthy diet through community-messaging and improving access to nutrient-dense foods, are delivered in a coordinated manner; and the interventions should include an evaluation of feasibility and impact.

Additionally, proceedings from workshops of the standing committee on Childhood Obesity Prevention detailed nutrition-related challenges and opportunities for change in marketing to children and youth [56] and identified allies for obesity prevention and common ground for dialog among them [57]. Both reports commented on the need for addressing both personal responsibility of healthy nutrition and lifestyle behaviors through evidenced-based nutrition and lifestyle interventions and environmental change.

a. In the summary report from the workshop on "*Alliances for Obesity Prevention: Finding Common Ground*," a diverse group of potential allies were identified that cut across sectors and may be unexpected and unlikely. It is noted that while parents have a responsibility in the nutrition-related aspects of childhood obesity epidemic, they also need support to parent effectively and the environment needs to be modified to make it easier for them to protect their children from the threats of obesity [57].

b. In the summary report from the workshop on "*Challenges and opportunities for change in food marketing to children and youth*," in trying to get change in food marketing to children, industry partners are needed to lower the high level of exposure children have to abundant commercial advertising and marketing for food. It is suggested that food and beverage companies use creativity, resources, and marketing practices to promote and support more healthful diets and meals [56]. The objective of these recommendations is to promote product development of healthy foods; product reformulations of unhealthy ones; expansion and promotion of healthier meals; and provision of nutrition information at the point of choice and consumption. Ultimately, efforts on the part of food industry are needed to ensure that the guidelines can ultimately promote and maintain health.

c. A workshop which included representatives from food industry, academia, and government discussed how food technology can be leveraged for obesity prevention and reduction efforts [55]. In this workshop's summary report, it was documented that food technologies have been used to find sugar substitutes, reduce fat and energy density of foods, decrease portion size, and increase micronutrient intake. However, it was

suggested that there is no "magic bullet," and taste and affordability is important to consumers making it important to educate consumers and create partnerships between industry and government to develop novel food products for commercialization.

There is remarkable consistency, across the Food and Nutrition Board's reports, in the conclusions that state and local public health jurisdictions integrate evidence-based nutrition guidelines into programmatic efforts toward systems, environmental, and policy changes that will support healthful eating and lifestyles at individual and population levels. Ongoing efforts are also needed to create recommendations for future action and to measure indicators of progress in implementing actions. These reports have served as roadmaps to solutions in professional practice, and are a resource for many practitioners.

A public health approach, addressing both individual and population approaches, is strongly advocated in the *2015–2020 DGAs* with recommendations that everyone has a role in creating and supporting healthy eating patterns in multiple settings nationwide, from home to school to healthcare and public health systems, to worksites to communities; and including public–private partnerships and addressing eating environments that are conducive to overconsumption. This is supported in an IOM report emphasizing that broad-based public health strategies have been impactful in public health efforts such as automobile safety and reducing tobacco use [1].

VI SUMMARY

Diet not only is related to the prevention and treatment of many chronic diseases, but also demonstrates the efficacy and impact of preventive nutrition and lifestyle behavioral interventions on a wide range of health outcomes. Achieving a dietary pattern that is healthful in quality and quantity and increasing the proportion of the population who meet the *DGAs* will require public health approaches that are designed to reach individuals as well as entire communities. Evidence-based approaches that address the needs and preferences of individuals and communities served are critical. In addition, every level of the socio-ecological model will need to be addressed and collaborations will be needed at the local, state, and national levels to change individual behavior and enhance food environments. Partnerships across sectors will be needed to reach the public with preventive and therapeutic nutrition services and to make it as easy as possible to adopt healthy nutrition and lifestyle behaviors. Nutrition policies and expert guidelines serve an important role in improving diet and ultimately advancing health at individual and population levels.

Chapter 13

Nutritional Recommendations for Athletes

Sara C. Campbell and Paul J. Wisniewski

Rutgers, The State University of New Jersey, New Brunswick, NJ, United States

I INTRODUCTION

Successful performance in sport is a result of many different factors. Arguably one of the most important factors is genetic predisposition; however, meeting optimal energy requirements is also critical for performance. Athletes who make poor food choices may prevent themselves from achieving their optimal potential. There is a strong evidence base that has established a role for optimal dietary strategies to enhance performance [1]. This begins with the recognition that when performing regular exercise, hard physical labor, or exercise training, utilization of carbohydrate (CHO), fat, and protein to make energy increases. As a result, the requirements of macro- and micronutrients increase.

The relationship between nutrition and physical performance has fascinated people for a long time. It has become clear that different types of exercise and different sports have different energy and nutrient requirements, and therefore food intake must be adjusted accordingly. It has been clearly shown that certain nutritional strategies can enhance performance, improve recovery, and result in more profound training adaptations. However, the diets of athletes are often reported as nutritionally inadequate [2]. The knowledge an athlete possess on proper nutrition, which is typically greater than that of the general public, is still lacking and mostly based on coach-driven advice and may be influenced by financial constraints [3]. The role of the sports nutritionist becomes increasingly critical to correct dietary inadequacies and promote health by creating a positive impact on the optimal performance of the athlete [4]. Nutrition strategies should be aimed at modulating training-induced adaptations, most important in muscle. This chapter reviews the nutritional demands of exercise in relation to the physiological demands and examines strategies to fuel exercise performance.

II ENERGY REQUIREMENTS FOR ATHLETES

Adequate energy requirement is a delicate balance between the amount of food intake required to maintain total daily energy expenditure (TDEE) and body weight [5]. TDEE is the sum of resting metabolic rate (RMR 60−75%), diet-induced thermogenesis (DIT 10%), and thermic effect of exercise (TEE 15−30%). During exercise, the energy expenditure increases several-fold mostly as a result of skeletal muscle contraction. Therefore, depending on how much exercise an individual performs, TEE is by far the most variable component of TDEE. TEE includes all energy expended above the RMR and DIT. In addition, it is influenced by lifestyle activities, the nature of exercise performed, gender, and prior nutritional status. TEE can contribute from virtually nothing to more than 80% of energy expenditure. In highly trained, very active individuals, the TEE can amount to up to 8000 kcal per day. In sedentary people, the TEE may be as low as 100 kcal per day. Energy expenditure during physical activity ranges from 5 kcal/minute for very light activities to up to 25 kcal/minute for very high-intensity exercise (Table 13.1).

Because of the variable nature of TEE, it is imperative that athletes understand how much energy they use to perform their sport, which will be indicative of energy intake required to maintain this performance. Energy restriction in athletes has deleterious side effects because in most situations, substrate (CHOs, fats, and proteins) availability can become critical for the continuation of exercise.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00013-8

TABLE 13.1 Rough Estimation of Energy Expenditure in a Variety of Sports[a]

Activity Level	kJ/min	kcal/min	Examples
Resting	4	1	Sleeping, watching TV
Very light activities	12–20	3–5	Sitting and standing activities, driving, cooking, card playing, desk work, typing
Light activities	20–28	5–7	Walking (slowly), baseball, bowling, horseback riding, cycling (very slowly), gymnastics, golf
Moderate activities	28–36	7–9	Jogging, cycling (at a moderate pace), basketball, badminton, soccer, tennis, volleyball, brisk walking, swimming (at an easy pace)
Strenuous activities	36–52	9–13	Running (10–13 km/h), cross-country skiing, boxing, cycling (30–35 km/h), swimming, judo
Very strenuous activities	>52	>13	Running (>14 km/h), cycling (>35 km/h)

[a]*Energy expenditure depends on body mass, the intensity, and the duration of rest periods.*

These substrates and their availability for energy production during exercise must be obtained through nutrition. In endurance athletes, e.g., CHO depletion is one of the most common causes of fatigue. Therefore, adequate CHO intake is essential to prevent early fatigue as a result of CHO depletion.

A Energy Balance

Energy balance represents the difference between energy intake and energy expenditure. When the energy intake exceeds the energy expenditure, there is a positive energy balance, which results in weight gain. When the energy intake is below the energy expenditure, there is a negative energy balance and weight loss results. Over the long term, energy balance is maintained in weight-stable individuals, even though on a day-to-day basis this balance may sometimes be positive and sometimes negative. Although life is not always that simple, basic manipulation of the energy balance equation will yield weight loss or gain. For example, if someone wishes to lose weight, it is important to increase the energy expenditure relative to the energy intake or decrease energy intake below daily energy expenditure. The opposite would be true if an individual is trying to achieve weight gain.

B Energy Balance in Different Activities

Some physical activities require higher energy outputs than others, as shown in Table 13.1. Tennis, e.g., has relatively low energy expenditure if played recreationally. However, during a match the exercise can be intense, and energy expenditure during that short burst of exercise can be very high. However, because this is typically followed by a longer period of relatively low intensity (walking) or even standing, the average energy expenditure for this activity is relatively low. On the other hand, in continuous sports such as cycling and running, in which there is usually no recovery during the activity, energy expenditures can be relatively high.

Physically active individuals need to be aware of the energy input necessary to maintain weight and performance. The simplest way to do this is to calculate resting daily energy expenditure (RDEE): RDEE (kcal) = 370 + 21.6 (fat-free mass (FFM), kg). In order to calculate FFM, two simple steps must be followed. First, determine your weight in kilograms. This can be done by taking your body weight in pounds and dividing it by 2.2; e.g., if you weigh 220 lb, your weight in kilograms is 220/2.2 = 100 kg. Second, calculate FFM in kilograms. Take your weight in kilograms and multiply it by (1 − your body fat percentage). For example, if you weigh 100 kg and your body fat percentage is 12%, then your FFM = 100 kg × (1 − 0.12) = 88 kg. These simple calculations allow individuals to understand exactly what their energy requirements are so that they can match energy intake with expenditure. As stated previously, inadequate energy intake relative to energy expenditure can compromise performance and will negate the benefits of training. This is because limiting nutrient intake can result in loss of lean tissue mass that results in the loss of strength and endurance as well as compromising the immune, endocrine, and musculoskeletal systems.

Energy expenditure varies by type, frequency, intensity, and duration of the activity. The energy systems (Table 13.2) used during exercise will dictate expenditure. These energy systems are the immediate energy system (i.e., the ATP-PC system, phosphagen system, and power system), short-term energy system (i.e., anaerobic energy system, glycolytic system, and lactic acid system), and long-term energy system (i.e., aerobic energy system). The immediate energy system uses adenosine triphosphate

TABLE 13.2 Energy Systems and Energy Use

Energy System	Rate[a]	Capacity[b]
ATP-creatine phosphate	1.6–6.0	24
Anaerobic glycolysis	1.0–1.5	240
Aerobic		
CHO	0.5	3000
Fat	0.24	Unlimited

[a] *μmol/g muscle/s (power).*
[b] *μmol/g muscle (energy supply).*

TABLE 13.3 Sources of Energy for Exercise

Source	Storage Form	Total Body Calories (kcal)	Distance Covered
ATP	Tissues	1	17.5 yards
Creatine phosphate	Tissues	4	70 yards
CHO	Serum glucose	20	350 yards
Liver glycogen		400	4 miles
Muscle glycogen		1500	15 miles
Fat	Serum fatty acids	7	123 yards
Serum triglyceride		75	0.75 mile
Muscle triglyceride		2500	25 miles
Adipose tissue		80,000	800 miles
Protein	Muscle	30,000	300 miles

(ATP) and phosphocreatine to supply muscles with energy to do work, and exercises of this nature typically last only approximately 6–10 seconds so they are short, powerful, and high-intensity activities. Examples include the golf swing, tennis serve, and 40-yard dash. The short-term energy system is the anaerobic system, meaning that it does not require oxygen to produce energy. This system's primary substrate is CHO in the forms of glycogen and glucose, which is broken down via glycolysis. As no oxygen is being used for ATP production in this system, it results in the over accumulation of hydrogen ions in the muscle, thus lowering the pH (more acidic environment) and leading to a cessation in exercise due to the disruption of the glycolytic enzymes. This system can provide energy for approximately 60 seconds to 3 minutes, and some examples of exercises include a 440-m run or 100-m swim. Finally, the long-term energy system will provide fuel for exercise lasting longer than 3 minutes. This fuel is provided by muscle and liver glycogen; intramuscular, blood, and adipose tissue triglycerides; and a small amount of amino acids. This system requires oxygen for ATP production, and as it becomes available, oxidative pathways are used, which can produce large amounts of ATP for exercise events such as marathons, endurance cycling, and swimming. Because each energy system is supplied by various macronutrients, it is imperative that athletes eat a well-balanced diet that meets the recommendations. A summary of the macronutrients that are used to make ATP for muscular contraction is provided in Table 13.3.

1 What Is the Role of Body Composition?

Body weight and body composition are two factors that govern an athlete's decisions in food choices. Body weight may be an important influence on speed, endurance, and power, whereas body composition may influence strength, agility, and appearance. For example, a lean (more muscle than fat) appearance may be important for speed. In many sports in which body composition or body weight is believed to be important (gymnastics, dancing, body building, and weight category sports such as wrestling, judo, and boxing), athletes often try to maintain a negative energy balance in order to lose weight [6]. It is known that energy intakes in these sports can be very low [7,8] and this can be a detriment to performance.

At the other extreme are endurance or ultra-endurance sports, such as marathons, triathlons, and cross-country skiing, in which extremely high energy expenditures are known to occur that must be matched by appropriate calorie intake. Optimum performance in these sports depends on the individual maintaining energy balance on a day-to-day basis.

Females generally have lower energy intakes than males and often have lower intakes than would be necessary for being physically active [8,9]. For females, energy intake ranged from 5.1 MJ (1600 kcal) to 10.2 MJ (3200 kcal). For males, energy intake ranged from 12.1 MJ (2900 kcal) to 24.7 MJ (10,500 kcal). These differences in energy intake may be related to body size and weight, body composition, and the training volume. Team sport athletes have a moderate energy intake, whereas some of the endurance sports have been characterized by very high energy intakes. In fact, energy intakes in excess of 12.6 MJ (3000 kcal) for females and 16.7 MJ (4000 kcal) for males were reported only in endurance sports.

In summary, an individualized assessment of the athlete's body composition is warranted to determine an optimal competitive body weight and relative fatness, with the goal to optimize the athlete's health and performance. In addition, particular attention should be paid to female athletes, who are frequently known to consume less calories, and sports in which weight is of particular importance for competition.

2 How Do Athletes Assess Energy Cost of Activity?

As mentioned previously, one can use the RDEE equation to calculate resting energy requirements; however, there is also a need to understand how much energy is being used during exercise. There are several ways to accomplish this, including both direct and indirect means of measurement. To directly measure energy cost, one would use a human calorimeter. Although use of a human calorimeter is the most accurate way to assess energy cost, few facilities have one of these and it is not the most convenient or practical means of measurement. As such, indirect calorimetry has become the standard of measurement for this purpose. These measurements can be obtained by placing the subject on a metabolic cart, which can measure the amount of oxygen consumed and carbon dioxide produced. These values can then be used to calculate the respiratory quotient (RQ). Each macronutrient has its own RQ value. It is important to note that the RQ for protein is approximated at 0.80; however, an equation for protein is typically more convoluted and mostly unavailable compared to those for fats and CHOs. This is because proteins are not simply oxidized to carbon dioxide and water during energy metabolism. During metabolism, the protein is deaminated and the nitrogen and sulfur are excreted. The resulting keto fragments are then oxidized. All of this complicates things; however, the actual contribution of protein to energy metabolism is very low. For example, see the following equations:

$$\text{Respiratory quotient (RQ)} = \frac{\text{CO}_2 \text{ produced}}{\text{CO}_2 \text{ consumed}}$$

Examples of macronutrient RQ calculations.
CHO RQ calculation:

$$\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 = 6\text{CO}_2 + 6\text{H}_2\text{O} + 38 \text{ ATP (CHO)}$$
$$\text{RQ} = 6\text{CO}_2/6\text{O}_2 = 1.0 = 5.05 \text{ kcal/lO}_2$$

Fat RQ calculation:

$$\text{C}_{16}\text{H}_{32}\text{O}_2 + 23\text{O}_2 = 16\text{CO}_2 + 16\text{H}_2\text{O} + 129 \text{ ATP (fat)}$$
$$\text{RQ} = 16\text{CO}_2/23\text{O}_2 = 0.74.68 \text{ kcal/lO}_2$$

Additional indirect means of measurement include doubly labeled water (deuterium), heart rate monitors, accelerometers, or activity tracking by keeping daily activity logs. During activity tracking, each activity is given a metabolic equivalent (MET) that corresponds to how many times resting level the activity corresponds to. For example, an activity that is 6 METs would be six times resting metabolism. A full list of activities and their MET values are found in the "Compendium of Physical Activities" [10].

III MACRONUTRIENT RECOMMENDATIONS FOR ATHLETES

The previous sections provided a summary emphasizing the importance of proper nutrition with the understanding that this nutrition is what ultimately provides one with the substrate necessary to make ATP for muscular contraction (i.e., work). The remaining sections of this chapter summarize the pertinent literature related to appropriate recommendations for macro- and micronutrient intake.

A Carbohydrate

CHO fuel plays a major role in the performance of many types of exercise and sport. The depletion of body CHO stores is a cause of fatigue or performance impairments during exercise, particularly during prolonged (>90 minutes) sessions of submaximal or intermittent high-intensity activity (Fig. 13.1). Unfortunately, total body CHO stores are limited and are often substantially less than the fuel requirements of the training and competition sessions undertaken by athletes. Maximizing glycogen stores in both liver and muscle prior to the exercise bout is essential for optimal performance. Studies have shown that after exercise, muscle

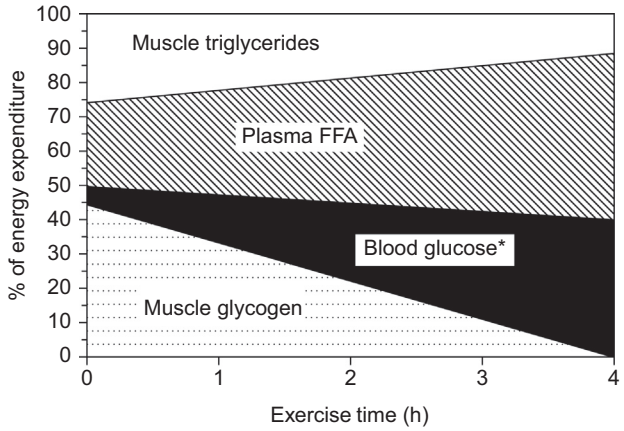

FIGURE 13.1 Percentage of energy derived from the four major substrates during prolonged exercise at 65–75% VO_2 max. The asterisk designates the importance of blood glucose contributing as a source of CHO energy for muscle as exercise is prolonged. Reproduced with permission from E.F. Coyle, Substrate utilization during exercise in active people, Am. J. Clin. Nutr. 61 (Suppl.) (1995) S968–S979.

TABLE 13.4 GI of Select Foods

High GI (>85)	Medium GI (60–85)	Low GI (<60)
Glucose	Banana	Fructose
Sucrose	Oatmeal	Apple
Bread	Pasta	Lentils
Potatoes	Rice	Milk
Sports drinks	Corn	Yogurt

glycogen stores can be returned to normal resting levels (350–500 mmol/kg dry weight muscle) with 24–36 hours of rest and an adequate CHO intake (6–10 g/kg body weight per day) [1,11,12]. Therefore, strategies for athletes include consuming CHO before, during, and in the recovery period between prolonged exercise bouts.

1 Preexercise CHO Intake

Feeding prior to exercise should take into account the timing of the meal prior to exercise, the intensity of the exercise that will be performed, and the type of CHO ingested—i.e., the glycemic index (GI) of the food and whether it is a solid or liquid. GI is assessed by how rapidly blood glucose levels rise after a fixed amount of ingested CHO. The GI of some foods can be found in Table 13.4.

Studies examining preexercise feedings have focused on various times prior to the bout and types of CHO given. Early research [13] examined feeding glucola (glucose solution), milk, or water 30 minutes prior to exercise at 80% maximal oxygen uptake (VO_2 max). Results of this study showed that glucola participants could not exercise for as long because of the stimulated insulin response to the skeletal muscle glucose uptake. This early study raised some issues about potentially restricting CHO consumption prior to competition so that exercise hypoglycemia could be avoided. Later findings, however, do not fully support this early study. Although research has consistently found clear metabolic differences in response to the timing of preexercise CHO ingestion within the hour before exercise, the performance effects have been somewhat equivocal. With the exception of the Foster study [13], research has either found no performance effects [14–21] or a performance improvement [22–24]. Based on current research, it appears that there is little evidence to suggest benefits from avoiding CHO intake in the hour before exercise. If one is concerned that he or she might be susceptible to hypoglycemia during exercise, CHO can be ingested just prior to exercise (in the last 5 minutes), or foods that have a low GI can be consumed. This can be done to minimize the risks of hypoglycemia because as exercise begins and the glucose transporter-4 (GLUT-4) is stimulated to translocate to the cell membrane, it will be responsible for bringing in glucose to the cell for energy metabolism. To support this idea, Thomas et al. [25] fed participants glucose, potato, lentils, or water 60 minutes prior to exercise at 75% VO_2 max. Results showed that blood glucose and insulin response was higher in the glucose and potato groups compared to the lentil group. Finally, a large body of work has shown that the intake of a substantial amount of CHO (~200–300 g) 3 or 4 hours before exercise enhances various measures of exercise performance compared to performance undertaken after an overnight fast [26–28].

The form of CHOs ingested—solid versus liquid—before exercise has also been examined for its potential effects on metabolism and performance. It is known and accepted that ingestion of solid foods significantly slows gastric emptying, digestion, and absorption rates compared with liquid foods [29]. This will have an impact on blood glucose concentration, and because this can be a concern for athletes, it has been suggested that consuming solid food may provide a slower release of glucose to the blood for maintenance of levels during exercise [30]. Interestingly, data from studies comparing ingestion of solid versus liquid CHO [31] and solid versus gel CHO [32] found no significant differences in blood glucose concentrations between groups. Furthermore, additional research has found no differences in CHO oxidation rates between solid versus liquid [33] or liquid versus gel [34] CHO consumed during exercise. Performance studies have found no significant differences following preexercise ingestion of solid versus liquid [32] or solid versus gel [31,32] CHOs. It appears that the form of CHO consumed does not play a significant role in performance or metabolism, and it is therefore suggested that whatever the athlete's preference is to consume can be supported.

Finally, the amount of CHO consumed prior to exercise does not appear to play a major role in performance or changes in blood glucose concentrations. This is particularly true of the emerging area of research examining CHO mouth rinse studies [35–39]. Performance benefits can be seen with these rinses for exercise lasting between 30 minutes to 1 hour, however anything more prolonged would require ingestion of greater amounts of CHO as suggested above [40]. The mouth rinse studies suggest that the presence of CHO in the mouth activate the taste buds stimulating some cranial nerves (VII, IX, X) resulting in a modulation of motor activity through higher brain functions [41–43].

Ultimately, the concerns that should be addressed by athletes prior to competition should be: (1) to ensure that optimal levels of liver and muscle glycogen are attained to sustain performance and (2) if the individual

is concerned that he or she might be a hypoglycemic responder during exercise, to consume low GI foods prior to exercise, consume CHO right before exercise, or avoid CHO completely for at least 60 minutes prior to exercise bouts.

2 CHO Feedings During Exercise and Postexercise

Numerous studies have documented that consumption of CHOs (glucose or glucose polymers) during exercise improves endurance performance in events lasting 60 minutes or longer [31,44,45]. Feeding for bouts lasting less than 60 minutes has produced mixed results [46,47] unless the intensity is high, in which case it appears to be beneficial [48]. The mechanisms appear to be the maintenance of blood glucose levels and the additional CHO to maintain muscular contraction. In the literature, most of the results that support these notions have been obtained using tracer techniques and naturally enriched ^{13}C glucose. What does this body of literature tell us? It suggests that CHO is being oxidized at a rate of approximately 1−1.1 g/minute. This will be influenced by several factors, including: (1) The rate of gastric emptying, which is known to decrease as the concentration of CHO increases and the rate of administration increases; (2) the decreases in absorption that are seen with exogenous levels of CHO administration of 1.2−1.7 g/minute; and (3) the liver, which can potentially release up to 1 g/minute of exogenous CHO to the bloodstream. Due to these factors it is ideal to consume CHOs that utilize multiple transporters. For example, glucose and galactose are absorbed by secondary transport coupled to sodium transport into the epithelial cells and then move in to the blood by facilitated diffusion. Fructose is absorbed through the epithelial cells and into the blood by facilitated diffusion. As a result the glucose can help to maintain the blood sugar levels and the fructose can be moved to the liver to aid in homeostasis. This strategy is particularly important for long duration events (greater than 2.5 hours), in which it is recommended to only consume CHO that will utilize these multiple transporter mechanisms.

CHO restoration postexercise is imperative for athletes, especially for those who train multiple times in one day or on successive days so that performance during these sessions can be at the highest level. Optimizing glycogenesis, the making of glycogen for storage, can be achieved by consuming 7−12 g/kg per body weight per day [1]. This is equivalent to roughly 65% CHO diet when a 70-kg person is consuming 3000 calories (Fig. 13.2). Glycogen synthase (GS-1) is the enzyme responsible for reforming glycogen, and it is aided by GLUT-4 (mentioned previously). When muscle is inactive, GLUT-4 remains in the center of the muscle cell; however, when we are exercising, it is translocated to the cell membrane, allowing glucose to enter the cell, and this starts glycogenesis. Upon cessation of exercise, GLUT-4 does not immediately return to the center of the cell. It is by this premise that high GI CHO foods and drinks may be more favorable for glycogen storage than some low GI food choices [49] because glycogen storage may occur at a slightly faster rate during the first few hours after exercise [12]. Again, this is especially true for athletes who have limited time between workouts. For athletes who have extended time periods of inactivity, it is not as critical to consume CHO immediately; however, these athletes still need to meet the goals for total CHO intake throughout the day.

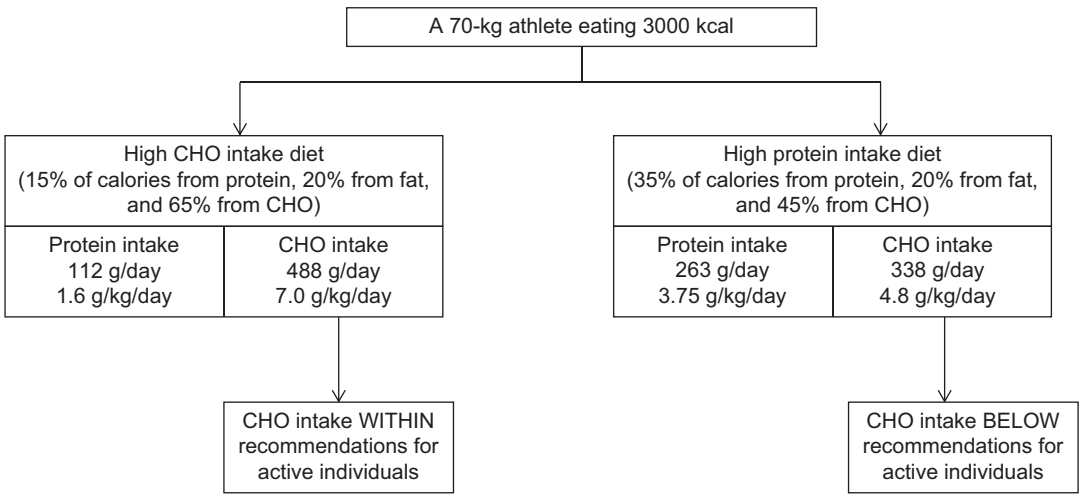

FIGURE 13.2 CHO consumption and meeting daily needs.

In summary, the recommendations for CHOs for after exercise are:

1. Feed approximately 1−1.2 g/kg/hour during the first 4−6 hours of recovery.
2. Over a 24-hour period, feed 7−9 g/kg/body weight for females and 8−12 g/kg/body weight for males.
3. High GI foods provide the best glycogen replacement to increase the insulin response and glucose transport into the cell for glycogenesis.
4. Beverages containing 70−90 g CHO (4−6% CHO) can be used immediately postexercise and consumed at a rate of 1.2 g CHO/kg/hour.

3 CHO Loading (Supercompensation)

CHO loading is a special practice that aims to maximize or "supercompensate" muscle glycogen stores up to twice the normal resting level (e.g., ~500−900 mmol/kg dry weight). The first protocol was devised in the late 1960s by Scandinavian exercise physiologists who found, using the muscle biopsy technique, that the size of preexercise muscle glycogen stores affected submaximal exercise capacity [50−52]. Several days of a low-CHO diet resulted in depleted muscle glycogen stores and reduced endurance capacity compared with a mixed diet. However, high CHO intake for several days caused a "supercompensation" of muscle glycogen stores and prolonged the cycling time to exhaustion. These pioneering studies produced the "classical" 7-day model of CHO loading. This model consists of a 3- or 4-day "depletion" phase of hard training and low CHO intake, followed by a 3- or 4-day "loading" phase of high CHO intake and exercise taper (i.e., decreased amounts of training) [53]. Early field studies of prolonged running events showed that CHO loading enhanced performance not only by allowing the athlete to run faster but also, rather, by prolonging the time that the athlete could maintain the race pace.

Further studies undertaken on trained subjects have produced a "modified" CHO loading strategy [54]. The muscle of well-trained athletes has been found to be able to supercompensate its glycogen stores without a prior depletion or "glycogen stripping" phase. For well-trained athletes at least, CHO loading may be seen as an extension of "fueling up"—involving rest/taper and high CHO intake over 3 or 4 days. The modified CHO loading protocol offers a more practical strategy for competition preparation by avoiding the fatigue and complexity of the extreme diet and training protocols associated with the previous depletion phase. Typically, CHO loading postpones fatigue and extends the duration of steady-state exercise by approximately 20% and improves performance over a set distance or workload by 2% or 3% [55,56]. In summary the recommendation works out to be approximately 10−12 g/kg body weight for every 24 hours prior to competition. While the depletion-taper outlined method above appears to be effective, the 10−12 g/kg body weight over 24 hours needs to be initiated by minimally 36 hours prior to competition to obtain performance benefits [1].

B Fat

Fat represents the primary substrate for aerobic exercise; however; athletes typically avoid fat as a part of their diet. As mentioned previously, this is especially true for athletes for whom body weight and/or composition is an important part of the sport. It would be remiss not to discuss, even briefly, fat and its importance in energy metabolism during exercise because it is the primary substrate used at rest and during low- and moderate-intensity exercise (Fig. 13.3). In addition, exercise training substantially enhances fat oxidation and utilization (Fig. 13.4) by increasing enzyme concentration in the major metabolic pathways associated with fat oxidation; muscles also become more densely populated with capillaries to facilitate greater blood flow and oxygen extraction, and mitochondrial volume is increased (major site for fat oxidative pathways).

Research in this area has focused on gender differences, which seem to support women having a greater

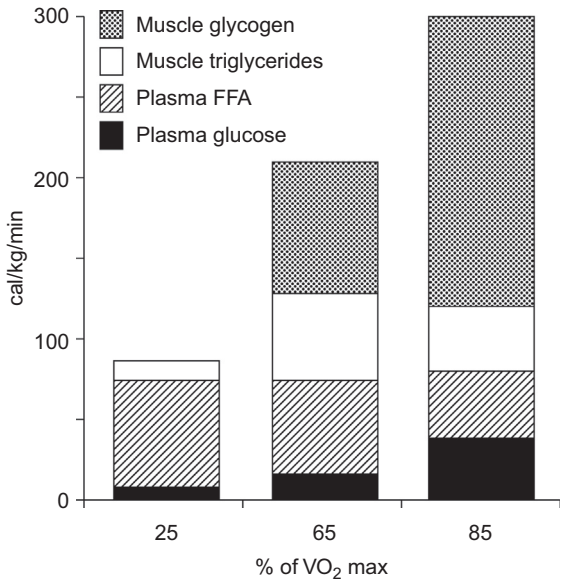

FIGURE 13.3 Contribution of the four major substrates during low (25%), moderate (65%), and high (85%) intensity exercise. During low and moderate intensity, IMTG and plasma-free fatty acids provide the substrate for ATP production, whereas at high intensity muscle glycogen is the major contributor. Reproduced with permission from J.A. Romijn, E.F. Coyle, L.S. Sidossis, A. Gastaldelli, J.F. Horowitz, E. Endert, R.R. Wolf, Regulation of endogenous fat and carbohydrate metabolism in relation to exercise intensity and duration, Am. J. Physiol. 265 (1993) E380−E391.

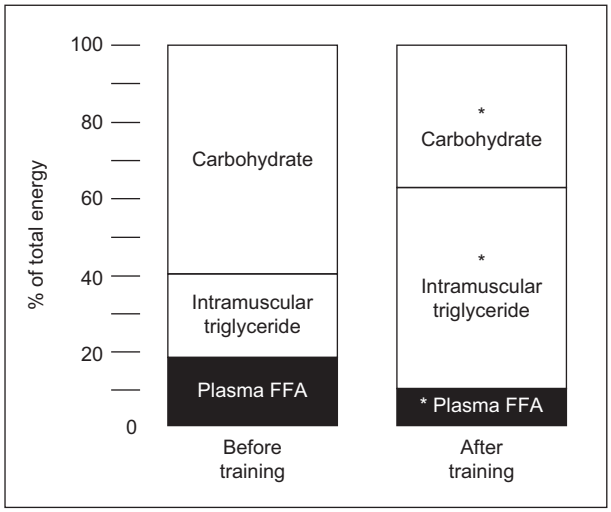

FIGURE 13.4 Changes in substrate use after training. The asterisk denotes a significant increase in using IMTG for ATP production with a significant decrease in CHO use. Reproduced with permission from B.F. Hurley, P.M. Nemeth, W.H. Martin, 3rd, J.M. Hagberg, G.P. Dalsky, J.O. Holloszy, Muscle triglyceride utilization during exercise: effect of training, J. Appl. Physiol. 60 (1986) 562–567.

reliance on fat oxidation compared to men. Several studies specifically showed that women increased the amount of intramuscular triglycerides (IMTG) stored in the muscle and had a significant decrease in IMTG postexercise compared to men [33,34,57]. These men and women were matched for VO_2 mL/kg FFM/minute and training volume, and the women were tested during the same menstrual phase to control for the influence of sex hormones. These studies suggest that athletes, especially female athletes, should consume enough fat in the diet to adequately replenish what they use during their training sessions. It has been shown that women who consume low-fat diets and who perform endurance events can have depleted IMTG levels 2 days after these events. This will compromise performance [58–61], and as such it is recommended that for females who perform this type of exercise, energy intake from fat can be as high as 30% of daily caloric intake. Furthermore, low-fat diets also compromise the intake of the important fat-soluble vitamins A, D, E, and K as well as the essential fatty acids (α-linolenic acid and linoleic acid) [62].

There are no specific recommendations for fat intake for athletes as there are for CHO and protein (discussed next) other than not to restrict levels that would be detrimental to health by limiting important vitamin and essential fatty acid intake. It is important to remind the athlete that fat oxidation is the primary way to produce ATP during aerobic exercise, and IMTG stores need to be replaced like the glycogen stores. Athletes should be advised to take in healthy fats such as mono- and polyunsaturated fatty acids. These are healthier and examples include consuming foods such as nuts, using olive oil for cooking, and consuming "fatty" fish, which contain the essential fatty acids.

1 Fat Adaptation

Interest in metabolic retooling for the optimization of fat utilization among well-trained endurance athletes has gained significant headway due to its theoretical applicability. Of note, metabolic adaptations that enhance the ability of skeletal muscle to use fat as a substrate during exercise may be advantageous in that an increase in fat utilization promotes a glycogen sparing effect. In theory, these metabolic adaptations have the potential to improve performance and delay fatigue by allowing the athlete to take full advantage of the almost unlimited capacity of fat to generate energy during continuous exercise. In practice however, there appears to be no performance advantage with fat adaptation despite distinct changes in substrate metabolism.

The traditional fat adaptation protocol involves the consumption of a low-CHO, high-fat diet (LCHF) for approximately 14 days while maintaining current training volume and intensity, whereby roughly >60% of energy is derived from fat and <25% from CHO [63,64]. The goal of this dietary intervention is to maximize IMTG stores, increase rates of whole-body and muscle fat oxidation, and reduce rates of muscle glycogen breakdown (glycogenolysis) specifically during submaximal exercise [63]. Alternatively, research suggests that this period for fat adaptation is far shorter than what is traditionally practiced as significant increases in fat oxidation and decreases in CHO oxidation can be achieved within only 5–10 days [65]. As such, significant metabolic adaptations can surely be achieved under CHO-restricted dietary conditions.

One of the key mechanisms by which a LCHF diet suppresses CHO oxidation is by regulating the activity of pyruvate dehydrogenase (PDH), the mitochondrial enzyme responsible for converting pyruvate to acetyl-CoA. This is accomplished primarily through the activation of PDH kinase (PDK), an enzyme that inactivates PDH through phosphorylation. In short, a rise in acetyl-CoA as a result of CHO restriction significantly upregulates the activity of PDK which moves PDH into a less active form, shifting fuel reliance away from CHO and more toward fat [66–68]. In addition, chronic intake of LCHF diets can lead to dramatic increases in fat oxidation rates and a greater reliance on fat metabolism at higher exercise intensities. Of note, a recent study showed that ultra-endurance runners who habitually consume (for an average of 20 months) a LCHF (10% CHO; 19% PRO; 70% FAT) have a 2.3-fold higher peak fat oxidation rate

(1.54 g/minute vs 0.67 g/minute) when compared to those who consume a traditional high-CHO diet (59% CHO; 14% PRO; 25% FAT) [69]. Further, peak fat oxidation rates were achieved at higher exercise intensities in athletes who consumed a LCHF diet (70% VO_2 max vs 55% VO_2 max) and also demonstrated a significantly greater energy contribution from fat during submaximal exercise intensities (88% vs 56%). These results further corroborate the efficacy of fat adaptation in improving fat utilization during prolonged exercise. It is important to note, however, that both short-term fat adaptation (1−3 days) and complete fat adaptation (2 weeks) can result in a reduction of resting glycogen stores and therefore cannot be considered "true glycogen sparing" despite changes in CHO oxidation rates [70,71]. Thus, a key strategy to restore precompetition glycogen levels and maintain elevated fat oxidation rates is to implement a dietary periodization protocol that includes a CHO restoration period (1−3 days) after fat adaptation is achieved; the details of which are outlined extensively here [63]. Interestingly, research shows that CHO restoration can be accomplished even sooner, within a single day [72−74].

Despite extensive metabolic retooling as a result of LCHF diets, there still appears to be no performance advantage at submaximal intensities and current research lacks sufficient evidence to suggest otherwise (for a more recent review, see Ref. [64]). In contrast, fat adaptation can compromise performance at higher intensities as demonstrated by Havemann et al. [75]. Here, they showed that 100-km time trial performance was not significantly different in endurance-trained male cyclists when fed either a high-fat diet (HFD) or high-CHO diet with one day of CHO loading (∼90% energy from CHO) after 6 days of fat adaptation. Mean power output was significantly reduced during high-intensity 1-km sprints in the HFD group throughout the 100-km time trial however. These findings highlight an important observation in that although fat adaptation confers no performance advantage at submaximal intensities, submaximal exercise capability postfat adaptation is comparable to that of higher CHO diets as reported in earlier studies [76,77]. Furthermore, endurance events such as the one simulated in Havemann's study may contain intermittent sprint intervals that require exercise intensities approaching near maximal effort. In this scenario, fat adaptation can restrict performance by limiting anaerobic exercise capacity.

In summary, fat adaptation results in a significant metabolic retooling that optimizes fat oxidation and reduces fuel reliance on CHO at submaximal intensities. Further, submaximal performance postfat adaptation is significantly comparable to performance based on a higher CHO diet. Although fat adaptation can result in a reduction of resting muscle glycogen concentrations, such detriments can be attenuated with a short CHO loading period (1−3 days) prior to competition day. However, fat adaptation can significantly limit performance at maximal intensities and the physiological demands of a given endurance event must therefore be strongly considered when determining appropriate dietary interventions. For the athlete, personal preference is equally important to consider as motivation and drive are profound determinants of sport performance. As such, implementing dietary strategies that they feel best facilitates their performance, and lifestyle is essential.

C Protein

There is still considerable debate about how much dietary protein is required for optimal athletic performance. This is most likely because muscle contains a large proportion of the total protein in a human body (∼40%). Muscle also accounts for 30−50% of all protein turnover in the body. In muscle, the majority of amino acids are incorporated into tissue proteins, with a small pool of free amino acids. This pool undergoes turnover, receiving free amino acids from the breakdown of protein and contributing amino acids for protein synthesis. Protein break in skeletal muscle serves two main purposes: (1) to provide essential amino acids when individual amino acids are converted to acetyl CoA or tricarboxylic acid cycle intermediates. (2) In addition it provides individual amino acids that can be used elsewhere in the body for the synthesis of neurotransmitters, hormones, glucose, and proteins. If protein degradation rates are greater than the rates of synthesis, there will be a reduction of protein content; conversely, muscle protein content can only increase if the rate of synthesis exceeds that of degradation.

Exercise (especially endurance exercise) results in increased oxidation of the branched-chain amino acids, which are essential amino acids, and cannot be synthesized within the body. Therefore, increased oxidation would imply that the dietary protein requirements are increased. Some studies in which the nitrogen balance technique was used showed that the dietary protein requirements for athletes involved in prolonged endurance training were higher than those for sedentary individuals. Whether requirements are really higher remains somewhat controversial (for review, see Refs. [78,79]).

It has been estimated that protein may contribute up to approximately 15% to energy expenditure in resting conditions. During exercise, this relative contribution is likely to decrease because energy expenditure is increased and most of this energy is provided by CHO and fat. During very prolonged exercise when CHO availability becomes limited, the contribution of protein to energy expenditure may amount to approximately 5% of the total energy expenditure. Thus, although protein oxidation is increased during endurance exercise, the relative contribution of protein to energy expenditure remains small. Protein

requirements may increase somewhat, but this increased need may be met easily by a moderate protein intake. The research groups that advocate an increased protein intake for endurance athletes usually recommend a daily intake of 1.2−2.0 g/kg body mass. This is approximately twice the level of protein intake that is recommended for sedentary populations.

There are reports of increased protein breakdown after resistance exercise. The suggested increased dietary protein requirements with resistance training are related to increased muscle bulk (hypertrophy) rather than increased oxidation of amino acids. Muscle protein breakdown increases after resistance training, but to a smaller degree than muscle protein synthesis. The elevations in protein degradation and synthesis are transient. Protein breakdown and synthesis after exercise are elevated at 3 and 24 hours after exercise but return to baseline levels after 48 hours. These results seem to apply to resistance exercise and high-intensity dynamic exercise.

There is controversy regarding whether strength athletes really need to eat large amounts of protein. Nitrogen balance studies conducted on such athletes have been criticized because they generally have been of short duration and a steady-state situation may not be established [79]. The recommendation for protein intakes for strength athletes is therefore generally 1.4−2.0 g/kg, depending on body mass, per day. Again, this seems to be met easily with a normal diet, and no extra attention to protein intake is needed. Protein supplements are often used but are not necessary to meet the recommended protein intake. There is also no evidence that supplements would be more effective than normal foods. An exception to the rule is athletes who need to drop weight in order to compete in a weight-dependent sport like boxing or martial arts, as such, exceeding the current recommendation may be advantageous. These athletes are often required to implement short periods of hypoenergetic weight loss for many reasons such as competing in a certain weight class, to improve aesthetic appearance or to improve physical performance. In general, rapid weight loss is usually achieved through fluid restriction (dehydration) and increased exercise, while gradual weight loss is commonly achieved through calorie restriction (−75 to 130 kJ/kg/day for >1 week) [80]. As such, loss of lean body mass may compromise performance and an increased protein intake may offset these detriments when intense training is continued [78,80]. Specifically, research suggests that a protein intake of ∼2.3 g/kg (or ∼35% protein in diet) significantly attenuates lean body mass loss in athletes during these periods of hypoenergetic weight loss [81].

In conclusion, it is very important to understand the difference between complete and incomplete proteins when planning meals. Complete proteins contain all of the essential amino acids (those that the body cannot produce), including the branch-chain amino acids. Food sources include meats, fish, poultry, eggs, and dairy. Incomplete proteins are those that do not contain all of the essential amino acids and are typically plant-based sources such as legumes and grains. Animal protein sources (complete proteins) have a high digestibility, whereas the plant sources do not. This is not to suggest that athletes cannot be vegetarian; however, it does suggest that these athletes need to pay particular attention to their protein intake and ensure that they are eating complimentary proteins. This means they must eat a variety of plant-based protein sources to ensure that they get all of the essential amino acids required each day.

IV MICRONUTRIENT REQUIREMENTS FOR ATHLETES

A Vitamins

Vitamins are essential organic compounds that serve to regulate metabolic processes, energy synthesis, and neurological processes and to prevent cell degradation and/or death. Vitamins can be either water or fat soluble. Fat-soluble vitamins are A, D, E, and K (as previously mentioned), and examples of water-soluble vitamins are C and the B vitamins. The body can store fat-soluble vitamins and therefore consumption of these in excess can result in toxicity. In contrast, water-soluble vitamins cannot be stored by the body, with a few exceptions such as vitamin B_6, so they are excreted in the urine when consumed in excess. Research has suggested that some vitamins may possess some health benefits (e.g., vitamins C and E, niacin, and folic acid); few of these have been shown to enhance performance in athletes when sufficient intake is present.

Studies have reported that active individuals tend to be deficient in certain B vitamins including B_6, thiamin, and riboflavin [82,83]. The B vitamins are an important group because they act as coenzymes in metabolism. This means that they can help donate or accept methyl group items, especially in substrate metabolism. For example, the active form of thiamin, thiamin pyrophosphate, can help to remove carbon dioxide and hydrogen ions from pyruvate to help create acetyl CoA. Acetyl CoA is the molecule required to enter the Kreb's cycle and initiate oxidative metabolism. As a result, deficiency in the B vitamins can be detrimental to energy metabolism. In addition, vitamin B_{12} and folate deficiencies manifest themselves as either pernicious or megaloblastic anemia, respectively. This is a serious concern as well because improper red blood cell function will adversely affect the oxygen carrying ability of the body, which will limit performance. Finally, for vegetarian athletes, vitamin B_{12}

should be carefully monitored because the best sources of B vitamins are found in meat products; as such, supplementation of B_{12} in vegetarian athletes is essential.

Other vitamins, such as A, C, and E, are known antioxidants. This means they have the ability to scavenge free radicals and decrease oxidative stress. This may be of particular interest to athletes because theoretically it may help athletes to tolerate heavy training loads and potentially accelerate recovery. However, the literature on antioxidant supplementation is convoluted and in some cases inconclusive. What is known is that athletes do have enhanced antioxidant status and enzymes as a result of exercise training [84]. In addition, it has been suggested that supplying antioxidants to athletes may actually negate the natural antioxidant health-promoting effects of exercise [85]. As such, caution should be exercised with regard to the efficacy on intake and the purpose for supplementation.

Finally, vitamin D is important (Recommended Daily Allowance (RDA) 600 IU/day for males and females aged 19−50 years). Its partnership with calcium and their role in bone health are well-established [86]. Although this vitamin is typically not a concern with regard to deficiency, it can be in sports in which body composition is an issue. This has previously been mentioned and it is likely because these athletes tend to underconsume fat, which will be reflected in the status of the fat-soluble vitamins and essential fatty acid intake. As a result, it is recommended that these types of athletes would benefit from supplementation of vitamin D.

In summary, athletes who consume a balanced diet with appropriate calorie intake will meet their vitamin requirements and there is no need for additional supplementation. However, as mentioned previously, athletes do tend to have some dietary inadequacies and as such a multivitamin is sometimes recommended to ensure that all vitamin requirements are met.

B Minerals

Minerals are essential inorganic compounds that help with tissue structure and metabolic processes such as components of enzymes and hormones and regulators of metabolic and neural control. As is the case with vitamins, some minerals have been found to be deficient in athletes—e.g., iron (RDA 8 mg/day for males and 18 mg/day for females aged 19−50 years) and calcium (RDA 1000 mg/day for males and females aged 19−50 years). Lacking these minerals will negatively impact performance. Conversely, supplementing these minerals can improve performance.

Exercise is an outstanding form of weight-bearing activity; however, many athletes still have low bone density, especially female distance runners. The more common problem with this group of athletes, however, is menstrual disturbances that disrupt hormonal status and predispose women to the female athlete triad (disordered eating, low bone density, and menstrual dysfunction). In these athletes, calcium supplementation may be increased to 1200−1500 mg/day, and this has been shown to help maintain bone mass.

Iron is a common mineral found to be deficient especially in early training periods. This is reflected by reductions in both hematocrit (percentage of red blood cells) and hemoglobin (oxygen-carrying component of the red blood cell). This can be due to several factors, including changes in plasma volume that dilute hemoglobin, exertion hemolysis, and dietary practices that include low iron intake, low iron bioavailability, and increased iron excretion. Heme iron, such as that found in meats, fish, and poultry, is better absorbed and bioavailable compared to nonheme iron, which is found in grains, vegetables, and legumes. Factors that enhance iron absorption include vitamin C, peptides from fish/meat/chicken, alcohol, and food acids, whereas factors that inhibit absorption include phytates, polyphenols, calcium, and peptides from plant sources such as soy protein. The absorption of both heme and nonheme iron is increased as an adaptive response in people who are iron deficient or have increased iron requirements. Prevention and treatment of iron deficiency may include iron supplementation, with a recommended therapeutic dose of 100 mg/day of elemental iron for 2 or 3 months. However, the management plan should include dietary counseling to increase the intake of bioavailable iron and appropriate strategies to reduce any unwarranted iron loss.

In addition, zinc and magnesium are two other minerals that are important for energy production. Zinc plays a role in growth, building, and repair of muscle tissue; energy production; and immune function. Survey data suggest that Americans have zinc levels below the recommended intake [87−89] and that female athletes are at a particular risk for deficiency [89]. Zinc levels can be difficult to measure; however, deficiency has serious consequences, including decreases in cardiorespiratory function, muscle strength, and endurance. Vegetarian athletes are again at a particular risk for zinc deficiency. The RDA for zinc is currently 11 mg/day for males and 8 mg/day for females. There is no reason to consume more than 40 mg/day because this is the upper limit for toxicity [87]; however, intake at 25 mg/day has been shown to minimize exercise-induced changes in immune function [90−93]. Magnesium plays a role in cellular metabolism; membrane stability; and neuromuscular, immune, and hormonal status. Magnesium deficiency impairs performance due to inefficient oxygen use, and in sports in which weight is an issue; deficiency has been reported [94,95]. The RDA for magnesium is 420 mg/day for males and 320 mg/day for females.

V FLUID REQUIREMENTS FOR ATHLETES

Water represents approximately 50–60% of total body weight and functions as a transport medium, lubricant, solvent, and thermal regulator (Fig. 13.5). The body is constantly exchanging fluids between the interstitial fluid (fluid between tissues) and intracellular fluid (fluid within the cells) compartments to maintain both hydrostatic and osmotic pressures. The maintenance of these fluid compartments occurs through osmotic forces that are regulated by properly working sodium–potassium pumps. Sodium controls the extracellular fluid (fluid outside the cell) volume, regulates osmolality, helps with acid–base balance, and maintains resting cell membrane potential. Potassium controls the intracellular fluid volume, and it also regulates osmolality, acid–base balance, and cell membrane potential. The body has active mechanisms in place for monitoring sodium levels, ensuring that they are always in acceptable ranges. No such mechanism exists for potassium; potassium simply relies on ion exchange pumps for maintenance.

When we sweat during exercise, we lose fluid from the interstitial fluid compartment and this will disrupt balance, calling on our electrolytes to help correct the disruption. The issue is that when we sweat, we also lose electrolytes, so the replenishing of the fluid and electrolytes before, during, and after exercise sessions is of utmost importance. Regulation of fluid balance is dictated by our thirst mechanism (the sensation of feeling thirsty is not perceived until a person has lost at least 2% of body mass), monitoring of the extracellular fluid volume, and blood pressure. To maintain fluid balance, water intake may vary from 1 L to approximately 12 L/day. However, during exercise and especially during exercise in hot conditions, sweat rates (and thus water losses) may increase dramatically and dehydration may occur (i.e., the body is in negative fluid balance). Depending on the sport, sweat rates can range from 0.3 to 2.4 L/hour [96], with the average sodium concentration in sweat approximately 1 g/L [97].

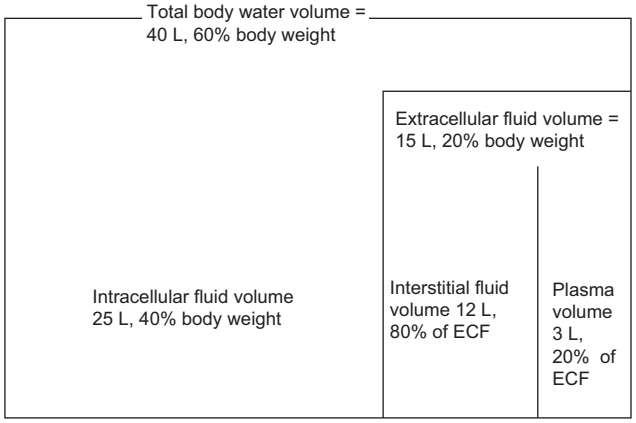

FIGURE 13.5 Body water distribution.

A Dehydration and Performance

The literature is clear that dehydration will negatively impact performance (Fig. 13.6). Dehydration can cause several physiological disturbances, all of which negatively impact performance (Fig. 13.7). Several studies have shown that mild dehydration, equivalent to the loss of only 2% body weight, is sufficient to significantly impair exercise performance [96,98]. In addition, it is often reported that greater losses result in greater reductions in performance. Even very low-intensity exercise (i.e., walking) is affected by dehydration. The capacity to perform high-intensity exercise that results in exhaustion within only a few minutes has been shown to be reduced by as much as 45% by prior dehydration (2.5% of body weight) [99]. Although there is little opportunity for sweat loss during such short-duration, high-intensity events, athletes who travel to compete in hot climates are likely to experience acute dehydration, which can persist for several days and can be of sufficient magnitude to have a detrimental effect on performance in competition. Although dehydration has detrimental effects especially on performance in hot conditions, such effects can also be observed in cool conditions. Both decreases in maximal aerobic power (VO_2 max) and decreases in endurance capacity have been reported with dehydration in temperate conditions [100], although not all studies have found such an effect [101,102].

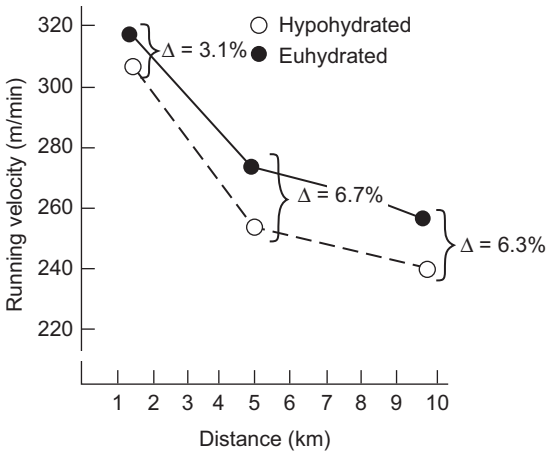

FIGURE 13.6 Effects of dehydration on running velocity over distance covered. Results clearly show that velocity is significantly different at all three distances. Reproduced with permission from M.N. Sawka, R.P. Francesconi, A.J. Young, K.B. Pandolf, Influence of hydration level and body fluids on exercise performance in the heat, J. Am. Med. Assoc. 252 (1984) 1165–1169.

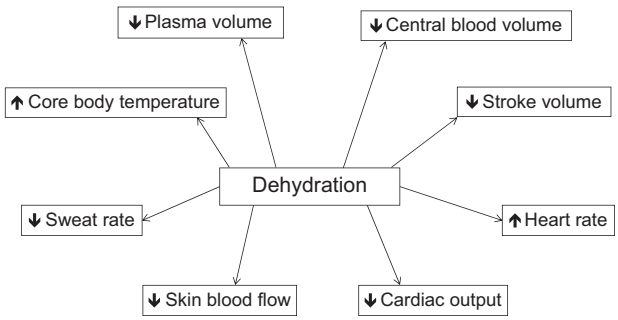

FIGURE 13.7 Physiological side effects of dehydration.

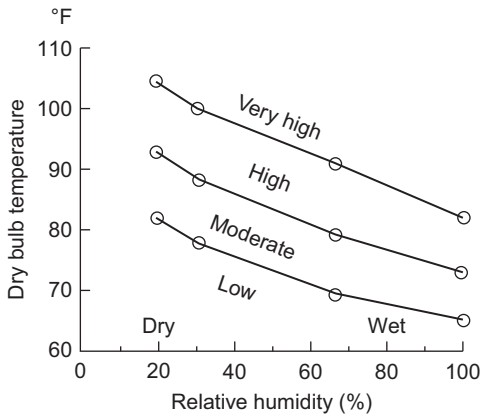

FIGURE 13.8 Temperature, relative humidity, and risk for heat illness. Reproduced with permission from L.E. Armstrong, C.M. Maresh, Fluid replacement during exercise and recovery from exercise, in: E.R. Burkirk, S.M. Puhl (Eds.), Body Fluid Balance: Exercise and Sport, CRC Press, Boca Raton, FL, 1996, pp. 259–281.

B Dehydration and Heat Illness

Dehydration also puts the athlete at increased risk for heat illness. Heat illness can be assessed by calculating wet bulb globe temperature (WBGT) index = 0.7 T_{wb} + 0.2 T_g + 0.1 T_a, where T_{wb} is the wet-bulb temperature, T_g is the globe temperature, and T_a is the ambient or dry bulb temperature. Risks based on this formula are as follows: very high risk; WBGT > 28°C (82°F)—race should be postponed, rescheduled, or canceled. High risk; WBGT 23–28°C (73–82°F)—runners should be aware that heat illnesses may occur, particularly in susceptible persons. Moderate risk; WBGT 18–23°C (65–73°F)—remind runners that heat and humidity will increase during the race if early in the day. Low risk; WBGT < 18°C (<65°F)—does not guarantee heat illness will not occur (Fig. 13.8). Early symptoms of heat injury are excessive sweating, headache, nausea, dizziness, a reduced consciousness, and impaired mental function. When core body temperature rises to more than 40°C, heat stroke may develop; heat stroke is characterized by hot dry skin, confusion, and loss of consciousness.

C Hyponatremia

Hyponatremia or low sodium level is defined by dilution of serum sodium from normal levels of 135–145 to less than 130 mEq/L. Causes of hyponatremia include sodium loss, water retention, or both due to excessive sweating, vomiting, diarrhea, or excessive use of diuretics. The most common symptoms, if water intake is excessive and hyponatremia develops slowly, are mental confusion, giddiness, and coma. Muscle twitching, irritability, and convulsions occur if the development is rapid.

Hyponatremia appears to be most common among slow runners in marathon and ultramarathon races and probably arises because of the loss of sodium in sweat coupled with very high intakes of water. This means that there can be a danger of misdiagnosis of this condition when it occurs in individuals participating in endurance races. The usual treatment for dehydration is administration of fluid intravenously and orally. If this treatment were to be given to a hyponatremic individual, the consequences could be fatal.

D Fluid Intake Before, During, and After Exercise

The American College of Sports Medicine's (ACSM) position stand [96] on exercise and fluid replacement provides a comprehensive review of the research and recommendations for hydration before, during, and after exercise. ACSM has also published position stands on exercising in environmental conditions [103,104]. This section summarizes the position stand on fluid replacement and serves as a guide that athletes should follow.

1 Before Exercise

Athletes should start drinking at least 4 hours prior to exercise approximately 5–7 mL/kg body weight of water or sport beverage. This allows for adequate time to optimize hydration status and excrete any excess fluids in the urine prior to competition when it would not be timely to do so. Over-hydrating (hyperhydration) with excess water or glycerol solutions will substantially expand intra- and extracellular fluid volumes and will increase the risk of voiding during the competition. In addition, it confers no clear performance benefit.

2 During Exercise

As mentioned previously, decreases that are 2% or more of body weight initiate the thirst response and are typically indicative of dehydration, which is detrimental to performance. Fluid intake during exercise should be aimed at preventing this from occurring. Although this seems easy in theory, this is highly dependent on the

athlete due to body size, sweat rate, and the exercise being performed. In addition, fluid balance during exercise may not occur because sweat rates may be greater than gastric emptying rates that limit fluid absorption and ultimately fluid ingestion rate by the athlete. To help, gastric emptying rates can be maximized when the stomach is full, and absorption rates can be maximized when the CHO concentration in the beverage is approximately 6−8%. Athletes should start drinking fluids right away during exercise and at regular intervals to replace water loss. Athletes should ingest fluids cooler than the ambient temperature (15−22°C). CHO−electrolyte drinks are beneficial for exercises that last longer than 1 hour; these help replace electrolytes and maintain blood glucose levels. The sodium level in fluids when exercise lasts longer than 1 hour should be approximately 0.5−0.7 g/L.

3 After Exercise

Because most athletes will not consume enough liquids during exercise, postexercise hydration is critical. If the athlete has adequate time between exercise sessions, then intake of normal meals and beverage should replenish hydration status. Rapid and complete recovery from exercise can be accomplished by drinking at least 16−24 oz (450−675 mL) of fluid for every pound of body weight lost during the exercise bout. This can easily be tracked by simply weighing oneself before and after exercise and then hydrate accordingly. Another easy way to determine hydration status is to observe the color of the urine (Fig. 13.9).

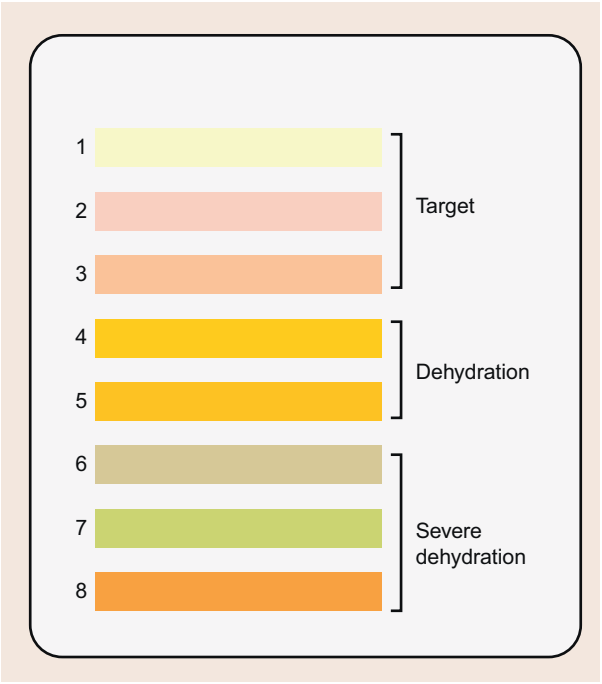

FIGURE 13.9 Urine color hydration chart. Scientific validation for this chart can be found in the *International Journal of Sport Nutrition*, vol. 4 (1994) 265−279 and vol. 8 (1998) 345−355.

VI SUMMARY AND CONCLUSIONS

The basic difference between athletes and the general population is that athletes typically need more fluids to recover sweat and electrolyte loss during physical activity and greater food intake to maintain energy balance demands that are associated with exercise. Much of this energy can be in the form of CHO, but neglecting protein or fat could be detrimental to performance. Although there are general rules for how to govern these increased energy demands, each individual is different and the concept of one diet fits all is obsolete. However, the types of foods recommended can be standard in that good CHOs in the forms of grains, fruits, vegetables, and breads should be encouraged along with fats that are high in mono- and polyunsaturated fatty acids such as nuts, olive oil, and "fatty" fish and proteins that are lean and complete (e.g., that contain all of the essential amino acids) such as meat, poultry, and fish. Requirements for these macronutrients may vary between strength-trained and aerobic-trained athletes and also may vary between genders. Special attention is warranted for sports that place a strong emphasis on body composition and weight to ensure that these athletes are consuming enough calories. Furthermore, vegetarian athletes need to be mindful of ensuring that they are consuming complimentary proteins to obtain all of the essential amino acids recommended as well as vitamin B_{12}, which is typically found only in animal products. In addition, female athletes, especially in body composition and weight-dependent sports, need to be counseled on the importance of maintaining adequate calorie intake for both macro- and micronutrients to avoid disturbances such as those seen in the female athlete triad. Consuming adequate nutrients is essential for an athlete to achieve optimal performance. The guidelines put forth in this chapter provide a thorough overview of the evidence-based nutritional recommendations to help athletes understand energy requirements allowing for both energy balance and peak performance.

Chapter 14

Nutrition for Children With Special Health Care Needs

Beth Ogata[1], Hope Wills[2] and Marion Taylor Baer[3]

[1]University of Washington, Seattle, WA, United States, [2]University of Southern California, Los Angeles, CA, United States, [3]University of California at Los Angeles, Los Angeles, CA, United States

I INTRODUCTION

According to data available from the National Survey of Children with Special Health Care Needs, 11.2 million children in the United States (15.1%) have special conditions that increase their need for health care services and educational supports beyond those of children without special needs [1]. Children with special health care needs include those with specific diagnoses related to developmental disabilities such as genetic disorders (e.g., trisomy 21 (Down syndrome) and phenylketonuria (PKU), cognitive and behavioral challenges (e.g., autism and intellectual disabilities), and neuromotor impairments (e.g., cerebral palsy and spina bifida). Children who are born prematurely or with a low birth weight are considered to be at high risk of developing a special health care need. There are also children with common chronic health concerns (e.g., asthma, diabetes, and obesity) who can be included in the broader definition of children with special health care needs, but the focus of this chapter is on children with functional conditions related to prematurity or a known developmental disability.

As many as 40−60% of children with special health care needs are at risk of one or more problems with nutritional status, ranging from slow growth and poor feeding to more severe gastrointestinal problems and metabolic disorders [2,3]. Specific segments of the population experience greater impact. Brooks et al. [4] illustrated the impact of weight status on morbidity and mortality in children with cerebral palsy. Children with the highest degree of neuromotor dysfunction (Gross Motor Function Classification System—GMFCS V) and in the lowest quintile for weight-for-age, demonstrated higher rates of morbidity and mortality than children with less severe motor dysfunction. Table 14.1 provides a list of special health care needs, including the sequelae of prematurity, the more common genetic disorders, and other developmental disabilities, and the associated functional problems with nutrition. Because of the increasing prevalence of children with special health care needs, the essential role that nutrition therapy plays in treating several conditions, and the high risk of developing comorbid nutritional problems (e.g., underweight and overweight), nutrition professionals will encounter children with special health care needs in their practices and should be able to anticipate their most commonly seen nutrition problems [5,6].

Intrauterine nutrition insults occurring prenatally can predispose children to developmental disabilities and poor growth, as well as to problems with obesity and chronic illnesses later in life. Children with special health care needs receive services in multiple settings, including prenatal public health nutrition programs such as WIC (the Special Supplemental Nutrition Program for Women, Infants and Children; http://www.fns.usda.gov/wic), early intervention programs, schools, and primary and tertiary care practices. To ensure that those at high risk of nutrition problems are identified and referred to appropriate services, nutrition screening is an important part of care in all of these settings [7,8]. Evidence establishing the cost-effectiveness of appropriate nutrition interventions, especially preventive interventions, for high risk populations of mothers and children is mounting [2,9,10]. Mothers who receive adequate nutrition during pregnancy have better birth outcomes, and children who have their nutritional risks identified and receive appropriate intervention

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00014-X

TABLE 14.1 A Comparison of Specific Developmental Conditions with Types of Nutrition Risks

	Growth			Diet		Medical		
Disorder	Underweight	Over-weight	Short Stature	Low Energy Needs	High Energy Needs	Feeding Issues/ Special Diet	Constipation	Chronic Medications

Prader-Willi Syndrome		X	X	X		X		
Spina Bifida	X	X	X	X		X	X	X

demonstrate better growth, health, and developmental outcomes than those who do not.

This chapter describes nutritional risk for mothers during pregnancy that affects their offspring and for infants and children identified with a special health care need, with the intent to prevent disability through good nutrition, to provide secondary prevention of further disability in specific conditions with known nutrition issues, and to preserve and promote function in order to enable the child with special health care needs to reach his or her potential in terms of growth and development.

Section II addresses primary and secondary prevention of developmental problems by examining the evidence that nutrition—and specific nutrients—during fetal development and infancy affect developmental outcomes and subsequent special needs for children.

Section III outlines the functional approach to identifying nutritional needs—how growth, diet, and medical issues are assessed, including issues specific to children with special health care needs in each of these areas.

Section IV covers selected pediatric conditions in more depth—inborn errors of metabolism, Prader-Willi syndrome, feeding problems, and autism spectrum disorders—including a description of the diagnosis, assessment of nutritional status, and ongoing intervention, where there is evidence for nutrition interventions.

II THE ROLE OF NUTRITION IN PREVENTING DEVELOPMENTAL PROBLEMS

An optimal supply of nutrients, both macro and micro, may be the most important environmental factor in determining health throughout the lifespan and across generations [11]. Low birth weight (LBW), resulting from preterm birth or intrauterine growth restriction, has long been established as a major risk factor for developmental disabilities (discussed next), but, relatively recently, maternal and even paternal nutritional status is being considered to be more important than previously recognized as part of the life course approach to health development, which characterizes health as the result of the accumulation of both positive and negative environmental impacts over a lifetime, rather than simply one's genetic makeup alone. As conceived by Kotelchuck and Fine [12], these impacts are either viewed as occurrences over the lifespan which are mutable (**timeline**), or, if sustained at critical developmental stages, the impact may be irreversible (**timing**). These positive or negative factors are also dependent on environmental determinants which may be beyond the control of the individual, such as living in poverty or being exposed to toxins (**environment**) and, finally, they may be related to the inequities, such as access to health care—a problem faced by large numbers of individuals worldwide (**equity**). A description of the role of nutrition in terms of the life course perspective and these concepts: timing, timeline, equity, and environment (also called T2E2) has been published elsewhere [13], as has evidence for the importance of nutrition to overall life course health development [14]. This evidence includes epidemiological and experimental studies which suggest that preconceptional, and even intergenerational, nutrition plays a key role in the later development of obesity and its associated chronic diseases—the theory that early "nutrition programming" determines the set point of energy balance in the fetus [15].

Preconception and interpartum nutritional care is now clearly understood to be an essential part of comprehensive infant health strategies [16]. The Centers for Disease Control and Prevention (CDC) has recommended that women of reproductive age receive preconception counseling to improve intakes of calcium, folic acid, iodine, iron, and essential fatty acids; [17] also mentioned in an earlier publication were vitamins A and D, with lesser strength of evidence [18]. The following brief review of research findings illustrates the growing awareness of the associations between nutrition and pregnancy outcome in terms of disability, as well as chronic illness.

A Low Birth Weight (LBW) and Preterm Birth

Risk of preterm birth (before 37 weeks of gestation), LBW (<2500 g), or being small for gestational age (SGA) increases by approximately 50% in the United States (US) with short interpregnancy intervals (<18 months) and less than 2 years postmenarche in young adult women compared to those who are older or who have an interpregnancy interval of 18–23 months; this cannot be entirely explained by social or behavioral factors [19]. Evidence is accumulating that if the pregnant woman is still growing herself or has not had sufficient time since her last pregnancy to replace depleted stores, the physiological changes that normally favor improved nutrient utilization during gestation may not be adequate to meet the needs of both mother and fetus. In such cases, it appears that nutrients are partitioned between the mother and the fetus depending on the initial nutritional status of the mother [19,20]. This underscores the importance of optimal nutritional status of women, from the preconception period and throughout pregnancy, detailed in a recent publication by the International Federation of Gynecologists and Obstetricians (FIGO), on optimal pregnancy outcomes and the prevention of low birth weight as well as defects such as neural tube defects (NTDs) [11]. In one study, the incidence of preterm birth was lowered in women given a diet of fish, oils, low-fat meats and dairy, whole grains, fruits, vegetables, and legumes compared to women who continued their usual diet. Although the study goal was to lower cholesterol in the mothers, it is likely that this diet also improved their nutritional status [21], and evidence that this is likely the case has been recently shown in another study where consuming a "DASH" diet (similar to that described above) resulted in reduced odds of preterm births [22]. Other studies have shown that zinc [23], folate [24], and iron [25] deficiencies all increase the risk of preterm birth and LBW. In addition, low serum selenium early in pregnancy has been shown to predict lower birth weight [26].

A study of women in the Danish National Birth Cohort (~36,000 subjects) indicates that periconceptional use of multivitamins, particularly regular use, is associated with a lowered risk of infants being born SGA [27]. This study also showed that the association between pre- and postmultivitamin use and preterm birth varied according to prepregnancy weight; women whose body mass index (BMI) was less than 25 had significantly less risk of either preterm labor or delivery, whereas the same was not true for overweight women [27]. In a report that was part of the "Generation R" study—a large (>6000 women) but prospective study in The Netherlands—Timmermans and colleagues [28] showed that periconceptional folic acid supplementation (starting prior to conception or up to the eighth week of pregnancy) was associated with decreased risk of preterm birth and LBW, whereas preconception use also reduced the risk for birth of an infant SGA.

On the other hand, a recent meta-analysis has suggested that there are protective effects of maternal overweight or obesity on risk of delivering low birth weight infants, both in developed and developing countries, but especially the latter. However, there was also an increased risk of having an infant of very low birth weight (<1500 g) or extremely low birth weight (<1000 g); the heavier the woman, the higher the risk [29]. This seeming contradiction may be explained by a high risk for malnutrition due to a lack of micronutrients in obese women, as reported by Bodnar and Parrot [30,31].

Finally, it is worth mentioning that a recent study found an association between maternal vitamin D levels at 26 or fewer weeks of gestation and growth measures of newborns. Serum vitamin D levels were positively related to birth weight and head circumference, and negatively associated with the risk of an infant being born SGA [32].

B Other Risks

In addition to the risk of developmental disabilities subsequent to preterm delivery or LBW, intellectual disability (ID) in children has long been linked to known maternal nutrition-related conditions such as those described below.

1 Iron

ID of unknown cause, including autism spectrum disorders (ASD), has been found to be higher in children of mothers with anemia [33]. In 2002 data from 2865 children with ID of unknown cause (grouped into mild to moderate, $n = 2462$; severe to profound, $n = 212$; and ASD with ID, $n = 181$) and 236,964 children without ID were studied. In this study mothers with anemia ($n = 1101$) were five times more likely (odds ratio (OR) = 5.26) to have a child with severe ID (IQ <35 to

40), even after socioeconomic variables were introduced into the stepwise logistic regression model (OR = 4.93). In a large population-based study of children in Hungary with ($n = 781$) and without ($n = 22{,}843$) Down syndrome, the investigators found a lower incidence of Down syndrome among mothers given supplementation of large doses of iron (150–300 mg/day of ferrous sulfate) and folic acid (6 mg/day) during the first month of gestation [34], although only iron was protective when given alone. Note that iron and folate, two nutrients related to LBW, are both depleted in pregnancy and must be replaced [19].

2 Iodine

Iodine deficiency remains the leading cause of preventable ID, including its most severe manifestation, cretinism, and has been identified with other risks during pregnancy such as miscarriages and infant mortality as well as maternal and fetal goiter [35]. The need for iodine increases during pregnancy from an RDA of 150 ug/day to 220 ug/day (RDA for lactation is even higher, 290 ug/day). However, low urinary iodine levels indicate that at least some pregnant women in the US are not currently consuming sufficient iodine. This is likely due to public health efforts to reduce overall salt intakes as well as the increasing preference for sea salt or kosher salt, neither of which contain iodine. Furthermore, according to one study, nearly half of the prenatal supplements marketed in the US contain iodine [36] and that only an estimated 20% of women use supplements that contain iodine [37].

3 Omega-3 Fatty Acids

The toxic effects of mercury on the developing fetus are well known [38], and the US Department of Health and Human Services has recommended limiting seafood consumption by pregnant women because of its high mercury content. This recommendation was revised upward in June, 2014 to at least 8 and up to 12 ounces of fish (2–3 servings) with lower levels of mercury/week in order to support fetal growth and development [39]. This recommendation followed research findings indicating that restricting seafood intake resulted in adverse neurodevelopmental outcomes in children, presumably due to a deficiency in omega-3 fatty acids which have been shown to have positive effects on neurodevelopment [40,41], whereas higher intakes had no ill effects [42]. These findings have been supported more recently by a large study in the Seychelle Islands where fish consumption is high [43], as well as a recent review of the evidence [44]. Fish are also a good source of iodine, choline, zinc, and vitamins A, D, and B_{12}, all important for optimal development. A concern at present is that many women in the US have a low consumption of omega-3s [45], and moreover they are not eating much fish. Using data from 1000 pregnant women, an FDA analysis found that 21% ate no fish in the previous month, and those who did ate less than recommended in the 2010 Dietary Guidelines, with 50% eating fewer than 2 oz a week, and 75% eating fewer than 4 oz [39]. Another concern is the decrease in the availability of fish in the US, from 16.5 pounds/capita in 2006, to 14.4 pounds in 2012 [46].

4 Paternal Nutritional Status

Current research interest is also turning to the role of the father's nutritional status/diet in influencing pregnancy outcomes, reflected in identified paternal epigenetic contributions in animal models [47,48]. Evidence that paternal epigenetic influences are present in humans as well is also beginning to accumulate. Donkin and colleagues [49], e.g., have demonstrated epigenetic changes in human spermatozoa in obese men following bariatric surgery; they postulate that these phenomena might explain earlier observations that the risk for obesity in offspring of obese men is increased independent of the weight of the mother.

C Spina Bifida and Other Birth Defects

The recognition of a relationship between nutrition and the etiology of certain developmental disabilities has been most fully realized in the case of spina bifida and other neural tube defects (NTDs). Although the link between diet and NTDs was suspected as early as the 1960s [50,51] and demonstrated repeatedly in studies that implicated vitamins and minerals in general [51], and gradually focused on folate in particular [52], there was no public health campaign in the US to increase folate intake until the mid-1990s after the publication of the Medical Research Council's definitive study. Then, rather than directing efforts toward increasing women's intake of folate-containing foods, the emphasis was on folate supplementation for pregnant women followed by the passage of the mandatory fortification of cereal grain products in the US that went into effect in January 1998. The latest CDC data show the estimated prevalence has decreased from 10.7 per 10,000 live births in 1995–6 (prefortification) to 6.5 per 10,000 in 2009–2011 (postfortification) and that about 1326 fewer infants have been born over this three-year period with NTDs [53].

The report from the Center on Birth Defects and Developmental Disabilities (CBDDD) noted that the decrease is less than predicted from research trials [54], which led to the Healthy People 2010 goal of a 50% reduction [53]. The Healthy People 2020 goal, MCH 28-1, is a more modest 10% improvement in the incidence of spina bifida using a baseline of 34.2 live births or fetal deaths/100,000 live births [55] and a target of

30.8/100,000 live births [56]. It is worth noting that the incidence of spina bifida is not equally spread among racial groups. Hispanic babies are affected disproportionately (41.7/100,000 live births) compared to either Non-Hispanic Blacks (26.4/100,000) or Whites (32.2/100,000) [55].

The US Public Health Service and CDC recommend a folic acid intake of 0.4 mg/day (supplements or fortified foods) and also a diet that includes folate-rich foods for women of reproductive age [54,57]. There is also evidence that folate, in combination with other vitamins, may play a role in preventing urinary tract defects and congenital hydrocephalus, according to a meta-analysis [58].

Further evidence for the importance of micronutrients other than folate has come from data collected by the Hungarian Periconceptional Service between 1984 and 1994 [59]. In an RCT to test the efficacy of a multivitamin supplement containing folate (0.8 mg) in the prevention of NTDs, researchers were surprised to find that not only were NTDs reduced, but there was a very significant reduction (21 per 1000 population versus 41 per 1000 population) in the incidence of other major anomalies as well, notably cardiovascular anomalies and urinary tract defects [18,60]. This may explain the slow reduction in incidents past the initial period of fortification. A group of investigators in the Netherlands reported significantly lower dietary intakes of iron, magnesium, niacin, fiber, plant protein, and polysaccharides in mothers of infants with spina bifida ($n = 106$) compared to controls ($n = 181$), independent of periconceptional folic acid use [61]. For example, it has been suggested that choline, the dietary requirements for which were set in 1998 [62], is another nutrient that, along with folate and B12, may increase the risk of NTDs when inadequate in the diet. This is because, like folate and vitamin B12, choline has an important role in the methionine cycle, crucial to brain development [63]. Although these and other anomalies are not considered developmental disabilities per se, there also is evidence of an association between the occurrence of orofacial clefts (cleft lip or palate or both) and maternal nutrition as well as a rationale for the potential contribution of several nutrients (folate, niacin, thiamine, B_6, B_{12}, riboflavin, zinc, amino acids, and carbohydrate) to their etiology [64].

Our current understanding of the role of folate in the pathogenesis of NTDs awaited the unraveling of the mystery of the human genome and the development of the field of epigenetics. The research on DNA, RNA, and human chromosomes tells us that the genome, or the inheritable information held in the chromosomes, is not immutable but may be affected by epigenetic markers that interact with other components of the genome. Nutrigenomics, or nutritional genomics, introduces a molecular approach that integrates genomics, nutrition, and health, and was recently reviewed in an Academy Position Paper [65]. The science focuses on the differential influences that nutrients have on the regulation of gene expression by way of nuclear receptors that regulate processes such as embryonic development and cell differentiation and proliferation [66]. It is thought, in the case of folate, because of its role in the methylation of DNA, that a deficiency occurring during the periconceptional period can lead to epigenetic alterations in the DNA of the embryo and to NTDs in the fetus of those women who are genetically susceptible and/or whose need for folate is elevated. Interestingly, the gene for the enzyme methylenetetrahydrofolate reductase (MTHFR), important in the methylation cycle, has a polymorphism that is common in Mexico (32%) but has a very low frequency among African Americans, paralleling the racial demographics of the prevalence of spina bifida alluded to previously [67]. It is certain that nutrigenomics holds future promise in improving maternal and child health and decreasing the incidence of developmental disability (DD).

Another food-related factor that has been implicated in the high incidence of NTDs among Mexican Americans is fumonisins, a class of mycotoxins produced by mold, which interfere with folate metabolism. In response to an "outbreak" of NTDs along the Texas–Mexico border in 1990–1991, an epidemiological study linked it to high levels of fumonisins in the corn used to make tortillas, and other corn products, which form a large part of the diet of this population [68]. Other risk factors, such as folate intake (dietary plus multivitamin), were not confounders. In fact, vitamin B_{12} levels have been shown to be a more important predictor of risk in this population than folate levels [69], and low maternal B_{12} status has been shown to be an independent risk factor in a folic acid-fortified population in Canada [70].

D Fetal Alcohol Syndrome

Fetal alcohol syndrome spectrum disorders (FASD) include fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder (ARNDD), and alcohol-related birth defects (ARBD), depending on the symptoms, and this is an example, according to the life course perspective, of "timing," where the impact of a negative environmental factor is irreversible. The spectrum is defined by pre- and postnatal growth disturbances, dysmorphic facial features, and ID; behavioral abnormalities are common, as are motor problems, facial anomalies, and cardiac defects [71]. The CDC has estimated that the prevalence of US women aged 15–44 years who are exposed to alcohol during pregnancy is 7.3% overall, and highest among married women aged 20–29 [72]. FASD

represents an example of a preventable DD in which prenatal nutrition likely plays a major etiological role, although this is not universally recognized; the recent CDC report does not mention nutrition as a risk factor, for example [72]. However, there are two major reasons for which nutrition should be considered. First, the dietary energy provided by alcohol (7.1 kcal/g or 29.7 kJ), replaces foods containing essential micronutrients, thereby putting the mother and fetus at risk for nutrient deficiencies, and second, alcohol interferes with the metabolism of all fat- and water-soluble vitamins, especially folate, and the mineral zinc [73,74]. These nutrients are key to fetal development because of their involvement in multiple systems: enzyme, gene transcription and regulation, and transport. Folate insufficiency, mentioned previously in the etiology of spina bifida and cleft lip and palate, has also been implicated in the etiology of limb and heart abnormalities and Down syndrome [73]. Severe zinc deficiency has been linked to intrauterine growth retardation and teratogenesis; mild to moderate deficiency has been associated with congenital malformations, LBW, and preterm delivery [73,75]. In recognition of the importance of folate and zinc to reproduction, Young and his colleagues [76] have recently explored the potential nutritional etiology of FAS in a review of current research, using animal models, into the effects of alcohol on folate and zinc metabolism, as well as other nutrients essential to favorable pregnancy outcomes (vitamin A, DHA, choline, vitamin E, and selenium) in relation to FAS. These authors postulate that providing nutrient supplementation to women who drink during their pregnancy might prevent, or at least mitigate, the severity of the disorder [76]. This notion that adequate nutritional status in these women may be protective is supported by observations in a Danish National Birth Cohort study that found effect of mild to moderate maternal drinking (1−8 drinks/week; one drink = 12 g pure alcohol) during early to mid-pregnancy on children's subsequent intelligence, executive function or attention at age 5 [77].

Because of the wide array of nutrients that have been implicated in promoting optimal birth outcomes, it would seem of utmost importance that clinicians and public health professionals urge women of childbearing age to eat a well-balanced diet rather than relying primarily on vitamin and mineral supplements or population-based fortification of foods or food ingredients, as has been suggested by some [78]. In fact, a recent publication by FIGO recommends that practitioners "Think Nutrition First" in order to improve pregnancy outcomes, from preconception to lactation [11]. Furthermore, in recognition of the stresses that a lack of food places on families, as well as the adverse effects on child growth and development, the American Academy of Pediatrics (AAP) has recently recommended that pediatricians routinely screen their clients for food security and access to healthy foods [79].

E Newborn Screening for Metabolic and Other Disorders

Population-based newborn screening (NBS) for metabolic disorders has been established as a preventive public health measure available to all neonates. If infants with specific metabolic, endocrine, and other disorders are identified by NBS in the first few days of life, the diagnostic process can be completed and treatment started before physical and neurological damage occurs. In the case of cystic fibrosis, outcomes (e.g., growth and hospital stays) are improved with the early identification and treatment afforded by NBS. Many of the disorders screened by NBS programs are autosomal recessive. This means that each parent carries the affected gene, and the risk of having an affected infant is one in four for each pregnancy. Thus, affected infants identified by NBS usually do not have a positive family history of the disorder.

Successful NBS of infants depends on reliable, valid, and timely laboratory results. Many states have established a central NBS laboratory, which supports a rigid quality control process. The initial NBS report provides a presumptive positive result that must be confirmed by mandatory laboratory confirmation of the diagnosis.

An expert panel [80] recommends that a NBS blood sample be collected before the infant is discharged from the hospital nursery. If the blood sample is collected before the infant is 24 hours of age, it is essential that a second screening sample be obtained. NBS programs require a small sample of dried blood, which is submitted on filter paper. This type of sample is easily transported to the central laboratory, and many tests can be completed on a single blood sample. Tandem mass spectrometry and other advances in technology have increased the number of disorders that can be effectively screened.

An effective NBS program involves timely community-based collection of initial blood samples, laboratory confirmation, education of primary care providers and families, as well as specific disorder follow-up, management, and evaluation components [80]. Each state has developed individual legislative NBS mandates. However, the Newborn Screening Expert Group, an expert panel, developed recommendations and guidelines for expanded NBS; the report was endorsed by the AAP. The general criteria for inclusion of a disorder in an NBS panel are shown in Table 14.2. Resources for up-to-date information on expanded NBS programs are shown in Table 14.3.

Expanded NBS programs provide the opportunity for earlier presumptive positive identification. Recent laboratory and clinical developments provide an increased specificity in diagnosis and treatment modalities. Thus, the long-term outcome for persons with inborn errors of metabolism and other NBS-identified disorders is brighter than in the past. The contrast between outcomes without early treatment and expected outcomes with early

TABLE 14.2 Criteria for Newborn Screening for a Specific Disorder Used by the Uniform Panel Working Group

Clinical characteristics (e.g., incidence, burden of disease if not treated, phenotype in the newborn)
Analytical characteristics of the screening test (e.g., availability, features of the platform)
Diagnosis, treatment, and management of the condition in both acute and chronic forms (including the availability of health professionals experienced in diagnosis, treatment, and management)

identification and treatment are shown in Table 14.4 and discussed further in Section IV.

III THE FUNCTIONAL APPROACH TO NUTRITION ASSESSMENT FOR CHILDREN WITH SPECIAL NEEDS

Special needs vary widely, from conditions that may only mildly affect nutrition status, such as ID, to those with severe and chronic nutritional implications, such as some neuromotor or metabolic disorders. The Nutrition Care Process (NCP) provides a framework for nutrition assessment regardless of the type of special health care need. The NCP is delineated into four steps: nutrition assessment, nutrition diagnosis, nutrition intervention, and nutrition monitoring and evaluation [81]. For this endeavor, the focus will be on the first step.

The assessment portion of the NCP is organized into 5 domains: food/nutrition-related history, anthropometric measurements, biochemical data, nutrition-focused physical findings, and client history. Food/nutrition-related history includes intake reported by the child or caregiver, medication use, and cultural food practices. In pediatrics, anthropometric assessment and nutrition-focused physical findings address growth, body composition, and development, all of which are key in assessing nutrition status. Laboratory findings may identify internal stressors that impact the body's ability to utilize nutrients for growth

TABLE 14.4 Selected Metabolic Disorders that Require Medical Nutrition Therapy (MNT)

Disorder	Pathway Affected	Outcome Without Treatment	Outcome with Early Identification and Treatment	MNT	Supplements/ Medications	Biochemical Parameters Monitored
Disorders of Amino Acid Metabolism						
Phenylketonuria (PKU)	Phenylalanine hydroxylase	Intellectual disability (IQ < 40)	Normal IQ (requires lifelong treatment)	Low phenylalanine, supplemented tyrosine	Potentially, BH4 for some patients	Plasma phenylalanine, tyrosine
Maple syrup urine disease (MSUD)	Branched-chain ketoacid dehydrogenase complex	Encephalopathy → death	Variable; may be cognitively compromised	Low leucine, isoleucine, valine	L-carnitine	Plasma leucine, isoleucine, valine, alloisoleucine
Glutaric acidemia, type 1	Glutaryl-CoA dehydrogenase	Impaired movement, dystonia, vomiting, seizures, coma	No long-term data	Low lysine, tryptophan	L-carnitine; riboflavin	Electrolytes, blood glucose, plasma amino acids
Homocystinuria (HCY)	Cystathionine β-synthase	Cardiac problems, organ damage, psychiatric disturbances, death	Variable; may be physically and cognitively compromised	Low methionine, supplement cysteine	Folate, betaine	Plasma methionine, total and free homocysteine
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Metabolic acidosis → coma → death	Variable; may be cognitively compromised	Low leucine	L-carnitine, glycine	Plasma amino acids (isovaleryl carnitine), urine organic acids (isovaleryl glycine)
Tyrosinemia, type 1	Fumarylacetoacetate hydrolase	Liver failure → death	Prevention of neurologic crisis, renal and hepatic failure, rickets	Low tyrosine, phenylalanine	Orfadin (nitisionine)	Plasma tyrosine, phenylalanine, methionine, succinate, alpha-fetoprotein
Disorders of Carbohydrate Metabolism						
Hereditary fructose intolerance (HFI)	Fructose-1-phosphate aldolase B	Hypoglycemia, liver cancer → death	Typical growth, development	Restrict fructose, sucrose		Liver function enzymes
Galactosemia	Galactose-1-phosphate uridyl transferase	Sepsis → severe delays, death	Often learning disabilities	Restrict galactose, use soy formula		Galactose-1-phosphate
Glycogen storage disease, type 1a	Glucose-6-phosphatase	Glycogen stored in liver, severe hypoglycemia, liver cancer → death	Normalization of glucose levels, moderation in liver size, decreased risk of liver cancer	Low lactose, fructose, sucrose; low-fat, high complex carbohydrate	Raw cornstarch, iron and calcium supplements	Cholesterol, triglycerides, uric acid, liver function (AST, ALT, GGT), blood glucose levels

Disorders of Fatty Acid Oxidation						
Long-chain acyl-CoA dehydrogenase deficiency (LCAD)	Long-chain acyl-CoA dehydrogenase	Cardiomyopathy, hepatomegaly, encephalopathy, hypotonia	Variable	Low-fat, low long-chain fatty acids, avoid fasting	L-carnitine, medium-chain triglycerides, thiamine, DHA, glycine	Plasma acylcarnitines, CK, uric acid, liver function studies, CBC, iron status
Medium-chain acyl-CoA dehydrogenase deficiency (MCAD)	Medium-chain acyl-CoA dehydrogenase	Encephalopathy, hepatomegaly, disability due to severe episodes	No sequelae if no episodes of severe hypoglycemia	Moderate fat, low medium-chain fatty acids, avoid fasting	L-carnitine	If ill, electrolytes, blood glucose
Disorders of Organic Acid Metabolism						
Methylmalonic aciduria (MMA)	Methylmalonyl-CoA mutase or cobalamin cofactor synthesis	Metabolic acidosis coma → death	Variable; may be cognitively compromised	Low protein, isoleucine, methionine, threonine, valine	L-carnitine, sodium benzoate, bicitra	Methylmalonic acid, electrolytes, kidney function (BUN, creatinine), carnitine
Propionic acidemia (PA)	Propionyl-CoA carboxylase	Metabolic acidosis coma → death	Variable; may be cognitively compromised	Low protein, isoleucine, methionine, threonine, valine, long-chain unsaturated fatty acids	L-carnitine, sodium benzoate, biotin, bicitra	Urine organic acids, plasma electrolytes, kidney function
Disorders of Urea Cycle Metabolism						
Ornithine transcarbamylase deficiency (OTC)	Ornithine transcarbamylase	Hyperammonemia → severe delays or death	Variable; may be cognitively compromised	Low protein, supplement essential amino acids, increased energy	L-carnitine, sodium benzoate, sodium phenylbutyrate, L-arginine	Plasma amino acids, ammonia, electrolytes, citrulline, arginine
Citrullinemia (CIT)	Argininosuccinate synthetase		Variable; may be cognitively compromised	Low protein, supplement essential amino acids, increased energy	L-carnitine, sodium benzoate, sodium phenylbutyrate, L-citrulline	Plasma amino acids, ammonia, electrolytes, citrulline, arginine
Carbamyl phosphate synthetase deficiency (CPS)	Carbamyl phosphate synthetase	Hyperammonemia → severe delays or death	Variable; may be cognitively compromised	Low protein, supplement essential amino acids, increased energy	L-carnitine, sodium benzoate, sodium phenylbutyrate, L-arginine	Plasma amino acids, ammonia, electrolytes, citrulline, arginine
Argininosuccinic aciduria (ASA)	Argininosuccinate lyase	Hyperammonemia → severe delays or death	Variable; may be cognitively compromised	Low protein, supplement essential amino acids, increased energy	L-carnitine, sodium benzoate, sodium phenylbutyrate	Plasma amino acids, ammonia, electrolytes, arginine

Sodium benzoate and sodium phenylbutyrate are chemicals administered to enhance waste ammonia excretion; other compounds producing the same effect are also used.

and development, in addition to assessing the functional level of nutrients. Elevated inflammatory markers like C-reactive protein indicate that nutrients might be diverted for healing instead of growth. Children exist within the framework of families and communities. Information about a child's social environment will inform how care is delivered and who needs to be involved.

Levels of nutrition assessment can be categorized from screening (level 1) to more comprehensive but still generalized (level 2) and specialized assessment as part of an interdisciplinary team (level 3) [7]. All three levels of nutrition screening and assessment should utilize the NCP, but the amount and type of information gathered are different depending on the purpose of the interaction and the training of the health care provider. The purpose of screening is to identify children at risk of nutrition problems, to refer children with more severe problems to the next level of care, and to provide anticipatory guidance and educational materials to children and their families regarding the prevention of nutrition problems [7]. Although screening can be completed with information from the caregiver working with health care providers from other disciplines [82], more in-depth nutrition assessment and intervention usually require a registered dietitian nutritionist (RDN), often in conjunction with a specialized interdisciplinary team. For many children with special health care needs, nutrition status will be assessed, monitored, and intervention provided on an ongoing basis by a pediatric RDN (preferably master's prepared) who has been trained in a particular area, such as pulmonary disease, metabolic disorders, or feeding skill development. These dietitians, working with the health care team, utilize their specialized skills to optimize a child's nutritional status in the context of the child's developmental level and medical conditions, as well as the other therapies being provided.

A Nutrition-Focused Physical Assessment

Nutrition-focused physical examination is part of a comprehensive assessment [83]. General inspection of the body for physical findings associated with nutrition status can be found elsewhere [83]. Most physical markers are associated with under nutrition, however there are markers associated with over nutrition like acanthosis nigricans, axillary and abdominal striae associated with metabolic syndrome [84,85]. Growth information is used in nutrition assessment to compare an individual child's growth to that of his or her peers and to evaluate the growth pattern over time. For the information to be valuable, anthropometric measurements must be accurate, the data must be plotted correctly, and the appropriate reference data should be used for comparison [8,86]. At a minimum, weight, height (or length for children who cannot stand independently), and head circumference (especially for children up to 3 years of age) should be measured. Ideally, some form of body composition measurement is also used, with the simplest and most well referenced being skinfold measurements obtained with calipers, which have been shown to be helpful in determining differences in body composition in children with developmental disabilities [87]. Mid upper arm circumference has gained wide acceptance as an indicator of nutritional status for both over and under nutrition and should be included in comprehensive anthropometric assessment [8].

To determine growth rate in children, weight and height for age can be plotted on the WHO growth charts for children 0−24 months and the CDC growth charts for children 2−20 years old [88]. The charts provide a useful reference to monitor weight in relation to stature, including BMI for children older than 2 years. In most cases, BMI-for-age charts are not available for special conditions and have not been validated for use with children with special health care needs whose body composition often differs from that of typically-developing children. For children whose growth parameters fall outside of median values, growth velocity may be a more valuable indicator of nutritional status than percentile of z-score [89]. Tools to calculate z-scores are available online (e.g., www.Pedi-tools.org, www.cdc.gov.growthcharts). Triceps and subscapular skinfolds along with arm circumference measurements can further define the growth and body composition data for the child, although they have also not been validated for children with different body composition. All of these anthropometric data used together can still give a general picture of the nutritional status of the child, whether the child is underweight or overfat, and how linear growth is progressing. In children with neuromotor disorders that make measuring length difficult (e.g., spasticity and contractures), other types of anthropometric measurements have been developed (e.g., knee height or segmental length) with which to estimate stature and linear growth [90], although their clinical usefulness depends on the knowledge and skill of the clinicians obtaining the measurements [91].

Although the WHO and CDC growth charts, which are based on the growth of large numbers of healthy children, can be used to plot growth, some physical conditions affect growth potential. There are specialized charts that may be considered for use with children affected by these conditions. The rationale for using specialized growth charts is clear for genetic disorders where there is evidence that linear growth potential is different. However, the development and use of growth charts for non-genetic conditions, such as cerebral palsy, is complicated by the fact that the underlying cause of the disorder does not change the genetic growth potential. The online training module, "Children with Special Health Care

Needs," is available for a full discussion of these charts (HRSA Growth Charts Training website at depts.washington.edu/growth). Although specialized growth charts may serve as useful references, they have significant limitations. Generally, they are developed from relatively small, homogeneous samples of children with unknown nutritional status, and data used to develop the charts may have been obtained using inconsistent measuring techniques. Also, for children with neuromotor problems, growth can be significantly affected by ambulatory status, as normal growth of the long bones requires weight-bearing; [7] thus using charts specific to cerebral palsy is particularly problematic. One recommendation is to plot the growth patterns of children on both the specialized charts, when appropriate, and the WHO or CDC growth charts [86]. This will allow comparisons of growth to the general population of children and to the references for children identified with a similar condition. Assessing serial growth measurements and using disorder-specific growth charts available for some genetic disorders (e.g., Down syndrome and Prader-Willi syndrome) will help differentiate between normal growth and alterations in growth rate resulting from poor nutrition. To interpret the growth data and understand the causes for unusual growth patterns, further information is needed.

Laboratory assessment of nutrition status is a helpful but less essential part of nutrition assessment for most children. Nutrition information is most commonly derived from plasma, serum, urine, and stool. Despite availability of biochemical assays, cost is a barrier to their consistent utilization. There is no standard battery of laboratory tests recommended for routine screening and assessment in typically-developing children or those with special health care needs. Laboratory tests are performed to confirm or investigate clinical findings. There are some public agencies that obtain laboratory values to screen for nutrition-related concerns. The Special Supplemental Nutrition Program for Women, Infants, and Children routinely collects hemoglobin and hematocrit as a screen for iron deficiency anemia. Some school districts require lead screening prior to entering school. Lead toxicity is associated with anemia and learning differences in young children. The CDC published guidelines that suggest minimal risk with lead levels <5 mg/dL.

B Assessing Dietary Intake

Analysis of a child's dietary pattern can predict and prevent nutrient deficiencies and, as with anthropometric data, requires accurate information to be useful. Data collection techniques may range from screening based on food groups and frequency of consumption, review of a 24-hour recall, or analysis of food records kept for three or more days with the chosen method dependent on the type and accuracy of information needed [92]. New methodologies for dietary assessment include electronic applications that allow participants to input data directly or upload photos that allow for assessment of data. Nutrient adequacy is usually compared to the dietary reference intakes (DRIs) for a child's age and size, unless there are known at risk nutrients [86]. For some conditions, there are known issues of marginal micronutrient status, such as vitamin D status with chronic use of some anticonvulsant medications [93] and for several nutrients when low food intake is a chronic problem (e.g., for some children with cerebral palsy) [94,95].

Dietary analysis will reveal if there are any specific nutrients or groups of nutrients of concern. If anthropometric data provide evidence that the child is overweight or underweight or has altered lean or adipose tissue patterns, this information should be considered along with the dietary assessment in determining the child's energy needs. For children with short stature or who are overweight or underweight, it may be best to calculate energy intake recommendations based on current height (kcal/cm) rather than weight (kcal/kg).

Information relating to other functional areas—elimination patterns, the use of medications, supplements and complementary therapies, the child's ability with varying food textures, feeding skills, and behaviors/interactions of the child and caregiver at meal/snack time should be included as part of the nutrition assessment. The RDN should assess drug-nutrient interactions, fluid intake and output, and the frequency/consistency of bowel movements can indicate if chronic constipation or diarrhea are present, which can compromise feeding behavior and nutrition status.

Often children with special needs have significant feeding skill delays, or feeding patterns that reflect their developmental level rather than their chronological age. Careful evaluation of the type, textures, and quantity of foods consumed is needed to ensure the child is meeting nutrient and energy needs. Food preferences and refusals, which may be related to past or current medical conditions, need to be taken into account when designing dietary interventions. An interdisciplinary team that includes the parent/caregiver, a feeding therapist, the RDN, and a nurse or physician can determine appropriate feeding methods, types/textures of foods, feeding position and equipment, and quantity/type of food to use to facilitate the child's optimal feeding skill development, as well as his or her nutritional intake (see Section IV).

Family-centered care acknowledges the family as the center of the child's existence and has significant relevance in nutrition and feeding. A client history includes information about the family and the household environment, including food security and the family's ability to prepare foods at home. Various caregivers may have

TABLE 14.5 Client History Questions Related to Family and Household Environment

1. Who lives in the home?
2. Who is (are) the primary caregiver(s)?
3. Who prepares the meals in the home?
4. Where does the family eat?
5. Who participates in mealtimes?
6. How would you describe mealtimes? (e.g., stressful, calm, pleasant)

different mealtime expectations and practices that impact a child's mealtime participation. Table 14.5 provides a sample of questions to ask when obtaining a client history.

C Considering Medical Conditions

Medical conditions and/or advancement in medical care can have an impact on nutrition status and growth (shown in Table 14.1). In 2011 it was recognized that children with Down syndrome were living longer and had better quality of life due to medical interventions. For children with Down syndrome, both the UK and US have created updated growth charts that reflect the change in growth status. Key findings of these two recent studies were improved growth in children 0–3 years old compared to the previous growth chart for Down syndrome, which the AAP no longer recommends [96]. Both the UK and the US have created updated growth charts that reflect the change in growth status. The US study also reported increased stature measurements in males 2–20 years old, compared to the previous chart. BMI of those 2–20 years with Down syndrome should be assessed using the CDC growth charts [96–98].

Some conditions (e.g., Prader-Willi syndrome) alter a child's energy and other nutrient needs, whereas other conditions interfere with adequate nutrient intake or utilization (e.g., feeding problems in some types of cerebral palsy). Examples of conditions that increase energy demands are cardiac and pulmonary complications of prematurity and cerebral palsy in which there are significant hypertonia/spasticity or athetoid movements. Other chronic illnesses associated with high energy needs are HIV/AIDS, cystic fibrosis, and mitochondrial disorders. Some genetic disorders are associated with lowered metabolic rates resulting in decreased energy needs (e.g., Down syndrome and Prader-Willi syndrome). Conditions associated with reduced or low muscle mass (as in muscular dystrophies) also result in decreased energy needs. In genetic disorders in which short stature occurs, overall food, nutrient, and energy needs may be lower than those of age peers throughout adolescence and adulthood. If a child has reduced activity levels because of immobility, energy demands will also be lower.

With a few exceptions, such as copper deficiency in Wilson's disease and some metabolic disorders, most medical conditions do not have a primary effect on an individual's micronutrient needs. There is not enough evidence to suggest that nutrients associated with energy metabolism be adjusted even with very high or low energy intakes. Therefore, the DRIs are still the most appropriate guideline for nutrient requirements for children with special needs. In the self-study curriculum "Nutrition for Children with Special Health Care Needs" (available online at http://www.pacificwestmch.org), the following questions are suggested to assess whether and how a medical condition will affect nutritional status:

1. Does the condition (or medication used to treat the condition) have an effect on the child's nutrient needs?
2. Does the condition change the types of foods the child can eat?
3. Does the condition alter the amount of food that the child can reasonably be expected to consume?
4. Does the condition affect the amount of time the child can spend at the table (eating)? Does this make a smaller intake likely?
5. Does the medication or therapy schedule interfere with scheduled meal or snack times?

Consideration of these issues and the impact on overall nutrient intake and nutritional status should be the final component of the nutrition assessment for children with special needs.

IV EVIDENCE-BASED INTERVENTIONS FOR SELECTED CONDITIONS

A Inborn Errors of Metabolism

Inborn errors of metabolism (IEM) are the classic example of the secondary prevention of disability through nutrition therapy. The basic concepts, principles, and strategies of treatment of selected disorders of protein, carbohydrate, and fat metabolism are presented here. A complete discussion of diagnosis and management of the array of IEM can be found elsewhere [80,99]. Table 14.6 outlines the essential components of medical nutrition therapy (MNT) for treatment of IEM. Although the clinical and biochemical presentation of each metabolic disorder is unique and the disorders present a range from mild to life-threatening illness, metabolic disorders can be thought of as a group in which the absence or inactivity of a specific enzyme or cofactor causes the buildup of the substrate and deficiency of the product. The goal of treatment for IEM is to strive for correction of the biochemical

TABLE 14.6 Components of Medical Nutrition Therapy for Metabolic Disorders

Identify precise modifications required for treatment of the disorder
Provide nutritional surveillance to ensure that medical nutrition therapy is adequate
Provide a mechanism for follow-up of child for symptoms of nutritional deficiency or toxicity
Provide emotional and educational support for child and family

abnormality. The outcome of treatment for these disorders is variable and depends on early diagnosis and intensive and continuous intervention. MNT is the primary mode of treating metabolic disorders.

1 Principles of Medical Nutrition Therapy

The two major principles of MNT for IEM are (1) to mitigate the effects of the altered enzyme by modifying components of dietary intake to adjust the environment at the cellular level and (2) to provide protein, energy, and other nutrients to support growth and development.

For many disorders, the treatment is determined by the identification of the missing or inactive enzyme. In an effort to modify the detrimental effect of the decreased or absent enzyme activity, the paradigm of "working around" the enzyme is used. In many cases, decreasing the substrate available for the reaction and supplementing the product to promote "normal" blood levels prevents or decreases the deleterious effects of the disorder. For example, in the treatment of PKU, phenylalanine (substrate) is restricted because of the absence or inactivity of phenylalanine hydroxylase (enzyme), and tyrosine (product) is supplemented. In some disorders, the absent or inactive enzyme is further down the amino acid degradation pathway and may affect the metabolism of two or more amino acids—e.g., leucine, isoleucine, and valine in maple syrup urine disease (MSUD).

The affected amino acids in most disorders of amino acid metabolism are "essential," that is, they cannot be synthesized by the body and therefore must be provided in the diet. These critical essential amino acids (EAAs) must be provided at a level that promotes growth and development but is restricted enough to prevent toxic buildup of amino acid(s) that cannot be metabolized.

In some disorders, the additional step of enhancing enzyme activity by supplying its cofactor can be helpful. An example of this is providing pharmacological doses of biotin in biotinidase deficiency [100] or providing vitamin B_6, on which cystathionine β-synthase is dependent, in some forms of homocystinuria [101]. Use of a synthetic cofactor (tetrahydrobiopterin or sapropterin) for some individuals with phenylketonuria is based on this principle [102].

In metabolic disorders of carbohydrate metabolism, such as galactosemia, the nutrient of concern (galactose) is not essential. Therefore, the goal of effective MNT is to eliminate as much of the exogenous component as possible from the diet [103]. There is no established requirement for galactose because it is produced endogenously. Other sources of nourishment need to be provided to compensate for the omitted foods and their nutrients.

Disorders of fatty acid metabolism require a source of energy other than fat because fat cannot be metabolized to meet energy needs. Fatty acids of specific carbon lengths are often minimized or eliminated, depending on whether or not the fatty acid is essential for growth and development. For example, in long-chain acyl-CoA dehydrogenase deficiency or very long-chain acyl-CoA dehydrogenase deficiency, shorter chain fats can be metabolized and are often supplemented; e.g., medium-chain triglycerides are provided as MCT oil [104]. However, in medium-chain acyl-CoA dehydrogenase deficiency, sources of medium-chain fat should be modestly restricted. Other essential components of treatment are (1) supplementation of L-carnitine, an amino acid that functions in the transport of fatty acid acyl-CoA esters during mitochondrial β-oxidation, and (2) avoidance of fasting because of the accumulation of partially oxidized metabolites associated with impaired energy production [105].

2 Providing Medical Nutrition Therapy

The general principles of protein and energy management that support general nourishment as well as the issues of biochemical control specific to the disorder must be addressed [106]. The infant or child needs to be provided with adequate amino acids, total protein, nitrogen, and energy to support growth. Energy needs may be increased when L-amino acids provide the protein equivalent, and maintaining an adequate energy intake is essential in preventing catabolism. It must also be noted that suppression of destructive metabolites can produce striking biochemical and clinical improvement.

3 Providing Adequate Nourishment

For some disorders, total protein is not restricted, but the composition of the protein may be adjusted. For example, treatment of PKU requires the restriction of phenylalanine intake but not total protein. This is accomplished by using a specially designed semisynthetic medical food (formula). Infants and children with many IEM must obtain most of their protein from specialized metabolic formulas. Natural foods seldom provide more than 25% (often 10%) of the protein requirements of infants and children with amino acid, organic acid, or urea cycle disorders.

Protein in the specialized formulas is provided as individual L-amino acids (excluding those amino acids that are contraindicated for each condition). L-amino acids are more readily oxidized than intact protein; thus, the requirement for protein when L-amino acids are the protein source is greater than usual. Adequate protein and energy are required to maintain an anabolic state. If adequate formula is not prescribed or consumed, a catabolic state will develop, causing both high plasma amino acids levels and clinical problems. Advances in food technology, combined with clinical nutrition research, have produced a naturally occurring protein moiety called glycomacropeptide, refined from whey, which is very low in phenylalanine and has been shown to improve protein retention, phenylalanine utilization, and to reduce hunger when substituted for some of the amino acid formula in the diets of people with PKU [107,108].

The urea cycle disorders require the restriction of overall protein intake because excess nitrogen from any source can be neurotoxic. However, it is also imperative to provide enough protein and energy to support growth. The formulas for the treatment of urea cycle disorders have a high concentration of amino acids to ensure ready incorporation into protein. Most children with these disorders also require medications to enhance the excretion of excess nitrogen through secondary pathways other than the urea cycle. For infants and children with urea cycle disorders, catabolism from excess protein, weight loss, illness, or infection is a danger. Hyperammonemia can occur rapidly (in several hours) and be life-threatening. The total amount of protein tolerated by the individual child depends on residual enzyme activity, age, and growth rate.

4 Supplying Restricted Amino Acids

Small amounts of the restricted EAAs specific to each disorder are required for growth and development. These EAAs are provided to the infant by including small amounts of proprietary infant formula in the metabolic formula mixture. As the child grows and matures, adding small amounts of cow or soy milk or fruits, vegetables, and grains can provide these essential amino acids.

5 Breast-Feeding

Some infants with metabolic disorders are able to maintain low and stable plasma amino acid levels with a combination of breast milk and metabolic formula feedings; e.g., some infants with PKU are able to tolerate partial breast-feeding and maintain low plasma phenylalanine levels. Many infants are too metabolically fragile to maintain appropriate plasma levels with breast-feeding. Breast-feeding is overtly contraindicated for infants with some disorders, such as galactosemia.

6 Feeding

Poor appetite is not uncommon for children with IEM, especially urea cycle disorders, MSUD, and the organic acidemias. Reasons for poor appetite and poor feeding may be organic, behavioral, or both. Many children with IEM who have had acute episodes may also have a history of vomiting, which may lead to feeding avoidance.

7 Growth

Poor growth is often a reflection of several factors: (1) Infants who have endured a severe neonatal illness may require an extended time of appropriate nourishment before they catch up on growth, (2) frequent febrile illness may interfere with achieving expected physical growth, or (3) poor metabolic control or an inadequate protein or energy intake may interfere with growth. Many children with IEM who have little or no enzyme activity are medically fragile, and it is difficult to maintain metabolic balance and support typical growth patterns.

8 Monitoring for Children with Metabolic Disorders

The frequency of monitoring biochemical parameters depends on the age and health status of the child. Maintaining metabolic balance for children with IEM requires frequent and intensive monitoring of biochemical parameters specific to the disorder as well as those that reflect general nutritional status. The goal of treatment for all disorders is to achieve biochemical levels at or near the normal range. Laboratory parameters that are frequently monitored include plasma amino acids, urine organic acids, hematological status, protein status, electrolytes, blood lipids, and ammonia levels. A general plan to guide biochemical assessment is shown in Table 14.4.

9 Specialized Metabolic Team

As a group, children with IEM comprise a small percentage of the pediatric population, and even the most common of these disorders is rare in the general population. However, the health care needs of these children are specific and urgent. Experts groups have recommended that a team experienced in management supervise the therapy of these children [80]. Effective treatment generally requires the expertise of a geneticist, dietitian, nurse, genetic counselor, psychologist, and neurologist. The complex nutritional and medical management of these children cannot occur effectively without the follow-up and support of the community teams. Communication among the team at the tertiary center, the community, and the family is crucial for supporting the best possible medical, nutritional, and intellectual outcome for these children.

B Prader-Willi Syndrome

Prader-Willi syndrome (PWS) is caused by a microdeletion on genes on chromosome 15. Most frequently, this is caused by paternal deletion, some are due to maternal disomy, and about 15% of cases are caused by imprinting defects. PWS is associated with early failure to thrive, hypotonia, abnormal body composition, hypogonadism, short stature, and behavioral and learning issues [109]. Recently seven distinct phases have been identified: [110]

- Phase 0 (in utero): decreased fetal movement, birth weight, and length
- Phase 1: hypotonia without obesity
  - Phase 1a (0−9 months): feeding difficulties with or without failure to thrive
  - Phase 1b (9−25 months): improved growth and feeding
- Phase 2: increased weight
  - Phase 2a (2.1−4.5 years): increased weight without increased appetite or intake
  - Phase 2b (4.5−8 years): continued weight gain, increased interest in food
- Phase 3 (8 years-adult): development of hyperphagia, food-seeking, lack of satiety
- Phase 4: appetite no longer insatiable (has only been observed in some adults)

Delay in identification and treatment of PWS can lead to the onset of gross obesity after infancy.

Abnormal food-seeking behavior is characteristic of PWS and includes hoarding and foraging for food as well as eating items generally considered to be inedible, such as garbage, pet food, or uncooked frozen food. Infants and children with PWS demonstrate a low metabolic rate and thus decreased energy needs. An intake as low as 60−80% of the RDA is often required to maintain a stable weight in older children [109]. Strict and consistent behavioral limits and the establishment of regular routines are helpful behavioral management strategies for food intake and behavioral concerns for children with PWS [111].

Controlled trials have shown that children with PWS benefit from growth hormone therapy from infancy through childhood and into adulthood, with gains in stature and lean body mass. Some studies have also indicated improved lipid profiles. However, growth hormone treatment does not "cure" the underlying causes of short stature in PWS, and it is unclear if the other observed benefits continue after growth hormone therapy is discontinued [109]. New standardized growth curves based on white children with PWS from birth to 36 months of age not treated with growth hormone have been generated [112,113], and charts based on children who did receive growth hormone were recently published [113]. These charts can be used to monitor growth patterns and assess nutritional status for similar infants and children with PWS both treated and not treated with growth hormone.

C Feeding Problems

With increased survival rates of premature and medically fragile infants, there is an increased population of children who are at risk from, or who demonstrate, feeding difficulties with multifactorial origins, depending on the degree of prematurity or LBW and the presence of hypotonia [114]. For example, in premature infants, gastroesophageal reflux, a physiological and developmental consequence of prematurity, may occur three to five times per hour [115]. Poor coordination of the suck−swallow and suck−respiration is often predictive of feeding abnormalities [116]. Feeding problems secondary to oral motor delay occur in 90% of young children with neurological impairment (e.g., cerebral palsy) [117]. Feeding problems may originate from structural anomalies like cleft lip or palate, esophageal strictures, or subglottal stenosis; or neurodevelopmental disabilities such as cerebral palsy, or behavioral challenges due to sensory food aversions [118], or posttraumatic feeding disorder. The range of feeding problems is beyond the scope of this chapter. The multifocal elements inherent in feeding problems requires assessment by an interprofessional team [119] to identify the cause of the feeding problem and prioritize strategies for intervention, which may include medical nutrition therapy.

Nutritional status and feeding development are of primary concern in the neonatal intensive care unit (NICU). Feeding skill development and transitions from parenteral to enteral nutrition in the medically fragile newborn are facilitated by an interdisciplinary team composed of health care providers and the parents. Breast-feeding, or the feeding of breast milk, is encouraged as much as is possible for the newborn to support nourishment, developing attachment, and for feeding skill development. Current recommendations support the use of transitional formula feeds for several feeds in addition to breast milk over fortified human milk, stating that it does not meet the nutritional needs of the VLBW infant [120]. Many infants are discharged from the NICU only after achieving at least a portion of their nutrient intake through oral routes, although the use of nasogastric, orogastric, and gastrostomy tube feedings has increased. Parents of preterm infants reported more problems with early feeding than parents of typical children, and 3-year olds who were born prematurely were more likely to be overweight [121]. If a feeding tube is needed, the plan should encourage developmentally appropriate oral feedings as soon as the child is medically stable and physically able. Early introduction of low volumes (trophic feedings), as early

as 33 weeks' gestational age, has been shown to accelerate the rate at which preterm infants are able to attain full oral feedings [122]. More recently the literature supports the use of standardized feeding protocols to achieve full feeds in VLBW infants [123].

Among children with developmental delays and special health care needs, especially those born prematurely, the estimated prevalence of feeding disorders ranges from 33 to 80%, depending on the definitions of feeding disorders [124–126]. Problems with feeding occur when the components for the development of normal feeding are missing or delayed. Significant behavioral refusals due to multiple etiologies may include discord between the child and caregiver, medical interventions and medications that interfere with appetite and regulation, or physiological problems related to the medical condition or disability (Table 14.7). A recent review classified children with feeding disorders as: (1) children with fear of feeding as a result of adverse events, (2) children with limited appetite due to medications, and (3) children with food selectivity. An extensive discussion of the physiological and behavioral contributors to feeding problems is included in a special issue of *Developmental Disabilities Research Reviews* devoted to this topic [127]. Whereas inpatient behavioral therapy has been shown to be effective for children with feeding interaction problems [126], children with persistent physical challenges resulting in swallowing and other difficulties often require supplemental or total tube feedings for long periods of time and may never become independent oral feeders. Utilizing a sophisticated statistical method (latent class analysis) of chart review data from 286 children referred to a feeding team, Berlin and colleagues [128] demonstrated that children fed by gastrostomy tube had both more behavioral feeding problems and higher weights across all categories sharing common medical, developmental, and behavioral conditions. This group concluded that the presence of multiple comorbid conditions confers general, rather than specific, risk from feeding problems.

An interdisciplinary team that can determine factors leading to feeding difficulties and develop and coordinate appropriate interventions is recommended [125,129]. The role of the RDN on the interdisciplinary feeding team is to assess nutrition status and to determine how best the child can meet his or her nutritional needs using developmentally appropriate feeding methods and forms of foods whenever possible [86,130]. Use of dietary supplements, including nutritionally complete formulas, either orally or through a tube, may be needed to supply adequate energy, protein, and other nutrients. It is often best to use the child's size and developmental stage (e.g., pubertal and prepubertal) to estimate nutrient needs, rather than the child's chronological age.

Nutrition interventions for children with ASD are discussed in the next section, but it should be mentioned here that although children with ASD often have feeding challenges, the diet often meets or exceeds the RDA for protein, carbohydrates, and fat [131–133]. However, rigid mealtime patterns or limited food repertoires are common feeding issues for children with ASD [131,133,134]. For example, the child with ASD may insist on only white foods or demand a particular plate. The child may have a preference for only salty or only sweet foods or only foods of a certain texture. These behaviors may make family meals difficult, and severe food jags can lead to nutrient deficiencies. If entire food groups are missing, or if there is excessive intake of a particular nutrient, a vitamin/mineral supplement may be appropriate. Pica (the eating of "nonfood" items) may also be more common than in the general population [133], and nutrition

TABLE 14.7 Feeding Problems in Children with Special Health Care Needs

Feeding Difficulty	Frequent Causes	Associated Conditions
Delayed or slow development Posturing or seating difficulties Persistence of primitive reflexes Craniofacial anatomic problems Uncoordinated sucking, chewing, swallowing Behavioral refusals Decreased appetite	Hypertonia Hypotonia Hypersensitivity Developmental immaturity (prematurity) Gastroesophageal reflux Unpleasant intrusions into the oral cavity Unpleasant feeding experiences (past or present) Constipation Increased secretions Decreased gastric motility Medications	Developmental delay Cerebral palsy Cleft lip and cleft palate Down syndrome (trisomy 21) Prader-Willi syndrome Rett syndrome Muscular dystrophy Williams syndrome Myelomeningocele with accompanying Arnold-Chiari malformation Autism Chronic respiratory diseases (cystic fibrosis, bronchopulmonary dysplasia, respiratory distress syndrome)

education and intervention may need to address this behavior. Therapies to expand food choices vary and can be difficult to implement. Families can be encouraged to offer new items with preferred foods [135] and to offer them repeatedly, possibly over a period of months. Interdisciplinary intervention is usually necessary, including a behavior specialist, or an occupational or speech therapist where texture or oral issues are also present.

Identifying the need for nutrition intervention early in a child's life—and providing ongoing and coordinated services between inpatient, early intervention, and school- and community-based services—is ideal but often challenging based on the complexity of the health care system and lack of nutrition services available in many settings [5,136]. A practical and detailed description of feeding problems, developmental conditions leading to feeding problems, and suggested feeding and nutrition assessment strategies is included in the self-study curriculum referred to earlier, "Nutrition for Children with Special Health Care Needs," Module 3: Feeding Skills (available at http://www.pacificwestmch.org).

D Autism Spectrum Disorders

1 Definition and Etiology

Autism spectrum disorder (ASD) is a group of disorders characterized by deficits in social communication/interaction and symptoms related to restricted and repetitive behaviors. Previously, the diagnosis included subdiagnoses (Asperger syndrome, autistic disorder, pervasive developmental disorder not otherwise specified, and disintegrative disorder). The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) established modified diagnostic criteria [137]. ASD is characterized by two key manifestations that are functionally impairing:

1. Persistent deficits in social communication and social interaction across multiple contexts (e.g., problems with the following: establishing or maintaining conversations and interactions, shared attention, adjusting to different social situations, nonverbal communication such as eye contact, expressions, and gestures)
2. Restricted, repetitive patterns of behavior, interests, or activities (e.g., repetitive speech or movement, rigidity and need for routine, restricted interests, hyper- or hypo-reactivity to sensory input)

Intellectual abilities can range from typical to profound ID. Although the reasons are not clear, the prevalence of ASD appears to be increasing in the US; surveillance data from the CDC indicate that 1 out of 68 US children has ASD, and for boys, the estimated prevalence is even higher at 1 in 23.6 [138]. This survey showed that non-Hispanic black and multiracial children were at lower risk of having an ASD than were white children.

The etiology of ASD is unknown, and the diagnostic criteria are currently based solely on behaviors. However it is becoming clear that the etiology is likely to be multifactorial, with involvement of genetic, epigenetic, and environmental factors, which possibly include nutrition. Comorbidities often seen in the ASD population, which may affect feeding or nutritional status, include fragile X syndrome, seizure disorder, anxiety disorders, and gastrointestinal disorders [139]. Currently, there is active research focused on gastrointestinal, nutrition, and feeding issues in children with ASD. Each is briefly discussed next.

2 Gastrointestinal Issues

Although the current diagnostic criteria for ASD do not include gastrointestinal (GI) symptoms, reports since the 1970s describe chronic GI dysfunctions/symptoms, including diarrhea, constipation, abdominal bloating, discomfort, irritability, GI reflux, and vomiting among children with ASD [140], and a meta-analysis found a higher prevalence of GI symptoms among children with ASD [141]. Children with autism were four times more likely to have general GI symptoms, three times as likely to have diarrhea or constipation, and twice as likely to have abdominal pain.

Other studies have reported pathological findings in the GI tract of children with ASD, including increased intestinal permeability and compromised gut microflora [133,142]. Children with ASD who have a limited ability to communicate may be unable to express GI discomfort. GI problems should be considered along with other causes if negative behaviors are present and/or escalate in children with ASD.

A consensus report sponsored by the Autism Forum—a group of 28 participants in seven working groups (including nutrition) and representing 10 disciplines and multiple organizations—identified, graded, and evaluated publications related to GI issues and autism and found a general absence of high-quality research data, which precludes evidence-based recommendations at this time [143]. They developed and published 23 consensus statements, including the following:

- GI disturbances in ASD, likely highly prevalent, are incompletely understood and may be difficult to evaluate because of problems communicating discomfort/pain
- Children with ASD and GI symptoms may have more problem behaviors than others with ASD; these may be a sign that a GI evaluation is warranted

- GI disturbance specific to ASD has not been established; evidence for abnormal GI permeability in ASD is limited, and the studies are methodologically challenged
- ASD caregivers and health care providers need to know how to recognize signs and symptoms of GI disorders and other nutritional problems
- Evaluation by a nutritionist is recommended; anthropometry should be monitored; those with limited diets or taking supplements should be evaluated
- Additional studies are needed before recommending specific diets for ASD; data do not support the use of a casein-free or gluten-free diet (or both) as primary treatment
- Detailed history to identify potential associations between GI and/or behavioral symptoms and allergies; involvement of specialists (GI, nutrition, and feeding therapists) can be beneficial
- Direct relationship between immune dysfunction and ASD is not yet proven, but it warrants further investigation
- Well-defined phenotypes and genotypes will enhance further clinical investigations

Recently, an expert panel developed an algorithm for nutrition management of GI concerns in children with ASD [144]. Their report addressed barriers specific to ASD, including the following:

- Food selectivity
- Complementary-alternative diet therapies
- Nutritional deficits/excesses
- Importance of interdisciplinary approach
- Behavioral response to changes in mealtime routine

Special diets are popular complementary therapies for children with ASD. The theories behind their use are numerous and include GI-related implications, possible food sensitivities and/or allergies, altered immune responses, and altered intestinal microflora. The "opioid excess" theory holds that a "leaky gut" allows undigested opioid-like peptides from the proteins gluten and casein to cross the intestinal wall and then the blood–brain barrier, where they stimulate opioid receptors and disturb brain neurotransmission, causing or increasing behavioral symptoms [132,145]. Although some earlier studies reported increased urinary peptides in some children with ASD, a case-control study found no differences between those with ASD and typically-developing controls [146].

Case studies and anecdotal reports often lead families to choose an alternative diet for their child. Inflammation of the GI tract resulting from exposure to irritants is uncomfortable or even painful. Because most studies use parent or caregiver reports of behavior changes in children after implementing the diet, a significant potential confounder is the placebo effect because parents seeking to find any treatment for their child may be susceptible to suggestion. Also, most studies have not been of a prospective, randomized, blinded design; e.g., they begin with a population of children with ASD who already have GI issues. This makes it difficult to generalize findings to the entire ASD population. Thus, there is controversy around whether the gluten/casein-free diet is a valid treatment for ASD or simply a treatment for comorbid gluten/casein sensitivity in a subgroup of these children. A meta-analysis of 14 studies concluded that published data do not support the use of gluten- and/or casein-free diets for children with autism. Conclusions of randomized controlled trials are mixed. The ScanBrit study (single-blind) suggested that the diet "may positively affect developmental outcome" [147]. However, a more recent double-blind, placebo-controlled challenge trial found no differences in physiologic and behavioral outcomes [148]. Worse, the recommendations for alternative diets may be influenced by profit or ideology (some physicians sell the products they recommend). At this time, therefore, there are no recommended diet therapies for ASD.

The role of the RDN who works with families of children with ASD is to ensure adequate growth and development and to support the family who wants to try an alternative diet. Parents need to understand what is currently known about the efficacy of the diet (based on current evidence) and if there are any potential deficiencies; the more restrictive the diet, the greater the risk. It is important to help families clearly understand the difficulties that may arise in attempting to follow a special diet, especially when a child eats outside of the home on a daily basis (e.g., at school or with other caregivers). At school, eating separately or different foods may further isolate the child from his or her peers. The diet can be more costly than a traditional diet. If the child is a "picky eater" or has feeding problems, these may be complicating factors when introducing a restrictive diet.

3 Nutrition Issues

The growth patterns of children with ASD are thought to be normal. However, studies have shown an increased rate of head growth in children with ASD [149]. Others have shown an increased rate of linear growth, weight gain, and body mass index [150]. Anthropometric data for this population should still consist of length, weight, weight/length, and head circumference. When the child is found to have a large head size, this should be considered when making weight/height comparisons because they could be deceptively increased. In children with ASD, it is not unusual to see a very low or very high BMI as a result of feeding issues.

Complementary therapies are very popular; dramatic testimonials abound, and there is an active promotion of alternative and diet therapies in books, on websites, and at autism conferences attended by parents. Of more than 3000 participants in the Autism Speaks Autism Treatment Network (ATN) registry, 28% reported use of a complementary or alternative therapy (CAM), with 17% using special diets and 20% using another form of CAM. CAM use was higher among children with GI symptoms, seizures, and higher scores on a behavior problem rating scale [151]. Given the lack of scientific evidence, the question is why do parents choose dietary therapies? Answers include: (1) frustration with the limitations of current therapies coupled with hope for a cure or at least an improvement in behavior, (2) comfort in knowing parents have done everything possible for their child, and (3) wanting to have some control over the treatment. Some parents prefer "harmless" treatments over drugs. Finally, parents may give the therapy credit for changes that would have occurred anyway. The greater the efforts, the more biased they may be toward seeing them "pay off."

Potential nutrition problems with the casein-free, gluten-free diet—an example of a popular diet—include risks associated with the avoidance of casein such as insufficiency of vitamin D and calcium [152]. Hediger and colleagues found decreased cortical bone in males with ASD [153]. Milk is often a major source of protein for children as well. The elimination of gluten leads to a risk of inadequate sources for B vitamins in the diet. Vitamin/mineral supplementation for these children may not be appropriate, sufficient, or safe (not regulated). For example, children's multivitamins typically lack enough calcium and vitamin D to make up for the lack of milk in the diet; the popular chewable children's "gummy" brand formulations lack iron. And, even if an appropriate supplement is identified, a child with an extremely limited food repertoire might not accept it.

The ATN is a national research project (17 sites throughout the country) that is studying and establishing the medical standard of care for ASD. Included in this effort are several nutrition-related studies to describe the nutritional status of children with ASD, their associated medical and behavioral symptoms, and investigate any relationships among dietary intake, feeding behaviors, and food preferences of the children and their families [154]. One report of the Diet and Nutrition Study of the ATN found that children with ASD had similar intakes to controls—neither group met recommended intake levels for fiber, choline, calcium, potassium, and vitamins K and D. Supplements were used by 66% of children with ASD [131]. This study underscored the need for nutritional surveillance for children with and without ASD, and the authors recommended dietary assessment corroborated with anthropometric and laboratory data.

Currently, risperidone is the only FDA-approved medication for treating symptoms associated with ASD. Other medications are also sometimes used to treat specific ASD symptoms. Drug-nutrient interactions should be assessed if children are prescribed drugs to treat comorbidities such as seizures or psychiatric symptoms. The most common drugs used in this population that have significant drug-nutrient interactions have been reviewed by Geraghty and colleagues [140]. They include stimulants used for ADHD (Concerta and Strattera), which may cause a decrease in appetite and also nausea, vomiting, constipation, and diarrhea in the case of Strattera. Another category of commonly used medications are anticonvulsants (Depakote and Keppra). Depakote may also decrease appetite with associated nausea, vomiting, and diarrhea and also decrease serum vitamin D and calcium. The antipsychotic drugs (Zyprexa and Risperdal), on the other hand, may increase appetite and cause weight gain, at least in the case of Zyprexa.

Finally, it has been suggested that some nutrient deficiencies, or relative deficiencies, have been implicated in the etiology of some of the behavioral symptoms of autism. Vitamin B_6 is an example because of the role it plays in neurotransmission and based on evidence that there is a lack of an enzyme needed to convert it to its active form. To date there is not enough evidence to support the recommendation for vitamin B_6 supplementation as a treatment for ASD [155].

4 Feeding Issues

Many children with ASD have hyper- or hypo-reactivity to sensory input, which may include taste, smell, and oral sensitivities. These sensory issues may be responsible for the high prevalence of problem eating behaviors seen in children with autism [156,157]. These behaviors may include selective food refusals such as textures, colors, and food groups [134,157]. Other selective behaviors affecting feeding may relate to the GI issues referred to previously, fear of new foods, or obsessive mealtime rituals such as the need for sameness. The child with ASD may also have difficulties with changes in the environment [158], which may lead to problems with school mealtimes where a loud and boisterous cafeteria may be overwhelming such that a child with ASD may have difficulty eating lunch with a group of peers.

V CONCLUSION

In this review, we have provided examples of nutrition issues related to the role of nutrition in the primary (maternal nutrition) and secondary (MNT for IEM) prevention of developmental disabilities, and in the secondary prevention of nutrition-related disorders that are

commonly seen in children with special health care needs. Emphasis was given to several important concepts. First is the growing evidence regarding the contributory role of nutrition to the life course trajectory, through epigenetic and nutrigenomic relationships as yet not fully understood, in the etiology of preterm birth, low birth weight, and some birth defects, as well as the essential role of nutrition in early postnatal development. Because of the growing numbers of nutrients shown to be involved in normal development, the importance of whole foods versus supplements is also becoming apparent. The second major point, which follows from the first, is that early nutrition intervention is crucial to the individual child's attaining his or her highest potential and optimizing human development throughout the life course. Third, we presented a functional approach to assessment, early detection, and treatment of nutrition problems in children with special health care needs, stressing the point that although diagnoses may differ, the nutrition issues are often similar. Finally, although we did not cover the importance of training dietetics professionals in this area or the need to improve families' access to nutrition services for children with special needs, we refer the reader to the latest position paper of the Academy of Nutrition and Dietetics for an excellent review of the legislative history and a presentation of the challenges that remain for the profession [5] as well as another recent paper [159].

I INTRODUCTION

A Dietary Phytochemicals

Plants produce a variety of compounds that exert biological activities in humans and animals. Bioactive components in edible plants are of interest for disease prevention, as their widespread use with minimal toxicity has the potential to impact human health on the individual and population level. The majority of plant bioactives are secondary (2°) metabolites, as opposed to primary (1°) metabolites. The 1° metabolites are required for the biochemical processes of cells (such as amino acid, energy, and nucleic acid metabolism), while 2° metabolites are not required for survival of the organism that produces them. Rather, 2° metabolites are specialized compounds which confer added survival and competitive advantages to the plant. Plant 2° metabolites are referred to as natural products as well as phytochemicals (although "phytochemical" technically refers to any plant metabolite).

Major classes of plant phytochemicals are the phenolics/polyphenols, alkaloids, and terpenoids. Minor classes include polyacetylenes, polyenes, miscellaneous pigments, cyanogenic glucosides, glucosinolates, and nonprotein amino acids. Refer to Table 15.1 for chemical properties of major classes. The majority of the dietary bioactives associated with disease prevention are phenolics or terpenoids.

Dietary phytochemicals are often divided into two distinct classes based on their structure, solubility, and physiological absorption properties: water-soluble and lipid-soluble. In terms of relevance to diet and disease, the principal water-soluble phytochemicals in the diet are the phenolics, and more specifically, polyphenols. The principal dietary lipid-soluble compounds with potential health benefits include the carotenoids, tocochromanols (vitamin E derivatives) and curcuminoids. Although curcuminoids are technically phenolics, their hydrophobicity and digestive behavior align them more with lipid-soluble compounds for the purpose of this chapter.

Dietary phytochemicals have a variety of roles in nutrition and health. Some (such as certain carotenoids, through provitamin-A activity, and tocochromanols, with vitamin E activity) are essential human nutrients required for development, maintenance, and health. They may also exert benefits beyond basic nutritional value, including reduced risk of chronic diseases. Conversely, nonnutrient (i.e., nonessential) phytochemicals are considered xenobiotics: chemicals consumed by an organism, but which are not normally produced by the organism (metabolites from the organism's own biochemical pathways) and are not expected to be present in the organism or used for normal metabolic function (nutrients). The term xenobiotic does not imply either harmful or beneficial biological activity, but rather denotes that the compound is regarded as foreign to the body and is metabolized and excreted as such. This commonly includes pharmaceuticals, pollutants, and natural products such as phytochemicals all of which may be toxic, beneficial, or neutral. A growing body of evidence in medicine, biochemistry, nutrition, and epidemiology supports the role of both dietary nutrients and xenobiotic phytochemicals in the prevention of disease (Table 15.2) [1–17].

B Definition of Bioavailability

The bioavailability of dietary phytochemicals is a measurement of their distribution in body fluids and exposure to tissues. Ultimately, bioavailability is critical for

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00015-1

TABLE 15.1 Properties of Plant Natural Products

	Natural Product Class		
	Terpenoids	**Alkaloids**	**Phenolics**
Biosynthetic precursor	 Isoprene	 Amino acids	 Phenylalanine, tyrosine
Chemical nature	Hydrocarbon	Nitrogen-containing	Phenol ring(s)
Characterized compounds	>25,000	>12,000	>8000
Example	 (–)-Limonene	 Morphine	 Coniferyl alcohol

TABLE 15.2 Reported Roles of Dietary Phytochemicals in Basic Health and Disease Prevention

Solubility	Class	Functions as Essential Nutrients	Putative Functions in Prevention of Disease
Water-soluble	Phenolic acids	None	Inflammation, cancer, vascular function and cardiovascular disease, general antioxidant activity
	Flavonoids	None	Inflammation, cancer, vascular function and cardiovascular disease, metabolic syndrome (obesity, diabetes, low-grade inflammation), neuroprotection, general antioxidant activity, modulation of colon microflora, and immune stimulation
Lipid-soluble	Carotenoids	Eye health and vision, cell growth and differentiation, cell signaling, reproduction, immune function	Cancer, cardiovascular disease, osteoporosis, skin health, general antioxidant activity
	Tocochromanols	Antioxidant activity, membrane function, immune function	Cardiovascular disease, neuroprotection, general antioxidant activity
	Curcuminoids	None	Inflammation, cancer, neuroprotection, skin health, general antioxidant activity

bioactivity, because exposure to target tissues determines the potential of these compounds to deliver beneficial activity. A standardized definition of bioavailability for pharmaceutical agents is defined in the United States as follows: "the rate and extent to which the active ingredient or active moiety is absorbed from a drug product and becomes available at the site of action. For drug products that are not intended to be absorbed into the bloodstream, bioavailability may be assessed by measurements intended to reflect the rate and extent to which the active ingredient or active moiety becomes available at the site of action" (21 Code of Federal Regulations 320.1). This definition can be modified to apply to bioactive phytochemicals from the diet (foods, supplements, etc.): "bioavailability is defined as the rate and extent to which the phytochemical or active moiety is absorbed from the

ingested matrix and becomes available at the site of action." Essentially, this definition results from the two factors governing the activity of any compound in vivo: (1) the active compound must be present at the site of action to impart its biological activity, and (2) the concentration and the length of exposure of the active compound at the site of action determine the magnitude of activity.

Interest in the biological activities and resultant health-promoting and/or health-protecting functions of plant foods and their constituents has resulted in research endeavors to elucidate the factors that impact the bioavailability of dietary phytochemicals. The aim of this research is primarily to identify food and dietary factors (macro- and microcomposition, physical form, phytochemical concentration, dose, and exposure rate) and physiological factors (digestion, absorption, metabolism, distribution, and excretion processes) that alter bioavailability. Recently, disease conditions including obesity and diabetes have been identified as factors that may impact absorption and metabolism of dietary phytochemicals. Such knowledge is then used to optimize the bioavailability of dietary phytochemicals, and by extension, their activities at the tissue of interest.

It should be noted that the definition of bioavailability refers to the availability of one or a few specific compounds at their known or desired site of action. This definition is more easily applicable in its purest sense to pharmaceuticals than to phytochemicals originating from complex food matrices. Pharmaceuticals are comprised of one or a few active ingredients with rigorously established activity, and are designed to exert a specific function in a specific tissue in a specific "intent to treat" population (age, gender, disease state, etc.), with a specific indication of an existing or likely disease (an indication is a symptom or cause which suggests the proper and efficacious treatment). Foods and supplements generally do not meet these criteria, complicating the utility of bioavailability as a means to optimize the efficacy of dietary compounds in several ways.

First, with the exception of deficiencies in essential nutrients, definitive science on the relationships and exact mechanisms linking specific diets and/or phytochemicals to the prevention or amelioration of diseases continues to evolve. Dietary phytochemicals, other dietary components (fiber, toxins, pesticides, etc.), genetic factors, environmental factors, age, gender, and lifestyle all contribute to the interaction between diet and disease risk.

Secondly, foods and dietary supplements typically contain hundreds, if not thousands, of phytochemicals with diverse and largely unknown biological activities. The biological activities of foods and supplements are likely due to the combined effects of numerous phytochemicals including additive, synergistic, and/or antagonistic activities, rather than a single compound or small group of compounds. This is a potential obstacle for bioavailability research, as it is both desirable and practical to measure only a small percentage of the compounds ingested. Typically, bioavailability studies select the phytochemicals to be measured based on three main criteria: (1) predominance of the compound(s) in the dietary source to be studied (which is problematic, as abundance does not necessarily indicate activity), (2) epidemiological or other evidence suggesting a link between consumption of the phytochemical(s) or foods rich in the phytochemical(s) with the biological outcome of interest, or (3) in vitro or in vivo studies suggesting that the phytochemical(s) provide the desired biological outcome when administered in purified or semipurified form.

Thirdly, the observed biological effect of a phytochemical is not necessarily due to the native form found in foods. A variety of metabolic processes that occur during and postabsorption can chemically transform the phytochemical into metabolites. These systems break down native dietary phytochemicals into smaller compounds (via gut microbiota preabsorption) and alter their functional groups (phase-I and -II detoxification systems postabsorption). Therefore, these metabolites may, in fact, be the putative compounds responsible for some or all of the observed biological activities in vivo. However, many studies measure the bioavailability of the native phytochemicals, while ignoring the metabolites, for several reasons: (1) most phytochemicals can be converted into many metabolites, which exponentially increases the number of compounds to measure, (2) the profile of metabolites arising from a single phytochemical is often unknown or incomplete, (3) the activities of the native compound are better characterized both in vivo and in vitro, and (4) the native compound serves as a marker for all of its metabolites (albeit an imperfect one). Furthermore, many phytochemicals, particularly phenolics and polyphenols, can be broken down into a similar or even identical suite of metabolites, meaning that distinct native compounds may produce similar bioactive compounds.

Finally, the actual disease-modulating activity of a particular dietary compound may occur in different known and unknown sites in the body. Furthermore, the site where the compound exerts its activity need not be the site of the desired effect. Stimulation of sensory, neurological, endocrine, and immune function by the active compound at one site may result in a significant biological response at another distant site where the active compound either is not present, or is present but does not produce the observed effect locally. Therefore, selection of the site at which bioavailability is to be determined is critical for accurately assessing phytochemical delivery with relevance to specific biological outcomes. Similarly, benefits of phytochemicals are often associated with

population studies that link chronic (multiple doses over extended time periods) dietary patterns of food rich in phytochemicals. However, bioavailability of phytochemicals from foods is typically assessed using only acute (single dose) experimental paradigms that are not reflective of common dietary practices or exposure. Also, bioavailability studies measure the concentration of the phytochemicals(s) of interest in one of several blood fractions (plasma, serum, lipoprotein fraction or whole blood). This has several advantages: (1) it provides a measure of general systemic availability, (2) blood is readily accessible in a healthy clinical study population and does not require highly invasive collection procedures, (3) data from blood bioavailability are in some cases representative of a wide variety of tissues. Blood bioavailability, however, has the disadvantage of not being specific to the desired organ or tissue of interest (unless blood or the circulatory system, i.e., the vasculature or heart, is in fact the site of interest) and may not be representative of chronic dietary exposure for rapidly cleared compounds. Several tissues where venous blood from an extremity is less than ideal for assessing bioavailability include the brain (due to the high selectivity of the blood−brain barrier), kidneys (urine may be a better marker), adipose tissues (where lipid-soluble compounds may accumulate over chronic exposure), and the intestines (due to flow of absorbed dietary components from the intestines to the liver prior to entering systemic circulation). These limitations should be considered when planning and interpreting bioavailability studies.

C Measurement of Bioavailability

The bioavailability of dietary phytochemicals is commonly assessed through characterization of their acute absorption and distribution, otherwise termed "pharmacokinetic (PK) behavior," following ingestion. PK refers to the kinetics (concentration with respect to time) of the phytochemical's appearance in and subsequent clearance from circulation, typically measured in a desired blood fraction. Typically, PK data are obtained by measuring the concentration in a blood fraction following an acute dose at several time points, starting with baseline (time of ingestion, where concentration is essentially zero), and continuing until the compound has been cleared from circulation (concentration returns to zero). Studying PK from baseline to clearance is more accurate and less biased than collecting data at a single time point following acute or chronic dosing. PK parameters may then be calculated from the concentration-time data based on several distinct mathematical models. Bioavailability can also be assessed by quantifying delivery to a specific target tissue, as opposed to blood, as a function of time. However, most tissues are difficult to collect for these purposes, due to the destructive and invasive nature of tissue sampling.

PK calculations and comparisons are of interest as a means to quantify phytochemical availability for delivery to target tissues and subsequent bioactivity and the adaptability of these parameters to chronic exposure or under specific disease conditions. While PK calculations can be complex, typically four main parameters are observed in the literature: C_{MAX}, T_{MAX}, AUC, and $t_{1/2}$ (Fig. 15.1). C_{MAX} refers to the maximal concentration obtained in the blood fraction during the specified experimental period. The magnitude of C_{MAX} indicates the maximal concentration to which tissues may be exposed; higher C_{MAX} values are commonly desirable for improved delivery to tissues with additional endothelial barriers such as brain. T_{MAX} refers to the time at which C_{MAX} was observed. Smaller T_{MAX} values indicate more rapid absorption and appearance in the blood. AUC (area under the curve) represents the calculated area (in units of concentration × time) under the concentration (y-axis) versus time (x-axis) curve. AUC is typically the best comprehensive measure of bioavailability (total systemic exposure), as it reflects both concentration and time and accounts for the entire shape of the PK curve. The elimination half-life, $t_{1/2}$, reflects the time required for 50% clearance (excretion and/or degradation) from the blood fraction (calculated as the time between C_{MAX} and ½ C_{MAX}). Smaller $t_{1/2}$ values indicate rapid clearance from the blood, which may limit exposure and efficacy. These parameters are used to quantify the bioavailability and clearance of selected compounds of interest from circulation. The parameters above reflect absolute bioavailability (where bioavailability is assessed by a single delivery method). For dietary phytochemicals, absolute bioavailability is assessed by oral administrations. Another

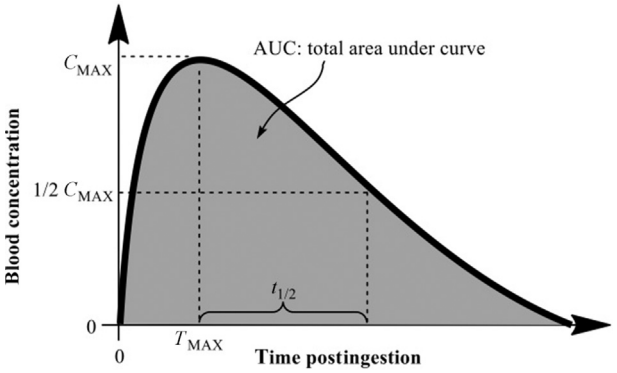

FIGURE 15.1 Illustration of PK parameters used to assess systemic bioavailability of dietary bioactive compounds: C_{MAX} (the maximal concentration obtained in the blood), T_{MAX} (the time at which the maximal blood concentration occurs), AUC (area under the concentration × time curve), and $t_{1/2}$ (the elimination half-life, which is the time required for 50% clearance from the blood).

parameter of interest is relative bioavailability, determined as a ratio by comparing the AUC or C_{MAX} values obtained by two different administration routes. Typically, bioavailability from oral administration is expressed relative to that obtained from intravenous (i.v.) injection. Oral bioavailability is typically lower than i.v. bioavailability, as i.v. injection bypasses several limiting processes (digestive release and solubility, etc.), absorptive barriers (intestinal epithelium), and metabolizing tissues (first-pass metabolism by intestinal epithelium and liver) encountered by orally delivered phytochemicals.

II BIOAVAILABILITY OF WATER-SOLUBLE COMPOUNDS

A Polyphenols

Polyphenols are a structurally diverse group of compounds that contain multiple phenol functional groups (a hydroxyl group bonded to an aromatic ring) [18]. Thousands of polyphenolic compounds are distributed in fruits, vegetables, and beverages such as tea and coffee. These compounds comprise several broad structural classes that each has closely related subclasses of compounds with differing oxidation states and/or substitution patterns [18]. Polyphenolic compounds are divided into four principle structural classes: phenolic acids, stilbenes, lignans, and flavonoids [18]. This section will focus specifically on the phenolic acids and flavonoids due to their dietary prevalence.

1 Phenolic Acids

Phenolic acids are the simplest polyphenols in terms of chemical structure. Phenolic acids are carboxylic acids derived from either benzoic or cinnamic acid skeletons (Fig. 15.2). Predominant dietary phenolic acids and their sources are listed in Table 15.3 [18–21].

2 Flavonoids

Flavonoids are composed of two phenyl rings linked by a propane bridge to form an oxygenated heterocyclic ring with a benzo-γ-pyrone structure, resulting in the

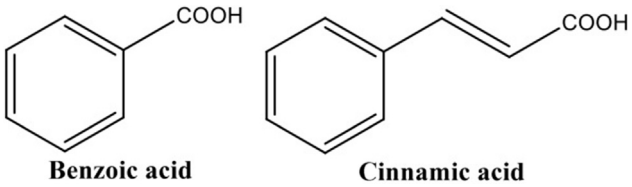

FIGURE 15.2 Structures of benzoic acid and cinnamic acid, the backbones of phenolic acids.

TABLE 15.3 Major Dietary Sources of Water-Soluble and Lipid-Soluble Phytochemicals

Class	Subclass	Representative Compounds	Food Sources
Phenolic acids	Benzoic acids	Gallic acid, protochatechuic acid, hydroxybenzoic acids	Tea, berries
	Cinnamic acids	Chlorogenic acid, coumaric acids, caffeic acids, ferulic acids	Coffee, berries, cherries, apples, cereal grains
Flavonoids	Anthocyanins	Cyanidin, delphinidin, malvidin, pelargondidin, petunidin, peonidin	Grapes, berries
	Flavonols	Kaempferol, myrecitin, quercetin	Apples, onions, leeks, broccoli, tomato
	Flavan-3-ols	Catechins, procyanidins	Tea, grapes, chocolate, apples, berries
	Flavanones	Hesperitin, naringenin, eriodictyol	Citrus and citrus products
	Flavones	Apigenin, luteolin	Green leafy herbs and spices, peppers
	Isoflavones	Daidzein, genestein, glycetin	Soybeans, legumes
Carotenoids	Xanthophylls	Lutein, zeaxanthin, β-cryptoxanthin	Green leafy vegetables, other green vegetables
	Carotenes	α-Carotene, β-carotene, lycopene	Tomatoes, red vegetables, yellow/orange vegetables
Tocochromanols	Tocopherols, tocotrienols	α-, β-, γ-, and δ-Tocopherols and tocotrienols	Nuts, seeds, plant oils, green leafy vegetables, cereal grains
Curcuminoids		Curcumin, desmethoxycurcumin, bis-desmethoxycurcumin	Turmeric, mustard

characteristic C6-C3-C6 flavan skeleton with three rings (Fig. 15.3) [19,22–25]. The A- and B-rings are benzenes, and the C-ring is the central pyran heterocycle. Flavonoids are divided into subclasses based upon the oxidation state, substitution pattern, and functional group composition of the C-ring as well as the nature of the B–C ring linkage [18,19,24,25]. The six major classes of flavonoids are the anthocyanins, flavonols, flavan-3-ols, flavanones, flavones, and isoflavones (Fig. 15.4) [18,19,22,23]. Predominant plant-derived flavonoids and key dietary sources are listed in Table 15.1 [18–21].

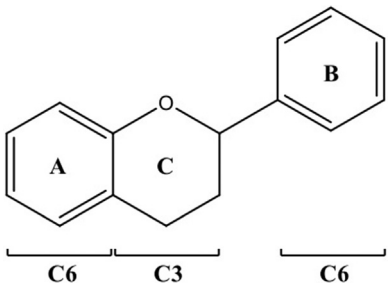

FIGURE 15.3 The C_6–C_3–C_6 three ring flavan skeleton characteristic of flavonoids.

B Bioavailability of Polyphenols

1 Absorption

Ingested polyphenols are present in the gastrointestinal lumen (inner cavity) and technically remain outside of the body until they have been absorbed through the gastrointestinal epithelia. The majority of intact polyphenol absorption occurs in the upper small intestine, with subsequent absorption of major microbial metabolites in the lower intestine. In order for dietary polyphenols to be absorbed in the small intestine, they must first be made bioaccessible. Bioaccessibility is defined as presentation of the compound to the luminal (apical) absorptive surface of intestinal epithelial cells (enterocytes). The bioaccessible fraction (or % bioaccessibility) is the fraction of the consumed phytochemical dose that is extracted from a food during digestion and made accessible and available for absorption by enterocytes.

Several factors determine polyphenol bioaccessibility. First, to be absorbable, polyphenols must be released from molecular interactions with other food components (such as protein, fiber, and lipid) as well as bulk-phase physical interactions with the food matrix. During digestion, polyphenols are released from the food matrix by mechanical action such as chewing and grinding in the

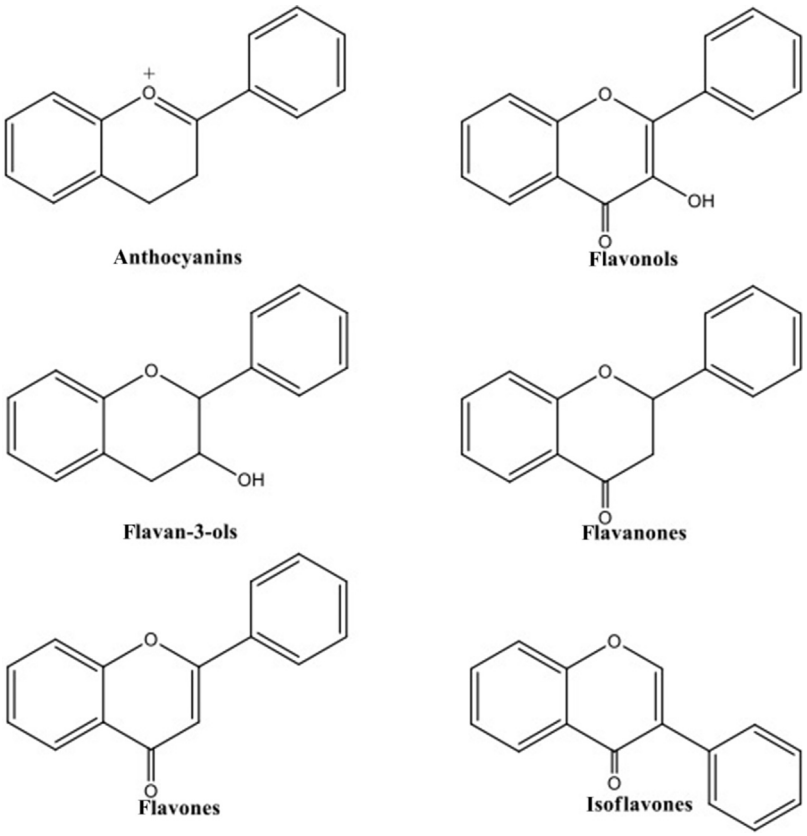

FIGURE 15.4 Basic structural features of the six major subclasses of flavonoids.

oral cavity. Further digestive release continues in the stomach and small intestine due to the action of gastric acid as well as a variety of gastric and intestinal enzymes that hydrolyze lipids, proteins, and carbohydrates. The breakdown of the physical food macrostructure, as well as disruption of molecular interactions between phytochemicals and food components, frees the polyphenols to diffuse into the aqueous milieu of the gastrointestinal tract. Secondly, stability of phenolics in the gastrointestinal tract will affect the concentration available to the intestinal epithelia [26]. Saliva, gastric juice, and intestinal secretions contain a wide array of enzymes designed to degrade food components (pepsin, trypsin, esterases, lipases, amylases, etc.), as well as wide pH variations, that may affect the amount of the ingested dose that remains intact during digestion. Thirdly, polyphenols must be soluble in the bulk aqueous phase, in the gastrointestinal milieu, in order to facilitate the final step: diffusion across the unstirred water layer that protects the absorptive enterocyte surface [27]. Only the fraction of the ingested dose that meets these criteria of stability, release, solubility, and diffusion will be available for absorption (i.e., bioaccessible) (Fig. 15.5). The fractional bioaccessibility varies greatly between polyphenols, depending on the compound, and the nature of the food matrix (macronutrient composition, physical form, etc.) and the whole meal [28].

The portion of the ingested polyphenol dose that reaches the surface of the small intestine is then available for absorption into the enterocytes and subsequent transport to circulation. Identification of specific transport systems for polyphenols remains an active area of research. Intestinal uptake of several polyphenol classes has been attributed to the action of transporters, including monocarboxylic acid transporter, sodium dependent glucose transporter 1, glucose transporter 2 as well as by passive diffusion [29–31] and possible paracellular transport (through spaces between cells). Polyphenols may compete for transport with other polyphenols as well as macronutrients such as glucose, making the process somewhat inefficient [32]. Passive diffusion appears to contribute significantly to absorption of some flavonoids (e.g., isoflavones, flavanones), as the lipophilicity (log P) appears to highly correlate to intestinal permeability and these flavonoids have a high log P value [29]. However, passive transport is a minor contributor to the absorption of others, particularly those which are highly hydroxylated or glycosylated and thus have lower (i.e., more water-soluble) log P values (e.g., flavan-3-ols, anthocyanins, etc.).

Typically, only a small fraction (<20%) of the oral polyphenol dose is absorbed in the small intestine and transported into circulation. One reason for this inefficiency is that enterocytes act as the first barrier against xenobiotics due to their barrier function as well as through the action of efflux transporters. These transporters limit cellular accumulation and transepithelial transport of xenobiotics (and hence, systemic distribution), by inhibiting their initial uptake and then actively removing them from the cell interior and returning them to the lumen, or transporting them to interstitial space, or into the bloodstream. Efflux of polyphenols by enterocytes appears to be facilitated by members of the ATP-binding cassette superfamily of transmembrane transporters, specifically P-glycoprotein (Pgp) and multidrug resistant

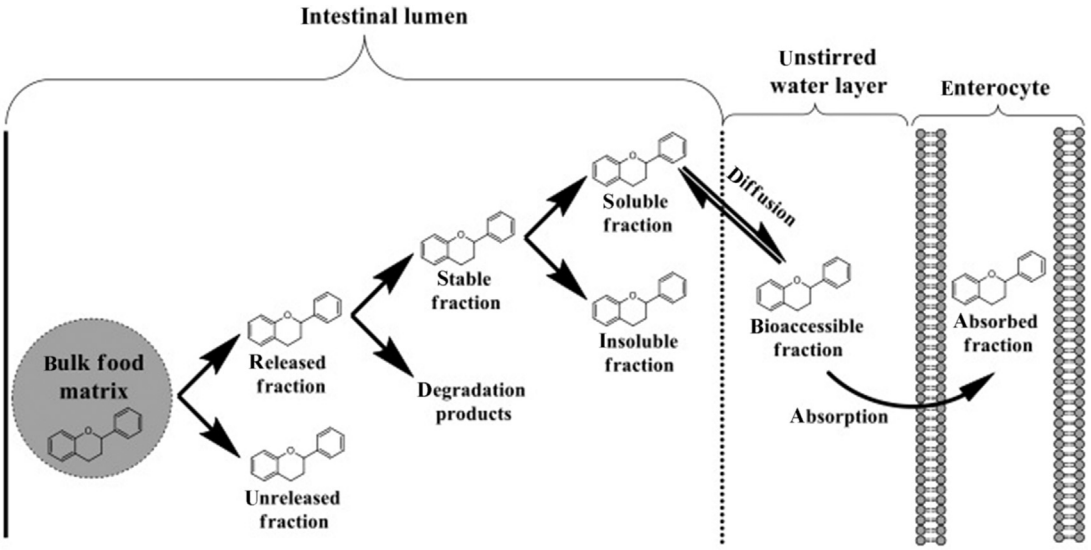

FIGURE 15.5 Digestive and absorptive processes involved in the bioaccessibility of polyphenols.

proteins (MRPs) 1 and 2 [33,34]. This active efflux of xenobiotics has been termed Phase-III metabolism. Pgp and MRP2 are apical transporters that efflux xenobiotics back into the intestinal lumen rather than into the blood stream [30]. MRP1 is expressed on the side of the basal lamina and provides access to the bloodstream via the mesenteric veins on the serosal side of the intestinal epithelia. From the mesenteric veins, these compounds enter the portal vein and are circulated into the liver.

2 Metabolism and Excretion

As xenobiotics, polyphenols are substrates for the body's inducible detoxification system. This system reduces the potential toxicity of foreign compounds by metabolizing them to compounds that are more readily excreted or have reduced biological activity. This detoxification system consists of three primary activities, called phase I, phase II, and phase III metabolism. Phase I metabolism is performed by members of the cytochrome p450 (CYP) superfamily of enzymes, and typically involves hydroxylation. The addition of a hydroxyl group is a functionalization step that renders xenobiotics more reactive to subsequent metabolism, such as phase II. Due to their hydroxylation, polyphenols are not typically substrates for phase-I activation by most CYP phase-I detoxification enzymes [35,36].

Phase II metabolism involves conjugation reactions whereby a hydroxyl group on the xenobiotic is modified by addition of a sulfate, glucuronic acid, or methyl group. Glucuronidation is carried out by uridine diphosphate glucuronyl-transferase (UDPGT), sulfation is carried out by sulfotransferase (SULT) or phenol-sulfotransferase (PST), and O-methylation is carried out by catechol *O*-methyl transferase (COMT) [33,35,37,38]. These reactions can typically occur at any phenol group on the molecule. The products of these reactions can also be substrates for further phase-II metabolism, resulting in the generation of multiple conjugated and/or methylated products. These reactions decrease the potential toxicity of xenobiotics, and facilitate their excretion into bile and/or urine by the liver and kidneys, respectively [35]. Structures of predominant phase-II metabolites of a representative flavonoid are shown in Fig. 15.6. Polyphenol readily undergoes phase-II conjugation in a variety of tissues, particularly the intestinal epithelium, liver, and kidneys.

Polyphenols absorbed from the intestinal lumen by enterocytes are mostly subjected to phase-II detoxification reactions in the cell interior, which is a common site of phase-II metabolism of these compounds in the body.

It is important to note that some phytochemical-rich plants, including foods and herbs, are known to drastically affect the expression and activity of xenobiotic

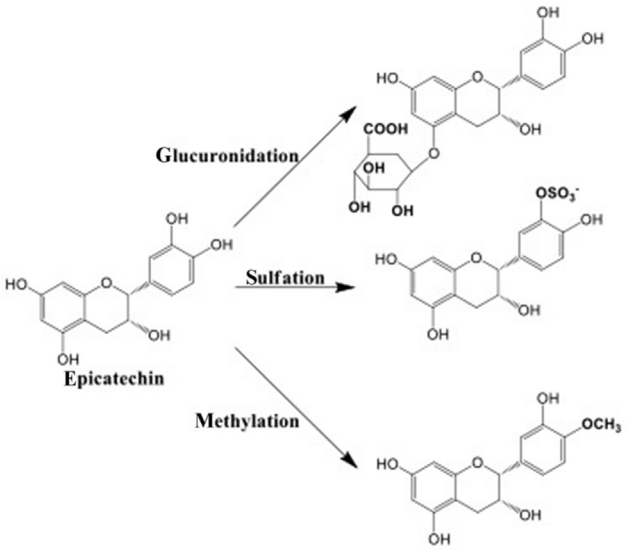

FIGURE 15.6 Structures of selected phase-II metabolites of a representative flavonoid compound [(−)-epicatechin]. Conjugation may occur at a variety of positions on the molecule. Polyphenols may also undergo multiple phase-II modifications on the same molecule.

detoxification systems [39−42]. For example, grapefruit flavanones inhibit detoxification pathways, while phytochemicals from St. John's wort significantly upregulate detoxification pathways. These activities can significantly affect the bioavailability of phytochemicals and pharmaceuticals. Pharmaceutical doses are designed to deliver drugs within their therapeutic window (the range between the minimum effective level and minimum toxic level). Changes in pharmaceutical bioavailability can result in concentrations outside the therapeutic window, often resulting in serious health complication, including death. Upregulation of detoxification can reduce blood levels of pharmaceuticals to below their effective concentration, resulting in loss of efficacy for antirejection drugs for transplant patients, chemotherapeutics for cancer patients, and so on. Conversely, inhibition of detoxification can lead to greater than anticipated blood levels of pharmaceuticals, potentially leading to toxic levels of drugs such as digoxin.

Finally, phase III metabolism involves the efflux of both native xenobiotics and their phase I/II metabolites from enterocytes to lower their intracellular concentration. The phase-II conjugates formed in the enterocytes appear to be efficiently transported into the interstitial space and bloodstream by MRP1 and into the gut lumen by MRP2, but do not appear to be effectively transported by Pgp [33,34,43,44]. Like the native compounds, phase-II conjugates effluxed into the blood stream enter the mesenteric veins and are circulated into the liver by the portal vein prior to systemic circulation.

From intestinal tissues, both native compounds and phase-II metabolites secreted into the bloodstream are passed to the liver through the portal vein. The liver is another key site of extensive xenobiotic metabolism, including phase-II metabolism. Studies have indicated that the activity of COMT is highest in the liver [33,38,45,46]. The liver also possesses strong glucuronidation and sulfation activity from UDPGT and SULT, respectively [33]. The metabolism of dietary xenobiotics in the enterocytes and liver is termed "first pass" metabolism, as this is where absorbed compounds are often first exposed to metabolism prior to entering general circulation.

Circulating forms of polyphenols are largely extracted from the bloodstream by the kidneys and excreted in urine [47]. Glucuronides and sulfates appear to be more readily excreted into the urine than the native forms [48,49]. In addition to urinary elimination, native polyphenols and their O-methylated forms are secreted from the liver into bile, either by first-pass or subsequent metabolism, and appear in feces [50–52]. Excreted compounds may be reabsorbed by the intestines, a phenomenon known as enterohepatic recycling.

The majority of the studies indicate that the total small intestinal absorption of dietary polyphenols is relatively poor, typically accounting for 0.3–43% of the total amount ingested depending on the compound, with most values at the extreme lower end of this range [53]. Therefore, the majority of the ingested dose passes through the small intestine unabsorbed, and reaches the colon. The colon harbors a complex bacterial community comprised of over 500 species, mainly anaerobes of the groups *Bacteriodes*, *Eubacterium*, *Bifidobacterium*, *Fusobacterium*, *Peptostreptococcus*, and *Atopobium* [54–56]. These bacteria reside in both the lumen and the epithelium/mucosa of the colon. The bacterial load of the colon is extremely high, with 10^9–10^{12} cells/g luminal contents, and bacteria can comprise up to 60% of fecal matter by dry weight [57]. Colonic bacteria essentially possess the metabolic potential of an organ, and perform numerous functions critical to the health of the host, including competition versus invasive pathogens, salvage of unabsorbed energy, stimulation of immune function, and control of colonocyte differentiation and proliferation [57–59]. The varied metabolic capacity of colonic bacteria results in extensive fermentation of unabsorbed material. Studies have consistently demonstrated that the colonic bacteria metabolize polyphenols to many simpler metabolites. Similar to native compounds, these metabolites may be absorbed, subjected to xenobiotics metabolism, and excreted. Microbial metabolites may account for many of the reported bioactivities of dietary polyphenols in vivo.

The contribution of colonic fermentation products to overall bioavailability of polyphenols is illustrated well by the flavan-3-ols. Both monomeric flavan-3-ols (catechins) and their oligomeric/polymeric forms (procyanidins) have modest net small intestinal absorption. Typical reports indicate that systemic bioavailability of intact flavan-3-ols is generally poor (<25%), with most studies reporting from 0.1% to 10% of the ingested amount for C, EC, EGC, and EGCG and their phase-II conjugated metabolites [20,45,60–64] and much less for procyanidins (0.3–4%) [65–69]. These data suggest that a large portion of the ingested dose of these compounds is not absorbed in the small intestine but rather reaches the colon and its associated microflora as native compounds or as phase-II metabolites [20,45,70].

Polyphenol glycosides found in many foods and polyphenol conjugates, produced by phase I/II metabolism and apical efflux by enterocytes, are hydrolyzed by colonic microbiota to generate absorbable native polyphenols [71,72].

3 Microbial Metabolism

The result of the poor absorption of many phenolics in the small intestine is that the majority of an oral dose will reach the colon [73,74]. Thus, many of the benefits of dietary phenolics may occur in the gastrointestinal tract [18], with the major point of exposure as the large intestine and its resident microbiota [54–56].

Unabsorbed phenolics that reach the colon are metabolized by the colonic microbiota into several smaller constituents such as simpler flavonoids (from polymerized flavonoids), γ-valerolactones, phenolic acids, and so on [75–77]. For example, predominant microbial metabolites generated from flavan-3-olsols are 5-(*m*, *p*-hydroxyphenyl)-γ-valerolactone, 2-(*m*, *p*-hydroxyphenyl) acetic acid, 2-(*p*-hydroxyphenyl) acetic acid, 2-(*m*-hydroxyphenyl) acetic acid, 3-phenylpropionic acid, 3-(*m*-hydroxyphenyl) propionic acid, 3-(*p*-hydroxyphenyl) propionic acid, 3-(*m*-hydroxyphenyl) valeric acid, ferulic acid, isoferulic acid, vanillic acid, *m*-coumaric acid, *p*-coumaric acid, caffeic acid, gallic acid, and hippuric acid. Structures of a selection of these compounds are shown in Fig. 15.7A. Monomers are metabolized directly into smaller phenolic compounds, while larger compounds must first be broken into smaller degree of polymerization (DP) compounds [76,78]. Furthermore, larger metabolites are then metabolized into smaller and smaller compounds.

Due to the one-way nature of the GI tract and the progressive metabolism of phenolics, gradients of native compounds and their microbial metabolites are likely established along the length of the colon [66] (Fig. 15.7B). However, there are little data regarding distinct profiles present in the lumen of the proximal, mid, and distal colon. Recently, we examined the degradation kinetics of polymerized and monomeric flavanols and

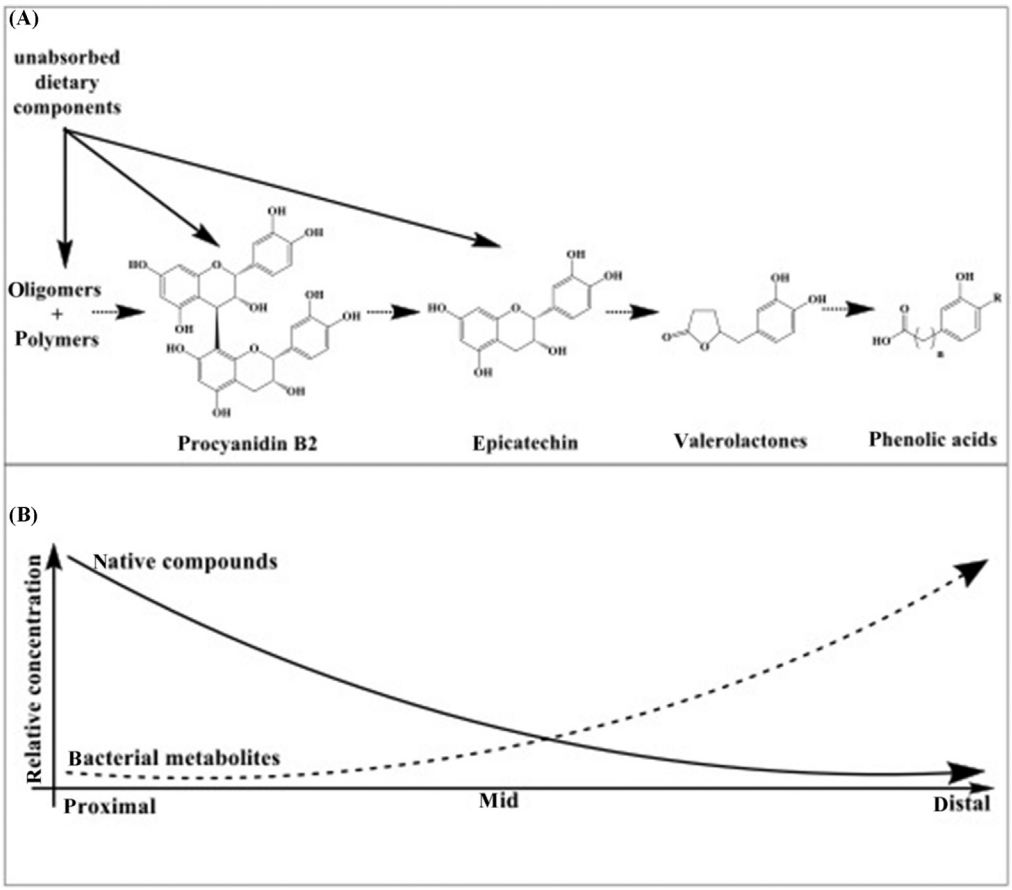

FIGURE 15.7 (A) Highly schematic representation of the colonic metabolism of unabsorbed dietary flavonoids. (B) Representation of the concentration gradients of native flavonoids and their bacterial metabolites that are likely generated along the length of the colon during progressive bacterial metabolism.

formation of their microbial metabolites throughout the length of the lower GI tract in rats [79–81], resulting in several novel findings. The degradation of native species and formation of metabolites appear to occur in all regions of the lower GI tract (cecum, proximal, mid and distal colon). Additionally, all classes of microbial metabolites were formed in each region. This indicates that all regions of the lower GI tract possess the necessary resident bacteria to completely metabolize native flavan-3-ols. Flavan-3-ol metabolism appears to be controlled predominantly by time, as opposed to distinct microbial populations along the lower GI tract. Second, appearance/disappearance kinetics of native compounds and their metabolites in the lower GI tract colon are significantly different: high levels of natives are present early and disappear quickly, while microbial metabolites are present at high levels over longer periods of time.

a Implications of Microbial Metabolism

Flavonoids and other phenolics have been identified as dietary bioactives with potential health-protective activities. Many of these flavonoids have very poor systemic bioavailability. Therefore, circulating concentrations typically represent a small fraction of the ingested dose, whereas the majority reaches the colon unabsorbed. Examples of flavonoids with poor bioavailability include quercetin and procyanidins. Despite poor bioavailability, many of these compounds appear to be effective at preventing or ameliorating chronic disease in vivo, even at low doses. This suggests three possibilities: (1) these flavonoids exert their activities in the gut lumen and epithelium, (2) these flavonoids exert their activities in peripheral tissues even at very low circulating levels, or (3) microbial metabolites of these flavonoids reach circulation and contribute significantly to their observed activities in peripheral tissues. While all three may occur simultaneously, the potential activities of microbial metabolites formed from unabsorbed flavonoids remain poorly understood.

Data suggest that these metabolites are comparatively more bioavailable than their native flavonoid precursors [76,82]. They are absorbed readily from the colon, and in many cases are the predominant circulating compounds

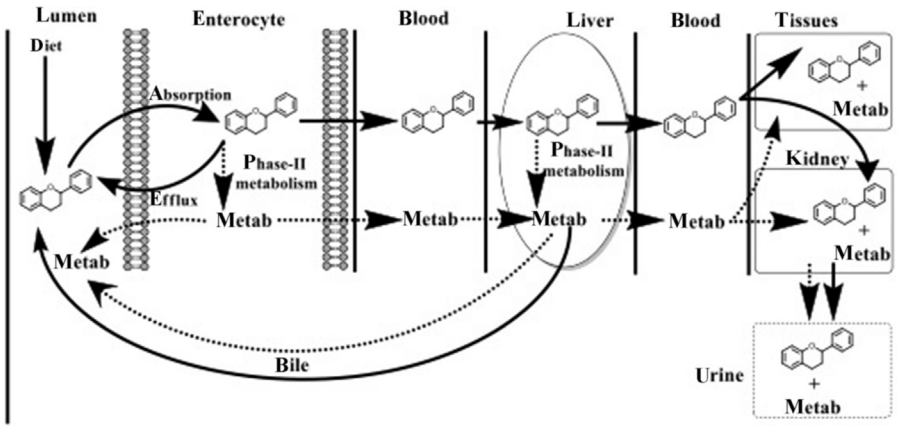

FIGURE 15.8 Schematic representation of processes that affect systemic bioavailability and metabolism of dietary polyphenols. Dotted lines indicate metabolism/metabolites.

derived from of the native flavonoids following flavonoid consumption. While flavonoids have often demonstrated efficacy in models of chronic disease despite poor bioavailability, most studies of flavonoids continue to focus on elucidating the activities, and improving the bioavailability, of the native compounds. The formation and absorption of the microbial metabolites has been extensively characterized, but comparatively little work has been done to characterize the effects of these metabolites in cell or animal models. The potential bioactivities of microbial metabolites have been identified as the potential "missing link" to explain the health benefits of flavonoids with limited bioavailability [83,84]. However, for various reasons, little work has been done yet to make this connection. Understanding these activities may demonstrate a key mechanism by which dietary flavonoids exert their observed effects.

A schematic of the bioavailability of polyphenols, encompassing the factors discussed above, is shown in Fig. 15.8.

b Additional Consideration in Assessment of Phenolic Bioavailability

Polyphenol bioavailability and metabolism is often experimentally assessed after acute oral doses in humans and experimental animals. However, recently there has been increasing awareness that long-term or chronic exposure to polyphenols more closely resembling dietary interventions may alter absorption and metabolism of these compounds, presumably by modifying enterocyte and/or liver physiology, including induction of distinct epithelial barrier function and transport and metabolizing systems. An increase in small intestinal absorption of flavonoids from foods and dietary supplements including green tea and grape seed extract has been documented with as little as 10 days of repeated exposure to oral doses in humans or animals [85,86]. Additional changes in patterns of flavonoid metabolism have been documented, including alteration of glucuronidation and methylation [87]. With inducible transport and metabolizing systems at play, consideration of and controlling for dietary patterns and polyphenol exposure should be included in any assessment of phenolic bioavailability from foods.

It is equally important to consider underlying health conditions that also impact phenolic absorption and metabolizing systems in the gut. For example, both obesity and diabetes are conditions that have been associated with enhanced inflammation [88,89] as well as altered GI motility, GI permeability, hormone secretion, and other factors that may modulate key xenobiotic processes [90–94]. As these at-risk populations are targets for polyphenol-based dietary strategies to promote health, changes in xenobiotic processing due to disease may lead to modification of phenolic absorption and ultimate efficacy. Diabetes is known to alter gastric emptying and motility, as well as expression of phase II xenobiotic enzymes key to generation of biologically relevant glucuronide and sulfate metabolites, including increased UDP-glucuronosyltransferase (UGT1A1) and decreased expression of sulfotransferases (SULT2A1) in experimental models of disease [95,96]. Ongoing research is beginning to define how these changes may potentially impact the design and implementation of long-term dietary strategies and recommendations to promote health in obese or diabetic human populations.

III LIPID-SOLUBLE COMPOUNDS

A Key Classes of Lipid-Soluble Phytochemicals

As described earlier, three main classes of lipid-soluble phytochemicals are predominant in commonly consumed fruits, vegetables, and spices: carotenoids, tocochromanols, and curcuminoids. The carotenoids are bright yellow and orange plant pigments characterized by their 40-carbon structures derived from the 5-carbon precursor

molecule isoprene. As such, carotenoids are long-chain hydrocarbons with highly conjugated double-bond systems, and bilateral or near bilateral symmetry around a central bond [10,97,98]. Carotenoids are further classified based on the presence or absence of end cyclization (e.g., straight-chain lycopene vs cyclized α- and β-carotenes) and the presence or absence of oxygen (strict hydrocarbons such as lycopene and β-carotene are called carotenes, while oxygenated carotenoids such as lutein and zeaxanthin are called xanthophylls; Fig. 15.9) [10,97,98].

The tocochromanols (Fig. 15.9), or vitamin E compounds, are isoprenoids-based amphipathic molecules, with a polar chromane ring head and a nonpolar 16-carbon phytyl tail [99–102]. Tocochromanols have varying methylation patterns in the chromane group, designated as the α−, β−, γ−, δ-tocochromanols. Tocochromanols are comprised of two distinct classes: the tocopherols and the tocotrienols. Tocopherols have a saturated phytyl tail, while tocotrienols have three double bonds in the phytyl tail. Therefore, tocopherols have three chiral centers and can exist as eight stereoisomers (naturally-occurring α-tocopherol is in the all-*R* configuration, while synthetic α-tocopherol is all-*racemic*, or an equal mixture of all eight stereoisomers). Due to the phytyl unsaturation, the tocotrienols have only one chiral center and two stereoisomers (naturally-occurring tocotrienols have the *R* configuration at carbon 2, and *trans*-double bonds at carbons 3′ and 7′).

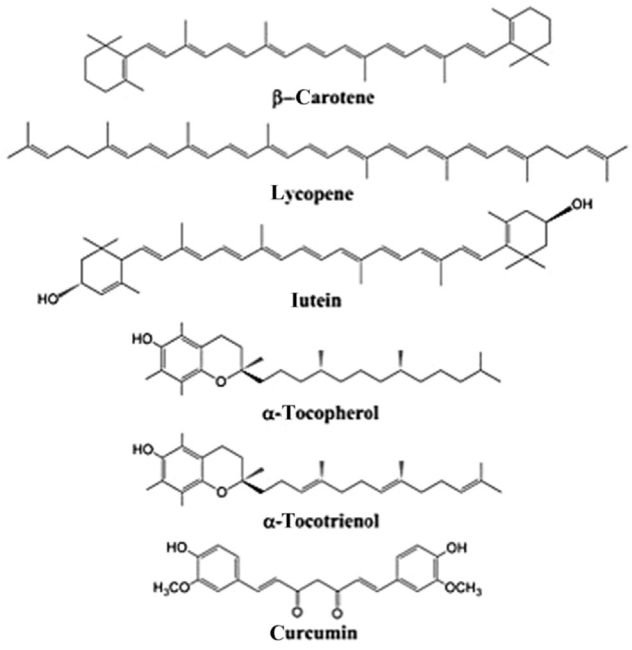

FIGURE 15.9 Structures of lipophilic phytochemicals from various classes: carotene carotenoids (β-carotene and lycopene), a xanthophyll carotenoid (lutein), a tocopherol tocochromanol (α-tocopherol), a tocotrienol tocochromanol (α-tocotrienol), and a curcuminoid (curcumin).

The curcuminoids are diarylheptanoids (two aryl rings linked by a 7-carbon chain). The curcuminoids have varying functional group substitutions on the aryl rings (hydroxy, methoxy, and sulfate and sugar groups), and the aryl rings may be symmetrical or different. Curcuminoids also may have distinct 7-carbon chain patterns (unsaturation, oxo groups, enone groups, 1,3-diols, 1,3-diketones, and cyclization), with all double bonds in the *trans*-configuration. The main curcuminoids in the diet are curcumin, demethoxycurcumin, and bisdemethoxycurcumin, which have the 1,3-diketone chain and differ by the number of aryl rings having a methoxy group (both, one, and neither, respectively) (Fig. 15.9). Although curcuminoids are not isoprenoids, their poor solubility in water and their digestive properties classify them as lipid-soluble phytochemicals.

B Bioavailability of Lipid-Soluble Phytochemicals

As with the water-soluble compounds, only the bioaccessible fraction of any lipid-soluble phytochemical that is ingested will be available in the small intestine for subsequent absorption. However, factors governing the bioaccessibility of lipid-soluble phytochemicals are dependent on the ability of the digestive process to solubilize these highly hydrophobic compounds in the aqueous milieu of the gastrointestinal tract lumen. Solubilization in the gut lumen is highly dependent on coconsumed lipid in the form of triacylglycerols, which, once digested, facilitate formation of bile salt lipid micelles (Fig. 15.10).

1 Bioavailability and Metabolism of Carotenoids

With the established provitamin-A activity of plant-derived carotenoids (α-, β-carotene and β-cryptoxanthin specifically), carotenoid bioavailability has been extensively studied [103]. Digestive release and bioaccessibility represent significant obstacles to carotenoid bioavailability. First, the carotenoids must be released from physical entrapment in the bulk food matrix in order to become bioaccessible [103,104]. For plant tissues, this involves disruption of the plant cell walls and organelles containing the carotenoids [105]. Thus, food processing, such as heating, mechanical breakdown, etc., can significantly increase carotenoid bioavailability simply by increasing the amount able to be released from the food matrix during the normal digestive process [105]. Following digestive release in the stomach and upper small intestine, the hydrophobic components aggregate, due to their poor aqueous solubility, to form crude lipid emulsion droplets in the gastric chyme, which

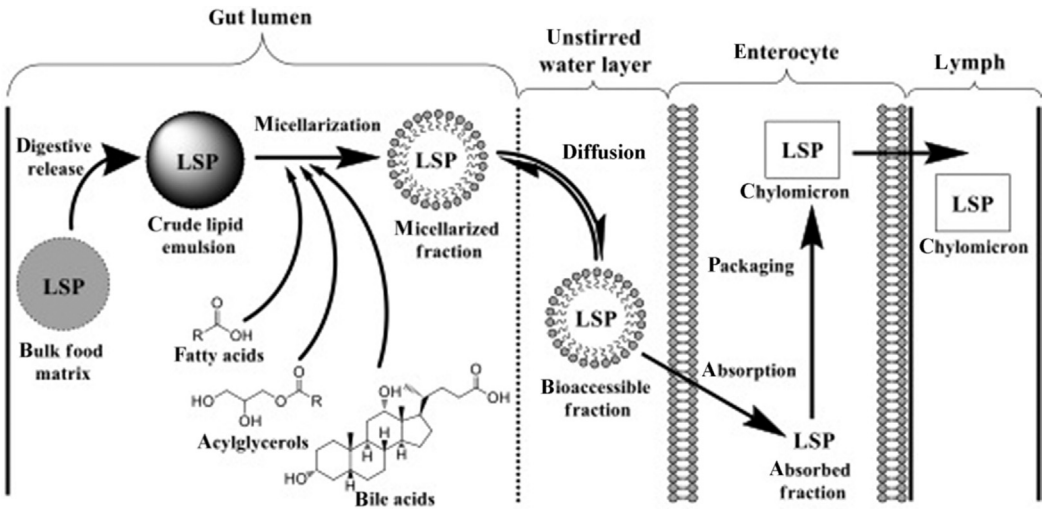

FIGURE 15.10 Schematic representation of processes impacting systemic bioavailability and metabolism of dietary lipophilic compounds.

progressively become smaller as mechanical disruption continues [104]. The carotenoids are then partitioned into mixed micelles in the small intestine. Mixed micelles are heterogeneous aggregates with hydrophilic exteriors and hydrophobic interiors, composed of bile salts, fatty acids, mono- and diacylglycerols, cholesterol, carotenoids, tocochromanols, and so on [98,104,106]. The formation of micelles allows carotenoids to be soluble in the hydrophobic interior while the micelle crosses the unstirred water layer at the intestinal epithelial surface. Carotenoids that escape micellarization are not typically bioaccessible, and remain unabsorbed [103–106]. Due to their relative polarity, xanthophylls (oxygenated carotenoids) are more readily micellarized than apolar carotenes, and are hence generally more bioaccessible [103].

Coconsumption of dietary fat has consistently been shown to improve carotenoid absorption [107–113]. Fat intake stimulates secretion of bile salts and lipases during digestion, and also provides essential components for the formation of mixed micelles (phospholipids, acylglycerols, fatty acids). Fat also assists in extracting carotenoids from the food matrix into the crude lipid emulsion during processing and digestion. Coingestion of 3–5 g fat is thought to provide optimal carotenoid absorption from a meal, and long-chain dietary fatty acids enhance absorption more than short- and medium-chain fatty acids [98,104,106]. However, the threshold value of coconsumed lipid required for efficient carotenoid absorption is still the subject of active investigation.

Upon diffusing across the unstirred water layer, mixed micelles come into contact with the intestinal epithelium, where the micelles are disrupted and the carotenoids are released onto the epithelial surface and then absorbed into the enterocytes by both passive and facilitated diffusion processes. Transporters participating in facilitated carotenoid diffusion include SR-B1, CD36, and NPC1L1 [103,104]. Once inside the enterocytes, carotenoids are transported to the Golgi apparatus with the assistance of fatty acid binding protein (FABP), where they are incorporated into chylomicron particles along with other lipid-soluble compounds and fatty acids and apoprotein B-48 [103]. These chylomicrons are then secreted into the lymphatic system for transport through the thoracic duct and subclavian vein to the liver [104]. During transport, chylomicrons are disrupted by the action of lipoprotein lipase in the vascular compartment, and the resulting chylomicron remnants are taken up by the liver [105]. In the liver, carotenoids are repackaged into very low-density lipoproteins (VLDL) for systemic export. VLDLs are subsequently converted into low-density lipoproteins (LDL) and then high-density lipoproteins (HDL) [103]. The apolar carotenes are believed to reside at the interior of these lipoproteins, while the more polar xanthophylls reside on the exterior [103,105]. During the conversion of VLDL to LDL and HDL, LDL becomes enriched in carotenes while HDL becomes enriched in xanthophylls [103].

The intestinal and hepatic metabolism of provitamin-A carotenoids to retinol as well as conversion of other carotenoids (lycopene, etc.) is the subject of intensive investigation beyond the scope of this chapter [104]. While carotenoids are not generally not metabolized by the classic Phase-I, and -II xenobiotic detoxification pathways, information on generation of apo-carotenoids through cleavage of intact species by BCO1 and BCO2 is yielding insight into factors that impact bioavailability and ultimate disease preventative activities of these plant pigments [114–116].

2 Bioavailability and Metabolism of Tocochromanols

Processes governing bioavailability of tocochromanols appear to be similar to carotenoids [117,118]. Tocochromanols must be released from the bulk food matrix, micellarized, and presented onto the enterocyte surface for absorption, and dietary fat plays a crucial role in this process as for carotenoids [117–122]. The absorption of tocochromanols occurs through both passive and facilitated diffusion, with the potential involvement of SR-BI [118,119,123]. In the enterocytes, tocochromanols are assembled into chylomicrons with the assistance of microsomal triglyceride transport protein, and secreted into the lymph [118,123]. Additionally, some fraction may be exported directly into portal circulation via HDL [118,119,123]. The liver absorbs chylomicron remnants, and tocochromanols are then repacked into VLDL for systemic distribution [102,119]. The majority of circulating tocochromanols reside in LDL and HDL, from which they are quickly deposited into tissues with the assistance of lipoprotein lipase [119]. In cells, tocochromanols are incorporated into cell membranes as antioxidants, and are not generally metabolized by the xenobiotic detoxification systems.

3 Bioavailability and Metabolism of Curcuminoids

Less is known regarding the bioavailability of curcuminoids compared to carotenoids and tocochromanols. Due to their observed effects in vitro via a wide assortment of mechanisms, there is great interest in their potential preventive and therapeutic activities, including: antimicrobial, antioxidant, antiinflammatory, anticarcinogenic, antithrombotic, neuroprotective, antirheumatic, and hypoglycemic activities [16,17,124–126].

Curcuminoids are hydrophobic polyphenols, with poor solubility in water [17,124,127], leading to poor intestinal solubilization and extremely low gut absorption and bioavailability relative to other polyphenols and also the lipid-soluble phytochemicals. The majority of an oral curcumin dose is not absorbed, but is excreted intact in feces (which also indicates limited metabolism by colonic microbiota) [17,124,125]. In many cases, native curcumin and its metabolites are present at levels near or below the analytical limit of detection in human blood fractions or urine following oral ingestion of gram quantities of curcuminoids [17,124]. The small fraction of curcumin that is absorbed is rapidly biotransformed by reduction reactions (to tetrahydro- and hexahydrocurcumin derivatives), as well as conjugated to sulfates and glucuronides, in the intestinal mucosa, liver, and kidneys [124,127–129]. The low levels of curcumin detected in blood and urine are almost exclusively conjugates of curcumin or reduced curcumin derivatives, and the half-lives of these compounds are exceedingly short due to rapid clearance [124,127–129].

Poor absorption, extensive biotransformation, and rapid elimination pose a major hurdle in exploiting the bioactivities of orally administered curcuminoids [16,17,124,127,129]. Studies of curcumin pharmacokinetics and pharmacodynamics typically rely on doses of gram per kilogram body weight in animals and grams in humans, which are much higher than doses typically employed for other phytochemicals [124,130]. Although curcumin is generally thought to be safe at high doses for short-term use, and has "generally recognized as safe" (GRAS) status in the United States, concerns have arisen over its long-term safety [17,124,127,129,130]. This is of particular importance for long-term use of curcumin as a preventive agent in healthy populations, where toxicity is less acceptable than in therapeutic uses for existing disease.

Several delivery strategies have been developed to improve the bioavailability and efficacy of curcuminoids in vivo. These include (1) coadministration with adjuvants to inhibit metabolism, (2) formulation of nanoparticles targeting delivery of curcumin to specific regions of the GI tract, (3) incorporation of curcumin into micelles, phospholipid complexes, and liposomes to improve diffusion across the unstirred water layer, (4) development of synthetic curcumin analogues with improved solubility, (5) heat-assisted solubilization, (6) synthesis of curcumin prodrugs which yield curcumin upon hydrolysis, and (7) formulation of curcumin metal chelation complexes to improve solubility [16,17,124,127,129–132]. Particularly noteworthy is the use of the adjuvant piperine, which is an alkaloid from black pepper. Coadministration of milligram quantities of piperine with curcumin has been shown to increase the bioavailability of curcumin by up to 2000% [16,124,129,130]. Piperine inhibits phase-II biotransformation and clearance of curcumin, increasing the persistence of native curcumin in circulation [16,124,129,130]. Piperine may also increase gut permeability [133,134]. Concern has recently arisen regarding this adjuvant, as reduced biotransformation of other drugs may result in toxicity due to abnormal accumulation [130].

Curcumin poses a particular challenge for correlating bioavailability to efficacy, as (1) curcumin appears to exert some efficacy even when no native or conjugated curcumin is detectable in blood, and (2) curcumin exerts activities distant from the GI tract, even though this is the primary site of delivery and accumulation. Therefore, the effective dose, active moiety, and mechanisms of action of curcumin remain to be fully characterized in vivo [17,125].

IV SUMMARY

Numerous bioactive phytochemicals are found in commonly consumed plant foods, including fruits, vegetables, beverages, and spices. Their widespread presence in the diet and apparent low toxicity suggest that phytochemicals have the potential to impact human health and disease risk on the population level. Considering this potential benefit, interest in factors affecting their bioavailability from common dietary sources has grown. When considering bioavailability, dietary phytochemicals can be divided into two distinct classes: water-soluble (phenolics and polyphenols) and lipid-soluble (carotenoids, tocochromanols, and curcuminoids). Significant efforts have been placed on the identification of food factors (macro- and microcomposition, physical form, phytochemical concentration, etc.) and in vivo biological factors (digestion, absorption, metabolism, distribution, and excretion processes) which impact bioavailability in humans and experimental animal models. Such knowledge is critical to improve the bioavailability of health-promoting phytochemicals, and to better understand the mechanisms by which they exert their biological activities at target tissues.

Chapter 16

Antioxidants in Health and Disease

Rebecca M. Seifried[1], **Earl Harrison**[2] **and Harold E. Seifried**[3]

[1]Walter Reed National Military Medical Center, Bethesda, MD, United States, [2]Ohio State University, Columbus, OH, United States, [3]National Cancer Institute, Rockville, MD, United States

I INTRODUCTION

Antioxidants are a loosely characterized group of compounds that are defined by their general ability to decrease or delay oxidative reactions. Dietary antioxidants are recognized to have the ability to inhibit the formation of both reactive oxygen species (ROS) and reactive nitrogen species (RNS), which can adversely affect normal cellular processes and physiological functions [1–4]. Under normal conditions, the balance between production and elimination of free radicals is maintained by endogenous enzymes (e.g., glutathione peroxidases, catalase and superoxide dismutases, thioredoxin reductase, and heme oxygenase) and a host of nonenzymatic components (some metals, glutathione, thiols, certain vitamins, and phytochemicals including flavonoids and other phenolics). Many of these components can be influenced by dietary patterns and behaviors [1–4]. Table 16.1 includes a number of these antioxidants with their respective structures and properties.

The range of chemical classes within the antioxidant domain is tremendous and is part of the reason why grouping of compounds by their ability to interact with reactive species (ROS and RNS) can lead to oversimplification and generalization. Hence, descriptors such as "conundrum" and "double-edged sword" are often used to characterize the relationship between antioxidants and health. Part of the controversy stems from the innate properties of ROS as a class of biologically active compounds that can influence both disease prevention and disease promotion. Although the generation of ROS had been viewed as primarily, or solely, detrimental to health, advances in research have demonstrated that ROS can have crucial roles in normal physiological processes, including functioning as growth factors, influencing immunocompetence, and initiating apoptosis in damaged cells. Despite these beneficial functions of ROS, abnormal production or nonhomeostatic regulation of ROS is linked to the development of many chronic diseases and associated conditions, including cancer and cardiovascular disease (CVD), as well as a number of neurological and metabolic diseases.

In consideration of these facts, antioxidants have been highlighted as promising preventative and or therapeutic agents for several of these diseases. Much of this optimism is based on the frequently observed case–control association between diets high in antioxidant-rich fruits and vegetables (and presumably antioxidant exposures) and decreased disease risk. Although there is evidence that antioxidants may offer health benefits in populations that are at increased risk because of environmental or medical conditions, there are many inconsistencies in the literature. Some of this inconsistency stems from different study end points (i.e., mortality, cancer, or CVD occurrence and individual study results vs meta-analysis of several "related" studies) and study design (prospective vs retrospective, the use of food frequency data vs controlled dietary or purified agent clinical trials, healthy population epidemiological vs disease intervention studies, and so on). The effect of the vehicle that contains the antioxidant also introduced variability because the bioavailability in a food matrix can be quite different from that in a pure compound, and synergistic interactions are likely within the whole food because there are several antioxidants present in most foods. Because evidence does exist that several antioxidants at "normal" exposure levels can regulate signal transduction and, thus, regulate proliferation and the immune response, both normal physiological processes and mechanisms other than their antioxidant properties may be functioning. Overall, the physiological or pharmacological importance of antioxidants as regulators of radicals as a possible means for promoting health continues to receive widespread scientific attention and debate in the literature and therefore

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00016-3

TABLE 16.1 Some Antioxidants and Their Biological Activity

Antioxidant	Structure	Detected or Effective Level	Cancer Activity	CVD Activity	Hormonal Response	Deficiency Symptoms
Carotenoids	β-Carotene 	5–50 μg/dL	Induces connection–differentiation, immune function	Food sources lower CVD	No	Only vitamin A—xeroderma, night vision
Curcumin		>2 μmol/L at 8 g/day	Antiinflammatory; increases apoptosis, interferes with chemotherapeutics and cell signaling; interferes with Phase I enzymes, stimulates Phase II	unknown	No	No
Flavonoids	Genistein 	1–10 μmol/L	Modulates cell signaling, inhibits angiogenesis, increases apoptosis, much data from cell studies	Food sources lower CVD, minimal cholesterol lowering	Some are estrogenic, some anti, some both (does related)	No
Glutathione			Substrate of GSH glutathione peroxidase reduction of H_2O_2 and lipid hydroperoxides and substrate for Phase II carcinogen metabolism	unknown	No	unknown
Oleanic acid			Inhibits proliferation angiogenesis, metastasis; induces apoptosis and cell differentiation; antiinflammatory	Antiatherosclerotic, hypolioidemic	No	No

Resveratrol		Mostly in cell culture	Inhibits proliferation angiogenesis, induces apoptosis and cell cycle arrest in cancer cells in culture	Inhibits platelet aggregation cell adhesion in culture	Both estrogen (E2) agonist without E2 and antagonist with E2	No
Selenium	Se	45−80 μg/L 40−100 μg/day	Increases glutathione peroxidase, stimulates immunity	Weakly cardioprotective	No	Muscle wasting, cardiomyopathy
Vitamin C		Saturated blood levels at 400 mg per day ~ 70 μmol/L	Reduces lung, breast, oral, upper GI, gastric, colorectal CA with oral C; IV doses increase survival	Mixed results on CVD reduction, more + than −, lowers blood pressure, coronary artery dilation	No	Scurvy, impaired collagen synthesis
Vitamin D			Induces differentiation, lowers proliferation	Lowers blood pressure	No	Rickets, seizures, osteomalacia
Vitamin E		20 μmol/L	Affects cell signaling, boosts immunity, inflammation; minimal CA effect	Platelet aggregation, lower MI, carotid atherosclerosis	No	27 to 40 + % of population below 20 μmol/L

continues to be at the forefront of discussion for disease preventative and therapeutic strategies (http://www.cancer.gov/about-cancer/causes-prevention/risk/diet/antioxidants-fact-sheet and http://preventcancer.aicr.org/site/News2?page = NewsArticle&id = 10655&news_iv_ctrl = 0&abbr = pr_hf_).

A Antioxidant Usage and Measures of Oxidative Stress

Both public interest and the scientific literature related to the purported health benefits of antioxidants [5–9] are often thought to parallel the increased use of antioxidant supplements by the U.S. adult population. However, meta-analysis of the available studies may not strongly support such a positive view [6,7]. Data from the National Health and Nutrition Examination Surveys (NHANES), first conducted in 1971, indicated an overall prevalence of dietary supplement usage of 23% in NHANES I; prevalence rates increased to 35% in NHANES II and 40% in NHANES III, with women's usage approximately 12% higher than that of men [10–12]. However, the total male intake was somewhat higher than that of females of all ages [13] (see also https://wwwn.cdc.gov/Nchs/Nhanes/2009-2010/DS1IDS_F.htm [14]). Based on 1999–2000 NHANES III data, approximately 33% take multivitamins and more than 12% use vitamin E or C supplements [5]. The increased interest in the health effects of vitamins in general and specifically the class of "antioxidants" as protecting agents was sparked by a series of articles beginning in the 1970s. In the decades since, an expanded knowledge base in the nutritional sciences about the potential molecular targets and interactions that may account for the health benefits of antioxidants has surfaced from a wide range of preclinical, clinical, and population studies [9,10,15] but there have also been cautionary reports and analyses concerning over-usage and potential harm [6,7].

The major cellular targets of ROS include membrane lipids, proteins, nucleic acids, and carbohydrates. Several biomarkers for oxidative damage and antioxidant defense have been introduced as potential indicators of alterations in normal homeostatic mechanisms. Basically, oxidative stress biomarkers can be separated into those that (1) reflect modified molecules caused by ROS and (2) reflect shifts in biological measures of low-molecular-weight compounds or the induction of enzymes (Table 16.2). The ability to monitor these biomarkers at multiple time points in blood, urine, ductal lavage, and so on allows for repeated measurement and greater sensitivity in detecting and understanding stress status, which is not always possible for multiple reasons, including ethical and patient compliance concerns with more invasive procedures. Unfortunately, it is not simple to link these biomarkers to a specific clinical outcome. However, the field continues to expand and mature. The uncertainty about normal and abnormal values, appropriate target tissues, and the unsubstantiated relationship of a change in a biomarker to a specific phenotypic response also raises significant concerns about many of these measures. Eventually, an "oxidative stress profile" that incorporates changes in multiple biomarkers could be useful in establishing who may benefit or who may potentially be placed at risk by the use of antioxidant supplements or through specific antioxidant-rich dietary interventions.

Two main types of methods have been used to evaluate the antioxidant properties of foods; these assays are based on hydrogen atom transfer (HAT) reactions or on

TABLE 16.2 Some Biomarkers of Oxidative Damage

Total Antioxidant Potential	Total Radical Trapping Antioxidant
Lipid peroxidation	Malondialdehyde-lysine, 4-hydroxy-2-nonenallysine, acrolein-lysine, F2-isoprostane, thiobarbituric acid reactive substances
DNA oxidation	8-Hydroxy-2′-deoxyguanosine
Glyco-oxidation	Carboxymethyl-lysine, pentosidine, argpyrimidine, methylglyoxal
Nitro-oxidation	Nitrotyrosine, nitrite to nitrate
Protein oxidation	*o*,*o*′-Dityrosine, *ortho*-tyrosine, bilirubin oxidative metabolites, oxidized glutathione
Enzyme activities	Superoxide dismutase, catalase, glutathione peroxidase, glutathione reductase, glutathione-*S*-transferase, thioredoxin reductase, heme oxygenase
Protein concentrations	Albumin, ferritin, transferrin, lactoferrin, ceruloplasmin, thioredoxin
Concentrations of low-molecular-weight molecules	Bilirubin, tocopherols, carotenoids, ubiquinol/ubiquinone, ascorbate, glutathione, cysteine, urate, selenium

electron transfer (ET). Most HAT-based assays use a competitive reaction scheme in which antioxidant and substrate compete for thermally generated peroxyl radicals through the decomposition of azo compounds. These assays include inhibition of induced low-density lipoprotein autoxidation, oxygen radical absorbance capacity, total radical trapping antioxidant parameter, and crocin bleaching assays. The ET-based assays measure the capacity of an antioxidant in the reduction of an oxidant and corresponding change in color when reduced. ET-based assays include the total phenols assay by Folin−Ciocalteu reagent, Trolox equivalence antioxidant capacity, ferric ion reducing antioxidant power, "total antioxidant potential" assay using a Cu(II) complex as an oxidant, and 2,2-diphenyl-1-picrylhydrazyl (DPPH), the oxygen radical absorbance capacity [16,17]. Although each of the methods has value for a relative comparison across a variety of food items, it remains unclear whether the measures truly reflect their physiological value after consumption because they do not measure true biomarkers of physiological activity. In addition, the lack of detailed information about multiple exposures and with variable durations makes the interpretation of existing studies, with sometimes subtle changes in fluids and cells in humans, extremely challenging. The merits of these analyses may also be questioned because possible postprandial or diurnal variations that are not directly related to the intake of dietary antioxidants per se are not considered. Finally, plasma antioxidant capacity may be significantly affected by nonantioxidant dietary constituents, which influence uptake, tissue mobilization, or metabolism of endogenous or exogenous antioxidants [2,15,16,18−20].

The potential beneficial health effects of fruits and vegetables have been attributed, at least in part, to their antioxidant content. Significant and generally transient increases in plasma total antioxidant capacity are frequently observed following the human consumption of flavonoid-rich foods [18]. These flavonoids or possibly other bioactive food components function by modifying oxidative stress has been challenged by observations that typical intakes only result in minimal shifts in circulating biomarkers in plasma, and that extensive metabolism of the agents likely diminishes their in vivo antioxidant capacity. Lotito and Frei [18] concluded that the large increase in plasma total antioxidant capacity observed after the consumption of flavonoid-rich foods is not caused by the flavonoids per se but is likely the consequence of increased uric acid levels. However, work on the metabolism of the glycoside or aglycone forms of the flavonoids has shown that metabolic products, including products of intestinal and hepatic metabolism, can have very different properties than the parent compounds, calling into question the extrapolation of observed in vitro antiinflammatory and antioxidant effects to the in vivo situation [19], whether the appropriate agents and studies are being investigated [19−21] and the accuracy of dietary reporting methods in current use.

The possible usefulness of antioxidants in disease prevention, particularly for cardiovascular, ocular, and neurological diseases as well as cancer, stems from a number of epidemiological findings and a number of follow-up intervention studies. However, a substantive compendium of negative cardiovascular and other effects of antioxidant use, especially relating to dietary supplements, has also emerged, and will be discussed subsequently. A resulting concern is the potentially deleterious effects of antioxidant supplements on normal ROS levels because precise control of ROS levels is needed to allow normal cell function or to promote apoptotic cell death of aged, precancerous, or transformed cells [21]. Conflicting findings on risks and benefits have led to the careful reviews of antioxidant efficacy, such as evidence reports from the Agency for Healthcare Research and Quality (AHRQ) on vitamin C, vitamin E, and coenzyme Q10 [22,23] and a Cochrane review of vitamins A, C, E, and β-carotene [20,21]. The AHRQ reports included broad, systematic searches of the literature; the Cochrane report focused on mortality. The report on prevention and treatment of CVD [22,23] concluded that the evidence did not support a positive benefit of vitamin E supplementation for cardiovascular events; neither did it support significant potential for harm. Conclusions about vitamin C and coenzyme Q were mixed. The review of the cancer literature [23] did not support the hypothesis that supplements of vitamins C or E or coenzyme Q10 generally help prevent or treat cancer. In this context it is important to always consider that isolated findings of benefit require confirmation. Taylor and Greenwald [24] reviewed a number of completed nutritional cancer prevention trials, helping to fill out the background picture on this question. The AHRQ standing has also been reported for specifically vitamin E and β-carotene as "there is no net benefit of supplementation with vitamin E or β-carotene for the prevention of cardiovascular disease or cancer" (Section 2, Recommendations for Adults (continued). Agency for Healthcare Research and Quality, Rockville, MD, June 2014. http://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/guide/section2d.html).

This collection of potential positive and negative antioxidant effects on ROS deserves further examination because of the molecular evidence for the multiple roles of ROS in the development and progression of cancer, CVD, and other diseases [2,15]. This increased attention is timely because there have been studies [2] that link some nutritional antioxidants with increased mortality from cancer and CVD, as well as some clinical studies

that do not support the cancer prevention efficacy of some antioxidants. A review [25] indicated there are a number of European antioxidant and cancer clinical and epidemiological studies under way, so the subject will continue to be closely scrutinized and debated as new information becomes available.

B ROS and Normal Physiology

ROS typically arises as by-products of cellular metabolism and ionizing radiation, usually reflected in the formation of the following four species: superoxide anion (O_2^-) hydrogen peroxide (H_2O_2), hydroxyl radical (OH*), and singlet oxygen ($^1O_2$). Although H_2O_2 and $^1O_2$ are not free radicals per se, these species often initiate and promote oxidation by their ability to react directly with electron-rich organic species. The reactivity of O_2^- or H_2O_2 with other molecules is not appreciable, but the presence of trace amounts of transition metals fosters their conversion to OH via the Fenton or Haber–Weiss reactions. ROS formation is a natural consequence of aerobic metabolism and is integral for maintaining tissue oxygen homeostasis [20,26].

Oxygen homeostasis—the balance between constitutive oxidants and antioxidants—is maintained through a natural series of reduction-oxidation (redox) reactions involving the transfer of electrons between two chemical species: compounds that lose electrons (oxidized) and those that gain electrons (reduced). When oxygen homeostasis is not maintained, the cellular environment becomes oxidatively stressed. Approximately 1–3% of oxygen consumed by the body is converted into ROS [27]. Three of the major ROS—superoxide radical O_2^-, hydrogen peroxide, and hydroxyl radical OH*—are normal metabolic by-products that are generated continuously by the mitochondria in growing cells [26,28,29]. Other significant intracellular sources of ROS include microsomal cytochrome P450 enzymes, flavoprotein oxidases, and peroxisomal enzymes involved in fatty acid metabolism [26]. The potentially damaging oxidative stress can be caused by excess ROS, which are kept in check by endogenous cellular antioxidant mechanisms. Oxidative stress-related enzymes include superoxide dismutases for eliminating the superoxide radical, as well as catalase and glutathione peroxidases for removing hydrogen peroxide and organic peroxides [26,28]. Polymorphisms have been observed in these enzymes, which can affect an individual's capacity to respond to changes in ROS; this is discussed in more detail later.

Transient fluctuations of ROS levels can influence activity of signal transduction pathways leading to cell proliferation or to apoptosis or necrosis, depending on the dosage and duration of ROS changes and also on cell type. Typically, low levels of ROS can be mitogenic, whereas medium (normal homeostatic) levels lead to temporary or permanent growth arrest (replicative senescence), and elevated levels usually result in cell death either by apoptosis or by necrosis [29–31]. Although necrosis and apoptosis may be viewed as negative events in terms of cell loss, these processes also have positive roles in the downregulation of immune responses [3] and the elimination of transformed cells ("tumor suppression" via apoptosis).

C ROS in Disease Conditions

Imbalanced ROS homeostasis has been linked to an increased risk of several diseases such as cancer, CVD, atherosclerosis, diabetes, and neurodegenerative conditions including Alzheimer's disease [32–38]. Understanding the molecular effects of ROS on these different disease processes should assist in unraveling the varied and sometimes contradictory evidence about these diseases and assist in evaluating the importance and safety of antioxidants.

1 Cancer

Cancer is a number of somewhat distinct diseases that can be characterized on the basis of uncontrolled cellular growth resulting from a series of altered sets of genetic and epigenetic manifestations. Hanahan and Weinberg [33] indicated the "hallmark capabilities" necessary for tumorigenesis: (1) self-sufficiency in growth signals, (2) insensitivity to antigrowth signals, (3) evasion of apoptosis, (4) limitless potential for replication, (5) sustained angiogenesis, and (6) tissue invasion and metastasis. Excessive ROS and RNS are involved in all these processes and thus contribute to cancer progression either positively by promoting cell division or negatively by stimulating apoptosis and slowing the growth. Belief in the protective effects of antioxidant supplements has led to their widespread use by cancer patients [34].

The expanded use of nutritional supplements is not limited to the United States. Many other countries are reporting increased use of various alternative and complementary approaches and strategies [35]. A greater understanding of both the negative and the positive consequences of ROS and antioxidants in the etiology and progression of carcinogenesis is crucial to making clear advances in cancer prevention and treatment. Currently, the two faces (benefit/risk) of ROS/RNS in malignant diseases make it difficult to present a true, clear, and concise message to consumers.

2 Cardiovascular Disease

CVD, encompassing atherosclerosis and its associated vascular disorders, is the leading cause of mortality in developed countries [36,37]. Atherosclerosis has three characteristics: inflammation, disturbed blood flow and abnormal shear stress, and arterial wall remodeling. Oxidative stress is associated with impaired arterial elasticity

and excessive ROS can contribute to the structural remodeling through smooth muscle proliferation and enhanced inflammation [38–40]. Other vascular insults such as those associated with cigarette smoking, diabetes mellitus, hypertension, autoimmune disease, and hyperlipidemia can trigger an inflammatory response in blood vessels. Chronic low-grade inflammation is generally accepted to accompany atherogenesis [41,42]. This inflammatory state, which has been linked in part to ROS mediation, can result in damage to smooth muscle and vascular endothelial cells. This in turn leads to a dysfunctional endothelium characterized by pathological alterations in the endothelial cell's anticoagulant, antiinflammatory, and vascular-relaxation properties, which can promote the recruitment of monocytes, macrophages, growth factors, and cellular hypertrophy. All of these factors can contribute to atherosclerotic plaque formation. In summary, increased ROS and related oxidative stress helps drive many of these processes involved in the development of CVD if left unchecked.

3 Neurodegenerative Disease

Neurodegenerative diseases and disorders (NDDs), including dementias such as Alzheimer's disease, are a rising public health problem due to the aging of populations and lack of effective treatments or a cure. As for CVD, there is a growing body of knowledge that suggests that the pathophysiology of NDDs involves mechanisms of oxidative stress and inflammation. There is also an accumulating literature on the positive effects of dietary antioxidants on delaying the progression or slowing the decline of moderate cognitive impairment (MCI), a precursor of frank dementia. Thus, a number of reviews have highlighted the effects of several classes of dietary antioxidants on both biomarkers and functional indicators of cognitive decline [43,44]. The evidence includes results from both prospective and retrospective epidemiological studies and from randomized controlled trials (RCTs). As with nutritional interventions in other diseases, there are reports of positive effects as well as those showing no benefit. However, the current state of knowledge suggests that it would be prudent to continue to investigate the mechanisms of the effects of dietary antioxidants on neurodegenerative processes. Further trials are necessary to more clearly define populations of individuals suffering from or at risk for NDDs who may benefit from consumption of antioxidant-rich diets or supplements.

II ANTIOXIDANTS IN DISEASE ETIOLOGY, PREVENTION, AND TREATMENT

Several studies have reported that diets high in fruits and vegetables can be associated with a decreased risk of CVD and cancer. This has been frequently attributed to high levels of antioxidants present in these foods. Other studies, however, do not provide clear and unequivocal support for this assumption. For example, data from historical food frequency questionnaires collected during the cohort Nurses' Health and Health Professionals Follow-Up Studies indicated that cancer incidence was not influenced by increased fruit or vegetable consumption; however, modest reductions in CVD were detected (Table 16.3) [45]. Similarly, studies of dietary supplements and individual antioxidants are not consistent; observed effects have ranged from benefit to possible harm [46,47] but could be affected by imprecise estimates of dietary intake. A number of other factors may contribute to these contradictory findings, including participant baseline health and ROS levels, exposure to environmental carcinogens, and genetic differences in ROS metabolism [48]. Some argue that higher doses of some antioxidants have a pro-oxidant effect [2], and there is a high probability that pharmacokinetics, including absorption, distribution, metabolism, and excretion of a simple ingested supplement, is quite different from the complex matrix in fruits, vegetables, and even complex meals, which contains many different types of antioxidants as well as other macro- and micronutrients and other phytochemicals.

Because many examples of J- and U-shaped dose–response curves have been reported among vitamins, other nutrients, and food additives, a critical question for cancer patients in active therapy should be the following: What is the potential interaction of ROS and antioxidants with chemotherapy and radiation therapy? The interaction occurs sometimes in a positive manner, enhancing the efficacy of the treatment, but also sometimes negatively, interfering with the agent or treatment. Similarly, individual antioxidants can inhibit or stimulate tumor cell growth or survival depending on the tumor, the antioxidant, and the oxidative status. This means that there is no simple answer regarding the overall effectiveness of antioxidants, and each must be considered on a case-by-case basis. The following sections provide the results of some major clinical and epidemiological trials on the antioxidant effects on cancer and observed side effects, particularly on CVD, focusing on the antioxidants selenium, vitamin E, vitamin C, and β-carotene, all of which are readily available in the marketplace as dietary supplements. Key study findings and some experimental details are presented in Table 16.3.

A Antioxidants and Cancer

The potential benefits of the dietary antioxidants selenium, vitamin E, vitamin C, and β-carotene in numerous observational and clinical trials have been examined for several years [7,49]. Since the 1990s, however, evidence has emerged indicating that some antioxidants, in certain

TABLE 16.3 Human Intervention Studies on Antioxidants

Study and Publication Date	Study Details, Size, and Duration	Intervention Details	Study Results
Linxian Study—China (1993) [52]	29,584 men (5 years)	βC (15 mg), vitamin E (30 mg), and selenium (50 mg) daily	Protective effects: cancer: −13%; mortality: −9%
ATBC Study—Finland (1994) [67,69,70,77−81,102]	29,133 male smokers (5−8 years) with up to 19-year follow-up	βC (20 mg) ± vitamin E (50 mg) daily	Lung cancer: +18% but mortality mixed Prostate cancer: −32% Colorectal cancer: −22% No decrease in CVD or angina Slight excess hemorrhagic stroke and βC-related mortality (+7%), but decreased with vitamin E
CARET Study—United States (1996) [47,68,71]	18,314 male smokers or asbestos exposed (4 years + 6-year follow-up)	βC (30 mg) ± vitamin A (25,000 IU) daily	Lung cancer: +28%; mortality: +17%; baseline levels after 10 years
CHAOS—United Kingdom (1996) [110]	2002 atherosclerosis patients, ∼80% males (510 days)	535 or 263 mg vitamin E daily	Decreased nonfatal MI (77%)
PHS—United States (1996) [54,56,128]	22,071 physicians (12 years) (11% smokers, 39% former smokers)	50 mg βC every other day	No significant overall effect on cancer or CVD; decreased prostate cancer −32%
NPC Trial—United States (1996) [86−88]	1312 men and women with dermal basal or squamous cell carcinoma (4.5 years + 6.4-year follow-up)	200 mg selenium daily	No effect on skin cancer; lung (−46%); colorectal (−58%); prostate (−63%); mortality (−50%)
WHS—United States (1999) [55,92,108]	39,876 female 45 + year-old health professionals (2.1 years + 10-year follow-up) (13% smokers)	50 mg βC or vitamin E (400 mg) every other day ± aspirin	No βC effect on cancer rates nor on CVD; CVD death decreased 24% with vitamin E; no change in cancer, MI, or stroke; high fruit and vegetable intake associated with lower MI
GISSI—Italy (1999) [138]	11,324 MI survivors, ∼85% male (3−5 years)	Vitamin E (300 mg) ± PUFA (1 g) daily	No effect of vitamin E on CVD; PUFA effects protective; cardiovascular deaths: −30%; mortality: −20%
ASAP—Finland (2002) [125]	520 high-cholesterol male and female (postmenopausal) smokers and nonsmokers (6 years)	Vitamin C (250 mg) and 91 mg α-tocopherol, twice daily	Carotid atherosclerosis −25% combined, −30% in men, decreased plaque size in >50%
IVUS—United States (2002) [126]	40 cardiac transplant patients (1 year)	Vitamin C (500 mg) and vitamin E (263 mg) twice daily	Decreased atherosclerotic plaque size
British Heart Protection Study—United Kingdom (2002) [127]	20,536 increased risk of MI; 15,454 males, 5082 females (5 years)	Vitamin C (250 mg), vitamin E (600 mg), and 20 mg βC	No effect on cancer, stroke, or dementia
SU.VI.MAX—France (2003) [82−85]	12,741 men (aged 45−60 years) and women (aged 35−60 years) (7.1 years)	βC (6 mg), vitamin E (30 mg), vitamin C (120 mg) + Zn (20 mg), and selenium (100 μg) daily dosing	Protective in men: prostate cancer: ∼ − 58%; all cancer: −31% and mortality: −37%; no supplement effect in women but lower CVD with high fruits and vegetables
HOPE & HOPE-TOO—Canada, United States, Europe, South America (2005) [139,140]	1138 men and women (over 55 years) with left ventricular dysfunction or diabetes (4 years + follow-up to 7 years)	Vitamin E (400 mg) daily	No significant effect on cancer incidence or mortality; no significant effect on CVD events but heart failure +13%

(*Continued*)

TABLE 16.3 (Continued)

Study and Publication Date	Study Details, Size, and Duration	Intervention Details	Study Results
E3N Prospective Cohort Study—France (2006) [74]	59,910 women—selected 700 with smoking-related cancers (7.4 years)	βC intake divided into quartiles from diet reports	Nonsmokers 20% to 60 + % reduction in lung cancer; smokers 1.5−2X increase
SELECT—United States (2008) [66]	35,533 men (5.46 years); PSA <4 ng/mL and normal digital exam (aged 50 or 55 years) (5.5 years)	Se 200 μg/day as selenomethionine, racemic vitamin E 400 IU/day	No significant effect on prostate cancer or diabetes for combination, nonsignificant increase in prostate with vitamin E
PHS II—United States (2008) [65]	14,641 male physicians (50 years or more) + 8 year follow-up	Vitamin C (500 mg daily) vitamin E 400 IU every other/day	No significant effect on lung, colorectal, prostate, or total cancer; vitamin E-associated hemorrhagic stroke
WASC—United States (2009) [64]	7627 cancer-free women (40 years or more) (9.4 years)	Vitamin C (500 mg daily) and vitamin E 600 IU + βC (50 mg) every other/day	No significant effect on total cancer incidence or cancer mortality

individuals, perhaps at untoward high doses or in the presence of specific conditions or cancer treatments, may modulate normal protective benefits, whereas others may bring about deleterious effects, such as interfering with the efficacy of cancer drug treatment or increasing an individual's risk for cancer or heart disease [50,51].

1 Antioxidant Supplementation and Cancer Prevention

On initial examination of Table 16.3, large-scale trials do not consistently demonstrate a definite benefit of antioxidant supplements in healthy individuals. However, closer examination suggests that in individuals with initially low background antioxidant status, supplementation to achieve a normal range may bring about some health benefit [52]. In some cases, however, high-dose supplementation may lead to potentially harmful elevated blood levels, especially in oxidatively stressed individuals such as smokers who consume large amounts of β-carotene. This subject was further examined in a recent review by Yang et al. [53] focused on vitamin E, selenium, and β-carotene.

a β-Carotene

A major issue in assessing antioxidant efficacy is whether any antioxidant interventions, especially at elevated doses above the normal nutritional level, result in a dose-dependent benefit to individuals at risk from disease. For example, two large-scale, randomized intervention trials evaluated the effect of β-carotene supplementation over 12 years on the primary prevention of cancer and CVD in male physicians (Physicians Health Study [PHS]) [54] and over 2 years in female health professionals (Women's Health Study [WHS]) [55]. The dose administered was 50 mg β-carotene every other day. Upon initial evaluation, no evidence of either stimulation or inhibition of either disease was noted when placebo and treated groups were compared. However, subgroup analyses of the PHS data later found that men with the lowest quartile for plasma β-carotene at initial baseline had a lower risk for total cancer, particularly prostate cancer, when β-carotene supplement users were compared with placebo [56]. The average blood levels achieved during the PHS were 120 μg/dL [57], whereas normal serum β-carotene is in the range of 5−50 μg/dL [1]. An effect on smokers was not observable in these two studies, possibly because only 11% of the physicians and 13% of the women were smokers; therefore, the study was not adequately powered to examine this aspect. There is no reason to suspect that these individuals were nutritionally compromised, so the results may not be universally applicable to the general population. Additional β-carotene findings have been derived from nested cohort subsets of randomized clinical trials of β-carotene. These studies found no evidence that β-carotene supplementation prevented recurrence of basal or squamous carcinomas of the skin (50 mg/day) in the United States [58] or of colorectal adenomas (20 mg/day) in Australia [59]. However, rather recent meta-analyses of circulating carotenoids [60], carotenoid intake [61], and fruit and vegetable intake [62] and an European Prospective Investigation into Cancer and Nutrition (EPIC)-based plasma antioxidant (carotenoids, tocopherols, retinol, and Vitamin C) study on breast cancer risk [63] all indicate increased antioxidants (carotenoids and vitamin C) are associated with lower ER-breast cancer incidences. These recent studies give support to further

examination of metabolic effects of smoking and the metabolomics of food-based carotenoids and vitamin C, both areas of research drastically slowed by the two results of studies of high dose in smokers.

Similarly, several randomized trials in high-risk populations have reported reduced disease risk using antioxidants, at least in baseline deficient populations when subsets of the populations are examined. The National Cancer Institute (NCI) trials, conducted in Linxian, China, with a population at high risk for esophageal cancer, noted a significant benefit for those receiving a β-carotene/vitamin E/selenium combination: a 13% decrease in the cancer mortality rate, a 21% decrease in stomach cancer mortality, a 4% decrease in esophageal cancer mortality, a 10% decrease in deaths from strokes, and a 9% decrease in deaths from all causes [52]. However, the generalizability of these findings from Linxian may not be universally appropriate because individuals in this study appear to have limited intakes of several micronutrients. Thus, these prevention agent trial findings may not be applicable to well-nourished populations. Indeed, several studies did not show stimulatory or inhibitory effects on total cancers or the target organs in U.S. populations [64–66] (Table 16.3).

2 Effects in Smokers

When smokers were selected as the target population, very different views surfaced about the health consequences of β-carotene supplements. Two highly publicized trials provided evidence for potentially adverse effects of antioxidants, particularly in smokers and in individuals exposed to certain environmental hazards, such as asbestos. These two independent, randomized, clinical trials—the 5- to 8-year ATBC (Alpha-Tocopherol Beta-Carotene) [67] and the 4-year CARET (Beta-Carotene and Retinol Efficacy Trial) [68]—reported adverse effects of 20- and 30-mg β-carotene daily supplementation on lung cancer risk in these high-risk populations. The ATBC trial studied effects primarily in smokers, whereas the PHS included more than half who were nonsmokers [54]. Similar to the PHS results for β-carotene, the ATBC study data demonstrated a reduction (32%) in prostate cancer incidence in the α-tocopherol (vitamin E) supplemented group [69] and 22% fewer cases of colorectal cancer [70] upon reanalysis. Although lung cancer incidence was elevated in both ATBC and CARET smokers with β-carotene, after a 12-year follow-up of CARET participants, a significant decrease in lung cancer incidence in the placebo arm was observed that was linked to fruit and vegetable intake when the lowest versus highest quintiles were compared [71]. An earlier case–control study of lung cancer in nonsmokers conducted in New York concluded that dietary β-carotene, raw fruits and vegetables, and vitamin E supplements reduced the risk of lung cancer in nonsmoking men and women [72]. A subsequent evaluation of the Nurses' Health Study from Harvard implicated carrots but not β-carotene, further adding to the confusion [73]. Interestingly, in the French Etude Epidemiologique de Femmes de la Mutuelle Generale de l'Education Nationale (E3N) prospective investigation, the nonsmoking women showed a dose-dependent lowering of lung cancer risk when intakes were considered. The largest reduction was observed in women taking β-carotene supplements, but smokers showed the commonly observed increased risk [74]. Research has implicated β-carotene cleavage products as likely factors in the increased cancer activity of high β-carotene doses, exacerbated by smoking-induced alterations in β-carotene metabolism [57,75,76].

3 Follow-Up Examinations of Existing Studies

Follow-up examinations of a subset of the ATBC cohort have reported a marked association between elevated serum levels of α-tocopherol and reduced prostate cancer risk in a 6-year prospective study with 100 prostate cancer patients and 200 controls [77]; however, a separate postintervention study reported that the excess risk for lung cancer and the beneficial effect for prostate cancer were no longer significantly different from controls [78]. In addition, with the exception of a slight carotene protective effect on early stage laryngeal cancer, other upper aerodigestive cancers were not affected [79], although a dose–responsive decrease in mortality with increasing vitamin E serum levels was noted [80]. Interestingly, evaluation of dietary records in the ATBC study indicated that consumption of fruits and vegetables was associated with a lower lung cancer risk, as were the levels of dietary lycopene and other carotenoids, as well as actual serum levels of β-carotene and retinol, when the highest and lowest baseline quintiles were compared [81]. A 6-year follow-up of the CARET cohort reported that the increased risk was no longer significant for either lung cancer or CVD, but subgroup analysis suggests excess risk in heretofore unreported susceptible groups (females and former smokers), a difference from the ATBC study that may be due to the higher β-carotene dose in CARET [47] or perhaps the presence of vitamin E (α-tocopherol). The return to normal risk levels in the smokers suggests that subtle changes were introduced such that this group may have actually achieved protection from prior treatment. Thus, it is conceivable that the increased risk observed in the ATBC study may have reflected an increase in those with a preexisting precancerous lesion or tumor but protection in those without. This hypothesis would also explain the lack of increased cancer in the Women's Antioxidant Cardiovascular Study, in which cancer-free women were given vitamins C and E plus

50 mg β-carotene [64]. Thus, the question of benefits or merits of β-carotene in smokers remains controversial because it may depend on the presence or absence of precancerous lesions.

Further follow-up and reexamination of subgroup analysis may also help explain these unexpected results. For example, the French study, SUppléments en VItamines et Minéraux AntioXydants (Antioxidant Vitamin and Mineral Supplements [SU.VI.MAX]), examined the effects of supplementation with vitamins C and E (120 and 30 mg, respectively), 6 mg β-carotene, 100 μg selenium, and 20 mg zinc on the health of approximately 13,000 men (45−60 years) and women (35−60 years) [82−85]. In men only, antioxidant supplementation reduced the risk of developing all types of cancers by 31%. This effect was most pronounced in men with low baseline levels of β-carotene who had the greatest increased risk of developing cancer. An evaluation of the study data showed that there was a nonsignificant reduction in prostate cancer rate associated with the supplementation in all men, but there was a significant difference between men with normal baseline prostate-specific antigen (PSA) and those with elevated PSA. Among men with normal PSA, there was a statistically significant reduction in the prostate cancer rate among those receiving the supplements. Surprisingly, the supplementation was associated with an increased incidence of prostate cancer, with border-line statistical significance in men with elevated PSA at baseline [85]. The average β-carotene blood levels both at the beginning of the study (∼39 μg/dL in women and ∼25 μg/dL in men) and at the end (∼90 μg/dL for women and ∼50 μg/dL for men) were below those seen in the PHS, whereas no such change was observed for serum levels of vitamins E or C, selenium, or zinc.

a Selenium

Dietary selenium is another potentially important antioxidant and potential chemopreventive agent because of its importance in the functionality of glutathione peroxidase. Strong evidence linking selenium supplementation and decreased cancer risk comes from the secondary analysis of the Nutritional Prevention of Cancer (NPC) trial, a study designed for patients with a history of basal or squamous cell carcinomas [86]. Although no benefit was observed for skin cancer, the primary end point of the study, secondary end point analyses showed significant reductions in relative risk for total cancer mortality (50%), total cancer incidence (37%), as well as incidences of lung (46%), colorectal (58%), and prostate (63%) cancer for patients who received selenium supplements. Further reanalysis of the NPC data confirmed a 49% reduction in prostate cancer incidence in men receiving selenium supplements compared to controls, although follow-up suggests the benefits may be decreasing with time [87]. Another reanalysis that included three additional years of follow-up data found a nonsignificant decrease in lung cancer risk for all patients who received selenium supplements; however, the analysis suggested a significant risk reduction following supplementation among those with the lowest baseline plasma selenium [88]. A separate study by Li et al. [89] also indicated that a reduction in prostate cancer incidence occurred following selenium supplementation. The authors of these various studies differ in their conclusions concerning whether selenium prevents initiation of carcinogenesis or inhibits tumor progression; nevertheless, the benefit of selenium for prostate cancer prevention is fairly consistent. A wealth of preclinical studies supports the anticancer properties of selenium. Much of the evidence concerning selenium's anticancer/antitumor properties suggests mechanisms of action other than those associated with its antioxidant properties [90]. A clinical trial of selenium as selenomethionine in combination with vitamin E, however, failed to show a significant effect on prostate cancer or diabetes, but selenium alone gave a nonsignificant increase in diabetes and a similar effect on the prostate in a very large cohort of relatively healthy U.S. men [66].

4 Antioxidant Combinations

More broadly, a meta-analysis of antioxidant supplementation in patients at elevated risk of gastrointestinal cancers revealed no protective effect for vitamins A, C, and E on esophageal, gastric, colorectal, pancreatic, and liver cancers. However, selenium supplementation was noted as possibly a cancer deterrent. The authors have noted that the findings may not be easily extrapolated to the effects of fruits and vegetables, which are rich sources of only some of these antioxidants [46]. Likewise, the applicability of these findings to healthy individuals is unclear. The follow-up examination of fruit and vegetable use and breast cancer risk within the EPIC study indicated that fruits and vegetables had no effect on cancer when the highest versus the lowest quintiles were compared [91]. These findings add to the confusion in light of other studies that suggest fruits and vegetables have benefits, particularly when associated with their antioxidant content [71,72,74]. The WHS, however, saw a reduction in myocardial infarction (MI) [92]. These inconsistencies may reflect the variation in the intake of individual fruits and vegetables, their interactions with environmental insults, or the genetic background of the consumer.

Completion of the human genome sequence and the advent of DNA microarrays using cDNAs enhanced the detection and identification of hundreds of differentially expressed genes in response to antioxidants including

flavonoids, selenium, zinc, and several vitamins [93]. The phenolic antioxidant resveratrol found in berries and grapes has been reported to inhibit the growth formation of prostate tumor cells by acting on the regulatory genes such as p53 while activating a cascade of genes involved in cell cycle and apoptosis, including p300, Apaf-1, cdk inhibitor p21, p57 (KIP2), p53-induced Pig 7, Pig 8, Pig 10, cyclin D, and DNA fragmentation factor 45, although some findings were not confirmed by reverse transcriptase polymerase chain reaction [94]. Likewise, the expression of a host of genes is influenced by selenium supplementation [95].

B Antioxidants and CVD

While the safety of antioxidants and potential for efficacy in vivo and in vitro studies has been well established [50], clinically based studies have not been as promising for a number of antioxidant compounds including vitamin C, vitamin E, resveratrol, epigallocatechingallate, a tea polyphenol (EGCG), lycopene and other carotenoids, and coenzyme Q10. Meta-analysis of clinically based studies of vitamin E supplementation showed increased mortality above a 400-mg dose [96], compared to a protective effect of fruit and vegetable consumption in EPIC [91] and a meta-analysis of fruit and vegetable cohort studies [97], thus providing mixed evidence. A dose-dependent inverse relationship between vitamin E consumption and coronary heart disease mortality was detected in the prospective Iowa Women's Health Study [98]. The strongest inverse association was observed among the approximately 22,000 women who did not consume vitamin supplements compared to those who did [98]. Vitamin E meta-analyses showed no benefit of vitamin E supplementation, but high doses significantly increased overall mortality [99–101].

The meta-analysis of high-dose vitamin E supplementation by Miller et al. [96], however, suggested a positive association of all-cause mortality when supplementation was above 400 IU/day. Despite a number of issues with the choice of studies to be included and excluded in the meta-analysis, as well as the failure to consider a dose–response relationship in the physiological range, Wright's earlier analysis of continuous serum α-tocopherol values in the ATBC study indicated a dose-dependent reduction in mortality from chronic disease with increasing concentrations up to approximately 13 or 14 mg/L (30–33 mmol/L), after which no further benefit was noted. Those with the higher baseline blood levels showed decreased mortality [80]. The use of superphysiological exposures with questionable health benefits, especially for those at the highest status, raises serious concerns about the wisdom of megadoses of vitamin E supplements. A meta-analysis of more than 60 clinical trials that focused on antioxidant use (including vitamin E) reached similar conclusions about slightly increased mortality but again may have introduced some biases in the evaluation [102]. Another study, the Canadian Heart Outcomes Prevention Evaluation (HOPE)—a randomized controlled prospective investigation of vitamin E supplementation (400 IU/day) in approximately 4700 patients with diabetes and other cardiovascular risk factors—linked supplementation with an increased risk of heart failure but no protection from cancer in the 2.6-year follow-up portion of the study; no differences in cardiovascular effects were noted during the first 4.6 years [103]. More specifically, vitamin E supplementation of 1200 IU/day was associated with a 50% increase in chronic heart failure (CHF) in patients with left ventricular (LV) dysfunction, and despite improvements in plasma levels of markers of inflammation such as high-sensitivity C-Reactive protein and levels of oxidative stress such as oxidized LDL, there was no change in intima media thickness of carotid arteries and no significant change in CV events [104,105]. There is a strong inverse association between lycopene intake and incidence of MI, angina pectoris, and coronary insufficiency. Additionally, low lycopene levels were reported by many researchers in hypertension, MI, stroke, and atherosclerosis [106]. However, when supplementing with lycopene, there are less convincing results [107].

Research evidence from large-scale trials also indicated no clear benefit of antioxidant supplements in healthy individuals when considered in toto. Upon closer examination, supplementing individuals with low background levels to a normal range may be beneficial, but high-dose supplementation leading to markedly elevated blood levels may be harmful, especially in oxidatively stressed individuals, such as smokers in the case of β-carotene or in unhealthy or older patients in the case of vitamin E.

1 Targets of Antioxidant-Related Disease Protection

Vitamin E, vitamin C, and β-carotene intake, whether by supplementation or as components of foods, has been extensively studied for their potential to reduce CVD or conditions related to the sequelae of CVD and other vascular diseases. A number of older studies suggest that vitamin E, alone or in combination with other antioxidants, may be protective against atherosclerosis in at-risk populations. In the WHS, there was a significant (24%) reduction in cardiovascular deaths [108] in the vitamin E group. However, other studies question the overall benefits [67,109–111]. In addition to a potential role in minimizing oxidative DNA damage and lipid peroxidation, vitamin E may modify several other functions, some of which specifically protect against processes known to contribute to atherosclerosis, including inhibiting protein

kinase C activity and smooth muscle cell proliferation, inhibiting cell adhesion and platelet aggregation, counteracting inflammation, and enhancing bioavailability of nitric oxide to improve endothelium-dependent vasodilator function [112–114]. Vitamin E may also improve insulin-mediated glucose uptake, thus possibly decreasing the risk for type 2 diabetes, a condition that also contributes to atherosclerosis [115].

Endothelial dysfunction is the major target for vitamin C-mediated effects. In patients with coronary artery disease or hyperglycemia-induced impairment of vasodilation, NO-mediated vasodilation is restored with either oral (6 g over 2 days) or intraarterial infusion (24 mg/minute for 10 minutes) of vitamin C [116]. Vitamin C enhances nitric oxide bioavailability which is essential to preserve endothelial homeostasis and prevents nitrate tolerance [117,118]. Vitamin C supplementation also counteracts endothelial dysfunction which is a contributor to CVD [119]. The EPIC Norfolk study found that plasma vitamin C concentration was inversely related to incidence of CVD-related mortality, as well as all-cause mortality, in both women and men. By increasing plasma vitamin C by 20 mcg through increased intake of vegetables and fruit, CVD mortality was reduced by ~20% [120]. Diets high in vitamin C are associated with decreased stroke risk in those over 65 years old but no significant association occurs with coronary artery disease [121].

The PHS II studied the effects of vitamins E and C in prevention of CVD in men during a mean follow-up of 8 years. The trial did not find any benefit from antioxidant supplementation on major CVD outcomes. Additionally, vitamin E was associated with an increased risk of stroke [122]. Wannamethee et al. reported that higher vitamin C plasma levels are inversely associated with cardiovascular risk factors including blood lipid and blood pressure, but supplementation of Vitamin C did not exert any influence and has not been shown to have benefit in reducing major cardiovascular events [123], additionally, the dietary intake of vitamin E was significantly correlated with increased risk of heart failure [124].

2 Clinical Trial Interventions for CVD Amelioration

Antioxidants have been tested for the ability to ameliorate development of CVD in some at-risk populations. The Antioxidant Supplementation in Atherosclerosis Prevention (ASAP) study, a 6-year randomized trial, supplemented 520 hypercholesterolemic men and postmenopausal women (45–69 years old) with vitamin C and vitamin E [125]. A significant decrease (26%) in the progression of carotid atherosclerosis was observed in men, although no significant effect was seen in women. In the Harvard Intravascular Ultrasonography (IVUS) study, a combination of vitamin C and vitamin E was given to 40 (35 males) cardiac transplant patients. Cardiac transplantation leads to oxidative stress, which may contribute to atherosclerosis; supplementation of patients with these vitamins slowed the progress of coronary atherosclerosis [126].

Two large studies have reported preliminary results. The British Heart Protection Study, a multicenter, randomized, double-blind, placebo-controlled trial enrolled 20,536 patients aged 55–75 years who were at an increased 5-year risk of MI [127]. Participants received antioxidant vitamins (combination of 600 IU vitamin E, 250 mg vitamin C, and 20 mg β-carotene) and simvastatin or each separately. No adverse or beneficial effect on vascular or nonvascular morbidity or mortality could be attributed to supplementation with vitamins. The American PHS II enrolled 15,000 physicians aged 55 years or older in a randomized, double-blind, placebo-controlled trial to test β-carotene, vitamin E (400 IU synthetic on alternate days), vitamin C (500 mg/day), and multivitamin (Recommended Dietary Allowance [RDA] of most vitamins and minerals) [128]. This study was completed in September 2007 and investigated the effects of supplementation on prevention of total and prostate cancer, CVD, as well as age-related eye diseases (cataracts and macular degeneration). No effects on cancer were observed. Preliminary analysis reported no significant effect of any of the vitamins on cardiovascular outcomes, but a greater number of hemorrhagic strokes were observed in the vitamin E versus placebo group; the effects of multivitamin use are still being evaluated [65]. The WHS tested the ability of aspirin, vitamin E, and β-carotene to prevent cancer and CVD [55,108]. Analysis of β-carotene supplementation showed no effect of β-carotene on risk of CVD. In the vitamin E group, there was a significant (24%) reduction in cardiovascular deaths [108]. Despite the lack of evidence for an effect of the combined discrete nutrients on CVD, high fruit and vegetable intake was associated with lower risk for MI in the WHS study [92].

As seen in the WHS, dietary habits have been linked to decreased CVD risk, despite a lack of effectiveness for individual supplements. Similarly, Mennen et al. [129] found that a diet rich in flavonoids reduced CVD risk in a subset of women participating in the SU.VI.MAX study [82–85]. Dietary intakes were estimated using six 24-hour dietary records collected during the course of 1 year. In women, flavonoid-rich food consumption was associated with decreased systolic blood pressure and a decreased risk for CVD; this relationship was not observed in men. The lack of an effect in men could be attributed to the men's higher risk for CVD. However, inconsistencies in dietary reporting and measuring of

flavonoid consumption could also contribute to this discrepancy. Still, this study found that after 7.5 years of follow-up, no protective effect against ischemic heart disease attributable to antioxidant supplementation could be discerned in either men or women [129].

Multiple studies have reported a strong inverse relationship between lycopene and carotenoid intake and incidence of MI, angina pectoris, coronary insufficiency incidence, and stroke risk [130–132]. Additionally, low lycopene levels were reported by many researchers in hypertension, MI, stroke, and atherosclerosis [133]. Higher adipose lycopene concentrations correlated with a reduction in risk of MI and the effect was retained after correction for confounding factors. The odds ratio was found to be 0.52 suggesting the risk of mortality was substantially reduced in those with high-adipose lycopene [134]. Although lycopene from dietary sources has extremely low bioavailability [135], natural dietary sources are recommended as supplemental lycopene has not demonstrated the same cardiovascular protection as that of lycopene obtained from the diet [107,136].

Four large, randomized clinical trials specifically tested the ability of vitamin E supplementation to slow the progression of CVD in individuals at increased risk for CVD death (reviewed by Salonen [137]). The ATBC trial, originally designed to test cancer prevention abilities of vitamins C and E and β-carotene, tested supplementation with 50 mg α-tocopherol acetate daily for 5–8 years [67]. In this study of male smokers, α-tocopherol supplementation was associated with a modest trend toward decreased incidence of angina pectoris but no decrease in CVD mortality. β-Carotene supplementation had no preventive effect and was associated with a slight increase in the occurrence of angina [109]. An apparent excess of hemorrhagic stroke in the treatment group complicated this study. The Cambridge Heart Antioxidant Study (CHAOS) tested RRR-α-tocopherol from "natural sources" in 2002 participants with clinical evidence of CVD [110]. Trial analysis identified a 77% decrease in nonfatal MI but also a nonsignificant increase in early deaths from CVD and total mortality, although no increase in risk of hemorrhagic stroke was observed. Interpretation of this study was complicated by unbalanced randomization, incomplete follow-up, and a midstudy change in vitamin E dose (800 IU/day to 400 IU/day) [111]. The Italian Gruppo Italiano per lo Studio della Supravvivenza nell Infarto Miocardio (GISSI) study supplemented 11,324 participants with previous MI with 300 mg all-racemic α-tocopherol daily, with or without 1 g polyunsaturated fatty acids (PUFAs) [138]. No effect was observed in the group receiving both supplements, but a significant 20% decrease in cardiovascular death was observed in the group receiving only PUFAs [138]. In the HOPE study, 2545 women and 6996 men at high risk for CVD received either 400 IU/day "natural source" vitamin E or Ramipril; this study found no effect of supplementation on any parameters related to CVD [139,140]. As noted previously, however, the follow-up study suggests an increase in CVD after an additional 2.6 years [103]. The Women's Health Initiative examined multivitamin use in more than 160,000 women during an 8-year clinical trial follow-up period with nearly 8 years of observational follow-up. More than 40% used multivitamins, and this was not linked to increases in several common cancers, CVD, MI, stroke, and overall mortality [141].

ROS can influence the inflammatory process. As inflammation is thought to be a significant cause of damage to blood vessels, contributing to CVD, it has been a logical target for treatment with antioxidants. Vascular smooth muscle cell accumulation and hypertrophy, and nitric oxide regulation of endothelial vasorelaxation and vasodilation, are processes that may also be therapeutically modulated by antioxidants. Although individual supplements have not proven to be strongly effective, diets high in fruit and vegetables, and their native antioxidant and phytochemical combinations, have been shown to be fairly protective [97]. Plant-based diets such as the Mediterranean diet are promising in their ability to prevent cerebrovascular disease and CVD [142]. Of course, one must consider that diets high in fruits and vegetables may indirectly reduce the risk of CVD by promoting healthy body weight, decreasing the risk of developing conditions contributing to CVD such as hyperlipidemia and type 2 diabetes.

Studies with defined populations have generally failed to demonstrate marked prevention potential for cancer or heart disease, but animal studies suggest that benefits should occur. There are a number of possible explanations for this inconsistency. Foremost among these is that significant nutrient–nutrient interactions are likely occurring along with the importance of environmental insults as determinants of the overall response. Some of the case–control studies may actually be selecting participants with a general interest in the pursuit of a healthy lifestyle. It is known that volunteers for observational antioxidant studies tend to have better diets, exercise more, use less alcohol, and come from higher socioeconomic backgrounds, all of which may contribute to a decreased baseline risk for CVD and other disease conditions [143].

C Antioxidants and NDDs

Most of the antioxidant classes shown in Table 16.1 have been studied in relation to NDDs. In particular, multiple reports have focused on carotenoids, curcuminoids, flavonoids, selenium, and vitamins C and E. In various studies these compound classes have been either studied alone, in

combination, or from botanical extracts. Thus, it is often difficult to compare the studies directly to one another. This difficulty is also compounded by differences in subject population, study design, and duration.

A post hoc analysis of the SU.VI.MAX trial in France (see Table 16.3) looked at the effects of supplementation with vitamin C, β-carotene, vitamin E, selenium, and zinc for 6 years on cognitive performance of almost 4500 French subjects [144]. The results showed that subjects receiving the supplements had significantly better scores on some measures of verbal memory (as one of a number of measure of cognitive function). A recent RCT providing cocoa flavonols to a smaller number of subjects for only 8 weeks also suggested that regular consumption of the antioxidant reduced some but not all measures of age-related cognitive decline [145].

More recent work has suggested that lutein, a carotenoid with antioxidant properties, may play a role in maintaining cognitive function in aging. This work grew out of numerous studies demonstrating the selective accumulation of lutein in the eye (where it is a component of macular pigment) and its possible role in protecting against age-related macular degeneration [146]. This led to the finding that lutein is the predominant carotenoid in brain [147]. There is recent work demonstrating that macular pigment density is related to cognitive function and that direct supplementation of the diet with lutein improves some measures of cognitive function in older women [148,149].

Results of studies investigating the effects of single or multiple antioxidant interventions on cognitive function have been mixed, at best. Most studies use multiple measures and the effects, if seen at all, are reflected only in a few. Nonetheless, the potential that a simple dietary intervention or antioxidant supplement can slow the progression of MCI is important and merits further investigation.

More recently attention has turned to assessing the effects of "dietary patterns" as opposed to single or multiple dietary antioxidants. In this regard, other post hoc analyses of the SU.VI.MAX trial have shown provocative results [150,151]. In the first study, adherence to a "Mediterranean Diet" was assessed in 3083 subjects who were also assessed for multiple measures of cognitive function. The results showed no beneficial effects of adherence to the dietary pattern. In contrast, the subsequent study that focused on a "carotenoid-rich dietary pattern" found a significantly higher composite cognitive score for those adhering to that pattern. A recent study of Swedish subjects correlated adherence either to a "prudent diet" or a "western diet" with cognitive performance over time as assessed by the mini-mental state examination (MMSE) [152]. The highest adherence to the prudent diet was related to less MMSE decline, while adherence to the western diet was associated with more decline. Moreover, the decline associated with the western diet was ameliorated by a higher adherence to the prudent diet. Thus, the authors suggested that a prudent diet may alleviate the adverse effects of a western diet on cognitive function.

Given the variability in results in studies of dietary antioxidants and cognitive function in aging individuals without frank dementia, it is not surprising that there is an even more confusing picture on the role of antioxidants in the treatment or prevention of Alzheimer's disease and other dementias. Studies addressing these issues often, and necessarily, involve the use of brain imaging techniques and/or biomarkers of amyloid pathology instead of, or in addition to, measures of cognitive function. For example, the Alzheimer's Disease Cooperative Study, Antioxidant Biomarker Study, involved 78 subjects with mild to moderate Alzheimer's disease [153]. Treatment was for 16 weeks with (1) vitamins E and C and α-lipoic acid, (2) coenzyme Q, or (3) placebo. The antioxidant treatment had no effect on cerebrospinal fluid biomarkers of amyloid or tau pathology but vitamin E, vitamin C, and lipoic acid treatment accelerated the decline in MMSE scores. In spite of such results, there is still much hope in the use of antioxidants in the prevention, treatment, and management of Alzheimer's disease. There are several recent reviews supporting this optimism [43,44,154]. Some authorities suggest that it is useful to view the role of dietary components in Alzheimer's disease in terms of maintaining adequate antioxidant nutritional status and fulfilling possibly increased requirements [154,155].

D Polymorphism: An Additional Risk Factor in Cancer

Evidence is increasing that genetic polymorphisms can influence the response to an arsenal of agents used in the battle against cancer, including both drugs and dietary components. However, these investigations are often conflicting because the development of cancer is not a simple process but, rather, involves multiple cellular events, many of which are likely influenced by genetic polymorphisms at the site of the target or by how the agent is modified through absorption, metabolism, or excretion.

Although ROS are integral to many cellular and biomolecular processes associated with acute coronary syndromes, metabolism, and early stages of cancer, the relationship to specific genetic polymorphisms has not been overly compelling and remains controversial. It may be that current eating behaviors prevent the easy identification of diet−gene−health interactions in this disease condition. However, mechanistically, the linkage with free radical-related gene polymorphisms is logical and deserves additional attention as a potential, subtle

long-term regulator of both cancer and heart disease risk. Little attention has been given to genes associated with oxidative stress and heart disease; the primary focus has been on cholesterol homeostasis and control [156]. However, two papers have focused on ROS and antioxidant vitamins. The overall view is that ROS are strongly linked with atherosclerosis, hypertension, and congestive heart failure, but a demonstrated efficacy of antioxidants has proved elusive [157,158].

A number of scientists have been exploring the effects of genetic polymorphisms on oxidative stress or the ability of antioxidants to influence cancer. Several examples concerning the possible utility of using specific polymorphisms as predictors of cancer risk have surfaced. For example, the manganese superoxide dismutase (MnSOD) protein is involved in decreasing the levels of superoxide anion generated during normal biochemical processes. A polymorphism that changes an alanine residue to valine in position 9 or valine to alanine in position 16 in the protein has been suspected to be a risk factor in prostate and breast carcinogenesis and has been found with higher frequency in individuals with prostate cancer [159–161] and, in some studies, with increased severity of the disease and earlier onset [161,162]. Likewise, breast cancer risk was observed to be slightly increased (odds ratio 1.3) in women with Ala/Ala genotype compared to those with Val/Val genotype [163]. Interestingly, patients carrying the Val allele may have a higher prevalence of cardiomyopathy [164]. However, these early findings need to be further investigated because a number of clinical and meta-analysis studies [160–162,165–172] examining the link of these mutations to both cancers are inconsistent, with some having failed to verify an association and others supporting it (Table 16.4). Some studies have shown the association to be primarily in those with low antioxidant consumption [160,170,173].

The catalase (CAT) gene polymorphism at 262C-T may also have a role in breast cancer development. This antioxidant enzyme neutralizes hydrogen peroxide and is known to be induced by oxidative challenges. A 262C-T polymorphism in the promoter region of CAT is associated with risk of several conditions related to oxidative stress. Interestingly, the CC genotype relationship with breast cancer reduction was only observed among Caucasians and not in African Americans [174]. CAT polymorphism at codon 262 does not appear to be related to diabetes and the risk of heart disease [175]. The reason for the disconnect among genetic polymorphisms (CAT and MnSOD), oxidative damage, and risk of cancer and heart disease warrants additional attention but may be due to an enhanced response to antioxidants in the CC genotype [173].

Still another gene involved in antioxidant activity and cancer risk is glutathione peroxidase 1 (GPX-1) [139]. Although codon 198 can lead to leucine or proline, it was determined that the leucine-containing allele was more frequently associated with breast cancer than was the proline-containing allele [176]; however, there are inconsistencies in the literature [177,178]. Combinations of gene polymorphism may offer additional insights into risk. Cox et al. [179] observed an increased breast cancer relative risk (OR = 1.87) in individuals with the MnSOD Ala16Ala genotype and the Leu198Leu genotype of GPX-1, whereas neither surfaced as risk modifiers when considered independently.

Environmental factors may also dictate the importance of genetic polymorphisms in determining cancer risk. For example, the T allele in the GPX-1 gene at position 198 is considered to be protective in smokers. In a study of smokers with 432 lung cancer cases and 366 controls, those possessing the variant T allele were significantly less likely to develop lung cancer than individuals without it [180]. Likewise, patients with alcohol-induced cirrhosis who had the genotype consistent with low MnSOD activity and also with high GPX-1 activity had much lower levels of potentially toxic levels of iron. In individuals

TABLE 16.4 Meta-Analyses of Prostate and Breast Cancer Risk with SOD Mutations

Mutation	Organ	No. of Studies	Cases	Controls	Results	Reference
Ala-9Val	Prostate	5	889	1841	Nonsignificant increase	[171]
Ala-9Val	Prostate	9	1660	2594	Positive	[160]
Ala-9Val	Breast	13	4278	5057	Nonsignificant increase	[160]
Ala-16Val	Prostate	4	2379	4066	Nonsignificant increase	[171]
Ala-16Val	Prostate	32	26,022	32,426	Negative	[172]
Ala-16Val	Prostate	12	3574	5388	Positive	[169]
Ala-16Val	Breast	17	9710	11,041	Negative	[165]

with both polymorphisms, none developed hepatocellular carcinoma, as opposed to other polymorphism combinations, for which 16−32% of the individuals developed liver cancer [181]. In addition, consumption of a number of food items may influence the relationship between individual polymorphisms and health. Both aldehyde dehydrogenase-2 (ALDH2) and X-ray repair cross-complementing 1 (XRCC1) genes have been identified as having a role in the response to dietary selenium. The glutamic acid 487 lysine polymorphism in the ALDH2 gene and the arginine 399 glutamine polymorphism in the XRCC1 gene are both associated with an increased risk of esophageal cancer in individuals consuming a low-selenium diet. In addition, this risk becomes even more pronounced in individuals who smoke or consume alcohol [182]. This may reflect the individual differences in the pharmacokinetics related to handling supplemental selenium. Likewise, the protective effect of the catalase CC genotype was even more pronounced among women who used dietary supplements, as well as those with high fruit and vegetable intakes [183]. In another study, an inverse association between fruit and vegetable consumption and breast cancer risk was observed among women with the wild-type genotype for codon 84 of their O6-methylguanine-DNA methyltransferase (MGMT) gene [184]. In this group, the observed OR was 0.8, whereas for individuals with other polymorphisms, the effects of a varied intake were not statistically significant. The association between fruit and vegetable consumption and reduced breast cancer risk was also seen in individuals with a variant allele for codon 143 in their MGMT gene. In another study, the intake of α- and β-carotene as modifiers of skin cancer was found to relate to MnSOD V16A polymorphism, such that an inverse association of intake was limited to the Val carriers, whereas no association was observed among women with the AA genotype [185].

E Antioxidants: Prevention Versus Treatment in Clinical Applications

As has been indicated, antioxidants can have both beneficial and deleterious effects on disease. In the case of CVD generally and atherosclerosis in particular, the effects of antioxidants would be expected to be primarily beneficial because lipid oxidation and inflammation are important factors in the sequelae involving atherosclerotic plaque development. The overall consensus is that interventions with dietary antioxidants seem to have a minor effect on prevention of atherosclerosis [186]. However, reviews on the relationships of statin drugs with free radical generation and inflammation provide evidence that statin drugs have a strong protective effect over and above their more well-known cholesterol-lowering activity [187]. Some of these protective effects, however, may be due to increased expression of antioxidant enzymes such as catalases and a suppression of pro-oxidant enzyme systems that reduce the production of the free radicals superoxide and peroxynitrite [188,189].

Antioxidant and ROS effects on the cancer process are in part dependent on the status and behaviors of the consumer as well as the stage of development and type of cancer involved. The ability to predict and distinguish between the positive and negative effects of antioxidants is especially crucial in those receiving cancer treatments.

Many cancer patients take vitamin supplements for protection and health promotion. A survey of patients at a comprehensive cancer center found that 60% of patients used vitamins and the majority combined them with conventional therapy [190]. Similarly, among a Massachusetts cohort of women with early stage breast cancer, 60% used megavitamin therapy along with surgery, chemotherapy, and/or radiation therapy [191]. Given the large numbers of cancer patients taking antioxidant vitamins, with or without the knowledge of their oncologists, development of a greater understanding of the actions of antioxidants within the cancer disease and treatment milieu is crucial. Consumer awareness of the issues between antioxidants and cancer appears to be increasing but is far behind other health-related dietary practices [192].

Radiotherapy, as well as many chemotherapeutic agents, eliminates cancer cells by inducing apoptosis via generation of ROS. Thus, it was feared that antioxidants, especially in megadoses, may decrease ROS production and thus decrease the benefits of these treatments. Nevertheless, a number of in vitro and some clinical studies have shown that antioxidant treatment during standard cancer therapy does not always interfere with these therapies. The use of high-dose levels of antioxidants appears to be critical to achieve a beneficial outcome when antioxidants are used with more conventional treatments. In several reported studies, low doses of antioxidants stimulated the growth of human cancer cells in culture, and a single low dose of antioxidant before radiation therapy protected cells against radiation damage, suggesting that low doses of antioxidants might have detrimental effects on cancer treatment [193,194]. High-dose levels have been defined in humans as up to 10 g vitamin C/day, up to 1000 IU vitamin E/day, and up to 60 μg β-carotene/day; in tissue culture, high levels have been considered up to 200 μg vitamin C/mL, up to 20 μg vitamin E/mL, and up to 15 μg β-carotene/mL [195]. Low-dose levels have been defined in humans as approximately the RDA values and in tissue culture as up to 50 μg vitamin C/mL, up to 5 μg vitamin E/mL, and up to 1 μg β-carotene/mL [193].

Although antioxidants may cause some inhibition of ROS production caused by chemo- or radiation therapy, at high levels the antioxidant can directly inhibit tumor growth and can appear to stimulate the drug effects. Prasad et al. [195] described the ability of the α-tocopherol succinate form of vitamin E to enhance the cytotoxic effects of adriamycin in human prostate cancer, glioma, and HeLa cells; enhance cisplatin, tamoxifen, and decarbazine in human melanoma and parotid acinar carcinoma cells; and promote doxorubicin to inhibit murine leukemia cell lines.

The subject of antioxidants during cancer care has been reviewed [196], but data from large-scale trials with antioxidants are not available. Interestingly, some smaller studies provide limited evidence that antioxidant supplementation can increase the efficacy of standard chemotherapies in humans. In 18 nonrandomized patients with small cell lung cancer, supplementation with multiple antioxidants along with chemotherapy or radiation therapy resulted in increased survival times. Retinoic acid and interferon enhanced the effect of radiation on locally advanced cervical adenoma, again improving survival times [197]. Two patients with advanced epithelial ovarian carcinoma (stage IIIC) received antioxidant therapy (1200 IU vitamin E, 300 mg coenzyme Q10, 9000 mg vitamin C, 25 mg mixed carotenoids, and 10,000 IU vitamin A) before conventional chemotherapy and 60 g ascorbic acid twice weekly at the end of therapy. Both women had normal CA-125 levels and remained disease-free more than 3 years after initial diagnosis [198]. In an open trial in patients with small cell lung cancer, patients who received individualized daily supplements of trace elements, fatty acids, and vitamins (including 15,000−40,000 IU vitamin A, 10,000−20,000 IU β-carotene, 300−800 IU vitamin E, 2−5 g vitamin C, and 1600−3400 μg selenium) had a greater 2-year survival rate than historical controls (33% vs 15%) [199,200]. Furthermore, an analysis of 385 breast cancer patients asked to recall antioxidant supplement use showed that users of supplements were less likely to have a breast cancer recurrence or breast cancer-related death than nonusers [201]. In contrast, an analysis of outcomes for 90 women with unilateral nonmetastatic breast cancer who received megadoses of vitamins and minerals (β-carotene, vitamin C, niacin, selenium, coenzyme Q10, and zinc) showed no improvement in survival compared to matched controls (the 5-year survival rate was 72% for cases and 81% for controls) [202]. Although definitive conclusions cannot be drawn from this limited number of studies, improvement in survival of patients receiving antioxidants in addition to chemotherapy has been observed. The use of antioxidant vitamins in conjunction with standard therapy warrants additional attention [203].

III OVERALL CONCLUSION AND DISCUSSION

Excessive oxidative stress can lead to excessive ROS and oxidative free radicals. These in turn can attack proteins, lipids, and genetic material, leading to decreases in immune competence and increased inflammatory response, all linked to several chronic diseases, cancer, CVD, obesity, diabetes, and so on [32]. However, ROS is a potential double-edged sword in disease promotion and prevention. Whereas the generation of ROS once was viewed as detrimental to the overall health of the organism, advances in research have shown that ROS plays crucial roles in normal physiological processes, including response to growth factors, the immune response, and apoptotic elimination of damaged cells. Notwithstanding these beneficial functions, aberrant production or regulation of ROS activity has been demonstrated to contribute to the development of some prevalent diseases and conditions, including cancer and CVD. Antioxidant supplementation has historically been viewed as a promising therapy for prevention and treatment of these diseases, especially given the tantalizing but sometimes conflicting links observed between diets high in fruits and vegetables (and presumably antioxidants) and decreased risks for cancer and CVD. Trials of individual antioxidants, however, have rarely shown strongly beneficial effects. In most healthy individuals, endogenous antioxidant defenses may be sufficient, and extra supplementation may have little effect on disease susceptibility. In some populations, particularly those with underlying illness or compromised nutritional status, dietary or other supplementation may be helpful. A better understanding of the impact of supplementation on disease risk may also be furthered by increased knowledge of individual genetic polymorphisms related to the metabolism and detoxification of ROS and antioxidants, as well as interactions of metabolic intermediates. A more critical issue is the interaction of antioxidants and orthodox cancer therapy.

Advances in tools used to determine oxidative status may allow for the estimating of an individual antioxidant profile. Whether supplements have positive or negative effects may depend on an individual's baseline antioxidant and ROS levels. Antioxidant supplementation in those with low baseline ROS could be detrimental because it may impair normal immune function and prevent ROS-mediated apoptotic elimination of precancerous or cancerous cells. Similarly, better measurements of ROS status may help to predict the potential for antioxidants in individuals exposed to specific environmental toxins, including but not limited to cigarette smoke, which may influence the magnitude and direction of the response.

Current measures of antioxidant status in an individual vary greatly among different research settings, making comparison of results problematic. The establishment of "gold standard" biomarkers of oxidative stress and establishment of guidelines to accurately and precisely determine levels of a given marker in normal, healthy individuals should help to resolve the uncertainties in the literature. Better measurements may also help to determine why a diet high in fruits and vegetables is often more beneficial than specific antioxidant supplements. Additional research focusing on critical events that contribute to disease progression will help in defining the most efficient times for intervention with antioxidant supplementation.

Future research must focus on defining molecular mechanisms that engender oxidative stress, transforming healthy conditions to diseased states, and identifying timelines for effective interventions with antioxidants as either preventive or therapeutic agents. Although much of the current literature about antioxidants, including administration of pharmacological or dietary amounts, focuses on enhancing ROS elimination and inhibiting ROS generation, many other cellular processes are likely involved. An improved understanding of these cellular processes and how they relate to measures of oxidative stress will provide important clues about those who will benefit most or be placed at risk from antioxidant usage, whether provided as foods or supplements. The identification of the reliable and sensitive biomarkers of antioxidant exposures, of their biological effects or consequences, and of susceptibility factors including genetic and environmental modifiers will have far-reaching implications for the monitoring and treatment of oxidative stress related to health and disease conditions.

Chapter 17

Choline and Brain Development

Mihai D. Niculescu
Advanced Nutrigenomics LLC, Concord, NC, United States

I INTRODUCTION

An increasing amount of evidence supports the hypothesis that chronic illness in adult life has, in part, its origins before birth due to various environmental exposures [1]. In such cases, prevention rather than treatment becomes the active principle in establishing long-term public health policies that will enable an overall improvement in the health status of the general population [2]. Various nutrient deficiencies (omega-3/6 fatty acids, iron, protein/amino acids, energy restriction, folate, choline, etc.), occurring during pregnancy or perinatally, have been associated with defects in brain development that range from impaired physiological functions such as decreased visual acuity to severe birth defects [3–9]. Moreover, such early alterations in brain development have been associated, in many cases, with long-term functional alterations of brain functions, within adulthood and the aging period [10–12].

The importance of adequate nutrition during brain development has been repeatedly reinforced by many studies. A growing body of evidence indicates that the relationship between various nutrients and the development of the nervous system is complex and not necessarily confined to one specific period of gestation, but there is no doubt that specific nutrients play essential roles in neural development [10,13,14]. This chapter discusses the role that choline and its metabolite betaine have in brain development and also the subsequent implications in the physiology of memory and brain aging.

II CHOLINE METABOLISM AND BIOCHEMISTRY

A Intestinal Absorption

Dietary free choline or choline-containing esters (e.g., phosphatidylcholine, PC) are first hydrolyzed in the intestine. The free choline is oxidized, in part, by the gut bacteria to betaine (Fig. 17.1) or further metabolized to methylamines [15], whereas the choline-containing esters are hydrolyzed by enzymes from the pancreatic secretions and from intestinal mucosal cells, such as phospholipases A_1, A_2, and B [16]. The remaining free choline is absorbed by the enterocytes via carrier-mediated transport [17,18], whereas betaine is absorbed most probably via active Na^+ or Cl^--coupled, and also via passive Na^+-independent transport systems (reviewed in [19]), at a faster rate than choline [17,18]. The bioavailability of choline-containing compounds is different in infants than in adults, probably as a consequence of differences in both the physiology of their digestive system [16] and the choline content of the milk [20].

B Transport and Tissue Uptake

Once absorbed into enterocytes, choline is transported to the liver via the portal circulation mainly as PC [21], or it is incorporated into chylomicrons and released into the systemic circulation via the lymphatic system [22,23]. Choline accumulates in all tissues [24] by diffusion and mediated transport (reviewed in [25,26]) using three distinct uptake systems: low-affinity facilitated diffusion, high-affinity Na^+-dependent transport, and an Na^+-independent transport with intermediate affinity [25,26]. Based on the affinity for choline, three types of transporters have been identified: cation transporters with low affinity, choline-transporter-like with intermediate affinity, and choline transporters (CHTs) with high affinity [25,26]. In addition, PC is trafficked via the ATP-binding cassette transporters (especially ABCA1 and ABCG1) [27–29]. In liver, choline uptake is also

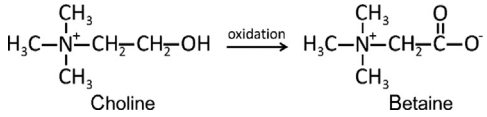

FIGURE 17.1 Molecular structures of choline and betaine.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00017-5

dependent on the remodeling of HDL-PC by secretory phospholipase A_2 [30]. Choline is transported across the blood–brain barrier by the CHT high-affinity system, represented by the solute carrier family 5 (CHT), member 7 (SLC5A7, known also as CHT or CHT1) [31–34]. Within the brain cells, this system depends partially on the integrity of endosomal apparatus [35], and it supplies choline for acetylcholine synthesis in presynaptic neurons [36]. Preliminary studies suggested that the CHT system could be enhanced by treatment with cytidine-5′-diphosphocholine (CDP-choline), specifically within cognitive areas such as the frontal cortex [37]. The CDP-choline pathway is the main source of endogenous PC synthesis in brain, and it contributes to axon formation, growth, and branching of primary sympathetic neurons [38]. Preliminary studies suggested that CHT trafficking to cell membrane (and the consequent increase in choline uptake) may be under the transient control of protein kinase C activation [39].

Choline is excreted in the primary urine by glomerular filtration, but only 2% of the filtered choline is found in the final urine because of the intense reabsorption present mainly in the proximal tubules [40], operated by an organic cation transport system [41].

C Metabolism

Fig. 17.2 presents a general overview of choline metabolism. Of special importance is the accumulation of choline by liver, kidney, brain, mammary gland, and placenta [24,25,42]. Choline is involved in three major pathways: acetylcholine synthesis, methyl donation via its oxidation to betaine, and PC synthesis. The latter two have a special importance in brain development [43,44]. PC synthesis occurs by two independent pathways (Fig. 17.2). Choline is phosphorylated by choline kinase and converted subsequently to CDP-choline. In combination with diacylglycerol, CDP-choline forms PC (reaction catalyzed by diacylglycerol cholinephosphotransferase). In an alternate pathway, choline is synthesized de novo by the methylation of phosphatidylethanolamine (PtdEtn) to PC in a reaction catalyzed by PtdEtn-*N*-methyltransferase (Pemt, EC 2.1.1.17) using *S*-adenosylmethionine as methyl donor [45,46]. Although most active in liver, this pathway is also active in other tissues, such as fetal brain and mammary gland [47–49]. In brain, choline regulates the Na^+, K^+-ATPase activity, although its mechanism of action is not yet completely understood [50].

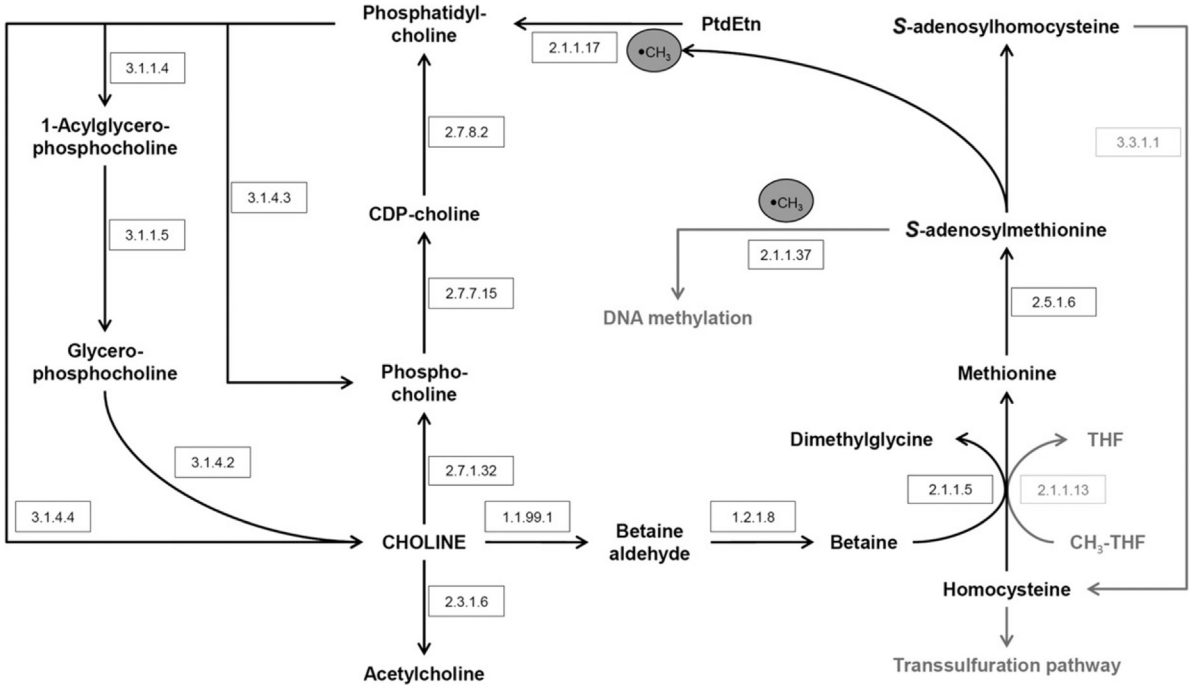

FIGURE 17.2 Choline metabolism. Enzymes are represented by EC numbers (1.1.99.1, choline dehydrogenase; 1.2.1.8, betaine-aldehyde dehydrogenase; 2.1.1.5, betaine-homocysteine *S*-methyltransferase; 2.1.1.13, methionine synthase; 2.1.1.17, PtdEtn *N*-methyltransferase; 2.1.1.37, DNA (cytosine-5-)-methyltransferase; 2.3.1.6, choline *O*-acetyltransferase; 2.5.1.6, methionine adenosyltransferase; 2.7.1.32, choline kinase; 2.7.7.15, choline-phosphate cytidylyltransferase; 2.7.8.2, diacylglycerol cholinephosphotransferase; 3.1.1.4, phospholipase A2; 3.1.1.5, lysophospholipase; 3.1.4.2, glycerophosphocholine phosphodiesterase; 3.1.4.3, phospholipase C; 3.1.4.4, phospholipase D; 3.3.1.1, adenosylhomocysteinase). PtdEtn, phosphatidylethanolamine; THF, tetrahydrofolate.

Choline is also involved in the one-carbon metabolism via its irreversible oxidation to betaine [51], which methylates homocysteine to form methionine, thus contributing to the *S*-adenosylmethionine synthesis and linking choline with folate metabolism (Fig. 17.2). Note that choline and folate metabolisms interact dynamically. Relative to brain, folate-deficient intakes or *Mthfr* heterozygosity enhanced the conversion of choline to betaine in order to sustain the homeostasis of methyl groups available for homocysteine methylation [52]. When rats were exposed to a folate-deficient diet for 10 weeks, choline levels decreased in liver, lung, kidneys, and heart [53]. Surprisingly, choline levels were moderately elevated in the cortex and striatum [53].

During pregnancy, choline is transported across the placenta by active mechanisms, against a concentration gradient [54]. The fetus is exposed to a high concentration of choline, and plasma choline concentration progressively declines after the first weeks of life [55]. In human newborns, plasma-free choline can reach concentrations of approximately 70 μM [56], whereas in adults, plasma-free choline is much lower (7−20 μM) [56,57]. The majority of choline in blood circulates as PC (1−2.5 mM) [56,57].

TABLE 17.1 Adequate Intakes for Choline

Group	Age	Adequate Intake (mg/day)
Infants and children	0−6 months	125
	7−12 months	150
	1−3 years	200
	4−8 years	250
	9−13 years	375
Boys	14−18 years	550
Girls	14−18 years	400
Pregnant women	All ages	450
Lactating women	All ages	550
Other men		550
Other women		425

III CHOLINE IN FOODS AND DIETARY REQUIREMENTS

A Dietary Sources

Most of the foods we eat contain various amounts of free choline, choline esters, and betaine [48]. In 2004, the U.S. Department of Agriculture (USDA) released its first database on choline content in common foods (https://www.ars.usda.gov/ARSUserFiles/80400525/Data/Choline/Choln02.pdf). In most foods, free choline and PC are the most abundant compounds. The foods most abundant in choline are of animal origin, especially eggs and liver, but some vegetables also have significant amounts of free choline and PC (Brussels sprouts, cauliflower, nuts, etc.). Cereals and many baked products contain high amounts of betaine as well.

In human breast milk, free choline and all main choline esters are abundant, with total choline levels between 0.6 and 2 mM [58]. Manufacturers of infant formulas have modified the content of choline compounds to levels similar to those of human breast milk [20,58].

B Dietary Requirements

Although choline was not initially considered an essential nutrient because of its endogenous de novo synthesis from PtdEtn [59], human studies during the past two decades have demonstrated that dietary choline is required (reviewed in [60]). In 1998, the U.S. Institute of Medicine (Food and Nutrition Board) established for the first time adequate intake (AI) and tolerable upper intake limit (UL) values for choline based on limited human studies [61] (Table 17.1). These values remained unchanged after the 2010 revision of the Dietary Reference Intakes by the USDA. The UL values range from 1000 mg/day in children to 3500 mg/day in adults [61]. However, for some age categories for which adequate data were missing, AI values have been set by extrapolating from adult values (for ages 1−18 years) and for infants (for ages 7−12 months) [61]. Although a previous controlled study indicated that choline intakes may be adequate [62], a later epidemiological study using participants from the Framingham Offspring Study indicated that the mean intake for total choline (energy adjusted) is below the AI values, with a mean intake of 313 mg/day; moreover, there was an inverse association between choline intake and plasma total homocysteine concentration in subjects with low-folate intakes [63]. This study strengthened previous similar findings in pregnant women, where a significant percentage of individuals had lower choline intakes than the recommended AI values [64,65]. The realization that choline intakes in the general U.S. population may not be adequate has been refined by studies indicating that high-frequency genetic variations within genes involved in choline and folate metabolism can significantly alter the threshold for dietary requirements, thus raising the issue of individual-specific AIs for choline, rather than the general recommendations that are in place today (Table 17.1) [60,66−69]. Age- and gender-specific

differences have also been reported for choline concentrations in plasma and human brain, indicating that the definition of dietary choline intakes should also take into consideration the physiological variations associated with gender and age [70,71].

C Interactions With Other Nutrients and Environment-Related Chemicals

Several animal studies have indicated that choline metabolism can be modulated by interaction with other nutrients and vitamins or by chemicals present in foods, water, food packaging, or food containers.

Dietary choline supplementation has proved beneficial against physical, neurological, and behavioral alterations induced by alcohol exposure. When pregnant rats were subjected to both alcohol and choline supplementation, behavioral measures in the offspring were improved compared to those of a group exposed only to alcohol, indicating that early choline supplementation could reduce the severity of fetal alcohol outcomes [72]. Within the same model, alterations induced by alcohol exposure in working memory were mitigated by choline supplementation [73]. Rats exposed postnatally to alcohol, and later choline supplemented, had significant reductions in the severity of trace eyeblink deficits induced by alcohol exposure [74].

The exposure to nicotine has been reported to adversely affect choline metabolism and brain development, although not all reported results are convergent. Gestational exposure of rats to nicotine decreased the choline uptake in the brains from offspring, due to lower binding to the high-affinity transporter, whereas changes in the acetylcholine esterase and choline acetyltransferase (ChAT) levels were variable and brain-area specific [75]. When young mice were exposed to cigarette smoke (containing a high and a low nicotine dose), those exposed to high nicotine smoke had increased choline uptake in the hippocampus and cerebral cortex compared to those exposed to low nicotine smoke or controls [76].

In rats, choline supplementation reversed the long-term alterations in learning and memory induced by Pb^{2+} exposure, which associated with higher gene and protein expression for the *N*-methyl-D-aspartate (NMDA) receptor subunit 1 (NR1), compared to the group exposed only to Pb^{2+} [77].

Mice fed on a choline-deficient diet registered increased nonheme iron in the liver. The assessment of protein and mRNA expression of genes involved in iron metabolism and transport suggested that dietary choline deficiency may be associated with enhanced iron intake and reduced hepatic iron efflux [78].

Choline availability is enhanced by supplementation with vitamins B_6 and B_{12}, which are involved in folate and homocysteine metabolism (Fig. 17.2) [79]. However, it is not clear whether these interactions have consequences for brain development.

Choline metabolism is also altered by the presence of other chemicals that, although not nutrients, can be found in packaging materials, drinking water, cosmetics, or other plastics used for foods. Examples are bisphenol A, diethanolamine, and arsenic [80–85].

D Consequences of Dietary Choline Deficiency in Humans

Studies performed in animals and humans have categorized the effects induced by dietary choline deficiency into three groups: (1) changes in acetylcholine synthesis and release in brain, (2) organ dysfunction/metabolic changes in adults eating a low-choline diet for a relatively short time, and (3) birth defects (abnormal neural tube closure and cleft palate) in newborns from mothers eating diets lower in choline content, as well as effects of choline on neural-related cell proliferation and survival in rodents.

Historically, the first reports on the effects induced by changing dietary choline focused on acetylcholine release in human brain and the consequences this had on memory, small motor movements, and the release of other neurotransmitters such as 7-aminobutyric acid (reviewed in [86]). In this context, the effectiveness of choline supplementation in improving the acetylcholine release was, for most of the studies, limited to individuals with neurological disorders such as tardive dyskinesia and Alzheimer's disease [87]. Using rodent models, dietary choline has been shown to modulate the density of the benzodiazepine receptors and the function of the GABAergic receptors in the cortex [86], but whether these findings can be applied to healthy humans remains unclear.

Human dietary requirements for choline have been studied in subjects fed low-choline diets under controlled conditions; they developed reversible fatty liver as well as liver and muscle damage [88,89]. These clinical outcomes were associated with increased apoptosis in lymphocytes [90]. Premenopausal women were less likely to develop organ dysfunction when fed a low-choline diet than were men or postmenopausal women, most likely because estrogen contributes to the activation of the gene that regulates the endogenous synthesis of choline (PtdEtn-*N*-methyltransferase gene (*PEMT*)) [91]. Interestingly, the risk of developing such clinical signs was associated with the presence of several polymorphisms within genes involved in folate and choline metabolism, such as the *PEMT* gene, the choline dehydrogenase gene (*CHDH*), and the 5,10-methylenetetrahydrofolate dehydrogenase (*MTHFD1*) gene, suggesting that dietary choline requirements may differ with genotype, gender, and estrogen status [68,92].

The third category of effects relates to critical periods when choline is needed for fetal and infant development, for which most studies have focused on neural and brain development.

IV CHOLINE AND NEURAL DEVELOPMENT

Dietary choline is essential in at least two distinct stages of brain development: neurulation (formation and closure of the neural tube) and a later stage (late pregnancy and potentially the neonatal period) during the maturation of hippocampus and other brain areas. Although the mechanisms responsible for these outcomes have been partially elucidated in animal models, confirmation in human studies is available only for early pregnancy.

A Choline Availability in Early Pregnancy

When gestation day 9 mouse embryos were exposed in vitro to either an inhibitor of choline uptake (2-dimethylaminoethanol) or an inhibitor of PC synthesis (1-*O*-octadecyl-2-*O*-methyl-rac-glycero-3-phosphocholine; ET-18-OCH3), they developed craniofacial hypoplasia and open neural tube defects in the forebrain, midbrain, and hindbrain regions [93]—alterations that are similar to those induced by folate deficiency [94]. Increased cell death was associated especially with the inhibition of PC synthesis [93]. A subsequent study using the same mouse embryo model revealed that the mechanisms responsible for these outcomes were related to alterations in choline metabolism pathways [95], stressing the importance of dietary choline. These two animal studies were enhanced by data from human epidemiological studies describing similar outcomes in newborns from mothers who ate diets low in choline during pregnancy. In these studies, Shaw et al. reported that maternal dietary choline and betaine intakes during pregnancy inversely correlated with the risk of having a baby with neural tube defects and orofacial clefts [64,65]. Women in the lowest quartile of total choline intake during the periconceptional period (290.41 mg/day) and eating diets low in folate content had a fourfold higher risk of having a baby with neural tube defects (spina bifida and anencephaly) than the women in the highest quartile for choline intake and with a low-folate diet [65]. A similar relationship was also found between maternal choline intake and the increased risk of cleft lip with cleft palate [64]. However, a recent study by the same group failed to replicate these findings [96]. It is not clear whether this discrepancy was due to differences in study design or differences in the recruited populations [96]. Another study performed by the same team found a surprising association between higher intakes of choline and increased risk for metopic synostosis [97].

Independent of the maternal choline intake, the presence of single nucleotide polymorphisms of two genes involved in choline metabolism—choline kinase A (*CHKA*) and CTP:phosphocholine cytidylyltransferase 1 (*PCYT1A*)—increased the risk of spina bifida in infants [98]. Together, these data suggest that the risk for neural tube defects may be related to the maternal dietary choline and folate intakes and to the presence of genetic polymorphisms in genes related to the metabolism of these two nutrients in the offspring.

B Choline Availability in Late Pregnancy

During later gestation, rat and mouse models have been used to explore the role of choline in fetal brain development.

1 Choline Deficiency Inhibits Cell Proliferation

Rats and mice fed a low-choline diet in late pregnancy (gestational days 12−17 in mice and days 12−18 or 20 in rats) had reduced neural precursor cell proliferation and increased apoptosis in fetal hippocampus and cortex [99−101]. Similar outcomes were reported when pregnant mice were fed a low-folate diet [102], again suggesting the potential synergistic mechanisms of action between folate and choline. These alterations were confirmed in cell culture studies using primary neurons, pheochromocytoma cells, and human neuroblastoma cells. Dividing neuron-like cells (PC 12) exposed to a choline-deficient medium had decreased cell division and increased apoptosis and had diminished concentrations of PC in their membranes [99,103]. The induced apoptosis is caspase 3-dependent in both cell culture and fetal brain models [101,103]. These changes were associated with important alterations of proteins involved in cell signaling, neuronal differentiation, and the regulation of cell-cycle progression. Choline deficiency altered the expression of structural and signaling proteins such as TGF-β_1, vimentin, and MAP1 in the rat hippocampus [104]. Decreased cell proliferation was also associated with increased expression of neuronal and glial differentiation markers vimentin, TOAD-64 (dihydropyriminidase-like 2; Dpysl2), and calretinin [100,104,105]. Moreover, choline deficiency altered the protein expression of netrin and DCC, two proteins required for axonal growth and guidance in the developing nervous system [106]. These data suggested that choline deficiency induces a net trend toward the differentiation of neural progenitors and a subsequent reduction of the pool of the available precursor cells. Some differences persist for the lifetime of the offspring of treated mothers; prenatal choline supplementation decreased calretinin protein levels in the adult (24-month) mouse hippocampus [105].

A study revealed that the alterations in cell proliferations induced by fetal choline deficiency are not confined to neural cells. Angiogenesis in mouse fetal hippocampus was inhibited by choline deficiency (gestational day 17) due to decreased proliferation of endothelial cells [107]. The reduction was associated with increased expression of genes involved in angiogenic signaling (*Vegfc* and *Angpt2*) [107].

Regarding the link between choline and folate metabolisms (discussed previously), limited studies indicated that choline supplementation could partially offset the deleterious effects of folate deficiency on fetal brain development. Whereas folate deficiency during late pregnancy (gestational days 11−17) presented less cell proliferation and increased apoptosis within septum, hippocampus, striatum, and the anterior and midposterior neocortex, the concomitant exposure to a folate-deficient, choline-supplemented diet partially mitigated these outcomes in some of the brain areas but not all [108].

The mechanisms associating choline deficiency with decreased cell proliferation are, in part, related to the overexpression of cyclin-dependent kinase inhibitors p27Kip1 [109], p15Ink4b [109,110], and Cdkn3 [110,111], indicating that choline deficiency inhibits cell proliferation by inducing G_1 arrest because of the inhibition of the interaction between cyclin-dependent kinases and cyclins. Moreover, in human neuroblastoma cells (IMR-32), choline deficiency decreased the phosphorylation of the retinoblastoma protein (p110, Rb) [111]. This interaction model between p27Kip1 and p15Ink4b cyclin-dependent kinase inhibitors, TGF-β, and the Rb proteins fits the previously described model of cell-cycle regulation (reviewed in [112]), in which the net outcome is cell-cycle arrest in the G_1 phase of the cell cycle. These findings were reinforced by a study using mouse hippocampal and cortical progenitor cells exposed to choline deficiency for 48 hours. Using oligonucleotide arrays, the authors reported extensive changes in more than 1000 genes, of which 331 were related to cell division, apoptosis, neuronal and glial differentiation, methyl metabolism, and calcium-binding protein ontology classes [113], where, again, the net result was toward reduced cell proliferation, increased apoptosis, and increased neuronal and glial differentiation.

2 Choline Deficiency Alters Gene Expression via Epigenetic Mechanisms

Epigenetic mechanisms consist of chemical changes of the chromatin (DNA and histones) that do not alter the DNA sequence and that establish meiotically and mitotically stable, heritable patterns of gene expression [114,115]. These mechanisms consist of DNA methylation and hydroxymethylation, histone modifications, along with the modulation of epigenetic marks by noncoding RNA species [14,115,116].

a Epigenetic Mechanisms Regulate Gene Expression

DNA methylation is represented by the substitution of hydrogen with methyl groups to DNA (reviewed in [117]). In mammalians, the majority of DNA methylation occurs at carbon 5 of the cytosine ring (5-methylcytosine; 5mC) only when the cytosine is followed by a guanine nucleotide (CpG site), but methyl groups can be also added to other nucleotides [117]. This process is catalyzed by DNA methyltransferases (DNMTs). During the S-phase of cell-cycle progression, the DNA methylation status of the parental DNA strand is duplicated on the newly synthesized DNA by maintenance DNA methyltransferase, DNMT1 [118]. However, DNA methylation can also occur at previously unmethylated CpG sites (de novo DNA methylation), catalyzed by de novo DNA methyltransferases, DNMT3a and 3b, and with participation of DNMT2 and 3L [118].

When DNA methylation occurs within promoter regions, it usually associates with gene underexpression and chromatin compaction [51], but instances have been described in which promoter hypermethylation prevented the binding of inhibitory factors, thus allowing for promoter activation and gene overexpression [119]. The establishment of cell type-specific DNA methylation patterns contributes decisively to shaping the cellular phenotypes of differentiated cells [118].

Within the concept of epigenetic regulation of gene expression, an important feature is genomic imprinting, allowing genes to be expressed in a parent-of-origin manner (imprinted genes), and this process being the molecular basis for monoallelic expression [120]. During early embryogenesis, most of the parental DNA methylation patterns are erased by active and passive demethylation mechanisms (with the exception of some imprinted regions), whereas new DNA methylation patterns are established by de novo methylation. The establishment of new epigenetic patterns continues during fetal morphogenesis and in the early postnatal period [121].

The epigenetics of DNA also includes the hydroxylation of methyl groups attached to cytosine, as an intermediary step in active DNA demethylation, with important functional consequences on gene activation [122]. This groundbreaking discovery provided the first plausible mechanism for the previously observed active DNA demethylation [116].

Chromatin modifications occur at the flexible tail regions of histones. These modifications include, but are not limited to, methylation, acetylation, phosphorylation, ubiquitination, and ADP ribosylation [123]. In concert with DNA methylation, histone modifications allow for

the reversible switch between chromatin relaxation and compaction and also the establishment of the degree of access that transcription factors have to promoter regions [118,123]. Examples are methylation of histone H3 at its lysine 9 and 27 residues (K9 and K27), allowing for chromatin compaction and inhibition of gene expression, and trimethylation of H3K4 that induces transcriptional activation and promoter activation [123].

MicroRNAs (miRNAs) are noncoding RNA species, up to 25 nucleotides in length, that contribute to gene expression regulation through RNA interference [124]. Their epigenetic role consists of the modulation of expression for several genes involved in the epigenetic machinery, which are responsible for DNA and histone modifications (e.g., *DNMT3a/b*, *HDAC1/4*, and *MeCP2*) [124]. Some genes encoding miRNA species can also be epigenetically regulated because their gene expression is highly dependent on their promoter methylation (reviewed in [124]).

b DNA Methylation, Fetal Development, and Cell Differentiation

DNA methylation is very important during embryogenesis and late fetal development. Although the original DNA methylation pattern is germline specific (sperm DNA is hypermethylated compared to oocyte DNA), almost immediately after fertilization (within one or two cell divisions) there is a dramatic erasure of methylation, which continues until blastocyst implantation [121]. Following implantation, mouse embryonic stem cells are subjected to de novo methylation catalyzed by *Dnmt3a* and *Dnmt3b* genes (de novo methylases), with the exception of certain tissue-specific genes that remain unmethylated [121]. Once established, the new methylation pattern is conserved during cell replication (catalyzed by Dnmt1 in the S-phase of cell division [125]). These methylation patterns can be changed as cells differentiate (cell differentiation is associated with a genome-wide DNA hypomethylation followed by remethylation [117]) and can be altered by dietary intake of methyl donors (discussed next).

c DNA Methylation and Neural Development

Neural development is influenced by DNA methylation. Overall levels of methylation decrease as neuronal differentiation proceeds [126], and the treatment of neural precursor cells with demethylating agents induces them to differentiate into cholinergic and adrenergic neurons [127]. These methylation patterns are cell type-specific: Whereas mature neurons express DNMTs, these genes have much lower levels of expression in oligodendrocytes and astrocytes in the white matter [128]. The expression of DNMTs has a different importance, based on the differentiation stage of the cell: deletion of Dnmt1 in postmitotic neurons does not affect overall levels of DNA methylation, whereas the same deletion in neural progenitors markedly decreases methylation levels and causes severe defects in neurogenesis [129]. Astrocyte differentiation is also dependent on the methylation status of glial fibrillary acidic protein (*Gfap*) promoter at the binding site of STAT3 transcription factor. This promoter site becomes hypomethylated before differentiation, and its methylation prevents gene activation by STAT3 and astrocyte differentiation in fetal brain [130].

d Choline Deficiency Alters Epigenetic Status in Fetal Brain

Although the relationship between nutrition and epigenetics has been firmly established [131], less is known about the epigenetic mechanisms involved in nutritionally triggered alterations in fetal brain development. However, available data allow us to identify an important role for choline in DNA methylation during brain development (reviewed in [132]). Maternal choline deficiency decreased the global DNA methylation in the neuroepithelial layer of the fetal hippocampus [110], whereas opposite effects were reported in the fetal brains from $Pemt^{-/-}$ mice, which also had increased *S*-adenosylmethionine levels [133]. Interestingly, $Pemt^{-/-}$ mice also had altered methylation of the lysine 4 and 9 residues within histone 3, suggesting that alterations in choline availability to the fetal brain may be crucial for both DNA and histone methylation [133]. Along with decreased global methylation, changes in gene-specific methylation were reported, where the promoter of cyclin-dependent kinase 3 (*Cdkn3*) was hypomethylated by choline deficiency in the progenitor layer of the hippocampus and in human neuroblastoma cells [110,111]. These alterations were associated with increased protein expression of this cyclin-dependent kinase inhibitor [110], and this model is consistent with previous findings regarding the epigenetic regulation of cyclin-dependent kinase inhibitors and their roles in cell proliferation [134]. Choline deficiency also induced DNA hypermethylation of the calbindin 1 promoter on the mouse fetal hippocampus, which associated with region-specific hypomethylation of monomethyl-lysine 9 of histone 3 (H3K9me1) and dimethyl-lysine of histone 3 (H3K9me2) in the hippocampus [119].

The epigenetic roles of choline are not confined to neural cells. Within the fetal hippocampus, the reduction in angiogenesis induced by choline deficiency also involved the DNA hypomethylation of CpG islands within the *Vegfc* and *Angpt2* promoters, two genes that are implicated in angiogenic signaling [107].

Because dietary choline is important in the maintenance of the *S*-adenosylmethionine pool (the methyl donor for DNA methylation), along with folate and methionine (Fig. 17.2), it is attractive to hypothesize that

choline, by influencing the epigenetic status of the developing brain, could thereby induce permanent epigenetic changes associated with alterations of brain function at later ages [14]. Fig. 17.3 summarizes the hypothesized role that choline may play in the regulation of early brain development.

V LONG-LASTING CONSEQUENCES OF PRENATAL CHOLINE AVAILABILITY

A Molecular and Functional Changes

The changes induced by dietary choline in fetal brain have long-lasting effects that alter the neuronal function throughout the adult life. When pregnant rats were choline supplemented during late gestation, basal and receptor-stimulated phospholipase D activity was upregulated in the hippocampus of the offspring during postnatal development [135]. Acetylcholine metabolism and choline uptake mechanisms were also permanently altered in the adult brain. ChAT and acetylcholinesterase (AChE) activities were increased in the adult hippocampus of rats exposed to choline deficiency while in utero, and choline incorporation into acetylcholine was more dependent on high-affinity choline uptake mechanisms, compared to controls or to rats that were choline supplemented while in utero [136]. The increase in AChE activity was later found to be due to increased AChE protein synthesis [137], strongly suggesting that gene expression or post-transcriptional regulation was permanently altered by choline deficiency. This hypothesis was confirmed later in a study showing that the gene expression of the choline transporter, Cht, was increased in the adult hippocampus from rats exposed to prenatal choline deficiency, and that this correlated with an increased number of neurons that were CHT immunoreactive [138]. In addition, many other changes in gene expression were described to occur in the adult hippocampus and cortex, initiated by prenatal choline manipulation [139].

Cell signaling is also influenced by prenatal choline availability. In juvenile rats, the phosphorylation and activation of hippocampal mitogen-activated protein kinase and cAMP response element binding protein in response to glutamate, NMDA stimulation, or depolarizing concentrations of K^+ were increased by choline supplementation and reduced by choline deficiency while in utero [140]. Choline supplementation while in utero also increased the levels of nerve growth factor (NGF) in the adult rat hippocampus and cortex [141], suggesting that prenatal choline availability has an important role in promoting neurogenesis in the adult hippocampus, which is mediated by the nootropic action of NGF [142]. Opposite changes were reported for choline deficiency while in utero in other areas of the forebrain, such as medial septal nucleus, nucleus of the diagonal band, and the nucleus basalis of Meynert [143].

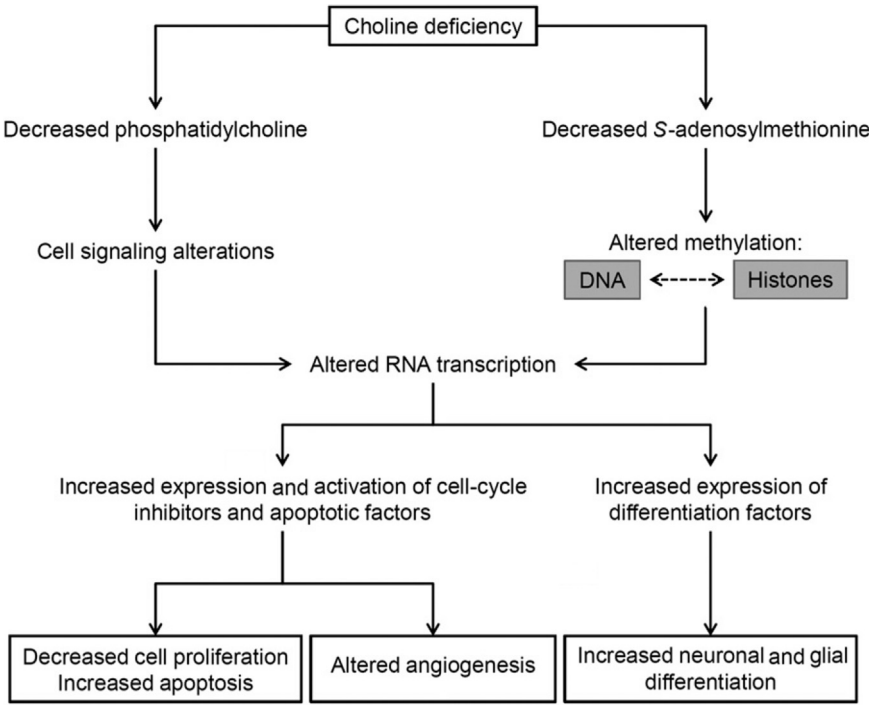

FIGURE 17.3 Choline deficiency alters brain development.

Although confirmation is needed in humans, these findings provided evidence that prenatal choline availability initiates a pattern of permanent metabolic alterations (metabolic imprinting) that, once established, plays an important role in later life [144].

B Choline Deficiency Induces Cognitive and Memory Deficits

The functional and molecular changes previously described are, at least in part, responsible for behavioral and memory changes initiated by prenatal variation in the availability of choline to developing brain (reviewed in [43]). Prenatal choline supplementation protects against the neurotoxicity induced by the administration of the NMDA receptor antagonist dizocilpine (MK-801) to female adolescent rats [145,146]. When status epilepticus was induced in adult rats using kainic acid, rats receiving supplemental choline between gestational day 11 and postnatal day 7 performed better in the water maze tests than did the deficient and control groups, whereas the hippocampal ChAT activity was 18% lower in the choline-deficient animals compared with the other two groups [147]. However, prenatal choline-deficient rats were not more susceptible to seizure induction by kainic acid than the group receiving adequate choline during fetal development [148].

Maternal dietary choline availability during late pregnancy was associated with long-lasting changes in the hippocampal function of the adult offspring. Choline supplementation during this period enhanced visuospatial and auditory memory in the adult rats throughout their life span [149–153]. It also enhanced a property of the hippocampus, long-term potentiation [154–156]. The offspring from mothers fed a choline-deficient diet manifested opposite outcomes [150,154].

In men, the choline concentration in the anterior cingulated cortex correlated with age, and higher total choline values were positively correlated with faster performance on the Stroop Interference task [157]. Postmortem assessment of choline levels in the brains of men with Alzheimer's disease indicated lower levels of plasmalogen choline in the prefrontal cortex than in controls, but it was unclear whether there was a mechanistic association between choline levels and disease because other components within phospholipids were also altered (i.e., docosahexaenoic acid) [158].

VI IMPLICATIONS FOR HUMAN BRAIN DEVELOPMENT

It is difficult to extrapolate to humans the findings reported using animal models. However, data are available to support the hypothesis that similar mechanisms are involved in humans. Because of ethical constraints, no studies are available in children or pregnant mothers to validate the rodent model. Because pregnant women are at risk of becoming choline deficient [60,159–161], and possibly having increased risk of giving birth to infants with neural tube defects [65], the recommendation that pregnant women should attempt to consume diets adequate in choline content seems reasonable. In addition, because half of the population has gene polymorphisms that affect choline and folate metabolisms [68,92], it is likely that different individuals may have different dietary requirements for choline and may need to pay special attention to choline intake not only during pregnancy but also during all other life stages.

ACKNOWLEDGMENT

The author acknowledges and thanks A.R. Niculescu for his contribution to the artwork included in this chapter.

I INTRODUCTION

Over the past century there has been a significant increase in human life expectancy in developed countries, a phenomenon that is largely attributed to medical advances that have led to a decrease in mortality from infectious diseases and cardiovascular disease during this period [1]. However, a downside to this trend has been an increase in the incidence of age-related neurodegenerative diseases, including Alzheimer's disease (AD) and Parkinson's disease (PD). AD is the most common neurodegenerative disorder, affecting approximately 36 million people worldwide, including 11% and 32% of individuals over the age of 65 years and 85 years, respectively [2,3]. PD is the second most common neurodegenerative disease, affecting 5 million people worldwide including 5% of the population over the age of 85 years [4–6]. Not only do these devastating diseases have a profound emotional impact on patients and their families, but they also impose a major economic burden on society. For example, the cost of AD worldwide is estimated to have exceeded $800 billion in 2015 [7], and in 2010 the cost of PD is reported to have been greater than $14 billion in the United States alone [8]. These costs are expected to increase to unsustainable levels as our population continues to age over the next few decades.

A major limitation of current approaches to treating AD or PD patients is that no disease-altering therapies are available to slow the underlying neurodegeneration. Instead, the options available to patients consist of symptomatic therapies that provide only marginal benefits in the case of AD patients, or a real but temporary relief of motor symptoms in the case of PD patients. As a result, research in the AD and PD field is largely focused on elucidating the molecular underpinnings of these disorders to enable the development of disease-altering therapies. A substantial part of this effort has been aimed at characterizing a role for the diet in AD and PD, with a view towards identifying dietary components that reduce the risk of these diseases or that slow the underlying neurodegeneration in the brains of patients. In particular, dietary plant constituents including polyphenols have been examined extensively as potential neuroprotective agents based on epidemiological evidence suggesting that their consumption may lead to a reduced risk of AD or PD [9–17].

In this chapter, we provide an overview of dietary phytochemicals that have shown promise as potential neuroprotective agents in AD and PD. We begin with a summary of the symptoms, pathobiology, treatments, and underlying molecular deficits of both diseases. Next, we summarize neuroprotective effects of plant constituents in AD and PD models, with an emphasis on the effects of polyphenols, and we discuss molecular mechanisms by which these agents are thought to alleviate neurotoxicity in AD and PD models. We conclude by looking ahead to future research that could set the stage for using phytochemicals as neuroprotective agents in the treatment of AD or PD.

II ALZHEIMER'S DISEASE

A Symptoms, Neuropathology, and Treatments

Characteristic symptoms of AD include: memory loss that interferes with daily activities; an impaired ability to

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00018-7

learn, reason, or solve problems; confusion; changes in mood or personality; and anxiety, agitation, and sleep disturbances [3]. These symptoms are largely attributed to an array of pathological changes in the brain, including the presence of extracellular amyloid plaques (also referred to as neuritic or senile plaques) and intracellular neurofibrillary tangles (NFTs) [2,18,19]. Amyloid plaques are enriched with fibrillar forms of amyloid-β (Aβ), a peptide of 38−43 amino acid residues that is excised from a larger transmembrane protein, the amyloid precursor protein (APP), via sequential proteolytic cleavages catalyzed by β-secretase (BACE) and the γ-secretase complex (Fig. 18.1). $A\beta_{42}$, the 42-residue form of Aβ, has an enhanced propensity to form amyloid fibrils compared to the more abundant $A\beta_{40}$ peptide and is the predominant Aβ species found in amyloid plaques [19,20]. NFTs are enriched with fibrillar forms of the microtubule-binding protein tau [2,18,19]. AD neuropathology occurs in areas of higher cognitive function and is thought to spread from the entorhinal cortex, basal forebrain, and nucleus basalis to the hippocampus and neocortex during the course of the disease [21,22]. Extensive neurodegeneration in these areas ultimately leads to a pronounced loss of brain volume in AD patients [2,18]. A striking feature of neurons with NFTs and neurons in the vicinity of amyloid plaques is a destruction of synapses, in turn resulting in a marked decrease in levels of neurotransmitters, including acetylcholine, serotonin, norepinephrine, and dopamine. In addition, dysregulation of the neurotransmitter glutamate contributes to synaptic deterioration and neuronal cell death via mechanisms related to excitotoxicity.

A subset of drugs currently used to treat AD patients is cholinesterase inhibitors. These agents, including donepezil, rivastigmine, and galantamine, block the hydrolysis of acetylcholine catalyzed by the enzyme acetylcholinesterase, thereby compensating for the loss of acetylcholine that results from the degeneration of cholinergic nerve terminals in AD [23]. Galantamine is also thought to enhance the action of acetylcholine on nicotinic receptors by acting as an allosteric modulator [24]. Another drug used to treat AD, memantine, is an uncompetitive inhibitor of *N*-methyl-D-aspartate receptors that acts by down-regulating glutamate-mediated neurotransmission [25]. Although glutamate is an excitatory neurotransmitter that plays an essential role in learning and memory, excess glutamate signaling leads to excitotoxicity, a mechanism that can result in neuronal death. Unfortunately, memantine and the cholinesterase inhibitors provide only a modest, temporary relief of AD symptoms, and they have no impact on the relentless progression of the disease [3].

B Genetics and AD

The fact that aggregates formed by Aβ peptides and tau are both observed in postmortem AD brains led to a prolonged debate in the field regarding which of these two polypeptides plays a more significant role in pathogenesis. Several genetic findings support the idea that Aβ plays a central role in neurodegeneration in the brain of AD patients [2,18]. First, mutations in the gene encoding APP are linked to early onset AD, and these mutations promote the cleavage of Aβ from APP or favor the production of the more fibrillogenic $A\beta_{42}$ peptide relative to the shorter, less aggregation-prone $A\beta_{40}$ variant. Second, trisomy 21 (Down's syndrome) is associated

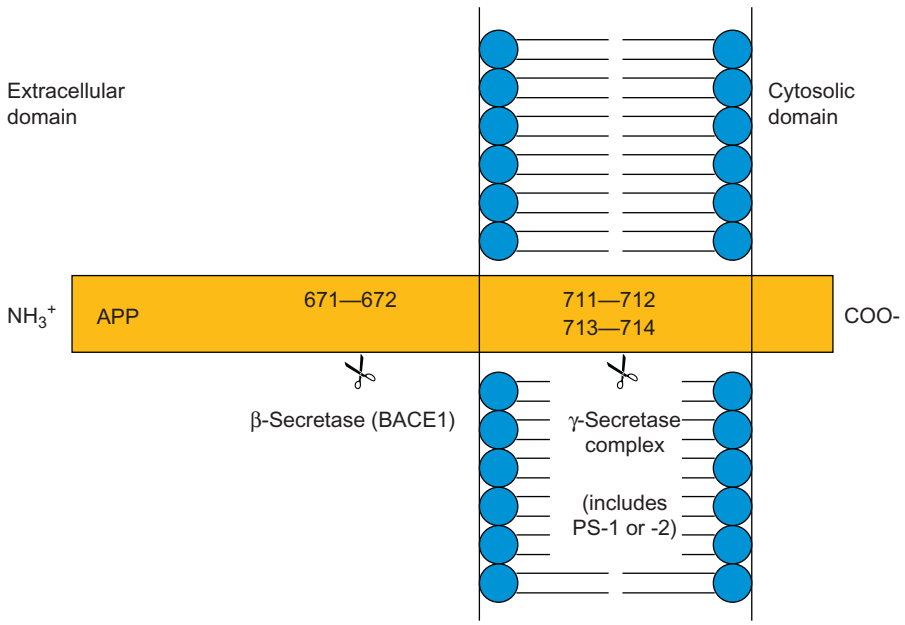

FIGURE 18.1 Diagram illustrating how Aβ peptides are released from APP via successive β- and γ-secretase cleavages. APP is shown as a transmembrane protein in the phospholipid bilayer (phospholipid headgroups are shown as filled circles; acyl chains are depicted as "tails" associated with each headgroup). The cleavage sites are shown in the representation of APP: β-secretase cleaves between residues 671 and 672, and γ-secretase cleaves between residues 711 and 712, yielding $A\beta_{1-40}$, or 713−714, yielding $A\beta_{1-42}$. PS, presenilin. *Adapted from J.-C. Rochet, Novel therapeutic strategies for the treatment of protein-misfolding diseases, Expert Rev. Mol. Med. 9 (2007) 1−34.*

with an AD-like phenotype in the fourth decade of life, and the APP gene is located on chromosome 21, further suggesting that an increase in Aβ levels can lead to AD-related neurodegeneration. Third, mutations in the gene encoding presenilin-1 or -2, proteins that constitute part of the γ-secretase complex involved in cleaving Aβ from APP (Fig. 18.1), are linked to early onset AD. Because presenilin mutations lead to an increase in levels of $A\beta_{42}$ relative to $A\beta_{40}$ [18,26,27], this observation further supports the idea that Aβ plays a major role in AD pathobiology.

Mutations in the gene encoding tau have been linked to frontotemporal dementia (FTD), but not AD [2]. Nevertheless, tau dysfunction is also thought to contribute significantly to neurodegeneration in AD, perhaps as a toxic phenomenon that occurs downstream of Aβ aggregation. Tau hyperphosphorylation results in dissociation of the protein from microtubules, tau aggregation and NFT formation, and a disruption of the microtubular network that is essential for axonal transport and proper synaptic function [28]. Evidence suggests that Aβ-induced oxidative stress [29,30] or the binding of secreted Aβ oligomers to neuronal receptors [31] results in the activation of downstream intracellular kinases involved in hyperphosphorylating tau, including GSK3β, CDK5, Fyn, and FAK1. Other findings suggest that oligomers formed by $A\beta_{42}$ can bind directly to GSK3α, resulting in stimulation of its tau hyperphosphorylation activity [32].

AD risk is modulated by allelic variation in the gene encoding apolipoprotein E (ApoE), a protein responsible for transporting cholesterol in the form of low-density lipoprotein [2,18,33]. There are three ApoE isoforms as a result of polymorphisms in the ApoE gene: ApoE2, ApoE3, and ApoE4. Individuals with one or two *ApoE* ε4 allele encoding ApoE4 have an increased risk of AD, whereas inheritance of the *ApoE* ε2 allele encoding ApoE2 decreases AD risk. A number of mechanisms could account for the increase in AD risk associated with the ApoE4 allele, including (i) decreased Aβ elimination via ApoE-mediated clearance pathways, including cellular uptake of Aβ through ApoE receptors; (ii) increased Aβ aggregation mediated by ApoE−Aβ interactions; and (iii) increased production of neurotoxic ApoE proteolytic fragments that promote tau pathology and interfere with mitochondrial function [2,34].

C Mitochondrial Dysfunction and Oxidative Stress in AD

The postmortem brains of AD patients are characterized by mitochondrial functional deficits, including a decrease in the activity of cytochrome C oxidase (complex IV) as a result of mitochondrial DNA deletions [30,35−37]. A deficit in complex IV activity has also been observed in platelets from AD patients [38]. Additional findings indicate that levels of the peroxisome proliferator activated receptor-γ co-activator 1α (PGC-1α), a transcriptional co-activator involved in regulating mitochondrial biogenesis and cellular energy homeostasis [39−41], are reduced in AD brain [42,43]. Postmortem brains of AD patients are characterized by elevated protein oxidation, protein nitration, and lipid peroxidation in regions enriched with amyloid plaques and NFTs [37,44]. Proteomic analyses have led to the identification of a large number of oxidized proteins in AD brain [45,46]. The loss of ATP and the accumulation of reactive oxygen species (ROS) resulting from mitochondrial impairment are early events in AD pathogenesis that are likely to play a key role in synaptic degeneration in the brains of AD patients [19,47].

Transgenic mice expressing AD-linked mutant forms of APP exhibit a range of mitochondrial deficits, including abnormal mitochondrial morphology and decreased mitochondrial membrane potential, ATP levels, and complex IV activity [37,47,48]. These impairments are accompanied by evidence of oxidative stress, including the presence of the lipid peroxidation product 4-hydroxynonenal [49]. Additional evidence from studies in APP transgenic mice suggests that oligomeric Aβ accumulates in mitochondria [50], where it interacts with a number of targets including the mitochondrial matrix enzyme Aβ-binding alcohol dehydrogenase [51,52] and the mitochondrial permeability transition pore subunit cyclophilin D [53,54], thereby triggering a loss of mitochondrial membrane potential, defects in mitochondrial electron transport, and a buildup of ROS [30]. Data from experiments in a cell-free system suggest that Aβ can be imported into isolated mitochondria via the action of the translocase of the outer membrane (TOM) machinery [55]. Transgenic mice expressing a mutant form of tau (P301L) linked to FTD also show evidence of mitochondrial dysfunction, including a decrease in complex I activity and ATP levels, accompanied by an increase in oxidative stress [37,47,56]. Data obtained from studies of triple transgenic mice expressing mutant APP, tau, and presenilin suggest that Aβ and tau act in a concerted manner to cause mitochondrial functional deficits (via inhibitory effects on complex IV and complex I, respectively), leading to a disruption of oxidative phosphorylation and an increase in oxidative stress [47,57,58].

In addition to triggering oxidative stress by causing an impairment of mitochondrial function, Aβ can directly trigger a buildup of ROS in neurons. In one study, membrane-associated Aβ was shown to trigger oxidative stress, potentially via a mechanism involving Cu^{2+} binding to Aβ, lipid peroxidation, and the diffusion of ROS by-products of lipid peroxidation into the cytosol [46].

Additional findings suggest that Aβ elicits oxidative stress by activating NADPH oxidase, an enzyme that produces ROS [59].

D Glial Activation in AD

The activation of glial cells (microglia and astrocytes) plays an important role in the pathogenesis of AD. Under normal conditions, not only do microglia and astrocytes provide nutrients to neurons, but they also fulfill an immune surveillance role aimed at eliminating pathogens from the brain [60]. In response to various inflammatory stimuli, glial cells become activated and release pro-inflammatory cytokines (e.g., prostaglandins such as PGE_2, interleukins such as IL-1β, tumor necrosis factor-α (TNF-α)) that cause neuroinflammation (Fig. 18.2) [61]. Activated glial cells also release ROS (superoxide, H_2O_2) and reactive nitrogen species (RNS) (e.g., nitric oxide (NO), which combines with superoxide to form peroxynitrite) due to the activation of enzymes such as NADPH oxidase and nitric oxide synthase (NOS) [60,61]. The production and release of cytokines, ROS, and RNS is mediated in part by the transcription factor NF-κB. Although the activation of glial cells is a part of the brain's innate immune response, in cases of AD, PD (see below), and other neurodegenerative diseases, excessive glial cell activation can be deleterious to neurons (Fig. 18.2).

Evidence from postmortem studies indicates that astrocytes and microglia are located near amyloid plaques in the brains of AD patients and have morphologies consistent with an over-activated phenotype associated with chronic neuroinflammation [18,61–63]. Additional evidence of microglial activation has been obtained from positron emission tomography (PET) imaging studies of living AD patients [64]. These observations have led to the suggestion that Aβ induces neurotoxicity indirectly by activating microglia recruited to amyloid plaques, potentially as an early event in AD pathogenesis, in addition to causing damage to neurons directly [61]. Consistent with this idea, evidence of microglial/astrocytic activation and elevated cytokine expression has been obtained in APP-expressing transgenic mice and in mice receiving intracerebral injections of oligomeric Aβ [63,65,66]. Although glial activation may be part of a physiological defense mechanism aimed at the clearance of Aβ aggregates (e.g., perhaps via phagocytosis) [65,67], this process is evidently ineffective in AD brain. Instead, cytokines, ROS, and RNS released by over-activated glia lead to enhanced Aβ deposition and neurotoxicity, thus contributing to a vicious cycle of amyloid formation, glial over-activation, and neurodegeneration in the brains of patients [61,65,66].

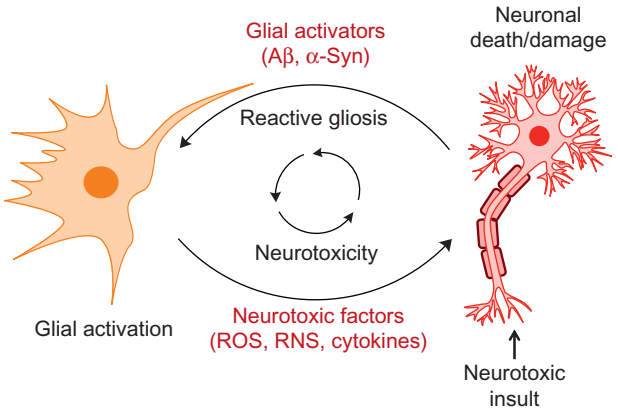

FIGURE 18.2 Model illustrating mechanisms of glial activation and neurotoxicity. Neurotoxic insults result in neuronal death or damage. Factors released from dying or damaged neurons (e.g., protein aggregates) can activate glial cells and result in the production of pro-inflammatory molecules including ROS, RNS, and cytokines. These agents can in turn damage neighboring neurons. Thus, a vicious cycle occurs between damaged neurons and activated microglia, resulting in progressive neurotoxicity. *Adapted from M.L. Block, L. Zecca, J.S. Hong, Microglia-mediated neurotoxicity: uncovering the molecular mechanisms, Nat. Rev. Neurosci. 8 (1) (2007) 57–69.*

III PARKINSON'S DISEASE

A Symptoms, Neuropathology, and Treatments

Characteristic motor symptoms of PD include the inability to initiate movement, resting tremor, rigidity of the limbs, and postural instability [68]. These symptoms result in large part from a loss of dopaminergic neurons from the *substantia nigra* pars compacta (SNpc) in the midbrain. Another neuropathological hallmark of PD is the presence of Lewy body inclusions enriched with fibrillar forms of the presynaptic protein α-synuclein (aSyn). Molecular events that are thought to play a role in neurodegeneration in PD include oxidative stress [69,70], loss of mitochondrial function [71–73], aSyn aggregation [74–76], and neuroinflammation [61].

Current PD therapies only temporarily alleviate symptoms and do not reverse the underlying neurodegeneration [77]. Dopamine replacement therapies (DRTs) are currently the most common therapeutic options available to PD patients. DRT medications include L-DOPA or synthetic dopamine receptor agonists, both of which are designed to rescue deficits in striatal dopamine neurotransmission. Patients on long-term DRT eventually experience highly disruptive side effects that include L-DOPA-induced dyskinesia, aggression, and/or insomnia [78]. In addition, multiple studies and case reports suggest that there is a risk of dependence and withdrawal in patients abusing their DRT medication [78–80].

Patients and health care providers are in need of safe and effective neuroprotective therapies that can stop or slow the neurodegenerative process.

The seeds of *Mucuna pruriens* (velvet beans) contain high levels of L-DOPA and are used as a PD therapy. Interestingly, clinical studies suggest that this plant may be equally or more effective than the standard L-DOPA therapy [81–83]. A number of studies suggest that a *M. pruriens* extract can not only provide a significant relief of tremor symptoms as a result of its L-DOPA content, but it can also slow the neurodegenerative process due to its neuroprotective activities [84,85]. For example, a *M. pruriens* extract was found to alleviate parkinsonian symptoms to a greater degree than a standard L-DOPA therapy in 6-OHDA-lesioned rats by both restoring motor function and protecting mitochondrial complex I activity [84]. Moreover, an extract prepared from *M. pruriens* seeds was found to alleviate plasmid DNA and genomic DNA damage induced after incubation with L-DOPA [86].

B Genetics and PD

It is estimated that familial cases of PD only represent 10% of the patients, whereas the majority of the cases are sporadic. Mutations in more than 20 genetic loci leading to an increased risk of developing the disease (referred to as "PARK" loci) have been identified [87–89]. The affected genes are involved in critical cellular processes such as regulating mitochondrial function and mitophagy (PARK2 (parkin) and PARK6 (PINK1)) [90–92], oxidative stress (PARK7 (DJ-1)) [93,94], or neurite outgrowth (PARK8 (LRRK2)) [95–98]. In addition, several mutations in the SNCA gene encoding the presynaptic protein aSyn, including substitutions encoding the variants A30P, E46K, H50Q, G51D, A53E, and A53T [5,99–105] and multiplications [106,107], are linked to familial cases of PD. Evidence suggests that mutant forms of aSyn have a higher propensity to undergo membrane-induced aggregation [108] or accelerated fibrillization in the absence of membranes (Fig. 18.3) [109]. Despite evidence of a role for genetics in determining PD risk, the development of the disease seems to be multifactorial, involving additional factors such as environmental exposure to toxicants and the influence of diet [110].

C Environmental Risk Factors and PD

Epidemiological evidence suggests that exposure to the environmental toxins rotenone and paraquat (PQ) is linked to an increased risk of developing PD [111–116]. Importantly, both of these agents are used extensively to model aspects of PD-related neurodegeneration in cellular and animal models of the disease (see later). Rotenone, a

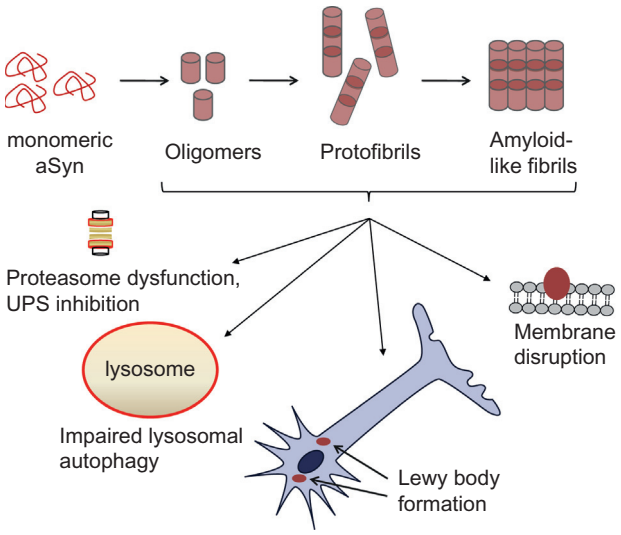

FIGURE 18.3 Model illustrating mechanisms of aSyn aggregation and neurotoxicity. aSyn is a natively unfolded protein that undergoes self-assembly under pathological conditions. aSyn aggregation involves the formation of intermediate species named protofibrils that undergo further assembly into larger amyloid-like fibrils. These fibrillar species are the main constituents of pathological inclusions named Lewy bodies. aSyn aggregation leads to membrane disruption, impairment of lysosomal autophagy, and UPS inhibition.

naturally occurring isoflavonoid extracted from plant material, is used as a pesticide [117,118]. Rotenone is a mitochondrial toxin that diffuses through the cell membrane to target the proton-translocating NADH:quinone oxidoreductase enzyme of the mitochondrial electron transport chain, referred to as complex I. Complex I is a large transmembrane protein complex composed of 45 subunits that is located in the mitochondrial inner membrane [119]. It is responsible for the transfer of electrons from NADH to ubiquinone, the first step in the series of reduction-oxidation (redox) reactions involved in mitochondrial respiration and ATP production [120–122]. Complex I is composed of two sites for quinone reduction, a hydrophobic site and a hydrophilic site, and it is the former that is targeted by rotenone. Under normal conditions, proton translocation at complex I occurs via a redox reaction that results from quinone reduction at the hydrophobic site. However, rotenone inhibits the NADH: quinone oxidoreductase activity at this hydrophobic, energy-transducing site of complex I [123,124]. The hydrophilic site of quinone reduction is nonenergy transducing and is not targeted by rotenone. Disruption of electron flux by rotenone leads to oxidative damage via the generation of superoxide (Fig. 18.4) [125–128]. In addition, rotenone-mediated complex I inhibition results in disruption of the cellular bioenergetic status as a consequence of impaired oxidative phosphorylation and ATP production [127]. Exposure to rotenone also leads to a

collapse of the mitochondrial membrane potential and a release of cytochrome C, a key initiating event of cellular apoptosis [129,130]. Rotenone treatment of cells expressing a rotenone-insensitive, single-subunit NADH dehydrogenase does not result in mitochondrial dysfunction, oxidative damage, or cell death, highlighting the essential role of complex I as the key target involved in rotenone toxicity [127].

Rotenone is used as a toxicant in a number of preclinical models that reproduce critical features of PD. Chronic systemic injection of rotenone in rats results in nigrostriatal damage with severe striatal denervation and a selective loss of dopaminergic neurons, particularly in the SNpc [73,131,132]. Rotenone-infused rats undergo selective targeting of complex I in all brain regions, leaving complex II and complex IV unaffected. In addition, the formation of aSyn-containing cytoplasmic inclusions in nigral neurons of rotenone-treated rats reproduces a hallmark feature of PD. Rats chronically treated with rotenone also develop behavioral deficits relevant to motor symptoms of PD such as tremor, rigidity, and reduced balance [73,132,133]. The exposure of neuroblastoma cells to rotenone results in impairment of mitochondrial respiration, ATP depletion, oxidative stress, and dose-dependent cell death [127,130,134]. However, ATP depletion does not seem to be a driving event leading to cell death, based on the observation that treating neuroblastoma cells with 2-deoxy-D-glucose depletes cellular ATP without generating oxidative stress but does not result in cell death [127]. Additional evidence from studies in cell culture suggests that oxidative phosphorylation inhibitors that do not affect complex I but deplete ATP without generating oxidative stress are nontoxic [134]. The fact that oxidative damage plays a critical role in rotenone neurotoxicity and the PD-like phenotype in cellular and animal models of rotenone exposure supports the rationale for discovering antioxidant therapies to stop or slow the neurodegenerative process [125,127].

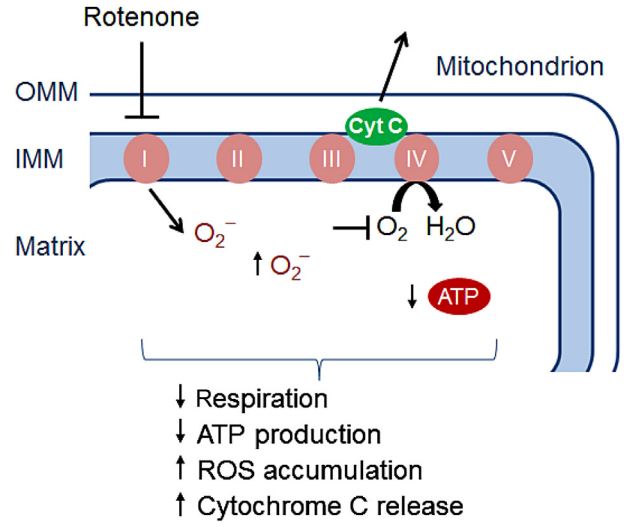

FIGURE 18.4 Model illustrating the mechanism of rotenone-mediated oxidative stress. Rotenone diffuses freely through the cell membrane and outer mitochondrial membrane (*OMM*) to the inner mitochondrial membrane (*IMM*), where it inhibits complex I of the electron transport chain. A decrease in complex I activity leads to electron leakage, a buildup of *ROS* (e.g., superoxide, O_2^-), disruption of oxygen consumption, depletion of *ATP*, and the release of cytochrome C into the cytosol.

The bipyridyl herbicide PQ (1′-dimethyl-4, 4′-bipyridinium dichloride) is a pro-oxidant that belongs to a family of redox-reactive heterocycles. PQ is converted from its native dicationic form (PQ^{2+}) to its monocationic form (PQ^+) by engaging in redox cycling reactions with molecular oxygen (Fig. 18.5) [135–137]. These redox cycling reactions, catalyzed by the cellular oxidases NADPH oxidase and NOS, lead to the generation of toxic free radicals and superoxide, initiating cellular oxidative stress and a cascade of events culminating in oxidative damage to DNA, protein, and lipids and eventually cell death [138,139]. Because PQ is structurally similar to the dopamine transporter (DAT) substrate MPP^+ (a toxin with selective toxicity to dopaminergic neurons—see later), it has been hypothesized that DAT plays a key role in shuttling PQ in dopaminergic neurons [140]. Additional evidence suggests that the organic cation transporter-3 (ORT-3) is involved in PQ toxicity [140]. ORT-3, a bidirectional transporter expressed in nondopaminergic cells such as astrocytes and GABAergic neurons, is thought to be involved in modulating the local concentration of toxic cationic species such as PQ near the cell body and synaptic terminals of midbrain dopaminergic neurons [141].

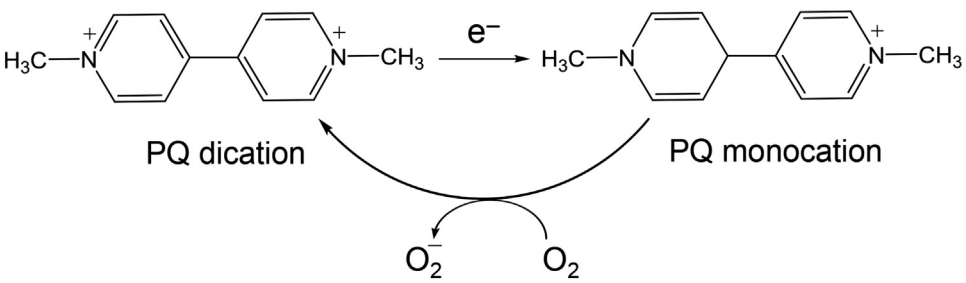

FIGURE 18.5 Schematic illustrating the mechanism of PQ-mediated oxidative stress. A redox cycling reaction involving the interconversion of monocationic and dicationic forms of PQ results in the production of ROS.

A number of studies have demonstrated that PQ triggers a PD-like phenotype in rodents. Male C57BL/6 mice exposed to a combination of PQ and the fungicide Maneb were found to undergo enhanced nigrostriatal dopaminergic neurotoxicity compared to animals exposed to either compound alone [142–144], a significant finding that yields insight into the role of multipesticide exposure in modulating PD risk. Mice treated with intraperitoneal PQ injections were characterized by PD-associated motor symptoms including reduced balance [145], a selective loss of nigrostriatal dopaminergic neurons [138,144], and evidence of aSyn aggregation [146]. Although cellular mechanisms contributing to PQ-mediated neurodegeneration are not fully understood, the pro-oxidant activity of PQ is thought to play a major role in nigrostriatal damage. In mice systemically injected with PQ, the loss of dopaminergic neurons was associated with an increase in lipid peroxidation and tyrosine nitration elicited by RNS [147].

D Mitochondrial Dysfunction and Oxidative Stress in PD

Mitochondria are central organelles that maintain the bioenergetic status of cells. Several observations suggest that mitochondrial dysfunction plays a key role in PD pathogenesis. First, the postmortem brains of PD patients are characterized by a decrease in complex I activity [148]. Second, human exposure to mitochondrial toxins is associated with an increase in PD risk, and animals treated with toxins that disrupt mitochondrial function develop a PD-like phenotype [116,127,149,150]. Third, mutations in a number of genes linked to familial PD are thought to cause mitochondrial impairment [92,151]. Mitochondrial functional deficits arising from environmental exposures or gene mutations include inefficient electron transport (resulting from a leakage of electrons from the transport chain) and a collapse of mitochondrial membrane potential, leading to ROS accumulation, oxidative damage, depletion of cellular ATP, a release of cytochrome C, and ultimately neuronal cell death [73].

Multiple observations provide pathological evidence for mitochondrial dysfunction in PD. Analysis of the mitochondrial electron transport chain in postmortem brains of PD patients revealed a selective loss of activity of complex I (but not in other complexes) in the SNpc and prefrontal cortex [148,152]. Defects in mitochondrial function and complex I activity have been reported in other tissues of PD patients including fibroblasts [153], platelets [154], and skeletal muscle [155]. Moreover, the brains and peripheral tissues of PD patients are characterized by extensive oxidative damage to macromolecules including proteins, lipids, and nucleic acids [70,73].

Toxins that impair mitochondrial function are thought to increase the risk of PD in humans and have been used to develop animal models of PD. As outlined earlier, rotenone is epidemiologically associated with an increase in PD risk in humans, and it triggers a PD-like phenotype that reproduces PD-like features in rats [73,116]. A study of individuals who developed severe parkinsonism after self-administering preparations of synthetic meperidine analogs contaminated with the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) led to the discovery of MPTP as a PD-related neurotoxin [156–158]. MPTP crosses the blood brain barrier (BBB) and is metabolized to its active form MPP^+ by monoamine oxidase B in astrocytes. MPP^+ is then shuttled from the extracellular space into dopaminergic neurons by DAT [159]. Evidence suggests that MPP^+ mediates its toxicity largely by targeting complex I in the mitochondrial electron transport chain [160–162].

An extensive body of evidence supports the idea that the accumulation of wild-type or mutant aSyn can lead to mitochondrial dysfunction. The brains of transgenic mice expressing human A53T aSyn, which develop a motor phenotype characteristic of PD, are characterized by mitochondrial damage and degeneration [163]. Transgenic mice over-expressing wild-type aSyn show evidence of enhanced mitochondrial degeneration in the SNpc compared to nontransgenic mice after treatment with MPTP [164]. A number of groups have reported that aSyn is localized to mitochondria when over-expressed in neuronal cell lines [165,166]. Depletion of mitochondrial DNA abrogates aSyn toxicity in aging yeast, suggesting that functional mitochondria are involved in mediating the toxic effects of aSyn in this model [167]. It has also been reported that an anomalous, high-affinity interaction between posttranslationally modified forms of aSyn and the outer membrane translocase protein TOM20 results in deficient mitochondrial protein import, impaired electron transport, enhanced ROS accumulation, and a decrease in mitochondrial membrane potential [168].

Loss-of-function mutations in the gene encoding DJ-1, a molecular chaperone and oxidative stress sensor [169–171], are associated with early-onset PD [93]. In addition, wild-type DJ-1 is oxidized to a greater extent in the brains of patients with sporadic PD than in age-matched controls [172]. A loss of DJ-1 function results in increased oxidative stress or sensitivity to oxidative insults in cellular and animal models [171,173–175]. Multiple lines of evidence suggest that DJ-1 is involved in modulating mitochondrial function. DJ-1 can transfer from the cytosol to mitochondria in cells subjected to oxidative stress, and this mitochondrial localization is regulated by the oxidation status of cysteine residue C106 [176]. *Drosophila* that lack functional DJ-1 are more sensitive to oxidative stress and the mitochondrial toxin

rotenone [171]. Brains of DJ-1 knockout mice show evidence of fragmented mitochondria, resulting in increased sensitivity to oxidative stress and neuronal cell death [177]. Additional findings suggest that deletion of the DJ-1 gene results in increased mitochondrial H_2O_2 production [178], and DJ-1 up-regulation has been shown to rescue a loss of function of PINK1, a protein involved in regulating mitophagy [179].

E Vulnerability of Nigral Dopaminergic Neurons in PD

Considerable effort in PD research has been focused on understanding why dopaminergic neurons of the SNpc undergo selective degeneration in the brains of patients. One explanation appears to be that dopaminergic neurons have relatively high basal levels of ROS, including hydrogen peroxide (H_2O_2) and hydroxyl radicals (˙OH), resulting from the metabolism and auto-oxidation of cytosolic dopamine [73,180,181]. In turn, these ROS can cause damage to cellular macromolecules, ultimately leading to cell death. Oxidatively modified forms of aSyn [182–186] and adducts formed by reaction of the protein with oxidized derivatives of dopamine [187–191] have been reported to have a high propensity to form potentially toxic aggregates. Dopaminergic neurons in the SNpc are more vulnerable than other dopamine-producing neurons in nearby brain structures, in part because nigral neurons have lower levels of the vesicular monoamine transporter-2, the transport protein responsible for dopamine uptake from the cytosol into vesicles [192]. In addition, dopaminergic neurons in the SNpc selectively express the L-type Ca(v)1.3 channel, and calcium entry through this channel results in a build-up of intracellular Ca^{2+} that in turn imposes a metabolic burden on nigral dopaminergic neurons, resulting in mitochondrial dysfunction and oxidative stress [175,193–195]. As a result of these multiple factors, nigral dopaminergic neurons are thought to have high basal levels of ROS that render them more vulnerable to further oxidative insults compared to other neuronal populations subjected to lower basal levels of oxidative stress.

F Glial Activation in PD

Glial activation plays an important role in PD pathogenesis [61,196–198]. Postmortem PD brains show evidence of microglial activation and increased levels of proinflammatory molecules [199], and activated microglia have been detected in the brains of living PD patients via PET imaging [200]. PD-related toxins such as rotenone [201,202] and PQ [203], as well as aSyn-encoding virus [204] and exogenous aSyn aggregates [205], have been shown to cause glial activation in cellular and animal models. ROS and aSyn oligomers produced and released by dopaminergic neurons are thought to trigger microglial/astrocytic activation, resulting in the release of proinflammatory molecules, ROS, and RNS from these cells and leading to a vicious cycle of neurotoxicity and glial activation [61,205–208]. Dopaminergic neurons may be particularly vulnerable to glial activation given the abundance of microglial cells in the SNpc [209]. Interestingly, lipopolysaccharide (LPS), a classic inflammatory agent that triggers astrocyte and microglial activation, has been shown to induce dopaminergic cell death [210,211], providing further evidence of a role for glial activation in the loss of dopaminergic neurons.

Additional observations suggest that nigral susceptibility to neuroinflammation is increased in animals exposed to peripheral inflammatory insults, including dextran sulfate sodium, an agent that triggers ulcerative colitis [212]. Another potential connection between nigral degeneration and peripheral inflammation is implied by the fact that LRRK2 is genetically linked to both PD and inflammatory bowel disease [213,214]. Collectively, these observations suggest that interactions between systemic inflammation and inflammation in the brain contribute to neurodegeneration in PD.

IV DIETARY PLANTS AND NEURODEGENERATIVE DISEASE

A Health-Promoting Plant Constituents

A number of phytochemicals are thought to play a major role in the health-promoting activities of herbal medicines. As one example, broccoli and other cruciferous vegetables are of great interest due to their unique chemical composition. Extensive research findings suggest that cruciferous vegetables and their main constituents, including glucosinolates and their hydrolysis products, isothiocyanates, have remarkable health benefits. Each type of cruciferous vegetable contains different glucosinolates that are hydrolyzed to different isothiocyanates by the bacterial microflora of the gastrointestinal tract [215]. Among the most studied of the isothiocyanates, sulforaphane (derived from glucoraphanin, found in broccoli) and allyl isothiocyanates (derived from sinigrin, also found in broccoli) show exceptional health-promoting qualities in various disease models [216–218].

Garlic belongs to the botanical family of Amaryllidaceae, along with onions, chives, and garlic chives. Garlic is characterized by high contents of various garlic organosulfur compounds including sulfur compounds derived from alliin (L-(+)-S-allylcysteine sulfoxide) such as allyl thiosulfinates, and sulfur compounds not derived from alliin such as γ-glutamyl-*S*-allylcysteine [219]. Garlic organosulfur compounds are responsible for many health benefits in multiple

disease states such as neurodegenerative diseases, cancer, and diabetes [215,220].

Polyphenols are the largest group of secondary plant metabolites with more than 8000 phenolic structures identified [221]. Polyphenols have chemical structures characterized by the presence of multiple phenolic groups and exist as aglycones or (more typically) as glycosidic derivatives. Polyphenols in the aglycone form are classified into two main classes, flavonoids and nonflavonoids, based on the number and arrangement of their aromatic rings (Fig. 18.6). The chemical skeleton of flavonoids consists of two benzene rings (referred to as ring A and ring B) connected with a carbon bridge forming a pyran ring (referred to as ring C) (Fig. 18.7) [222]. Flavonoids are further classified into subgroups including the flavonols (e.g., quercetin, isorhamnetin), isoflavones (e.g., genistein, daidzein), and anthocyanidins (e.g., cyanidin, delphinidin) on the basis of differences in the structure of ring C and the degree of hydroxylation of rings A and B (Fig. 18.6) [221]. The ubiquitous flavonol aglycone quercetin has been identified in a variety of fruits, vegetables, cocoa products, beverages, and cereals in 279 different glycosidic forms [221]. The flavonol isorhamnetin is found in its glycosylated and aglycone form in fruits, beverages, and nuts. Isoflavones are the main active principles of soy products and are found in medicinal plants such as red clover. Cultivated or wild berries such as blueberry, elderberry, or chokeberry are characterized by a dark red or black color resulting from large concentrations of anthocyanidin glycosides, termed anthocyanins (ANCs).

Nonflavonoid polyphenols are classified into the three subgroups: (i) phenolic acids, which consist of an aromatic ring with a carboxylic acid functional group; (ii) stilbenes, members of the phenylpropanoid family with a $C_6-C_2-C_6$ structure; and (iii) lignans, which have a characteristic dibutylbenzene skeleton (Figs. 18.6 and 18.7). Two important representatives of the phenolic acid and stilbene classes, curcumin and resveratrol (respectively), are discussed in more detail later.

B Epidemiology

The health-promoting effects of polyphenol-rich foods in neurodegenerative disorders have been validated by a number of epidemiological studies [9,10]. Some groups have reported that the consumption of wine or dietary flavonoids is associated with a reduced risk of AD or cognitive decline [11–14], and the consumption of polyphenol-rich juices may delay the onset of AD in carriers of the *ApoE* ε4 allele [15]. The results of one study suggest that the regular consumption of berries enriched with ANC or proanthocyanidins (PAC) is associated with a lower risk of developing PD [16]. Additional evidence suggests that the incidence of PD is reduced as a result of elevated tea consumption [17]. Collectively, these observations imply that the consumption of polyphenols can potentially decrease the risk of neurodegenerative disease and slow pathological decline of the aging brain.

C Brain Bioavailability

The BBB physically separates the circulating blood from the brain extracellular fluid and is formed by endothelial cells supported by various other types of cells including astrocytes [223]. The BBB enables the diffusion of factors that support brain development and function while preventing the entry of potentially harmful factors [224]. A number of polyphenols or polyphenol metabolites have

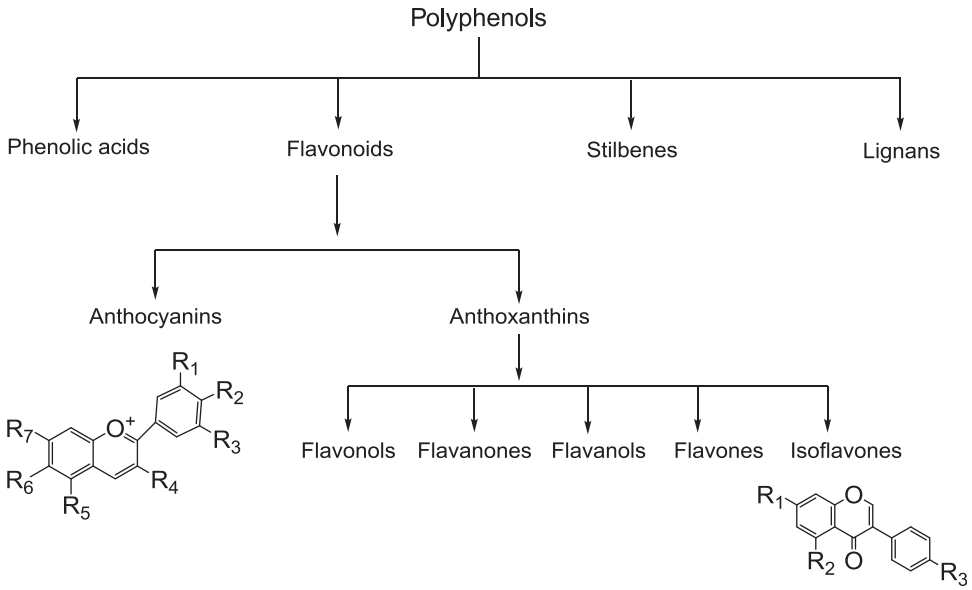

FIGURE 18.6 Classification of polyphenols, showing generic chemical structures of ANCs and isoflavones.

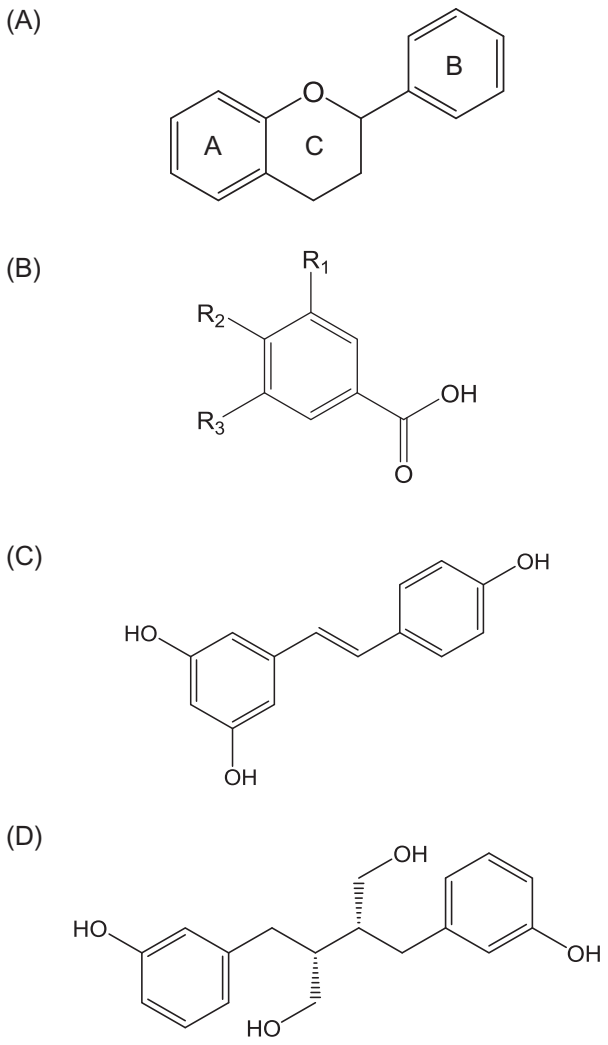

FIGURE 18.7 Chemical structures of different classes of polyphenols. The structures are of a generic flavonoid (A), showing the A, B, and C rings; a generic phenolic acid (B); the stilbene resveratrol (C); and the lignan enterodiol (D).

been found to penetrate the BBB in mammalian models [225]. Brain levels of total ANC from rodents fed a blackberry ANC-rich diet (14.8 mmol ANC per kg diet, 25 g diet/rat/day) were found to be 0.25 ± 0.05 nmol/g of brain tissue [226]. This concentration was lower than that in the plasma, liver, or kidney. In another study, significant amounts of ANC were detected in brain tissue from Yorkshire × Landrace male pigs fed a diet enriched with a blueberry extract (1%, 2%, and 4% (w/w)) [227]. One of the anthocyanidins examined in this study, malvidin, accounted for approximately 50% of the total ANC concentration in the cortex. Consistent with these results, rats fed a 2% (w/w) blueberry-supplemented diet were found to accumulate ANC in the brain, with malvidin derivatives exhibiting enhanced brain bioavailability compared to other ANCs [228]. A number of other polyphenolic constituents, including isoflavones (as either the intact forms or metabolites), quercetin, kaempferol, isorhamnetin, organosulfur compounds, and sulforaphane, have been shown to penetrate the BBB [219,229–235]. Collectively, these observations suggest that some polyphenols can cross the BBB and accumulate in brain tissue, albeit at relatively low levels. Extracts enriched in these polyphenols could potentially lower the risk of neurodegenerative disease or slow disease progression in patients. Because polyphenols accumulate in the brain at lower levels compared to endogenous antioxidants, their mechanisms of neuroprotection are likely mediated via the activation of cellular protective pathways rather than by radical scavenging [236].

V NEUROPROTECTIVE EFFECTS OF PHYTOCHEMICALS IN AD MODELS

A Anthocyanins

A number of ANC-rich extracts have been found to interfere with neuronal cell death in models of Aβ neurotoxicity relevant to AD. In one study, a blueberry extract was reported to alleviate neurotoxic effects of Aβ in a primary hippocampal neuron model [237]. Intragastric administration of black soybean ANC led to a decrease in mitochondrial apoptotic markers in the hippocampus of rats receiving intracerebroventricular injections of $A\beta_{42}$ [238]. An ANC-rich bilberry extract was shown to alleviate cognitive deficits in transgenic mice expressing APP and mutant presenilin-2, apparently via a mechanism involving a redistribution of Aβ into a nontoxic, aggregated form [239]. Another study revealed that extracts prepared from bilberries and blackcurrants attenuated spatial working memory deficits exhibited by transgenic APP/presenilin-1 mice, and this cognitive improvement correlated with a decrease in levels of soluble $A\beta_{40}$ and $A\beta_{42}$ or the ratio of insoluble $A\beta_{42}$ to $A\beta_{40}$ in the brains of bilberry- or blackcurrant-treated mice, respectively [240]. The ANC cyanidin-3-*O*-glucoside (C3G) was found to alleviate deficits in learning and memory in rats receiving intrahippocampal injections of aggregated Aβ, and this protective effect correlated with a decrease in GSK-3β activation and tau hyperphosphorylation in the brains of these animals [241].

B Proanthocyanidins

A PAC-rich grape seed extract consisting of catechin, epicatechin, and epicatechin gallate was found to alleviate deficits in cognitive ability and spatial memory exhibited by transgenic mice expressing mutant APP and PS1 [242]. Another study revealed that Tg2576 transgenic

mice expressing the Swedish mutant form of APP (KM670/671NL) have less pronounced cognitive deficits when dosed orally with monomeric but not polymeric PAC, and only monomeric PAC metabolites (glucuronide derivatives) can be detected in rodent brain [243,244].

C Stilbenes

Multiple lines of evidence suggest that resveratrol can alleviate neurodegeneration in rodent models of AD. In one study, resveratrol was found to alleviate spatial memory deficits and hippocampal neuronal damage in rats receiving intracerebral injections of aggregated forms of an Aβ fragment spanning residues 25−35 ($A\beta_{25-35}$) [245]. Additional research revealed that orally administered resveratrol interfered with Aβ accumulation, amyloid plaque burden, and microglial activation in the brains of transgenic mice expressing mutant APP with or without mutant presenilin-1 [246−248]. Another stilbene, tetrahydroxystilbene glucoside, was shown to attenuate deficits in learning memory in APP-expressing transgenic mice [249] and ameliorate memory impairment and synaptic degeneration in rats receiving intracerebral injections of $A\beta_{42}$ [250].

D Isoflavones

Soy isoflavones have been shown to ameliorate deficits in learning and memory in rats subjected to intracerebroventricular administration of $A\beta_{42}$ [251]. Another study revealed that the soy isoflavone genistein alleviates short-term spatial memory defects and hippocampal oxidative damage in rats receiving intracerebral injections of $A\beta_{40}$ [252]. Oral administration of puerarin, an isoflavone isolated from the root of *Pueraria*, led to an attenuation of cognitive impairment exhibited by transgenic mice expressing mutant APP and presenlin-1 and to a decrease in oxidative damage in the brains of these animals [253]. Puerarin was also shown to interfere with cognitive deficits and hippocampal neurodegeneration in rats receiving intracerebral injections of $A\beta_{42}$ [254].

E Curcumin

Curcumin, a major component of the Indian spice turmeric (*Curcuma longa*) [221], was found to interfere with cell death in primary rat hippocampal cultures transduced with adenovirus encoding $A\beta_{42}$ [255]. Other groups have reported that oral or intraperitoneal administration of curcumin results in a decrease in memory deficits, neurotoxicity, and glial activation in rats receiving intracerebroventricular infusions of $A\beta_{42}$ [256]. Additional studies have revealed that orally administered curcumin attenuates amyloid plaque burden, accumulation of insoluble Aβ, and neuroinflammation in Tg2576 mice [257,258], and amyloid plaque size and neuritic anomalies were found to be reduced in transgenic APP/presenilin-1 mice receiving curcumin via tail vein injections [259]. Although several human clinical trials of curcumin in AD have been carried out, so far none of these have provided evidence for a neuroprotective effect of the compound in AD patients [260]. These negative findings are potentially a reflection of suboptimal study design and also the fact that curcumin has weak bioavailability.

VI NEUROPROTECTIVE EFFECTS OF PHYTOCHEMICALS IN PD MODELS

A number of polyphenol-rich extracts and individual polyphenols have been characterized in terms of their neuroprotective activities in PD models. Typically, these models consist of neuronal cells, primary mesencephalic cultures, or rodents exposed to PD-related insults, including rotenone, PQ, MPP^+ (in the case of cultured cells), or MPTP (in the case of rodents). Another PD-related neurotoxin, 6-hydroxydopamine (6-OHDA), is used extensively to model dopaminergic neurodegeneration in cell culture and in vivo [159,261,262]. Because 6-OHDA is structurally similar to dopamine, it preferentially targets dopaminergic neurons as a result of DAT-mediated uptake; 6-OHDA elicits neurotoxicity via the generation of ROS that causes oxidative damage [159,263], and it has also been reported to elicit mitochondrial dysfunction via the inhibition of complex I [261,264].

A Anthocyanins

A number of ANC-rich extracts and individual ANCs have been shown to attenuate dopaminergic cell death in cellular and animal models of PD. An ANC-containing mulberry extract from *Morus alba* L. (Moraceae) alleviated nigral degeneration in mice exposed to MPTP and in primary midbrain cultures exposed to 6-OHDA or MPP^+ [265]. In addition, ANC-rich extracts prepared from blueberries and blackcurrants, but not purple basil, interfered with dopaminergic cell death in primary midbrain cultures exposed to rotenone [266].

The ANC molecule pelargonidin was reported to attenuate motor defects and nigral degeneration in rats exposed to 6-OHDA [267]. Moreover, malvidin-3-*O*-glucoside, cyanidin-3-*O*-sophoroside, and delphinidin-3-*O*-glucoside, as well as a hibiscus extract consisting of cyanidin-3-*O*-sambubioside and/or delphinidin-3-*O*-sambubioside, were found to interfere with rotenone neurotoxicity in primary midbrain cultures [266]. A comparison of active versus inactive ANC in this model led to the conclusion that the identity of the sugar molecule attached to the ANC core is an important factor in determining the level of

neuroprotective activity. Together with evidence that ANCs are detectable as intact glycosides in the brains of rats [226,228,268–270] and pigs [236] fed ANC-rich diets, these observations suggest that ANCs have the potential to attenuate neurotoxicity in the brains of PD patients.

B Proanthocyanidins

A PAC-rich cocoa extract was found to interfere with nigral degeneration and a loss of striatal dopamine in 6-OHDA-treated rats, whereas catechin-rich grape seed extracts failed to alleviate neurotoxicity in this model [271]. Monomeric PAC such as catechin and (-)-epigallocatechin gallate (EGCG) and extracts that contain these molecules but lack polymeric PAC (e.g., tea extracts) interfered with neurodegeneration in cellular and rodent models of PD [272–275]. A PAC-rich grape-seed extract was shown to alleviate rotenone-mediated dopaminergic cell death in primary midbrain cultures [266]. Together, these findings suggest that a number of PAC-rich extracts and monomeric PAC constituents can attenuate neurotoxicity elicited by PD-related insults and could potentially have neuroprotective activity in the brains of PD patients.

C Stilbenes

An oxyresveratrol-rich mulberry extract and the pure stilbene resveratrol were found to interfere with rotenone-mediated dopaminergic cell death in primary mesencephalic cultures [266,276], and resveratrol attenuated ER stress, caspase-3 activation, and oxidative stress in the brains of rotenone-treated rats [277]. Multiple groups have shown that resveratrol ameliorates behavioral deficits exhibited by MPTP-treated mice and alleviates dopaminergic cell death, striatal dopamine depletion, and oxidative stress in the brains of these animals [278–282]. Resveratrol has also been shown to relieve motor deficits and neuropathology in 6-OHDA-treated rats [262,283]. Another study revealed that resveratrol suppresses dopaminergic cell death and microglial activation in primary midbrain cultures exposed to LPS [284]. Together with evidence that resveratrol glucuronide is present in the brains of mice fed a grape polyphenol mixture [270], these observations suggest that stilbenes or their metabolites may slow neurodegeneration in the brains of PD patients.

D Isoflavones

Isoflavones from *Trifolium pratense* have been shown to suppress dopaminergic cell death triggered by LPS in primary midbrain cultures [285]. In addition, nigral degeneration and striatal dopamine depletion were alleviated in 6-OHDA-lesioned rats fed an isoflavone-rich red clover diet [271]. Genistein [286,287] and puerarin [288,289] were reported to attenuate nigral dopaminergic cell death and the loss of striatal dopamine and dopamine metabolites in the brains of rats exposed to 6-OHDA, and in some of these studies the isoflavone treatment led to an amelioration of motor deficits. Genistein and puerarin were also shown to interfere with nigral degeneration and striatal dopamine depletion in the brains of MPTP-treated mice and to improve the motor function of these animals [290,291]. Biochanin A, an *O*-methylated isoflavone from chickpea, was found to alleviate PD-like features of rats receiving an intranigral unilateral injection of LPS, including motor deficits, nigral degeneration, and microglial activation [292]. A number of isoflavones or their metabolites penetrate the BBB in rats [232,233], suggesting that isoflavone-rich extracts and individual isoflavones could potentially be of clinical benefit by reducing PD risk or slowing neurodegeneration in the brains of patients.

E Curcumin

Several groups have reported that curcumin protects immortalized neuronal cells against cytotoxicity resulting from intracellular aSyn over-expression [293] or from exposure to extracellular pre-formed aSyn oligomers [294]. Other studies have revealed that dietary administration of curcumin leads to an amelioration of behavioral deficits exhibited by aSyn-expressing transgenic mice [295] or flies [296] and attenuates oxidative stress and apoptosis in the fly model. Curcumin has also been shown to interfere with nigral dopaminergic cell death and striatal dopamine depletion in MPTP-treated mice [297,298] and in 6-OHDA-treated rats [299–301].

F Other Phytochemicals

The methionine analog *S*-methyl-L-cysteine, a substrate of the methionine sulfoxide reductase A (MsrA)-mediated antioxidant system, was found to mitigate aSyn-mediated toxicity in *Drosophila* [302]. *S*-allylcysteine alleviated motor dysfunction, lipid peroxidation, striatal dopamine depletion, and the production of superoxide in MPTP-treated mice [303]. In addition, *S*-allylcysteine and aged garlic extract ameliorated oxidative damage in cellular and animal models by scavenging free radicals and inducing activation of the antioxidant response [304]. 6-Methylsulfinylhexyl isothiocyanate (6-HITC) and sulforaphane attenuated PQ-induced toxicity in rat striatal cultures [305]. Sulforaphane was also found to interfere with neurodegeneration in a *Drosophila* loss-of-function parkin mutant [306] and to attenuate motor deficits and nigral dopaminergic cell death in mice exposed to 6-OHDA [307].

VII NEUROPROTECTIVE MECHANISMS OF PHYTOCHEMICALS

A Induction of the Nrf2-Mediated Antioxidant Response

Nuclear factor E2-related factor 2 (Nrf2) is a transcription factor that regulates the expression of more than 200 cytoprotective genes involved in cellular antioxidant and anti-inflammatory responses, including glutamate cysteine ligase (GCL), heme oxygenase 1 (HO-1), and NAD(P)H dehydrogenase quinone-1 (NQO1) [308]. In the cytoplasm, Nrf2 is sequestered by Kelch-like ECH-associated protein 1 (Keap1) and targeted for degradation by the ubiquitin-proteasome pathway (Fig. 18.8) [309]. Under conditions of oxidative stress, the interaction between Nrf2 and Keap1 is disrupted, resulting in Nrf2 stabilization and translocation to the nucleus where it binds the antioxidant response element (ARE) in the 5′ flanking region of its target genes [308,310–313]. In the brain, Nrf2 activity is prominent in astrocytes, which play a key role in neuronal antioxidant responses by producing and releasing glutathione (GSH) metabolites that are imported and reassembled by neighboring neurons (Fig. 18.9) [314]. Multiple lines of evidence indicate that activation of the Nrf2/ARE pathway alleviates neuropathology in the APP/PS1 transgenic mouse model of AD [315–317] and in toxin-based and genetic models of PD [306,313,318–323]. Hence, this pathway is considered as an excellent target for the design of antioxidant therapies with the potential to stop or slow neuronal cell loss in PD and other neurodegenerative diseases [324–326].

ANCs are largely responsible for the health-promoting benefits associated with regular consumption of various berries and berry extracts [16,327]. Not only can these ANCs cross the BBB (see earlier), but they also have potent antioxidant, antiaging, and neuroprotective activities [328–330]. Evidence from several reports suggests that ANC-rich berry extracts and individual ANCs activate the Nrf2 antioxidant response as part of their protective mechanism in various disease models [328,329,331]. A C3G-enriched fraction from Chinese Bayberry was found to induce Nrf2 nuclear translocation and HO-1 up-regulation in INS-1 cells [328]. HUVEC cells treated with serum from healthy individuals fed an ANC-supplemented diet showed increased nuclear translocation of Nrf2 and up-regulated expression of the Nrf2-regulated proteins HO-1 and NQO1 [329]. Interestingly, not all ANCs have the same capacity to activate Nrf2 signaling. For example, kuromanin, delphinidin, malvidin, and cyanidin were found to have higher propensities to induce up-regulation of Nrf2-mediated transcription compared to peonidin, pelargonidin, and petunidin in rat liver cells [331], suggesting that berries with different ANC compositions and concentrations likely differ in terms of their relative abilities to induce the Nrf2 response.

Evidence from multiple reports indicates that sulforaphane and other isothiocyanates activate the Nrf2-mediated antioxidant response. In one study, a microarray analysis led to the identification of genes up-regulated by sulforaphane in the small intestine of wild-type ($Nrf2^{+/+}$) and knock out ($Nrf2^{-/-}$) mice [332]. The transcriptional profile showed that sulforaphane modulates the transcription of numerous Nrf2 target genes, including glutathione-*S*-transferase (GST) and NQO1. Additional results demonstrated that (i) sulforaphane up-regulated striatal and ventral midbrain HO-1 and NQO1 levels in $Nrf2^{+/+}$ but not $Nrf2^{-/-}$ animals, and (ii) sulforaphane alleviated

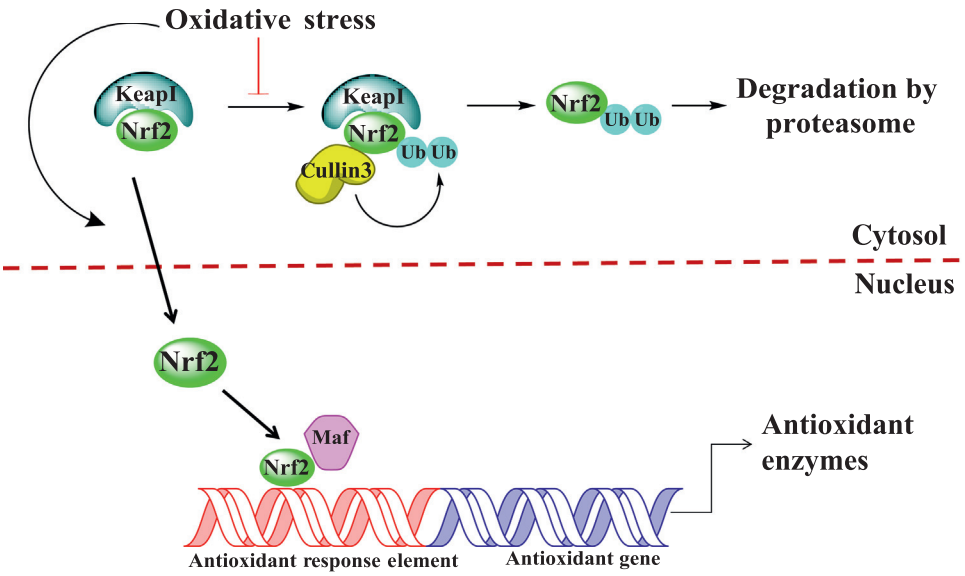

FIGURE 18.8 Schematic illustrating the classic mechanism of Nrf2 activation. Under normal conditions, Keap1 sequesters Nrf2 in the cytoplasm and regulates its ubiquitination by cullin-3 and subsequent degradation by the UPS. Under conditions of oxidative stress, the oxidation of cysteine residues on Keap1 results in its conformational change and the release of Nrf2. Nrf2 translocates to the nucleus, where it heterodimerizes with Maf, binds to the ARE, and activates the transcription of genes encoding antioxidant enzymes.

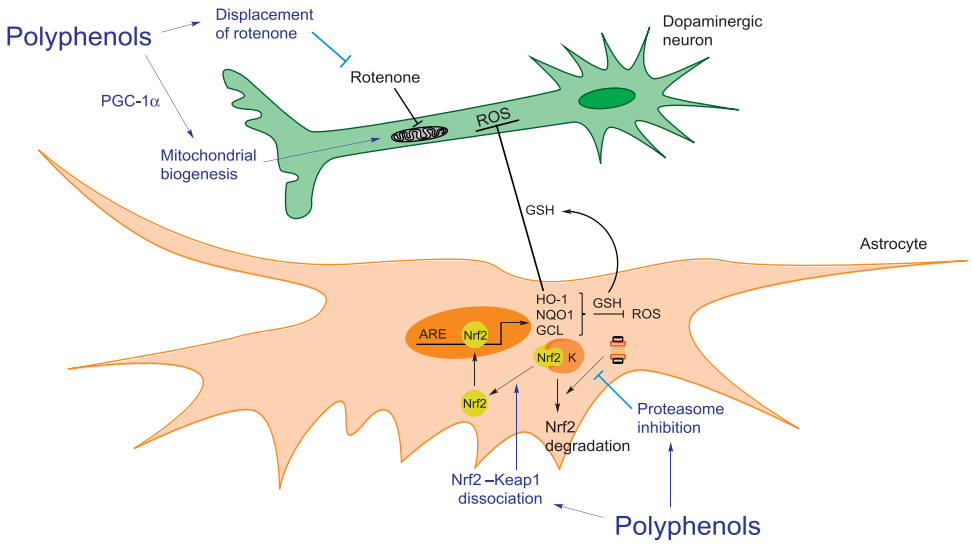

FIGURE 18.9 Model illustrating polyphenol-mediated antioxidant responses. Nrf2 levels increase in astrocytes as a result of ROS- or polyphenol-induced dissociation of Nrf2 from its repressor protein Keap1 ("K"), or as a result of polyphenol-mediated UPS inhibition. A build-up of astrocytic Nrf2 leads to an increase in the expression of genes involved in the cellular antioxidant response, including heme oxygenase 1 (HO-1), NQO1, and GCL, an enzyme involved in GSH synthesis. GSH subunits produced as a result of GSH metabolism are released from astrocytes and imported into neurons, where they are reassembled into GSH. Polyphenols can also induce an antioxidant response by ameliorating mitochondrial dysfunction (shown here in neurons exposed to rotenone) by (i) activating PGC-1α, a transcriptional co-activator that induces mitochondrial biogenesis and the expression of ROS-detoxifying enzymes; and (ii) displacing rotenone from complex I of the electron transport chain.

MPTP-induced dopaminergic cell loss in $Nrf2^{+/+}$ mice but not their $Nrf2^{-/-}$ littermates [235]. Sulforaphane was also shown to induce an increase in levels of GSH, a product of the Nrf2-mediated antioxidant response, in parkin loss-of-function flies [306] and in 6-OHDA-lesioned mice [307]. Another study revealed that 6-HITC and sulforaphane-induced Nrf2 nuclear translocation and up-regulation of GSH and HO-1 in rat striatal cultures exposed to PQ, although the increase in HO-1 levels was not necessary for the observed neuroprotective effects in these cultures [305]. Finally, mouse Hepa-1c1c7 cells and primary cortical neurons treated with a broccoli seed extract, sulforaphane, or allyl isothiocyanates exhibited an increase in Nrf2 antioxidant activity and the transcription of Nrf2 target genes encoding HO-1 and/or NQO1 [333,334].

Evidence suggests that extracts prepared from aged garlic (*Allium sativum*), as well as organosulfur compounds in these extracts, elicit antioxidant effects by activating the Nrf2 response. One organosulfur constituent of garlic extract, *S*-allyl-cysteine, was found to induce an increase in Nrf2 expression in rat cortex [304] and to alleviate neuronal damage in cellular and animal models of ischemia by inducing Nrf2-mediated transcription [335]. In addition, *S*-allyl-cysteine was reported to activate Nrf2-mediated transcription in rat striatum, an activity that could account for the ability of the compound to attenuate striatal neurotoxicity in the rat 6-OHDA model [336]. Garlic constituents have also been shown to activate the Nrf2/ARE pathway in nonneuronal cell models. For example, the garlic by-product ajoene was found to initiate protein kinase C-δ (PKCδ)-mediated activation of Nrf2 signaling in the human hepatoma cell line HepG2 [337]. Three other garlic organosulfur compounds, diallyl sulfide, diallyl disulfide, and diallyl trisulfide, were shown to activate the Nrf2 antioxidant response via a PKC-independent mechanism in the same cell line [338].

Curcumin is a very potent activator of the Nrf2 antioxidant response in multiple cell types. One group reported that curcumin induced an increase in HO-1 levels in renal epithelial cells via activation of the Nrf2/ARE pathway [339]. In another study, liver and small intestine collected from wild-type and Nrf2 knockout mice treated with curcumin (1000 mg/kg) were analyzed to generate a global gene expression profile. The data revealed that curcumin modulated the expression of 822 and 222 Nrf2-regulated genes in the liver and small intestine, respectively, including detoxification enzymes such as HO-1, GST, and thioredoxin-interacting protein [339]. Curcumin was also shown to activate the Nrf2 response in human monocytes in a protein kinase C delta (PKC)-dependent manner [340]. Multiple lines of evidence suggest that the neuroprotective properties of curcumin may involve Nrf2 activation. Rats subjected to permanent focal cerebral ischemia exhibited neurological deficits that were reduced in a curcumin-treated group, potentially as a result of Nrf2 and HO-1 up-regulation [341]. Curcumin was also shown to induce Nrf2 nuclear translocation, expression of

Nrf2 target genes (e.g., the gene encoding HO-1), and up-regulation of GSH and glutathione disulfide in primary cerebellar granule neurons [342]. Data from another study revealed that curcumin induced an increase in HO-1 and NQO1 expression levels, alleviated oxidative stress, and preserved mitochondrial potential in H_2O_2-treated spinal cord astrocytes prepared from $Nrf2^{+/+}$ but not $Nrf2^{-/-}$ mice [343].

The activation of Nrf2 signaling by polyphenols and organosulfur compounds could occur via multiple mechanisms. One mechanism involves the participation of these agents in redox cycling reactions (e.g., quinone oxidation/reduction reactions) that lead to the formation of ROS, which in turn oxidize key regulatory cysteine residues of Keap1 (Fig. 18.9) [308,312,313,344]. Alternatively, polyphenols and organosulfur compounds can themselves covalently modify the Keap1 cysteine residues. Both mechanisms should result in a disruption of the Nrf2−KEAP-1 interaction, thereby leading to Nrf2 stabilization and activation [312,345]. Because Nrf2 is degraded by the ubiquitin proteasome system (UPS), the activation of Nrf2-mediated transcription by polyphenols and organosulfur compounds could also occur via UPS inhibition (Fig. 18.9) [346−351].

B Stimulation of PGC-1α-Mediated Mitochondrial Biogenesis

PGC-1α is a transcriptional co-activator that forms a complex with several transcription factors including PPARγ, Nrf1/2, and estrogen-related receptors [41,352,353]. The PGC-1α-dependent transcriptional network plays a central role in regulating mitochondrial biogenesis and cellular energy homeostasis [39−41]. In addition, PGC-1α is up-regulated in cells exposed to an oxidizing insult and is involved in regulating the cellular antioxidant response by inducing the expression of ROS-detoxifying enzymes (Fig. 18.9) [354]. Several groups have shown that PGC-1α carries out a protective function in cellular and animal models relevant to PD. PGC-1α-null mice are sensitized to nigral dopaminergic cell death and oxidative damage elicited by MPTP [354], and nigral neurons from these animals are more vulnerable to degeneration resulting from aSyn over-expression [355]. Genes regulated by PGC-1α are down-regulated in PD brain, and PGC-1α expression alleviates dopaminergic cell death in primary midbrain cultures exposed to rotenone or aSyn-encoding virus [356], although other studies have revealed that prolonged PGC-1α over-expression can lead to a depletion of striatal dopamine in rodent midbrain [357,358]. Collectively, these observations suggest that small molecules or botanical extracts that rescue the down-regulation of PGC-1α triggered by PD-related insults by restoring PGC-1α expression up to (but not in excess of) basal levels could potentially slow neurodegeneration in the brains of PD patients.

A number of polyphenol-enriched extracts and individual polyphenols have been shown to enhance neuronal health by promoting mitochondrial biogenesis and cellular energy balance. In one study, an extract prepared from flowers of the elderberry tree and one of its polyphenolic constituents, naringenin, was found to activate PGC-1α in mouse embryonic fibroblasts [359]. A number of groups have reported that resveratrol stimulates mitochondrial biogenesis and induces an increase in the expression of genes involved in this process in cellular and animal models [281,360−363]. Mitochondrial biogenesis was also enhanced in brain and muscle tissues of mice fed a quercetin-rich diet compared to control animals [364]. Additional evidence suggests that various isoflavones, including genistein, biochanin A, and formononetin, promote mitochondrial biogenesis [365]. The stimulatory effects of plant polyphenols on mitochondrial biogenesis may be mediated by the up-regulation or activation of SIRT1, an enzyme that stimulates PGC-1α activity by catalyzing its deacetylation [361,364,366].

In addition to stimulating the function of PGC-1α, some plant extracts and polyphenolic constituents can apparently ameliorate toxin-induced mitochondrial dysfunction by directly interacting with components of the electron transport chain (Fig. 18.9). This direct interaction could be an effective way to interfere with an early stage of oxidative stress—namely, ROS formation associated with mitochondrial dysfunction. Consistent with this idea, quercetin, kaempferol, and epicatechin have been shown to inhibit mitochondrial H_2O_2 production triggered by rotenone, potentially by competing with rotenone for the hydrophobic pocket of complex I [124].

C Alleviation of Glial Activation

Evidence suggests that polyphenols protect against neurotoxicity by alleviating neuroinflammation elicited by the activation of glial cells [367,368]. Multiple groups have reported that polyphenol-rich extracts and individual polyphenols such as ANCs, stilbenes, apigenin A (a flavone), and chlorogenic acid (a phenolic acid) attenuate the up-regulation of pro-inflammatory agents, including cyclooxygenase-2 (COX-2), NOS, NO, TNF-α, and IL-1β, in RAW 264.7 macrophages or BV-2 microglial cells activated with LPS [266,369−374]. In some of these studies, it was demonstrated that the polyphenols carried out their antiinflammatory effects by inhibiting the LPS-dependent activation of NF-κB, a transcription factor involved in mediating the inflammatory response [369,370,372,374]. Resveratrol was shown to alleviate neurodegeneration in the 6-OHDA rat model of PD by

reducing the expression of COX-2 and TNF-α in the SNpc [262]. It was also reported that isoflavones from *T. pratense* alleviate LPS-mediated microglial activation and the production of TNF-α, NO, and superoxide in neuron-glia cultures and microglia-enriched cultures from rat midbrain [285].

VIII CONCLUSIONS AND FUTURE DIRECTIONS

From this overview, it is evident that there have been remarkable advances over the past 20 years in our understanding of neuroprotective effects of dietary phytochemicals in AD and PD. Plant constituents that have been characterized in terms of their ability to alleviate neurodegeneration in cellular and animal models of AD or PD include isothiocyanates (found in cruciferous vegetables), sulfur compounds (found in garlic), and polyphenols (including flavonoids and nonflavonoids found in a variety of fruits, vegetables, nuts, and cereals). Mechanisms by which these phytochemicals are thought to carry out their neuroprotective effects include activation of cellular antioxidant responses mediated by the transcription factors Nrf2 and PGC-1α, stimulation of PGC-1α-mediated mitochondrial biogenesis, and attenuation of glial activation. A number of dietary plant constituents, particularly polyphenols, are associated with reduced AD or PD risk and have been shown to penetrate the BBB, suggesting that they could be used as therapies in patients.

A goal for future research will be to achieve a better understanding of which types of phytochemicals have the highest neuroprotective activity in AD or PD models. In a recent study, extracts enriched with ANC and/or PAC were found to have a greater propensity to alleviate rotenone-induced neurotoxicity in primary midbrain cultures compared to extracts containing stilbenes or phenolic acids [266]. Another goal will be to better understand the extent to which the neuroprotective effects of complex botanical extracts are mediated by synergies among multiple constituents, as opposed to activities of individual chemical entities [375–379]. It will also be critical to develop formulations and semisynthetic derivatives of plant constituents with improved brain bioavailability and neuroprotective activity. For example, a number of innovative methods are being used to enhance the BBB penetration of weakly bioavailable polyphenols such as resveratrol and curcumin, including nanoparticle encapsulation [380–382]. Another focus will be to assess the role of the gut microbiome in modulating neuroprotective effects of plant constituents. For example, a recent study revealed that 3-hydroxybenzoic acid and 3-(3′-hydroxyphenyl)propionic acid, two phenolic acids generated by microbiota-mediated metabolism of anthocyanidins in grape-seed extract, accumulate in rat brain and interfere with Aβ aggregation [383]. Ultimately, the insights from these studies, coupled with advances in the ability to diagnose AD and PD at earlier stages via biomarker analysis [384,385], will set the stage for developing phytochemical-based intervention strategies to delay disease onset or slow neurodegeneration in the brains of patients.

Chapter 19

Diet and Supplements in the Prevention and Treatment of Eye Diseases

I INTRODUCTION

The existence of ocular manifestations of nutrient deficiencies has been well known for more than a century and is well-described. The reader is referred to other texts and reviews that describe the role of nutrition in other aspects of vision that are briefly summarized in the following paragraphs. The role of vitamin A in preventing night blindness and xerophthalmia, which are common problems in developing countries, has been widely discussed [1]. Food shortages, as occurred in Cuba in 1991–94 and among the allied prisoners of World War II, or chronic alcohol use can result in a condition broadly referred to as nutritional amblyopia, which results in blurred vision and reduced visual acuity (recently discussed in Ref. [2]). This may be the result of poor intake and absorption of B vitamins or antioxidants, alcohol and tobacco toxicity, or a combination of these factors.

More recently, it has become apparent that nutrition may be important to some patients with hereditary visual disorders. One of the more common conditions is retinitis pigmentosa, an autosomal dominant condition resulting in progressive visual loss. It begins with the loss of night vision in childhood or adolescence. This is followed by the loss of peripheral vision because of the degeneration of rods, and finally the loss of central vision because of the degeneration of cones (recently reviewed in Ref. [3]). Vitamin A supplements have improved some aspects of retinal function in patients with retinitis pigmentosa, but vitamin E had an adverse effect [4]. Subsequent research indicated that supplementation with lutein [5] or docosahexaenoic acid (DHA) [6] (in addition to vitamin A) slowed the rates of retina degeneration and visual decline, but it may be that adequate intakes through dietary means are effective and may pose less risk over the long term [7].

Nutrition may also be important to the development of the visual system in newborns. Some studies, but not all, have observed better visual development in infants who were breast-fed, as opposed to those who were bottle-fed. This has led to a search for the nutritional differences between breast milk and infant formulas that may explain better vision in breast-fed infants. In two recent studies, breastfeeding was associated with better visual acuity at age 3.5 [8] and 4–6 years [9]. Breast milk contains high levels of DHA, which rapidly accumulates in retinal photoreceptor membranes neonatally. DHA supplementation has been reported in some, but not all, studies to improve visual functions in some preterm and term infants (reviewed in Ref. [10]). Some suggest that improvements may only be transient. One study reported that DHA supplementation for 6 months postnatally did not improve vision in later childhood [9]. This suggests the possibility that other components of breast milk generally missing from infant formulas, such as carotenoids, may be responsible for better vision in breast-fed infants. Considerable evidence in the past two decades indicates a unique role for specific dietary carotenoids in eye health throughout the lifespan. This is discussed in the next section. Overall nutritional intake in infancy, childhood, and adolescence might influence chronic age-related eye diseases that develop in later life. Evidence suggests that childhood diet influences the risk of cardiovascular disease later in life [11], but the influence on age-related eye diseases, which are the focus of this chapter, has not been investigated.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00019-9

The impact of nutrition on age-related declines in vision and age-related eye disease has been investigated over only the past 30 years. The deterioration of human vision advances with age. Over 80% of blindness worldwide occurs in people over age 50. This chapter addresses the influence of diet on the most common causes of vision loss in middle-aged and older people: age-related cataract, age-related macular degeneration (AMD), glaucoma, and diabetic retinopathy (DR).

The aging public's awareness of the decline in vision with age, and of the possibility that nutrition may influence this decline, has driven the marketing of nutritional supplements, which are sometimes costly and of uncertain benefit. In this chapter, we consider the existing evidence for the benefits of certain diets and supplements in slowing age-related visual problems associated with cataracts, AMD, DR, and glaucoma.

II LUTEIN, ZEAXANTHIN, AND EYE HEALTH THROUGHOUT THE LIFESPAN

There is evidence to suggest that the eye may uniquely require three oxygenated carotenoids for good vision throughout life, as well as to limit degeneration of the retina and lens of the eye, which contributes to AMD and cataracts in later life. These include lutein (L), zeaxanthin (Z), and L metabolite, meso-Z (MZ). These carotenoids cannot be cleaved to vitamin A and have not been considered essential for life, growth, and reproduction (the criteria that typically defines essential nutrients). However, they may be uniquely important to the eye and essential for optimal vision in the young and aging. The reader is referred to recent comprehensive reviews [12–14]. Overall, the evidence is limited, but suggestive and actively under investigation. Below, an overview of these carotenoids is given and their possible role in vision throughout life is described. In Sections II–IV, the evidence that suggests their importance in slowing age-related cataract, macular degeneration, glaucoma, and DR is discussed.

L, Z, and MZ, together, are the most abundant carotenoids in the eye and are selectively concentrated in the macula and most other ocular tissues, to the exclusion of [15–17] other carotenoids which are found common in human blood and tissues. Exceptions are in the retinal pigment epithelium (RPE) of the eye (the blood–retina barrier between the blood vessels that nourish the back of the eye and the rod and cone photoreceptors), and ciliary body (part of the layer of tissue (uvea) that delivers oxygen and nutrients to other areas of the eye) [15]. Monkeys deprived of plant foods do not have these carotenoids L, Z, and MZ in their eyes, demonstrating that obtaining them from the diet is essential [18,19]. In humans, their concentration [15,17] and optically measured density [20,21] in the macular area of the retina is highly variable. The accumulation of these carotenoids is referred to as macular pigment (MP). It is absent in premature human infants [22], is low in autopsy samples of newborn infants, and is higher in samples from older infants and children up to 4 years of age [17]. Thus, the current evidence suggests that L, Z, and MZ accumulate in the retina rapidly during late gestation and infancy, if supplied by the mother's diet or, after birth, by breast milk or infant formulas containing these carotenoids.

Historically, breast milk has been the primary source of L and Z after birth. Consistent with the exclusive accumulation of L and Z in the macula in early life, breast milk appears to selectively concentrate these carotenoids, especially in the first few months of lactation. In fact, L and Z are proportionally more prevalent in breast milk than maternal serum [23,24]. In contrast to the carotenoid content of breast milk, carotenoids are not routinely added to infant formulas. Research is needed to determine immediate and long-term impact of breast feeding on vision, compared with feeding infant formulas which lack these carotenoids and appear to be less bioavailable than breast milk [25] when added to infant formulas. Additionally, more work needs to be done to determine the level of carotenoids that should be included in infant formula for infants who do not receive breast milk. Lastly, the need for these carotenoids might be particularly high in premature infants who do not have the benefit of optimally accumulating carotenoids in utero and are limited in ability to obtain them after birth. Until more is known, it is prudent to provide infants with early life nutrition such as can be provided by breast feeding from mothers with adequate intake of these carotenoids.

L and Z accumulate most markedly in the center of the macula. The timing of their accumulation and the relative proportion of L, Z, and MZ corresponds to the maturation of the macula over the first 4 years of life (recently reviewed in Ref. [26]). The time period of the accumulation of L and Z in the retina also corresponds to the accumulation of long-chain polyunsaturated fatty acid (LC PUFA), arachidonic acids (synthesized from essential fatty acid, linoleic acid) and DHA (synthesized from alpha-linolenic acid), which are also highly concentrated in retinal tissue (like the brain and other neural tissues (reviewed in Ref. [27])). These xanthophyll carotenoids and omega-3 fatty acids appear to be essential for the development and/or maintenance of normal RPE cells [28], the layer of cells that support the nutrient and metabolic needs of the rod and cone photoreceptors.

L, Z, and MZ in the macula (and L and Z in the lens) comprise is commonly referred to as "macular pigment."

These carotenoids absorb short wavelength (about 400−530 nm) light in the blue range of the spectrum that is known to damage photoreceptors and the RPE. In monkeys, depletion of L and Z in early life results in increased susceptibility to blue-light damage [29]. Preterm human infants supplemented with L had greater sensitivity responses of rod photoreceptors [30]. However, the extent to which a lack of carotenoids in early life creates lasting visual advantages or prevents lifelong vision problems is unknown. Vision throughout life might also be modified by the degree to which L and Z have accumulated in utero and by the intake of foods containing these carotenoids in later infancy and childhood. Supplementation of carotenoid-depleted monkeys reduced blue-light damage to the fovea [29].

It has long been proposed and recently demonstrated that these carotenoids enhance vision function. This was recently reviewed in Ref. [12]. Briefly, supplementation with L, Z, and/or MZ for 3 months to 3 years has improved visual acuity and or contrast sensitivity in many, but not all, clinical trials. Visual acuity improvements were noted in individuals with AMD or DR, but not, to date, in individuals with healthy vision. Differently, improvements in contrast sensitivity have been observed in samples of both healthy men and women and in individuals with diabetes or early- and late-stage AMD. Improvements in the time it takes to recover from bright lights (photostress recovery) or enhancement in the ability to see in conditions of glare have been observed in a few studies, but not most. Improvements in visual processing speed and rates of dark adaptation with adequate L and Z intake have been hypothesized and are supported by limited data, but have not been well-studied. Supplementation with L and Z slowed vision loss in adults with retinitis pigmentosa who were also taking vitamin A [5]. The ability to accumulate macular pigment is highly variable, particularly over a few months. The improvement in trials is often the largest in people who have made the most marked improvements of MP optical density levels. Also, improvements in vision outcomes have been more consistently observed when supplements include other antioxidants and/or long-chain polyunsaturated omega-3 fatty acids (LC omega-3 PUFAs).

The density of L and Z in the lens and retina may influence the eye diseases that occur in later life. It has been reasoned [31] that infant eyes are particularly vulnerable to oxidative damage in early life, which may have consequences decades later. Because of the redundancy of the visual system it may be difficult to observe the impact of early life nutrition on vision function in later life in small samples of people.

Sources of L and Z are also important from childhood through adulthood. Food sources of L and Z include a wide variety of fruits and vegetables, grains, and eggs [32]. They are particularly concentrated in green leafy vegetables, but corn products and eggs may comprise significant sources for some people, such as American Hispanics. Mean intake levels estimated in the 2011−12 National Health and Nutrition Examination Survey (NHANES) were 1.7 mg/day in adults over 20 years of age and 0.8 mg/day in children 2−19 years of age [33]. Levels of L and Z intake in some South Pacific study samples are higher [34] and reached 25 mg/day in one study in Fiji [35]. Increasing obesity in the United States might contribute to reductions in carotenoid status, as obesity (and other phenotypes related to metabolic syndrome) is associated with lower levels of L and Z in serum and MP after accounting for dietary intake [20]. It is hypothesized that obesity reflects genetic and lifestyle factors which lower the absorption of these oxygenated carotenoids and their uptake and stabilization in the eye [20,36].

III CATARACT

Cataract is the leading cause of blindness worldwide, accounting for almost half of all blindness [37]. The visual burden of cataract is largest in developing countries, where malnutrition is more common and the relatively simple surgical excision of cataract is less available. However, the economic burden of cataract in developed countries is high. For example, in the United States, the total direct medical cost of cataract was $6.8 billion in 2004, representing 42% of the total direct medical cost of all visual disorders in that year [38]. Seventeen percent of Americans older than 40 years have cataract in either eye, and 5% have had cataracts extracted [39]. The rate of cataract and extraction steeply increases with age. More than half of individuals over age 80 years have had cataract surgery (United States). Lens opacities can make seeing more difficult, especially under dim light and in the presence of glare (such as when driving at night), even before surgery is indicated. Over 30 years ago it was estimated that if preventive measures could delay cataract by only 10 years, the visual and surgical burden would be cut in half [40].

Lens opacities form as a result of protein aggregation or lens fiber disorganization due to either acute metabolic insults or the gradual accumulation of damage with age. The lens must remain clear in order to collect light and focus it on the retina. Lens opacities scatter light, blurring vision. With aging, the lens also slowly becomes brunescent, adding a brown tint to vision. When light transmission is blocked substantially enough to reduce visual acuity, a cataract exists; if opacities become severe, blindness can occur.

Cataracts generally occur in three regions of the lens (recently reviewed in Ref. [41]) (Fig. 19.1). The most common region is opacities in the nucleus, or center, of the lens. This is called a nuclear cataract, and most people develop this with age. Nuclear cataract may reflect cumulative insults that have occurred since early childhood.

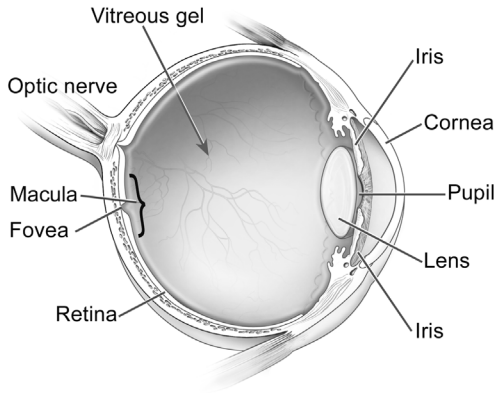

FIGURE 19.1 Anatomical features of the human eye. *Courtesy of National Eye Institute, National Institutes of Health.*

Nuclear lens fibers do not have mitochondria, nuclei, or other cytoplasmic organelles and thus lack the capacity to repair damage over one's lifetime. Less commonly, opacities develop in the region just under the lens capsule that separates the lens from the vitreous humor (posterior subcapsular cataracts, or PSCs), and in the fiber layer between the outside edges of the lens and the nucleus (cortical cataract). Cataracts sometimes occur exclusively in one region However, often opacities occur in multiple regions, particularly as cataracts become more severe.

A Causes

The pathogenesis of cataract involves the accumulated stresses caused by physiological and environmental stressors that arise from such things as the photochemical formation of free radicals and osmotic imbalances. Most cataracts are the result of aging, but cataracts can also occur as a result of surgical or other eye trauma, steroid use, or some types of radiation. Smoking is the most common modifiable risk factor for age-related cataract in population studies [42]. Exposure to smoke from combustion of wood or other fuels [43,44] may similarly increase cataract risk. Other nonnutritional risk factors include prolonged exposure to ultraviolet (UV)-B light (particularly in the cortical region of the lens), diabetes (especially for cortical cataract and sometimes nuclear cataract and PSC), obesity, heavy use of alcohol or elevated markers of systemic and local inflammation [45] or arthritis (as a marker of inflammation) [46]. Genetic factors have been most extensively investigated for nuclear cataract, and heritability studies suggest a substantial role of genetic factors in the development of nuclear cataract occurrence and progression, but specific genotypes are not well-studied [47].

Animal studies have indicated that cataract can be induced by high-galactose diets, experimental diabetes, nutrient deficiencies (riboflavin, calcium, zinc, and selenium), or nutrient excesses (selenium) (reviewed previously in Ref. [48]). Genetic mutations or polymorphisms that cause perturbations in calcium [49] or iron metabolism [50] have also been associated with cataracts. Otherwise, in the absence of extreme metabolic insults or deficiencies, lens opacities often develop slowly over many years. A gradual influence of nutrition on the development of cataract over adult life is suspected and is supported by animal studies. In Emory mice, a mouse strain that develops cataracts in adulthood, calorie restriction slows the development of lens opacities [51]. Since the 1980s, a body of evidence has been accumulated to indicate lower rates of cataracts among populations of people who eat micronutrient-rich diets or take multivitamins (summarized in Table 19.1 and discussed later).

B Healthy Diet Patterns

Generally, healthy diets or vegetarian diets have been associated with lower risk of cataract extraction or nuclear cataract in several studies in populations around the world [51–55]. The reduced risk associated with healthy diets in epidemiological studies of generally well-nourished populations [53,54] is about twofold and not explained by single nutrients [56], suggesting additional unknown food components that may lower risk and/or that food components work jointly to lower risk. The following sections consider many specific food components which may be responsible.

1 Carbohydrates

In experimental animals, cataracts are easily developed by feeding monosaccharide-rich diets or agents that promote diabetes (reviewed in Ref. [48]). Two mechanisms for cataract promotion within the lens are proposed. When the metabolic pathways to utilize sugars are overwhelmed, sugar alcohols are formed by aldose reductase, accumulate in the lens, and can cause osmotic cataracts. Another mechanism might involve nonenzymatic glycosylation and the accumulation of advanced glycation end products in the lens [57] or cataracts [58].

Humans with galactosemia, a rare, autosomal recessive disorder leading to an inability to break down dietary galactose, as found in milk, can be treated with a galactose-free diet. However, treated individuals are still at higher risk of developing cataract throughout life [59]. In a meta-analysis of human observational studies, higher dietary carbohydrate quantity and glycemic index were associated with the risk of cortical and nuclear cataracts, respectively [60]. In people with diabetes, poor glycemic control has been associated with higher lens density [61]. The prediabetic state has also been associated with cataract

TABLE 19.1 Summary of Evidence Relating Nutritional Exposures to Cataract

Nutritional Exposure	Strength of Evidence	Comment
Healthy Diet Patterns	*Benefit of following micronutrient-rich diet patterns is likely*: A large body of evidence suggests that healthy diets lower chronic diseases and their risk factors. Four observational studies suggest lower rates of cataract among people reporting the intake of healthy diet patterns.	Two population studies suggest that the benefit of healthy diets on lowering risk of nuclear cataract is stronger than the benefit of high intake of single nutrients. Many studies in animals and humans support the benefit of numerous specific micronutrients and phytochemicals.
Carbohydrate	*Possible increased risk associated with high levels of specific or overall refined carbohydrates:* Animal studies suggest several mechanisms. A meta-analysis of population studies suggests that higher dietary carbohydrate quantity and glycemic index was associated with the risk of cortical and nuclear cataract, respectively.	Results in population studies might reflect an influence of diabetes on cataract, rather than carbohydrates specifically and/or that high-carbohydrate diets are often nutrient-poor.
Antioxidants	*Benefit of food antioxidants is likely; supplemental antioxidants do not consistently lower risk and, there is the possibility that they increase risk in some cases:* Animal studies prove that oxidative stress leads to lens opacities and that antioxidants lower indicators of oxidative stress and/or damage. Population studies in many samples indicate lower risk of cataract with higher intake or blood levels of various antioxidants. The data are most consistent for diets rich in lutein and zeaxanthin.	In population studies, diets rich in specific antioxidant nutrients are likely to be markers for diets rich in plant foods (fruits, vegetables, whole grains) which contribute a wide range of nutritive and nonnutritive antioxidants. Clinical trials of high-dose antioxidants do not generally support the benefit of one or two specific antioxidant nutrients or a combination of high-dose antioxidants. In a meta-analysis of clinical trials, high-dose beta-carotene and/or vitamin E increased mortality.
Lead	*Exposure possibly increases risk:* Two observational studies suggest that intake of antioxidants in supplements increase the risk of cataract. This risk factor and the influence of other heavy metals, particularly when dietary antioxidants are low, require further research.	
B vitamins	*Benefit of dietary riboflavin and niacin in malnourished or healthy populations is possible:* Results of one clinical trial and many observational studies suggest protective relationships with the intake of these B vitamins. *High-dose intake of folate, B6 or B12 may increase risk:* Supplemental intake of a combination of these three increased the risk of cataract extraction in one trial. Dietary folate intake in a well-nourished study sample, in the time period after folate fortification, increased the risk of PSC over 9 years.	Considered together, the evidence for an adverse effect is strongest for folate in supplements or in fortified foods, but additional research is needed to better evaluate this possibility.
Vitamin D	*The benefit of good vitamin D status (from adequate sunlight, foods, and/or supplements) on cataract is unknown.* Animal and cell studies suggest antiinflammatory properties of vitamin D. Results of three observational studies indicate lower prevalence of cataract in persons with high levels of a biomarker of vitamin D status in the blood. Relationships of vitamin D intake from foods and supplements in relation to cataract are limited to four cross-sectional studies and are inconsistent.	
Multivitamin Supplements	*Both benefit and harm are possible:* Benefit may exist for persons at risk for nuclear cataract, but multivitamins might increase the risk of cortical of PSC.	

[62]. However, the specific impact of simple sugar consumption on cataract risk is uncertain. Epidemiological associations might reflect, to some extent, broader nutrient-poor diet patterns that often accompany diets high in carbohydrates or the impact of these diet patterns or diabetes on oxidative stress or inflammation.

Animal studies suggest that other aspects of the diet might modify cataractogenesis that develops as a result of diabetes- or galactosemia-induced cataract. The development of these cataracts has been lessened by intake of plant extracts [63] or a wide variety of nutrients and phytochemicals such as vitamins C and E (previously reviewed in Ref. [64]), soy isoflavones [65], caffeine [66], resveratrol [67], and cumin [68].

2 Antioxidants

It is well known that oxidative stress increases lens damage [41]. Relationships of antioxidant nutrients to cataract development in animals, and to the occurrence of cataract in populations, have been extensively reviewed [44,48,69–71]. Deficiencies of riboflavin, selenium, and zinc—cofactors for enzymes that play important roles in oxidative defense—cause cataracts in some species (previously reviewed in Ref. [48]). Deficiencies of vitamins C or E and major water and lipid-soluble antioxidants have not been reported to cause cataracts independently, but they do protect against oxidative damage in a variety of animal and cell systems. Vitamin C is abundant in human lenses, and its levels in the lens reflect those in the diet [72]. Lipid-soluble antioxidants in lenses include vitamin E and the specific carotenoids L and Z [16], which uniquely accumulate over other blood carotenoids. Both have been demonstrated to protect against UV-light-induced peroxidation in lens cells [73].

High levels of combined antioxidants in diet or serum [74–77], or of single antioxidant nutrient in diet and blood, have been associated with lower prevalence or incidence of cataracts or cataract extraction associations with numerous observational studies [44,71,78]. In contrast, there has been no evidence in randomized clinical trials for up to twelve years, that supplementation with one or more antioxidant nutrients (above recommended dietary allowances) slow the progression of age-related cataract [79]. An exception is in one trial in which they were accompanied by a multivitamin [80]. Moreover, taking vitamin C supplements was associated with an *increased* risk of cataract extraction over 10 years in women [81]. Both high-dose vitamin C and E were associated with higher risk of cataract over about 8 years in Swedish men, across many subgroups and risk increased among long-term users [82]. One explanation for these conflicting pieces of evidence is that both deficiencies and excess of antioxidants could be harmful. In the lens, vitamin C can enhance oxidative stress and contribute to glycation of lens proteins [83,84]. Moreover, there is evidence that oxidation of vitamin C can produce a compound that enhances photosensitivity which could further promote cataracts [85]. In addition, in a meta-analysis of trials, beta-carotene and vitamin E, singly or combined, significantly increased mortality [86]. For these reasons, caution is suggested in the consumption of high-dose antioxidants for the prevention or slowing of cataracts [79].

Supplements containing L and Z have only been available since about 1995, and they are likely to become more common since the addition of L and Z to high-dose antioxidants was recommended as a standard of care in treating intermediate or advanced stages of AMD (see Section III). There is mounting evidence that intake of these carotenoids may explain, in part, the lower cataract risk associated with people who eat diets rich in vegetables. Diets and serum rich in L and Z are consistently related to lower incidence or prevalence of nuclear cataract or cataract extraction in longitudinal studies [75,87–91], except in well-nourished men and women over 60 years of age participating in a clinical trial of high-dose antioxidants [92]. However, foods rich in these carotenoids, such as green vegetables and dark green leafy vegetables, are rich in many micronutrients and antioxidants, so that consistency of this association may simply reflect micronutrient and antioxidant-rich diets in general. In one large 5-year randomized trial in people with AMD, adding L to high-dose antioxidant supplements slowed the progression to cataract surgery among participants in the lowest quintile for levels of these carotenoids in their diets, although there was no protective benefit in the larger group of participants [93]. Relationships between high-dose L and Z supplement use and general health and mortality have not been well-studied.

Thus, the overall body of evidence from animal and population studies suggests that antioxidant components of the diet may contribute to protection against cataract development. However, there is little evidence to suggest that short-term supplementation with one or a few antioxidants is likely to have an important impact on the development of cataracts, which develop over many years and are influenced by a wide variety of dietary, health, and lifestyle factors. Moreover, adverse effects on cataract development or other aspects of health are possible when taken in high doses.

3 Minerals and Heavy Metals

Research on the benefits of antioxidants has not considered the potential larger importance that antioxidant protection might have under conditions of high oxidative stress. Oxidative stress can also result from genotypes

that result in iron overload [50]. Mechanisms for toxicity of heavy metals may include depleting cellular glutathione and/or heavy metals displacing zinc and copper on enzymes involved in protection against free radicals, causing oxidative stress [96].

Only a few epidemiological studies have examined the joint effect of low intake of antioxidant-rich foods and heavy metal exposure. In a sample of fish-eating people living in an area of the Amazon, with among the highest levels of mercury exposure in the world, joint existence of poor plasma selenium and high blood mercury is associated with a dramatically higher (16-fold) prevalence of age-related cataract [95]. In one clinical trial, beta-carotene was protective against cataract only in smokers who were likely to have higher exposure to heavy metals [97]. Thus, a benefit of food antioxidants may be greater in smokers or people who are exposed to industrial pollutants.

4 Other Vitamins

B vitamins: Results of several observational studies [75,92,98–103], and one trial in a malnourished population [104], have suggested protection against the development of lens opacities in individuals with higher dietary or blood levels of the B vitamins riboflavin, thiamin, and/or niacin. Riboflavin and niacin have roles in enzymatic mechanisms to protect against oxidative stress. Supplementation with these in an undernourished population in China protected them against the occurrence of nuclear cataracts [104].

In contrast, supplementation with a combination of B vitamins (vitamin B6, B12, and folate), at doses exceeding the recommended dietary allowances, increased the risk of cataract in U.S. physicians over 7 years [105]. Consistent with this finding, in participants already using multivitamins, high dietary folate was associated with higher risk of mild PSC among participants in the Age-Related Eye Disease Study (AREDS) [92]; cataracts in the PSC region of the lens was increased twofold [106].

Vitamin D: A role for vitamin D in the functioning or health of the lens is suggested by the evidence of the vitamin D receptor (VDR) in human lens epithelium [107]. As previously reviewed, inflammation is implicated in the development of cataract and the antiinflammatory properties of vitamin D [108] have been hypothesized to protect against age-related cataract.

Three investigations have recently described the lower prevalence of cataracts among people with high, compared with low, blood concentrations of 25-hydroxyvitamin D (25(OH)D) and cataract. Serum 25(OH)D reflects intake of vitamin D from foods, supplements, and the endogenous production of vitamin D that occurs upon exposure of skin to UV-B radiation in sunlight [109]. In 1988, results of an exploratory analysis of 112 participants, indicated a decreased odds of any and cortical cataract among those with high compared to low 25(OH)D concentrations [74]. Since then, data from two cross-sectional studies, one in a cohort of postmenopausal women [110] and the other in a population-based survey from Korea [111], have suggested possible protective associations between serum 25(OH)D and cataract, but only in subsets of their samples (e.g., postmenopausal women age <70 years [110] and in men [111]). The conflicting risks of sunlight—which may increase risk of cataract—and dermal production of vitamin D—which may decrease risk for cataract—make observational associations of vitamin D status and cataract exceptionally difficult to disentangle.

There have been a small number of studies examining relationships between the intake of vitamin D from foods and or supplements and the evidence is conflicting and does not take into account intraindividual differences in the level of vitamin D synthesized in the skin on exposure to sunlight or the competing risk of sunlight. Food sources of vitamin D include naturally occurring sources like fatty fish, fish liver oil, mushrooms, and egg yolk as well as fortified food sources such as milk, orange juice, breakfast cereals, and margarine [109]. A protective association of prevalent nuclear cataract with retrospectively recalled milk consumption [75] may reflect, in part, vitamin D intake or it could reflect a protective association of riboflavin, also associated with lower odds for nuclear cataract, or it could reflect an overall dietary pattern. Studies examining associations between cataract and estimated intake of vitamin D from all foods consumed reported null associations [52,101]. The evidence to describe relationships between the intake of vitamin D in supplements and cataract is limited to one retrospective study in which the intake of vitamin D from supplements was associated with increased odds of nuclear and cortical cataracts [112]. However, the confounding effects of other supplemental nutrients and lifestyle factors could not be accounted for.

In summary, study of the association between vitamin D status and cataract needs additional research in order for any conclusions to be drawn. Ideally, future studies will concurrently evaluate vitamin D intake from all sources and the competing risk of excess ocular sunlight exposure which may accompany higher rates of vitamin D synthesis in the skin. The role of vitamin D status in the eye is likely to vary by anatomical site and the extent to which vitamin D may influence the health of the cornea, lens, or retina differently is still under study.

5 Multivitamin Supplements

In contrast to the evidence for high-dose antioxidants and cataract, a large body of evidence from observational

studies [80,113–116] and clinical trials [104,106,114] indicate a protective effect of multivitamin use on nuclear cataract. However, evidence does not consistently support a benefit for cortical or PSC opacities. In one 9-year trial, the benefit of multivitamins was not observed for cortical opacities and the risk of cataracts in the PSC region of the lens was increased twofold [106].

IV AGE-RELATED MACULAR DEGENERATION

A Overview

AMD is a result of deterioration of the macula (see Fig. 19.1), the cone photoreceptor-rich part of the retina responsible for central vision and reading fine detail. AMD is the leading cause of blindness in developed countries and the third leading cause worldwide [37]. By the age of 65, roughly 8% of people in the United States have an intermediate form of AMD, which has a high risk of progressing to advanced AMD [117], and 2% of Americans over 80 years have advanced AMD [117]. There is no cure for this condition, and medical and surgical treatments are limited to people with one type of advanced AMD (wet AMD) with limited long-term effectiveness. Because of the steep increase in AMD with age, prevention is likely to have a large impact on the social and economic burden of this condition.

The early stages of AMD are signaled by yellowish white deposits, or drusen (Fig. 19.2), in the subretinal space and in the posterior part of the photoreceptor layer. Drusen can vary in size and area; more extensive drusen development is predictive of greater eventual progression to advanced stages. In intermediate stages, there are sometimes areas of hyper- or hypopigmentation (retinal pigment abnormalities) in the retina pigment epithelial (RPE) cells, a single layer of cells that support the rod and cone photoreceptors, caused by disturbances in the distribution of melanin pigments. Extensive drusen and retinal pigment abnormalities are thought to signal the existence of pathological processes associated with a distressed central retina. These changes are thought to compromise the ability of nutrients and oxygen to flow from the choroidal blood supply, through Bruch's membrane, to the RPE cells and the photoreceptors they support. Drusen may also reflect the existence of inflammatory processes that contribute to degradation of this area.

When deterioration of the macula proceeds to the extent that the RPE cells and the rod and cone photoreceptors they support die, advanced AMD occurs. It is sometimes referred to as "dry" AMD when it is limited to atrophy of the RPE and photoreceptors. If growth of new blood vessels occurs, then the advanced AMD is referred to as "wet" AMD. Impairment in visual acuity (after correction for glasses) is common with advanced AMD, progresses with the severity of disease, and can cause legal blindness. Bleeding or leaking of these vessels can also cause acute limits in vision. Advanced AMD of both types interfere with vision in the center of the visual field (such as that needed to view a person's face straight on) and the ability to read fine detail needed, for example, to read newspapers.

Rod-photoreceptor-related vision loss also occurs with advanced AMD, and often even before the loss of visual acuity associated with advanced AMD. There is impairment in rod-mediated dark adaptation, characterized by a slow recovery of visual sensitivity in low light conditions, such as when moving from areas of bright to dim illumination. This is thought to be caused by deposition of hydrophobic lipids in the RPE/Bruch's membrane complex with AMD and aging. This could slow the rate of delivery of vitamin A to rod photoreceptors, creating a transient local deficiency of vitamin A for rod photoreceptors

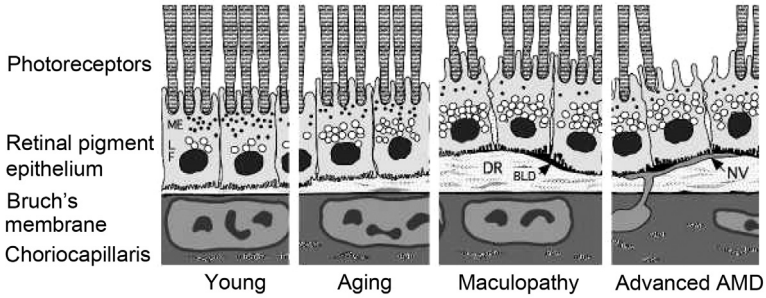

FIGURE 19.2 Changes to layers of retina in the macular region during aging, and progression of AMD in early and advanced stages. With age, there is an accumulation of lipofuscin (*LF*), a decline in melanin (*ME*) in the RPE, and a thickening and lipid enrichment of Bruch's membrane. Basal laminar deposits (*BLD*) are seen in early maculopathy but may also reflect aging. Drusen (*DR*) accumulation also characterizes early maculopathy. In intermediate AMD, *DR* becomes more extensive, and there are areas of the RPE that are hypopigmented or hyperpigmented (because of *ME* clumping). In more advanced AMD, there is atrophy of the photoreceptors and there may be neovascularization (*NV*)—the growth of new blood vessels and narrowing of the choriocapillaris. *Courtesy of Francois Delori, Schepens Eye Research Institute/Harvard Medical School, Boston, MA.*

(rods), slowing the recovery of light sensitivity by rod photoreceptors [118]. This localized vitamin A deficiency reduces the amount of vitamin A metabolite, 11-cis-retinal, available to combine with the protein, opsin, to form the visual pigment rhodopsin and the rate of phototransduction (converting light energy into neural impulses) [119]. This idea is consistent with the observation that short-term, high-dose retinol supplementation increased the rate of rod-mediated dark adaptation in people with early AMD or signs of retinal aging [120].

A significant proportion (22%) of adults over 60 years of age, in otherwise normal retinal health, have been also observed to have dark adaptation abnormalities [121], and were observed to increase the risk of developing AMD three years later [122]. This might explain common reports of problems seeing in low light conditions in people with early stages of AMD, even in persons with good visual acuity, tested at high illumination [123,124].

B Causes

AMD appears to develop as a result of a complex interplay of multiple dietary, environmental, and genetic factors that influence oxidative stress [125], inflammation [126,127], and light damage [128]. Smoking is the most commonly reported risk factor [129] for AMD in epidemiological studies. It is also commonly thought that damage by light, especially in the blue range, promotes AMD, although epidemiological studies have not consistently observed higher rates of AMD among people with high levels of sunlight exposure. This might be due to the difficulty in assessing the amount, type, and timing of sun exposure [130]. Some studies indicate high risk for AMD among people with cardiovascular disease [131,132] or risk factors such as obesity, diabetes, and hypertension [133,134].

Next to smoking, the most consistent, strong risk factor for AMD is family history [134]. People with AMD more commonly have certain variants within genes related to complement activation in the inflammatory response. While multiple complement related genes have been identified in AMD risk, the complement factor H (*CFH*) and age-related maculopathy susceptibility-2 (*ARMS2*) genes carry the greatest amount of risk. The *Y402H* variant A within *CFH* explains more than half of the population risk of AMD and is associated with 2.5−6.0 times greater AMD risk than individuals without the risk variant [135]. A variant with independent, yet similarly strong effects is the A69S variant (rs10490924) within *ARMS2* [136]. The genetic predisposition to AMD may involve a propensity for inflammation or exacerbation of an inflammatory response [126]. Some studies observe a higher prevalence of AMD among people with elevated C-reactive protein [137,138], an indicator of systemic inflammation, or among people with inflammatory diseases, such as gout [139], or who have used antiinflammatory medicines, which may signal the presence of inflammatory disease [140]. The evidence that diet and supplements may prevent or slow AMD is discussed later and summarized in Table 19.2.

C Healthy Diets

A wide body of evidence from a variety of study types supports the idea that food choices influence the development and progression of AMD, as discussed in subsequent sections. Healthy diet patterns that are rich in a wide variety of nutrients are consistently associated with lower AMD risk. Various healthy diet patterns have been related to a lower prevalence of early [141−143] and advanced AMD [142−145] and lower incidence of early AMD [146] and progression to advanced AMD [143,147].

Studies have looked at how healthy lifestyle factors, genetics, and/or diet patterns interact to contribute to AMD risk. It is unclear whether the impact of healthy diets and lifestyles is greater in people with high or low genetic risk. In one study, the reduction in the chance of having AMD was large (threefold lower) when healthy diets are jointly accompanied by moderate to high levels of physical activity and avoidance of smoking [141]. Moreover, women with a genetic predisposition for developing AMD (indicated by possessing two high-risk alleles for the *CFH Y420H* gene) significantly increased their odds of having AMD 6 years later if they had a history of heavy smoking, low scores on a healthy diet index and low levels of exercise. Results of another study in a separate sample found that higher adherence to a Mediterranean-style diet was protective in individuals who possessed at least one *nonrisk CFH Y420H* allele, but conferred no benefit in individuals with two high-risk *CFH* alleles [147]. Having high levels of body fat, which likely reflects a combination of genetic factors, diet, and physical activity, has been associated with a 12-fold higher risk for incidence of early or advanced AMD [148] and, together with smoking, has been observed to lower risk for progression of AMD 8- to 19-fold among people who had one to two copies of two common risk alleles [149]. The stronger associations observed when healthy diets, physical activity, not smoking, and genetic factors are considered jointly may be explained by the fact that they all contribute in lowering oxidative stress, inflammation, blood pressure and improving blood lipids, all of which are thought to promote AMD.

Moving forward, it might be possible to gain a better understanding of optimizing specific aspects of diet, by combining data from several large epidemiological studies and examining relationships with specific foods *within* groups of people who have similar overall diet quality.

TABLE 19.2 Summary of Evidence Relating Diet to AMD

Nutritional Exposure	Strength of Evidence	Comment
Healthy Diet Patterns	*Benefit of following micronutrient-rich diet patterns is likely:* A large body of evidence from results of studies in animals and humans support the benefit of numerous specific micronutrients and phytochemicals. Three studies suggest that scores on overall healthy diet patterns lower risk. (One study suggests risk lowering is particularly marked when combined with physical activity and not smoking.)	
High Glycemic Foods	Diets with low glycemic index scores might reduce the risk of developing AMD. Hyperglycemia in known to contribute to oxidative stress and inflammation, known to promote AMD. Results of a few observational studies suggest lower rates of AMD are associated with diets with low glycemic index scores.	A low glycemic index score is likely to be a marker for a plant- and nutrient-rich diet that contains many food components likely to lower AMD risk.
Antioxidants	*Benefit of foods or supplements rich in many antioxidants is likely*; Oxidative stress in the retina is high and known to contribute to AMD. In clinical trials, supplementing with individual antioxidants does not slow the progression of AMD. However, the benefits of a specific combination antioxidant supplement in slowing progression has been demonstrated in one large study sample (AREDS); benefits persisted over longer follow-up of the cohort for about 10 years. Benefit is also suggested by the results of several smaller studies. While observational studies suggest that antioxidant-rich diet patterns are likely to prevent AMD, antioxidant supplements have not been shown to *prevent* AMD.	*Caveats regarding AREDS-tested supplements:* – The longer-term risks and benefits are unknown. – Whether lower doses or different combinations of nutrients may have more benefit or lower long-term risk is unknown. Trials of one or two high-dose antioxidants have not shown benefit.
L and Z	*Benefit in slowing AMD and/or improving vision is likely:* The biological plausibility that L and Z can protect against oxidative stress, inflammation, and/or reduction of damage due to light exposure is strong and supported by studies in both animals and humans. In population studies, diets high in foods that contain L and Z are consistently related to lower risk for advanced AMD (although inconsistently related to lower risk for earlier stages). Several small and short-term clinical trials provide preliminary evidence to suggest that L and Z supplementation may improve vision in people with AMD. Benefit in slowing advanced AMD in individuals with low dietary intake is suggested by secondary analyses in a large clinical trial (AREDS2).	Diets rich in L and Z may reflect the overall benefit of high intakes of many micronutrient-rich foods. The ability to accumulate L and Z (and therefore, the potential benefit) varies across people. Differences in accumulation in the macula, genetic risk factors for AMD, and survival bias may make it difficult to observe consistent relationships between L and Z intake and AMD incidence and progression.
Zinc	*Benefit in slowing progression is proven:* High-dose zinc supplements slowed the progression of intermediate to advanced AMD in a large, multicenter, placebo-controlled clinical trial over 6 years; benefit was sustained over about 10 years of follow-up. In combination with antioxidant supplements, this supplement also reduced moderate visual acuity loss,	The safest dose with benefit is unknown. The long-term benefits and risks of consuming high levels of zinc in supplements are not well-studied. Inconsistency across observational studies might be explained by differences in the degree to which other components of foods rich in zinc (milk, beans, meats, and shellfish) or correlated nutrients or lifestyles have been accounted for. The benefit of zinc may depend on

(*Continued*)

TABLE 19.2 (Continued)

Nutritional Exposure	Strength of Evidence	Comment
	consistent with some other smaller studies that observed improvements if vision function with supplementation. *Benefit of adequate zinc intake from foods in slowing development of AMD is likely:* Zinc deficiency impairs retinal function in animals and humans. Diets high in zinc have been related to lower AMD in some but not all epidemiological studies.	the exposure to toxic metals from cigarette smoke and pollution.
Dietary Fat	*High intake of total fat might encourage the development of AMD:* High fat intake in mice with a genetic propensity to lipid disorder results in AMD-like lesions. Overall fat intake is associated with lower prevalence or progression of AMD in most population studies (although not always statistically significant). *Benefit of foods rich in LC omega-3 fatty acids is likely*: The retina is high LC omega-3 PUFAs which require a high rate of renewal. Diets high in omega-3 fatty acids are associated with lower inflammatory markers in the blood. Deficiency of omega-3 fatty acids in nonhuman primates increases sensitivity to blue-light damage. High intake of LC omega-3 fatty acids or fish is associated with lower risk for AMD in 7 of 8 study samples. In two randomized controlled trials of DHA and EPA supplements, added to high-dose antioxidants did not slow progression of persons with AMD over about 5 years.	Higher risk for AMD among people with diets high in fat might reflect lower overall nutrient density of high-fat diets or other aspects of lifestyle associated with the intake of high-fat diets. Diets high in LC omega-3 fats or fish may be related to lower AMD risk due to unmeasured and controlled for aspects of diet (intake of vitamin D and/or selenium) or lifestyle. Benefits should be considered in conjunction with the possibility that fish and some fish oils may contain mercury or other contaminants. Inconsistencies in protective associations in observational studies or across populations who vary in intake of omega-3 fatty acids or clinical trials might reflect modifying effects of genetic risk for AMD or the metabolism of omega-3 fatty acids.
B vitamins	Benefit is possible: Benefit is suggested by only one randomized clinical trial and two observational studies. More research is needed.	The evidence is insufficient to indicate which B vitamin(s) might be protective and whether folic acid supplements might be harmful over the long-term in some people.
Vitamin D	*Benefit of good vitamin D status (from adequate sunlight, foods, and/or supplements) is possible.* Animal and cell studies suggest antiinflammatory properties of vitamin D. In cohort studies and studies of population-based survey data, associations between 25(OH)D concentrations, as an indicator of vitamin D status, and early AMD are inconsistent. Only one study is of a prospective design, but data on vitamin D status was derived from a retrospective review of Medicare claim files and AMD diagnosis. Data from one national survey and two case-control studies suggest that an association between 25 (OH)D and late-staged AMD may exist but few robust studies have investigated this association.	Higher blood levels of vitamin D could be related to other aspects of diet or lifestyle that could protect against AMD.
Multivitamin Supplements	*Benefit is unknown:* The use of multivitamin supplements has not been associated with lower risk for AMD in population studies (except in Americans who did not report drinking milk daily). Multivitamins did not lower the incidence of AMD over 11 years in a large cohort of physicians.	The impact of multivitamins on the onset or worsening of AMD has not been tested in clinical trials.

Combining data will also allow for more statistical power to examine aspects of diet by levels of genetic risk, levels of physical activity, and other lifestyle factors.

D Glycemic Index

The glycemic index of foods was introduced to be another possible aspect of diet that could influence the development of AMD [150]. Although advanced glycation end products have been found in drusen, it is not yet known whether they are a cause or consequence of degenerative changes. Degeneration of the retinal vasculature is a well-known complication of diabetes mellitus; yet the presence of diabetes has sometimes, but not always, been related to AMD in epidemiological studies. The biological plausibility that elevation in blood sugar promotes AMD, particularly in the absence of diabetes, remains untested. Nevertheless, diets with a low glycemic index often include few refined grains and sugars and plenty of fruits, vegetables, whole grains, legumes, and milk, which have numerous components that could protect against AMD. Thus, high glycemic index diets, like high-fat diets, may be related to higher rates of AMD, in part or in whole, because they lack a wide variety of protective nutrients and other diet components.

E Antioxidants

Oxidative damage to proteins, lipids, and DNA, by free radicals within the photoreceptor outer segments (POS) or RPE, can be the result of photooxidation of lipids from light exposure. They can also be the by-product of metabolic events, such as oxidative metabolism or enzyme reactions that use oxygen (such as xanthine oxidase). The retina is particularly susceptible to oxidative stress, because of its high rates of oxidative metabolism and light exposure, and its high concentration of long-chain polyunsaturated fatty acids, whose double bonds are vulnerable. Free radicals that propagate oxidative damage may also be produced directly as a mechanism for biological defense, as is the case when white blood cells respond immunologically to pathogens with an oxidant boost.

In epidemiological studies, when associations with antioxidant nutrients are considered one at a time, low levels of one or more antioxidants in the blood or diet have often, but not always, been related to higher prevalence or incidence of certain age-related changes in the macula. Dietary antioxidant nutrients related to lower occurrence of AMD include vitamin E [146,151,152] or one or more carotenoids (reviewed in Ref. [153] and subsequently reported in Refs. [154–157]) or zinc [146,151,154–158]. In the Rotterdam Eye Study [146], a 35% lower risk of incident AMD was observed among the 10% of participants who were consuming antioxidant-rich diets (i.e., diets with above the median intake of all four antioxidants in AREDS supplements) compared with above median intake for only one. In this sample, high dietary intake of antioxidants particularly lowered the risk of developing AMD associated with high genetic risk [159].

Although the level of antioxidant vitamins in foods is usually lower than in high-dose antioxidant supplements, the number of different known and unknown antioxidants in foods is likely to exceed those in supplements. Foods high in antioxidants, such as vegetables, might lower oxidative stress to a greater degree than supplements. In a recent randomized, crossover trial, eating two or more cups of brassica vegetables (such as broccoli) lowered a urinary marker of oxidative stress, whereas moderate levels of supplementation with antioxidants in multivitamins did not [160]. A number of the flavonoids have been documented to have antioxidant or antiinflammatory activity or increase ocular blood flow (reviewed in Ref. [161]). The polyphenol, resveratrol, found in foods like grapes, peanuts, wine, raisins, and some berries, was found to inhibit damage to human retinal pigment epithelial cells due to substances in cigarette smoke [162]. However, the evidence regarding the effectiveness of these compounds in limiting AMD-related pathology is limited and conflicting. The impact of decades of consuming dietary nutrient and nonnutrient antioxidants on AMD may be substantial [163] and has not been adequately studied.

High-dose antioxidant supplements are considered a standard of care in the United States for individuals who have intermediate AMD or advanced stages of AMD [164]. This is based on results of AREDS, a 6.2-year randomized, placebo-controlled clinical trial, in which high doses of a combination of antioxidants (500 mg of vitamin C, 400 IU of vitamin E, 15 mg of beta-carotene, and 80 mg of zinc along with 2 mg of copper) slowed the progression of AMD from intermediate to more advanced stages by 28% [165]. The beneficial effects of the AREDS formulation persisted over 10 years, at which time there was a 27% reduction in risk of developing advanced AMD [166]. There is also evidence that this treatment reduces the age-related oxidation of cysteine in the blood, which supports the possibility that the benefit is due to a reduction in oxidative stress [167]. There was additional efficacy of the AREDS formulation when beta-carotene was replaced with L and Z (12 mg), particularly in those with low dietary intake of L and Z [168].

Genetics might modify the benefit of AREDS supplements on the rate of progression to advanced AMD, but the evidence is inconsistent. The inconsistent evidence was recently discussed by Seddon and colleagues [169] who observed a protective effect of these antioxidants and zinc only among persons with the nonrisk genotype for

CFH or *risk* genotype for *ARMS2*; whereas no modification be genotype was observed by others [170]. Whether the differential effects would be observed in other study samples or among persons taking these supplements over longer periods of time is unclear.

There is no evidence that people who have early AMD or who are at risk for AMD because of a family history will benefit from such high-dose antioxidant supplements. The levels of antioxidants that are safe and effective and efficacy of other supplement formulations over the long term is not well-studied. Results of a large meta-analysis suggest that vitamin A, beta-carotene, and vitamin E at high doses may increase mortality [171].

F Lutein and Zeaxanthin

L and its structural isomers Z and MZ are selectively concentrated in the retina where they are thought to protect against damage due to light and oxidative stress which would otherwise promote AMD (recently reviewed in Ref. [12]). They may also lower AMD risk by lowering inflammation in the retina, as a result of light damage in the retina (discussed later) or in other areas of the body [30,172] by suppressing an inflammatory response, which could indirectly promote AMD.

The highest density of these carotenoids in the central macula is found in the inner retina, in the Henle fiber and inner plexiform layers [173], where they comprise a yellow pigment referred to as MP. At these locations, they are likely to function as an optical filter that absorbs short-wavelength visible (blue) light [174]. This might protect against AMD or simply enhance vision (as discussed in Section II) They are also present in the lipid-rich POS where evidence suggests that they are likely to act as antioxidants in specific membrane domains which are rich in unsaturated lipids that are vulnerable to oxidation [175].

In the central macula, Z isomers predominate and include both Z and the L metabolite, MZ. The MP density reduces about twofold between the central macula and the periphery of the fovea, where the L isomer predominates [17]. The total concentration reduces 100-fold from the center of the cone-dominated fovea to the rod-dominated peripheral retina [176].

One mechanism by which the absorption of blue light by MP could protect against the development and progression of AMD is by blocking light-induced formation of a toxic di-retinal conjugate, A2E. Drusen deposits, characteristic of early AMD, which may be promoted by inflammatory processes [177], contain lipofuscin, the principal component of which is the toxic compound, A2E, which forms as a consequence of light-related vitamin A cycling in the retina. A2E accumulates in the RPE during phagocytosis of the rods and cones, and it is taken up by the lysosomes. A2E, in excess levels, has a variety of potential toxic effects, one of which is sensitivity to blue-light damage [178]. When a critical intracellular level of this compound has been reached, cell damage to DNA occurs, induced by blue-light irradiation [179]. Because MP could absorb 40−90% of incident blue light [174], it could reduce A2E toxicity.

There is evidence in animals that L and Z protect areas of the retina which are influenced by AMD in humans. Primates and some birds which selectively accumulate L and Z in their eyes are best to study the impact of MP on AMD or related photoreceptor health. Primates fed diets deficient in these xanthophylls [18,28] suffer a loss of RPE cells and increased photoreceptor cell death [180]. Subsequent supplementation with L protected the fovea of the retina against blue-light damage [181]. Retinal Z has also been demonstrated to prevent light-induced photoreceptor death in quail [182]. In mice, dietary L supplementation has been reported to inhibit inflammatory and angiogenic molecules related to neovascularization, similar to the inhibition of inflammatory and angiogenic processes in human retinal cell cultures [183,184].

The evidence for protection in humans comes mostly from epidemiological studies and clinical trials. In observational studies, lower rates of advanced stages of AMD have been associated with higher dietary levels of these carotenoids [185−190]. Associations between the intake or serum levels of L and Z and earlier stages of AMD are inconsistent [146,151,156,185,187,188,190]. However, results from the Carotenoids in Age-Related Eye Disease Study indicate that a protective association between dietary L and AMD is observed after excluding people who have made marked dietary changes and in women <75 years of age, in whom, the association is less likely to be influenced by survivor bias [156].

The relationships between dietary L, Z, and AMD may depend on a person's ability to accumulate carotenoids from the diet or supplements. A substantial amount of evidence (recently reviewed in Refs. [12,191]) suggests that many individual characteristics and aspects of individuals' diets modify the uptake of L and Z into the body and eye. Briefly, having indicators of metabolic stress (such as high levels of body fat, diabetes, or high levels of triglycerides) [20,192] or certain genetic variants [36,193−195] are related to lower MP density and/or the ability to increase MP with L and Z supplements [196].

A variable ability to accumulate carotenoids from supplements over the short term (2 months to 2 years) has been observed (recently reviewed in Ref. [12]). Variable accumulation in these studies might also reflect differences in supplement composition (with respect to the three xanthophyll carotenoids L, Z, and MZ) or doses, or other ingredients present in the supplement (such as omega-3 fatty acids or other antioxidants) or diets of individuals. The results of some small studies indicate

that the presence of lipids [197,198] or egg in foods [199,200] or omega-3 fats in supplements [201] might enhance bioavailability and the macular accumulation of these carotenoids.

Synergistic relationships between dietary L and genetic predisposition for AMD are possible and may explain some inconsistencies in relationships of dietary L to AMD. The presence of the common genetic risk variant in the *CFH* gene (*Y402H*), which increases risk for AMD, was less predictive of AMD in people whose diets were rich in L and Z [159,202].

The strong biological plausibility that MP protects against degeneration is supported by the observation of lower levels of L and Z in autopsy specimens of donor eyes with AMD, compared with donor eyes in people without AMD [176]. However, to date, relationships of AMD to MP density, measured noninvasively in living persons, have not been detected in cross-sectional studies [203–207]. This may be due, in part, to bias as a result of recent L supplement use in people who have been diagnosed with or have a family history for macular degeneration or survivor bias common in epidemiological studies of older people. Significant [207] or marginally significant [204] trends for a protective association have been observed when such people are excluded from analyses. A trend in the direction of protection of MP on AMD progression was observed in the only longitudinal study [208], but it was not statistically significant, nor well powered (only 27 people developed AMD over 10 years). Larger longitudinal studies that evaluate the magnitude of protection that higher MP density may have on lowering risk for AMD incidence and progression are underway, with results expected in 2018.

Even if MP density is found to be related to lower risk for developing or worsening AMD in future studies, it will remain to be determined whether this is due to dietary intake of L and Z, or the many other components in fruits and vegetables or healthy lifestyles in people with L-rich diets that may slow the development of AMD. Women who had a combination of healthy lifestyles (fruit and vegetable-rich diet, not smoking and high levels of physical activity) had higher MP density than women who did not, despite having only slightly greater intake of L and Z [141]. This suggests that many possible lifestyle factors may influence accumulation of MP and these factors may be other means of enhancing MP density.

Dietary or supplemental L, Z, and/or MZ could improve several aspects of vision in individuals with early or advanced AMD (summarized in Section 1A). However, whether this substantially improves the daily life of persons with AMD is unclear. Despite the possibility that vegetables, particularly green vegetables and dark leafy greens, may lower risk for AMD (and cataract as discussed previously), some older people limit their intake because they contain high levels of vitamin K, which could interfere with warfarin that has been prescribed to prevent blood clotting. A sudden increase in vitamin K intake from these foods can reduce the effectiveness of the drug. However, patients can consult with their health care team to have their warfarin dose titrated to the highest daily green vegetable intake that the patient can consistently eat.

G Zinc and Other Metals

Zinc may be particularly important to the retina because concentrations of zinc in the retina exceed those elsewhere in the body, with the exception of the prostate [209]. Deficiency of zinc in both animals and people impairs retinal functioning, as previously reviewed [210]. There is evidence for numerous mechanisms (catalytic, regulatory, and structural) [211] by which zinc could influence retinal integrity. Zinc catalyzes enzymatic reactions and is a cofactor of more than 100 enzymes, some of which are involved in oxidant defense. Zinc depletion in RPE cells has reduced levels of catalase, glutathione peroxidase, and metallothionein and has reduced ability to phagocytize POS [212]. Zinc performs structural roles; it facilitates protein folding to produce biologically active molecules (zinc fingers). Zinc is also involved in immune responses [213,214]. Both zinc deficiency and excesses impair immunity [214]. Zinc binds to and inhibits the activity of factor H protein in the complement system and has been proposed to contribute to deposit formation and inflammation associated with AMD [215]. Zinc depletion may also trigger apoptosis of RPE cells or increase the vulnerability of RPE cells to photic injury [216]. However, zinc supplementation can also enhance stress-induced effects in RPE cells [217]. Both lower and higher [218] levels of zinc in the choroid and RPE were observed in autopsy specimens from patients with AMD compared with those without the condition [219].

The long-term benefit of zinc on risk for AMD is suggested by the results of several but not all observational studies (reviewed in Ref. [220]). The use of high-dose zinc supplements (80 mg as zinc oxide, along with 2 mg of cupric oxide) for 6 years with or without antioxidants was associated with modestly lower progression from intermediate to advanced AMD in the AREDS [165]. Benefits persisted over 10 years of follow-up [166]. One smaller zinc supplementation trial had previously reported a benefit of zinc supplementation on vision loss in patients with AMD [221], whereas another did not [222]. In two short (6 months to 2 years) small randomized controlled studies in patients with early AMD, zinc supplementation modestly improved visual acuity, contrast sensitivity, and photostress recovery [221]. No serious safety issues

with zinc supplementation were identified in the 6-year AREDS study (aside from more frequent hospitalization for genitourinary problems in men and more frequent reports of anemia, unsupported by differences in hematocrit), and zinc supplementation was related to lower mortality in this sample [223]. This effect persisted for over 10 years of follow-up [166]. However, the long-term benefits and risks of zinc supplementation at the high levels tested in AREDS are unknown. A differential effect of zinc supplementation, based on the presence of AMD-risk alleles, has been reported in some studies [224–226], but these results were not confirmed in a larger sample of the same study population [170,224,227].

That a protective association of zinc on AMD is observed in most, but not all observational studies and clinical trials may reflect the possibility that protection is limited to individuals who are exposed to high levels of heavy metals through cigarette smoke, diet, or other environmental contaminants. Such high-risk individuals may comprise different proportions of the study samples in observational studies and trials. Two metals have been suggested to place persons at high risk for AMD, cadmium and lead [228]. These divalent cations often compete for the same binding sites as copper and zinc and have the capacity to displace these essential metals [229]. In one recent cross-sectional study in the Korean population, blood levels of lead, cadmium, and mercury were associated with a high odds for having late AMD, whereas, high blood levels of zinc and manganese (another divalent cation) were associated with lower risk.

Cadmium, a naturally occurring metal which is dispersed in the environment as a by-product of industrial activities, smoking, and fertilizers, is a potent inflammatory agent and increases oxidative stress [230]. Cadmium levels in the retinal tissues were approximately double in smokers compared to nonsmokers [231] and may explain, in part, the higher risk of AMD in smokers. Higher urinary cadmium levels were found in smokers who had AMD compared to smokers who did not have AMD [232]. Lead is also a naturally occurring metal which accumulates in our bodies with age as a function of smoking, drinking water, and other types of environmental contamination. Like cadmium, lead can contribute to the production of inflammatory cytokines and oxidative stress. Lead in the neural retina has been associated with the presence of AMD [228].
