Iron, another divalent cation, is essential for retinal function, but in excess can also be toxic to the retina by catalyzing the production of reactive oxygen species, causing oxidative damage. A recent review summarizes the evidence for the beneficial and toxic effects of iron [233]. The current body of evidence suggests that iron excess, rather than deficiency, is related to AMD risk. Accumulation of iron has been observed in the retinas of persons with AMD, but it is unclear whether iron accumulation is a cause or consequence of AMD. Higher levels of serum ferritin were weakly associated with higher odds for AMD in one study in the Korean population [234]. Observations of common variants in a gene that encodes a soluble transferrin receptor are related to the odds of having AMD [235] and medical approaches to chelate excess iron are being considered as a strategy which might lower the progression of AMD [233].

In summary adequate levels of zinc from foods (dairy, meat, or beans) is associated with lower risk for AMD in observational studies, but results are limited and not consistent. Supplementation with zinc lowered the risk of progression of AMD and improved visual acuity in some studies. The benefit of zinc intake from diet or supplements on AMD risk may depend on exposure to toxic metals which compete with zinc, but has been understudied.

H B Vitamins

The importance of B vitamins to eye health has been illustrated by their ability to resolve nutritional amblyopias occurring as a result of B vitamin deficiencies and exacerbated by conditions which interfere with the absorption and metabolism of B vitamins, such as chronic alcohol overuse (reviewed in Ref. [2,236]). However, an increasing body of evidence from observational studies [237,238] and one randomized clinical trial [239] suggest that improved status of B vitamins also lowers risk for the development and progression of AMD.

There are several mechanisms by which B vitamins may play a role in AMD. The most widely considered mechanism is through prevention of hyperhomocysteinemia, which was associated with increased risk for late AMD in several past studies [237,240]; a similar, but nonsignificant, trend was observed among non-Hispanic White Americans, in a third study [241]. Folate (B9), cobalamin (B12), pyridoxine (B6), and riboflavin (B2) deficiencies either singly, or in combination, can elevate homocysteine. In two of these studies, high folate levels were associated with lower risk of one or both types of late AMD [237,238]. In one small study, low plasma vitamin B12 levels were associated with having exudative AMD, compared to patients with geographic atrophy [242]. The fortification of foods with folaic acid might lead to a substantial increase in folate status which is thought to exacerbate manifestations of vitamin B12 deficiency in blood [243] and the central nervous system [244,245,246]. Trends for the increasing intake of folic acid-fortified foods and vitamin supplements has the potential to influence AMD risk in the future.

Vitamin B6 appears to play a role in inflammation and oxidative stress; both mechanisms are known to

contribute to AMD risk. High blood levels of the active form of vitamin B6 (pyridoxal 5-phosphate) are associated with low markers of inflammation and oxidative stress [247]. Flavins, derived from riboflavin, are highly concentrated in the retina, in the space between the RPE and the rod and cone photoreceptors and are needed for photoreceptor energy metabolism and function [248]; energy metabolism is particularly high in the outer retina containing photoreceptors because of a high rate of daily renewal of the outer segments and energy is needed in phototransduction.

In summary, a benefit of supplementation of B-vitamins is suggested by evidence from one clinical trial and two observational studies. However, it is not possible to discern which B vitamin(s) were responsible and supplementation with folic acid might be harmful to some people. Additional long-term prospective cohort studies are needed.

I Vitamin D

Vitamin D is hypothesized to suppress localized inflammatory responses that occur in the retina and are implicated in the pathology of AMD [246]. The VDR is found on cells of the immune system [108,250,251] and vitamin D has been shown to alter the proliferation and differentiation of immune cells, decrease immunoglobulin production [252–256], and promote a Th1 over a Th2 cell response [108,250–252]. Evidence of the VDR on human retinal cells [107,257,258] and evidence of decreased retinal inflammation in studies of vitamin D_3 supplemented mice [259] support this hypothesis. Vitamin D is also hypothesized to prevent development of late-stage, neovascular AMD. Endothelial cells express the VDR [260] and studies in cell culture [261,262] and animal models of retinal disease [263,264] show that vitamin D has antiangiogenic properties.

The first report of a protective association between vitamin D status, assessed with 25(OH)D concentrations, and AMD was observed in a sample of participants from a nationally representative survey of the U.S. population [265]. A statistically significant protective association was found with prevalent early, but not late, AMD. Analysis of a different nationally representative survey in Korea was unable to replicate these findings with early AMD, but did observe a protective association with late AMD, but only in men [266]. Analyses in cohort studies have observed conflicting results. A protective association between serum 25(OH)D and early, but not late, AMD was observed in a cohort of postmenopausal women <75 years of age [267], but not in population-based cohorts in France [268] or the United States [269]. Further, a large cross-sectional study of members of Health Maintenance Organization found no association between medical chart-derived vitamin D status and AMD status determined from medical diagnosis codes [270]. Null results for the association between vitamin D status and nonneovascular or neovascular AMD were observed in a retrospective chart review of Medicare beneficiaries' claim files [271].

Results of case-control studies support a protective association of vitamin D on AMD. Graffe et al. observed that cases, as compared to controls, were more likely to have 25(OH)D <50 nmol/L. A total of 24 of the 31 cases of AMD had late-staged disease [272]. Itty et al. found significantly lower concentrations of serum 25(OH)D among 146 patients with neovascular AMD than in patients with either nonneovascular AMD ($n = 146$) or controls ($n = 100$) [273], but Morrison et al. reported no statistically significant differences in 25(OH)D between 50 extremely discordant AMD sibling pairs [274].

One study has reported an association between AMD and polymorphisms in the *CYP24A1* gene (which encodes the enzyme that catabolizes the active vitamin D hormone, $1,25(OH)_2D$) [274]. A different study was unable to replicate this finding [267] but did observe that associations between 25(OH)D and AMD were modified by the presence of high-risk AMD genes.

Observations of a protective effect of blood measures of vitamin D on AMD are supported by the observation that high compared to low intake of milk [265], vitamin D from foods [275,276], and vitamin D from food and supplements combined [267] have been associated with a decreased odds of AMD. One study did not find a statistically significant association with dietary vitamin D intake [277]. Interestingly, previously reported dietary associations between AMD and fish, omega-3 fatty acids (found in fish), and zinc (for which milk is an important source) (*see previous sections in this chapter*) might reflect, in part, a protective effect from dietary vitamin D.

Collectively, the existing data suggest that vitamin D might be another nutrient that protects the aging retina. Studies to date are limited by cross-sectional designs, with only Day et al. [271] investigating associations between vitamin D status and incident disease (assessed from a Medicare claims review). Many existing studies are limited because they primarily have cases of early, not late, disease. For example, the existing studies conducted in national surveys or cohorts have not had adequate cases to investigate associations with late-staged disease [265–269]. Studies of vitamin D and AMD are also difficult to assess because of potential residual confounding or overadjustment from lifestyle factors highly associated with vitamin D status [278] or from genetic risk factors for AMD. Observed associations between AMD and food and supplement sources of vitamin D should be examined with caution as total intake of vitamin D from foods and supplements may not reflect an individual's true vitamin D status [278] as vitamin D can

also be obtained from sunlight exposure. Potential confounding from the detrimental effects of sun exposure, as sun exposure is needed to endogenously synthesize vitamin D [109], adds to the complexity of interpreting epidemiologic studies of vitamin D and AMD. Sun exposure may also increase risk for AMD (reviewed in Ref. [279]). The avoidance of excessive sunlight to minimize risk for skin cancers, cataract, and AMD might jeopardize systemic vitamin D status in older people leading to potentially increased risk of AMD if adequate vitamin D status is shown to be protective. If confirmed, vitamin D status could have an impact on risk for AMD, given that portions of the U.S. population are at risk for poor vitamin D status [280,281]. Continued investigation of this potential association is warranted, especially in cohort studies powered to examine the progression of disease from early to late stages. Since AMD has such a strong genetic influence, it is also important to continue to understand the role of vitamin D status and diet in those with differing genetic risk.

J Dietary Fat

There are at least three broad mechanisms by which dietary fats might either enhance or slow AMD. First, because of the high caloric density of fats, eating high-fat foods can displace other nutrient-dense foods that may have otherwise protected against AMD. Second, eating high-fat and low nutrient density foods may contribute to high body mass, which is sometimes reported to be a risk factor for AMD [282–284]. Third, fatty acids themselves have numerous biological effects as components of biological membranes and regulators of biochemical pathways. Some dietary fats increase risk for atherosclerosis, which is related to AMD risk in some studies [131,132] and in a mouse model of atherogenesis [285]. Certain fatty acids can also have direct human physiological effects on the retina by modulating oxidative stress or by the inflammatory response, which can promote AMD pathogenesis (discussed later).

In mouse models of atherosclerosis, feeding high-fat diets resulted in the accumulation of lipid-like droplets in the retina and degenerative changes in RPE cells and Bruch's membrane [286–289]. In epidemiological studies, high dietary fat levels have been generally associated with increased risk for early and late AMD [282–284,286–294], even though these associations have not always been statistically significant. Some exceptions to this trend include prevalence or short-term incidence studies with low power to evaluate associations with either early AMD [295] or advanced AMD [290,291,293].

However, there is inconsistency across studies in the type of fat that was most related to AMD. The presence of AMD was more strongly related to high intake of saturated fats in some studies [291–294,296] and to high intake of PUFAs [297] or monounsaturated fatty acids in other studies [284,292,296]. High intake of monounsaturated fatty acids, nuts, or olive oil were associated with *lower* risk in other studies [297–299]. The intake of *trans*-fatty acids, provided in diets by margarines and other processed foods, was related to higher risk for AMD in three studies [283,284,299]. Because fat intake often changes due to alterations in food formulation and diet patterns, and particularly in relation to the common diagnosis for cardiovascular diseases which can be related to AMD, these relationships are difficult to interpret.

In addition, there is limited knowledge about the joint effects of other risk factors which might influence the associations observed. For example, chronic light exposure reduces the loss of DHA from photoreceptors in rats [300]. This suggests that light exposure may modify the impact of dietary fats on AMD. The protective association of nuts on the incidence of early AMD was greater in people without other risk factors (smoking, low dietary carotenoids and low ratio of total to HDL cholesterol in one study) [298]. However, joint effects are highly inconsistent across single studies. Larger pooled studies are needed to evaluate such joint effects in human epidemiological studies. Moreover, there is limited ability in such studies to adjust for the numerous other protective aspects of diet that accompany a more moderate, as compared to high, intake of fat.

LC omega-3 PUFAs, such as DHA or eicosapentaenoic acid (EPA), may be particularly important to the health of the retina. DHA is the most abundant LC omega-3 PUFA in rod outer segment membranes [301,302] at a concentration that exceeds levels found elsewhere in the body (reviewed in Ref. [303]). Its presence in membranes affects their biophysical properties and may influence membrane-bound enzymes, receptors, and transport. This is important in visual transduction [304], but it may also influence the pathogenesis of AMD. LC omega-3 PUFAs may protect against AMD by direct influence on retinal cell survival [305]. DHA has also been demonstrated to protect RPE cells from oxidative stress [305,306]. Deficiency of omega-3 PUFAs in nonhuman primates increases sensitivity to blue-light damage [181].

DHA might also lower risk for AMD because of its anti-inflammatory properties [307]. Numerous cell culture studies provide clues for possible mechanisms by which LC omega-3 PUFAs could enhance the integrity of vascular and basement membranes and prevent neovascularization (recently reviewed in Ref. [308]).

A mostly consistent body of evidence from observational studies indicates lower risk for early or late AMD among people with higher intake of fish, fatty fish, or LC omega-3 PUFAs [292,294–296,298,299,309,310]. Two studies found no such associations [291,297]. However, curiously, the rates of intermediate and advanced AMD

(characterized by pigmentary abnormalities and geography atrophy) in a sample of older adults from Iceland are markedly higher than rates in three other populations of European ancestry [311], despite having the highest per capita fish intake among Europeans and the fact that 56% report to use cod liver oil, a rich source of LC PUFAs.

Clinical trials have not provided strong support for the benefit of omega-3 supplements. The addition of 350 mg/day of DHA and 650 mg/day of EPA to high-dose antioxidants in the AREDS2 trial did not lower the progression to late AMD in persons who already had intermediate AMD or late AMD in one eye [312]. A lack of effect of omega-3 supplementation (840 mg/day DHA and 270 mg/day EPA) was also observed in a trial of omega-3 supplements alone [313]. A lack of effect in clinical trials or inconsistencies in protective associations in observational studies or across populations, who vary in intake of omega-3 PUFAs, could result from modifying effects of genetic risk for AMD, from the presence of genotypes which influence the synthesis or metabolism of LC omega-3 PUFAs, or the dietary content of other fatty acids. In one clinical trial, a beneficial effect of LC PUFAs was observed only in persons lacking AMD risk alleles for the *ARMS2* genotype [314]. Consistent with this modifying influence of *ARMS2* genotype, lower risk for one form of late AMD (geographic atrophy) in one observational study [315] and early AMD in a Dutch study [159] was observed in persons who had *ARMS2* risk alleles. Weekly fish intake in persons who had two *CFH* risk alleles in an Australian cohort reduced the risk for late AMD [316].

A protective influence of omega-3 PUFAs could also be dependent on the omega-6 content of the diet. A higher ratio of omega-3 to omega-6 PUFAs could increase formation of anti-inflammatory eicosanoids from omega-3 PUFAs, because the omega-6 PUFAs compete for the desaturase enzyme that creates them or replace the omega-6 PUFA content of membranes. A high ratio of omega-6 to omega-3 PUFAs also upregulates genes involved in lipid trafficking in the neuroretina [317]. In the past three studies, the risk reduction associated with a high intake of LC omega-3 PUFAs was stronger among subjects who had low intake of omega-6 PUFAs [283,284,296].

K Herbal Supplements

The use of herbal supplements has increased in the United States. Several herbal supplements, such as those containing ginkgo biloba and bilberry, have been promoted to benefit the health of the retina. However, there are no scientific studies that support their benefit except one very small (20 persons) study of ginkgo biloba in patients with AMD, in which improvement in visual acuity was indicated in a preliminary report (previously reviewed in Ref. [318]).

V DIABETIC RETINOPATHY

A Overview

DR is a complication of diabetes that is considered to be the result of damage to the microvasculature of the retina. It is the leading cause of new cases of blindness in working aged U.S. adults (20–74 years) [319]. Approximately 12.3% of Americans aged 20 years and older have diabetes, and this is estimated to increase to 14.0% by 2030 [320]. Diabetes is especially burdensome in minority populations, such as African Americans, Mexican Americans [321], and Native Americans [322], in whom the prevalence and incidence are higher than the national average. The burden of associated complications like DR will likely also increase in the coming years.

Previous work has described the natural history of the disease (reviewed in Refs. [319,324]). In brief, preclinical stages of DR include changes in retinal blood flow. Nonproliferative diabetic retinopathy (NPDR) consists of the formation of clinical lesions (microaneurysms and intraretinal hemorrhages), the appearance of retinal exudates (lipid deposits from leaky blood vessels) and cotton wool spots (resulting from localized ischemia), and the appearance of venous bleeding and loops. Blindness can result at these stages if macular edema occurs. In the later proliferative stage, proliferative diabetic retinopathy (PDR), new vessels and fibrous tissue can originate from the optic disc or elsewhere in the retina. Problems arise if the vessels grow through the inner limiting membrane into the vitreous humor of the eye, which is constantly contracting and condensing. Often this movement can lead to vessel tear, hemorrhage, and blindness.

Limited treatment options exist that include invasive injections of antiangiogenic agents into the vitreous for PDR [325] and laser photocoagulation [323], to cauterize leaking, newly developed blood vessels. Both injections of antiangiogenic agents and laser photocoagulation involve investing time in treatment and may cause discomfort. Photocoagulation does not necessarily prevent vision loss in all individuals, and can result in peripheral vision loss or decreased dark adaptation [326].

B Causes

Randomized controlled trials have demonstrated that maintenance of tight blood glucose control via intensive insulin therapy is associated with lower incidence and progression of DR in individuals with type 1 and 2

diabetes [327−330]. Even so, intensive insulin therapy did not prevent the occurrence of DR in all individuals and was often associated with increased bouts of hypoglycemia [327] Other well-established risk factors for DR are duration of diabetes [324], hypertension [332], and elevated blood lipids [333].

Various types of diets, foods, or nutrients may influence risk for DR either by affecting (1) blood glucose control, (2) blood pressure, (3) serum lipid levels, or (3) via other mechanisms (e.g., those related to the antioxidant or antiinflammatory activity of differing diets, foods, and nutrients) (summarized in Table 19.3). Nutrition therapy for patients with diabetes could be targeted at preventing DR or its progression and may be less costly than current treatment. This section will highlight areas believed to be the most robust with respect to research on nutrition and DR.

C Healthy Diet Patterns

An accumulating body of work supports a protective association between DR and consumption of a healthy diet, one high in fiber and low in saturated fat (and most likely rich in certain micronutrients). To date, most work on diet patterns has involved examining the association between DR and numerous foods and nutrients individually rather than examining index-derived dietary patterns in relation to DR, as done in other studies of diet and chronic disease [53,141,334,328]. Previous studies have observed protective associations between DR and intake of fruits and vegetables [329−339]. Fruit and vegetable-rich diet patterns, like the Dietary Approaches to Stopping Hypertension diet, might lower DR risk by lowering blood pressure or other risk factors for DR [340]. Roy et al., in a study of African American participants [341], observed an increased risk of progression to macular edema with high, compared to low, sodium intake. However, two recently published, robust analyses have not corroborated these findings [329,342]. These studies considered sodium intake alone, not as a component of a more complex dietary pattern. Recently, findings from a post hoc analysis of a randomized dietary modification trial in individuals with type 2 diabetes observed a protective effect of a Mediterranean Diet (MedDiet) plus extra virgin olive oil, as compared to a low-fat dietary pattern, on the risk of sight-threatening DR over 6 years of follow-up [343]. A MedDiet likely improves DR by reducing blood pressure and improving blood glucose control and lipid profiles; as well as through other mechanisms involving its influence on oxidative stress, inflammation, and promotion of a healthy endothelial function (reviewed in Refs. [344,345]). More work on associations between dietary patterns would be beneficial in understanding the complex role of diet in DR incidence and progression.

D Alcohol Consumption

Research has shown a protective association between moderate alcohol consumption and risk of coronary heart disease and mortality in individuals with type 2 diabetes [346]. These finding have led to recent interest in investigating the association between alcohol consumption and diabetic microvascular disease, such as DR [347,348]. Moderate alcohol consumption is hypothesized to be protective due to a number of different mechanisms related to cardiovascular health and DR risk factors (e.g., inflammation, dyslipidemia and insulin resistance, platelet aggregation), reviewed in more detail elsewhere [349,350].

Alcohol consumption in relation to DR has been studied in a number of observational studies, many of which have found no association between alcohol consumption and DR [351−357]. In 1984, Young et al. reported that heavy alcohol consumption was associated with the development of DR, primarily exudative and PDR, in a sample of 296 men [358]. Since then, a handful of studies have observed protective associations between alcohol consumption and DR, primarily moderate consumption. In the Wisconsin Epidemiologic Study of Diabetic Retinopathy, average alcohol consumption was associated with the decreased odds of prevalent PDR among individuals with diabetes onset before age 30 [359]. Analyses examining alcohol's association with the incidence and progression of DR in the same sample, albeit a smaller subset, did not observe the same association [355]. Beulens et al. observed that moderate alcohol consumption was associated with the reduced odds of prevalent PDR among 1857 participants with type 1 diabetes [360]. Two recently published cross-sectional studies [347,361] support a protective association with moderate [347] or light [361] alcohol consumption and reduced odds of any DR or severe DR, respectively. These studies [347,361] also suggest associations may vary by beverage type. Further, a 5-year prospective study observed a protective association of moderate alcohol consumption on the incidence of microvascular disease among 11,140 individuals with type 2 diabetes [348].

Many of these studies are limited by their cross-sectional designs as well as limited data on alcohol consumption quantity and patterns. Further, if alcohol consumption is mostly influential on the development of PDR, smaller studies limited in the number of advanced cases of disease might not have the power to observe an association if it existed. The findings to date are intriguing and deserve further study. Continued work in the area of dietary

TABLE 19.3 Summary of Evidence Relating Diet to DR

Nutritional Exposure	Strength of Evidence	Comment
Healthy Diet Patterns	*A diet rich in fruits and vegetables, micronutrients, and high in fiber is likely beneficial.* Observational studies support a protective association between high fruit and vegetable consumption and high fiber intake with the reduced odds or risk of DR. A post hoc analysis of a dietary modification trial comparing those randomized to a MedDiet with extra virgin olive oil to a low-fat dietary pattern showed reduced risk of incident sight-threatening DR. Such a diet may be beneficial by helping maintain blood glucose control and by lowering blood lipids and hypertension.	Diets rich in fruits and vegetables are likely high in fiber and rich in other micronutrients.
Alcohol Consumption	*Benefit of light to moderate alcohol consumption on reduced risk of DR is suggested.* Protective associations between moderate alcohol consumption and coronary heart disease led to research on the role of alcohol and DR. Four cross-sectional studies and one prospective study support a protective association between light to moderate alcohol consumption on risk of DR or microvascular disease. Three of these studies show an association with severe or PDR.	Light to moderate alcohol consumption could reflect an overall dietary pattern or lifestyle that protects against DR. The role of alcohol consumption as a risk factor for DR should be continued to be studied, but with consideration of alcohol as part of an overall dietary pattern. Many previous studies are limited by the lack of detail collected on alcohol intake, including the quantity of alcohol consumed, the frequency of consumption, beverage type usually consumed, and duration of consumption.
Dietary Fat and Fiber	*Diets low in saturated fat but high in omega-3 fatty PUFAs are likely beneficial.* A few epidemiologic studies show associations between high saturated fat intake and an increased odds of DR, although results are not consistent. A recent large prospective analysis showed a decreased risk of sight-threatening incident DR among participants consuming >500 mg/day of omega-3 fatty acids. *Benefit of high fiber diets are likely:* There is consistent evidence from observational studies supporting a protective role of dietary fiber intake and high fiber food intake (with an emphasis on soluble fiber) and reduced risk of DR. High fiber intake may be beneficial in helping maintain blood glucose control.	To our knowledge, only one study has specifically studied the influence of LC omega-3 PUFA intake on DR. More research is needed.
Antioxidants	*Benefit of foods rich in antioxidants is likely but inadequately studied.* Studies from diabetes-induced animal models strongly support a protective effect of antioxidant intake and maintenance of a healthy retina. Findings from both small patient and population-based samples are inconclusive. Findings from larger epidemiologic studies examining associations between dietary intake or serum concentrations of antioxidants do not conclusively support a protective effect of antioxidants on DR. Some studies suggest that antioxidant exposure could be potentially detrimental; however some of these findings may be explained by bias inherent in cross-sectional study designs. One clinical trial, in a post hoc analysis, found no association between vitamin E supplementation and history of DR laser therapy.	Observational studies are limited in number and mostly are cross-sectional in design. Results may be biased by changes in diet and supplementation practices upon development of diabetic complications. Long-term observational prospective studies are needed.

(*Continued*)

TABLE 19.3 (Continued)

Nutritional Exposure	Strength of Evidence	Comment
	One observational study suggested that long-term intake of antioxidant supplements or multivitamins may protect against DR.	
Vitamin D	*Benefit of good vitamin D status (from adequate sunlight, foods, and/or supplements) is possible.* In the last 5 years, research on the possible protective association of vitamin D status with DR has led to over a dozen published studies on this topic. Many are limited by their cross-sectional designs. Data from prospective studies are not consistently supportive of a protective association.	Continued examination of this association in prospective studies is needed. Studies should be powered to examine progression of DR, especially progression to PDR. Studies able to adjust for pertinent confounding variables are needed as higher blood levels of vitamin D could be related to other aspects of diet or lifestyle that could protect against DR.

patterns may provide insight into the influence of alcohol, as a part of an overall dietary pattern, on DR.

E Dietary Fat and Fiber

Previous studies have also observed that high calorie and fat (% kcals), both total and saturated, intake may increase risk for DR. A small case-control study in India observed that diets high in energy, animal proteins, and animal fats were more common among persons with PDR than among controls [339]. Data from one ecological study showed a greater prevalence of DR in persons with type 1 diabetes in European regions with higher, compared to lower, mean intakes of cholesterol, total fat, and saturated fat (% kcals) [362]. Further, the Diabetes Control and Complications Trial (DCCT) reported that conventionally treated participants who followed the American Diabetes Association dietary recommendations with respect to fat and total calorie intake were less likely to experience DR progression [363]. Sasaki et al. also observed an increased odds of DR among those consuming high compared to low intake of energy-adjusted, saturated fatty acids, but only in those with good glycemic control; no associations were found for total or monounsaturated fatty acid intake [364]. A prospective study in 649 African Americans with type 1 diabetes observed that total kilocalories along with age, glycosylated hemoglobin (Ghb), and hypertension were found to be significant predictors of vision-threatening DR and severe hard exudates [341]. The authors suggest that increasing kilocalories increases hyperglycemia and dyslipidemia and thus oxidative stress, a proposed etiologic mechanism for DR [365]. Differently, two cross-sectional studies [366,367] observed no statistically significant differences in total calories, total fat (% kcals) [366,367], or saturated fat (% kcals) [367] consumption between persons with and without prevalent DR.

Some of the original investigations of the associations between dietary intake and DR were conducted in the 1980s and involved small intervention studies of linoleic acid, an omega-6 PUFA, among individuals with type 2 diabetes [368,369]. These studies suggested that intake of diets enriched with linoleic acid decreased development and progression of DR, especially among those with poor glycemic control. The authors hypothesized that linoleic acid enrichment of cell membranes would increase the sensitivity of the insulin receptor and thus improve blood glucose control [368]. However, these earlier intervention studies' effects could have been due to linoleic acid consumption displacing consumption of other more harmful fatty acids, such as saturated fat. A recent finding in a sample of 379 patients with diabetes supports a protective association with DR among those consuming high compared to low intake of PUFAs but only in those with good glycemic control [364]. This study did not differentiate between omega-3 and omega-6 PUFAs. A recent prospective analysis of 3482 participants with type 2 diabetes observed a 48% decreased risk of sight-threatening DR with self-reported consumption of 500 mg/day or more of LC omega-3 PUFAs [370]. The observed protectiveness of omega-3 intake on DR was hypothesized to be due to the antiinflammatory properties [371] of omega-3 oxylipins or via their proposed antiangiogenic properties [372] as shown by research in animal studies.

Diets rich in fiber, especially soluble fiber, have been shown to improve glycemic control and insulin sensitivity [373], and thus likely reduce risk for DR. This hypothesis is supported by previous findings of protective associations between consumption of high-fiber containing foods (e.g., fruits and vegetables) and DR, as previously noted [337–339,374]. The DCCT observed that intake of dietary

fiber (% kcals) was inversely correlated with progression of DR [363]. One of two studies [366,367] observed lower intake of fiber in persons with compared to without DR. More recently, a population-based, cross-sectional study of 1261 individuals with type 2 diabetes [375] observed a 41% and 24% increased odds, respectively, of overall and sight-threatening DR among persons with low compared to high consumption of fiber-rich foods with adjustment for confounding factors. However, total quantity or type of dietary fiber was not determined.

In summary, more research is needed to assess the effects of long-term calorie, dietary fat, and fiber intake with respect to incidence and progression of DR. The published studies of calories, dietary fat, and fiber have a number of limitations including the use of ecologic, case-control, or cross-sectional designs, dietary assessment methods, which do not adequately assess long-term dietary intake, lack of adjustment for confounding factors, and small sample sizes.

F Antioxidants

Hyperglycemia is thought to increase oxidative stress through a number of proposed mechanisms which include damage to DNA, lipids, proteins, and carbohydrates as well as functional alterations of a number of other metabolic pathways that promote oxidative stress (previously reviewed in detail elsewhere [376]). Increased oxidative stress is hypothesized to promote diabetic vascular complications such as DR [365,376]. The retina is especially susceptible to damage from reactive oxygen species due to the PUFA-rich endothelial cells of the retinal microvasculature [365,377].

Further, some studies have shown that individuals with diabetes compared to individuals without diabetes have lower blood levels of antioxidants [378,379], as well as lower carotenoids in the retina [20], perhaps as a result of increased oxidative stress. Antioxidant intake has been proposed to help alleviate the observed increased state of oxidative stress in individuals with diabetes and help prevent development of microvascular complications such as DR [380]. Supplementation of streptozotocin-induced diabetic rats for 12 months with antioxidant micronutrients resulted in less degeneration of the retinal microvasculature (indicating early signs of DR) [381] and better retinal function, mitochondrial homeostasis and less elevation in inflammatory biomarkers within the retina [382] than in nonsupplemented animals. However, numerous studies investigating associations between antioxidant micronutrients (primarily vitamins C and E) and DR in small patient or population-based samples have yielded conflicting results [383–385].

To date, insufficient data from robust epidemiologic studies exist to conclude that diets or supplements high in antioxidants prevent or slow DR. In a population-based cohort study no statistically significant associations were observed between dietary intake of vitamin C or vitamin E (assessed 6 years earlier) and prevalent DR [386,387]. In a population-based survey, serum vitamin C concentrations were unrelated to prevalent DR, but serum vitamin E concentrations were positively associated with increased odds of DR [388]. This relationship was attenuated when current supplement users were removed from the analysis. Mayer-Davis et al., in a different cross-sectional study, observed that the severity of prevalent DR was higher in subjects who had high intakes of vitamin C, in insulin users who had high intakes of beta-carotene, and in noninsulin users who had high intakes of vitamin E [389]. A recently published prospective study did observe protective associations between incident DR and vitamin C and carotenoid intake, but not with vitamin E [374]. Data from a clinical trial of vitamin E supplementation also did not observe differences in history of DR laser therapy between supplementation and placebo arms [390]; however, DR was not the primary endpoint for the trial. Associations of prevalent DR to short-term diet and blood nutrient levels in cross-sectional studies may be biased by the recent use of popular antioxidant supplements, particularly in people who may be experiencing more severe symptoms or complications of diabetes.

Most previous studies of antioxidants and DR have not been able to capture the measure of long-term exposure to these nutrients. In one study, participants who reported using multivitamins, vitamin C, or vitamin E supplements for 3 or more years before DR were assessed to have lower odds of DR [386]. It is possible that long-term use of antioxidant supplements may protect against DR. Only one smaller ($n = 97$) randomized clinical trial of patients with type 2 diabetes has reported the effect of antioxidant therapy with the primary outcome of DR [391]; however, the study failed to compare the change in DR stage over time between trial arms. Moreover, there exists only one [374] prospective study reporting data on the influence of dietary antioxidants on the onset or worsening of DR. Given the strong evidence for protection by antioxidants in animal studies, and the suggestion of benefit from long-term antioxidant use in one large observational study, additional prospectively designed studies are needed to better assess these relationships.

G Vitamin D

Over the last 5 years, there has been a rapid increase in the number of papers studying the association between vitamin D status and DR. For example, vitamin D has been shown to reduce the damage in cultured endothelial cells from

advanced glycation end products [392] formed in states of hyperglycemia and thought to propagate oxidative stress and inflammation. [393] The etiology of DR is hypothesized to involve hyperglycemia-induced chronic low grade inflammation [394] and advanced DR involves angiogenesis.

The majority of the work has been in cross-sectional [395–407] and case-control [408–412] studies with around half supporting a protective effect of vitamin D on DR [398,400,401,394,405,407,408,410,411]. Studies, other than those conducted in nationally representative surveys [398,392] and population-based cohorts [397,401], recruited participants from clinic settings. The degree to which this affects the generalizability of study findings is unknown. Other study limitations include small sample sizes ($n \leq 300$ for samples of individuals with diabetes) [395,399,403,394,404,407–410] and assessment of DR status from ophthalmologist examination rather than from standardized grading of retinal fundus photographs [395,396,393,403,405–412]. Only three studies to date have examined prospective associations between vitamin D status and risk of DR [413–415] with only one observing a protective association [414]. However, further adjustment of their multivariable model for Ghb, physical activity, or seasonal removed the statistical significance of the observed association. Studies of associations between polymorphisms in the VDR and DR have been inconclusive with some supporting [416–418] and others not supporting [419,420] possible associations.

Additional work in prospective epidemiologic studies are needed that can account for pertinent confounding variables as well as provide adequate cases to investigate associations between vitamin D status and PDR. Continued work in minority populations with the greatest burden of diabetes and the greatest risk for vitamin D deficiency (e.g., African Americans) [280] should be conducted.

H Summary

The last 20 years has provided a significant body of data suggesting that dietary intake and vitamin D status may be risk factors for DR with mechanisms affecting disease etiology that could extend beyond diet's influence on blood glucose control. Evidence from a large dietary modification trial has provided new evidence that fruit and vegetable-rich dietary patterns such as the MedDiet may protect against DR. Associations between DR and alcohol consumption, macronutrient intake, sodium intake, antioxidants, and vitamin D status still remain inconclusive. Prospectively designed studies are needed to evaluate the importance of these dietary components, as well as other healthy diet patterns, on the incidence and progression of DR in the general population. Given the broad aspects of diet that could protect against DR such data will particularly assist in making public health recommendations.

VI GLAUCOMA

A Introduction

Glaucoma is the leading cause of *irreversible* blindness worldwide, and is predicted to affect nearly 80 million individuals by 2020 [421]. Glaucoma is an umbrella term for a group of diseases that damage the optic nerve, the bundle of nerve fibers that connect the retina to the brain, causing loss of vision starting in the peripheral field of view. The most common form of glaucoma is primary open-angle glaucoma (POAG). In POAG, the "angle" where the cornea and iris meet is restricted. As a result, the flow of ocular fluid to nourish nearby tissues passes too slowly through the trabecular meshwork, increasing eye pressure and leading to progressive deterioration of the retinal ganglion cells that form the optic nerve. The impairment of vascular supply to the optic nerve head is an additional pathological process that is thought to contribute to the development of POAG [422].

Clinically, the focus of glaucoma treatment has been on management of intraocular pressure (IOP). Elevated IOP (reflecting either excessive aqueous humor production or inhibition of aqueous humor outflow) contributes to ganglion cell damage and progressive loss of vision, starting in the periphery of the field of vision. IOP can be modified surgically or through the application of topical medications [423]. However, glaucoma may develop in those who have normal IOP [424], suggesting that other factors may contribute to its pathology.

Age and family history of glaucoma increase risk for POAG. Globally, this condition is about two to three times more common among people of African than of European, Hispanic, or Asian ancestry. Risk has been higher in people who are obese and/or have diabetes and hypertension [436,437]. Diet could influence the occurrence of glaucoma, indirectly, by its influence on these chronic conditions. Diet can also influence IOP. The role of nutrition in both IOP and glaucoma development is still an emerging field. The current state of evidence linking diet directly and indirectly to glaucoma is summarized later.

B Obesity

A body of evidence indicates that a higher body mass index (BMI) is linked to higher IOP, the principle modifiable risk factor for glaucoma [427–430]. Change in BMI over 5 years was found to be associated with change in IOP during that time [431]. Increases in BMI, body fat percentage, and waist circumference were

prospectively linked to increases in IOP in a large cohort of Korean adults. A number of mechanisms have been put forth to explain the relationship between obesity and IOP, including high blood pressure, elevated blood glucose, increased blood viscosity, insulin resistance (and diabetes or metabolic syndrome), and oxidative stress. Hyperglycemia, which is common in individuals with high BMI, might reduce outflow of aqueous humor through the trabecular meshwork via glycosylation of extracellular matrix proteins [432] or by increasing oxidative stress (discussed later). Weight loss through diet and exercise may serve to lower IOP in glaucoma patients who are obese and/or have diabetes, but this hypothesis has not been tested in clinical trials. While there is convincing evidence that high BMI and diabetes mellitus are related to higher IOP, BMI has not been consistently related to the incidence of glaucoma [433].

C Antioxidants

A role for oxidative stress in the pathophysiology of glaucoma has emerged in recent years [434]. It has been suggested that chronic oxidative stress may contribute to death of retinal ganglion cells and to remodeling of the trabecular meshwork [435,436], an effect that may prevent proper draining of aqueous humor and increase IOP. High levels of reactive oxygen species can also contribute to signaling pathways that lead to cellular apoptosis. Therefore, dietary antioxidants could alter glaucoma risk. This includes sufficient levels of vitamins and minerals (iron, B vitamins, zinc, and selenium) that are cofactors for antioxidant enzymes (catalase, glutathione peroxidase, superoxide dismutase), glutathione, and food components that are direct antioxidants (vitamins C and E, carotenoids, and numerous other plant components).

Cross-sectional observational studies support a relationship between the status of antioxidants in the blood and the presence of glaucoma [426–439]. Likewise, similar studies have demonstrated that glaucoma patients have lower total antioxidant status of the aqueous humor [439–441], suggesting that a state of oxidative stress is present in the eye as well. Although total antioxidant status may be compromised, numerous studies have demonstrated that levels of antioxidant enzymes (e.g., glutathione peroxidase, superoxide dismutase) are *higher* in the aqueous humor of glaucoma patients [442,443], suggesting that the expression of these enzymes is upregulated in response to oxidative stress. Moreover, markers of oxidative DNA damage have been found to be elevated in the trabecular meshwork of glaucoma patients [444], suggesting that the tissue responsible for aqueous humor drainage is affected by oxidative stress. The trabecular meshwork may be particularly susceptible to oxidative stress, as it has poorly developed antioxidant defense systems relative to other ocular tissues [445].

Despite the evidence demonstrating a connection between oxidative stress and risk of glaucoma, little evidence from prospective cohort studies exist to support the idea that consuming dietary antioxidants can reduce glaucoma risk or progression. Although fruit and vegetable-rich diet patterns [338] and consuming a high number of fruits and vegetables [446] were associated with a lower likelihood of having glaucoma in cross-sectional studies, large prospective studies have observed no relationship between antioxidant-nutrient consumption and risk of developing glaucoma [447]. In addition, consumption of supplements containing vitamin A or vitamin E was not associated with glaucoma risk, although consumption of vitamin C supplements was associated with mildly decreased risk in the NHANES [448].

The inconsistency in relationships between the intake of fruit and vegetable-rich diets might reflect the possibility that only some fruits and vegetables lower risk more than others. This is suggested by a recent study in which total dietary nitrate intake (high in leafy greens and to lesser extents in certain fruits and vegetables) was associated with lower POAG risk (particularly with early visual field loss in the paracentral field of vision for which dysregulation of the ocular vascular system has been implicated) [449]. This finding contributes to a substantial body of evidence that suggests a key role of the nitrous oxide system in POAG pathogenesis, which may both elevate IOP and dysregulate ocular blood flow [450].

Leafy greens that are rich in L and Z might be protective against the development of glaucoma, as with other forms of age-related eye diseases. These carotenoids are known to have antioxidant effects (See Section II). Results of two small studies suggest that MP is lower in people with glaucoma. In one case-control study the density of L and Z in macular pigment (MP) were lower in glaucoma cases than controls [451] In another study, MP levels were lower in glaucoma patients who had a loss of the foveal ganglion cell complex, compared to glaucoma patients in whom this complex was intact [452]. MP level also correlated with retinal nerve fiber layer thickness and cup to disc ratio, both considered important indicators of glaucomatous optic neuropathy. However, higher dietary levels of L and Z have not been related to the prevalence or incidence or progression of glaucoma in the few studies which have examined these associations [446,447]. Variable abilities to absorb carotenoids and transport them into the eye (Section II) might explain the inconsistencies in these findings. Additional prospective studies of levels of L and Z in the diet or MP to the incidence and progression of glaucoma are needed.

There is generally a lack of randomized clinical trials that have directly examined the effect of antioxidants on

glaucoma incidence and progression. One 2-year supplementation trial in patients with preexisting glaucoma observed no effect of antioxidants (containing L and Z) with or without omega-3 fatty acids on visual field measures or ganglion cell thickness [453]. This may be too short of a period of time to observe a protective effect if there is one.

Ginkgo biloba extract, derived from a plant commonly used in traditional Chinese medicine, has received attention as a potent antioxidant that may be useful in the treatment of glaucoma [454]. Ginkgo biloba extract improved measures of visual field in patients with preexisting normal-tension glaucoma [455,456] and slowed the loss of the visual field in this subgroup of glaucoma patients [457]. These apparent benefits of ginkgo biloba for glaucoma patients may be related to its role as an antioxidant, or to improvements in the microcirculation feeding the retina, or to the inhibition of apoptosis in retinal ganglion cells [454]. Ginkgo biloba has gained some mainstream acceptance as a useful treatment for glaucoma, but only in normal-tension glaucoma patients, or in patients whose glaucoma has progressed despite successful lowering of IOP [458].

In summary, although there is considerable evidence to suggest a link between oxidative stress and glaucoma risk, there is less evidence to demonstrate that specific antioxidants can reduce this risk. There is also evidence that other components of certain fruit and vegetables (such as nitrates, or those rich in L and Z) might lower risk by mechanisms other than lowering oxidative stress, or in addition to it. At the current stage of knowledge, it is advisable that glaucoma patients, or those at high risk of glaucoma, get their antioxidants through a healthy diet rich in fruits and vegetables, as there is little evidence that high-dose antioxidant supplementation is either effective or safe in the long term.

D Omega-3 Fatty Acids

Animal research suggests that supplementation with omega-3 fatty acids may reduce IOP by increasing aqueous outflow [459], an effect expected to slow progression of optic nerve degeneration. Furthermore, omega-3 deficiency increased ganglion cell dysfunction when IOP is elevated [460]. Consistent with the idea that LC omega-3 PUFAs might play a role in the etiology of glaucoma, POAG patients were observed to have lower levels of EPA and DHA in several fatty acid fractions derived from red blood cells [461]. The authors speculate that omega-3 PUFAs may reduce risk of POAG by improving microcirculation around the optic disc, consistent with the role of n-3 fatty acids as inhibitors of platelet aggregation.

However, results of investigations in two large cohorts, followed prospectively do *not* support a protective role of omega-3 fats and POAG. In the Nurse's Health Study and the Health Professionals Follow-Up Study cohorts [462], and in the SUN cohort [463], a higher ratio of dietary omega-3 to omega-6 fatty acids were related to *higher* risk for POAG. One possible explanation suggested is that higher omega-6 consumption leads to greater availability of prostaglandin F_{2a}, an omega-6 derivative that is believed to reduce IOP [462]. Given the larger body of evidence suggesting that a higher dietary omega-3 intake may be beneficial for cardiovascular health and lowering AMD risk, lowering omega-3 fat intake is not recommended for the general population. Furthermore, other lines of evidence suggest a protective role for omega-3 fatty acids.

E Alcohol

Acute consumption of alcohol can transiently reduce IOP [464,465], raising the possibility that consistent, moderate consumption of alcohol over time would reduce the risk for glaucoma. It has been suggested that alcohol may reduce aqueous humor formation by the ciliary body, primarily through the inhibition of antidiuretic hormone [466]. In observational studies, which reflect the impact of alcohol over a longer term, relationships of alcohol to IOP are conflicting. Alcohol use was associated with lower IOP in one cross-sectional study [467], but with *higher* IOP in another [468]. Most often, alcohol intake has not been related to IOP [356,429,469–471]. In one large prospective study, there was a trend toward lower IOP in individuals consuming >30 g alcohol (approximately two drinks) per day [470]. The inconsistent relationships of alcohol to glaucoma risk might be explained by limited statistical power and variable adjustment for other lifestyle factors associated with alcohol. Furthermore, the range of habitual alcohol intakes is fairly narrow, making it difficult to study the effect of chronic binge drinking.

F Caffeine

Caffeine is a central nervous stimulant commonly consumed by most age groups and is found abundantly in coffee, dark colas, energy drinks, and certain teas. Caffeine has diverse effects throughout the body, raising the distinct possibility that caffeine influences eye health. Data from clinical trials suggest that consumption of caffeine can raise IOP [472,473,474], but other trials have not shown any effect [475,476]. A meta-analysis of randomized clinical trials revealed that acute consumption of caffeine can transiently increase IOP, but only in patients with preexisting glaucoma or ocular hypertension [477].

The increased IOP with caffeine consumption may be attributable to increased aqueous humor production or

inhibition of aqueous humor drainage. Caffeine raised IOP in dogs by increasing aqueous humor production without affecting drainage [478]. The same group demonstrated that caffeine- induced structural changes in the ciliary epithelium that would support transportation of aqueous humor [479]. Acute caffeine consumption increases systemic blood pressure [474] and this may also contribute to aqueous humor production via increased filtration through the ciliary body.

Results from the Blue Mountains Eye Study corroborate this finding, as regular coffee drinking was cross-sectionally linked to higher IOP in glaucoma patients only [480]. These findings from cross-sectional research and randomized clinical trials support the recommendation that glaucoma patients limit caffeine consumption. Although research has not yet linked caffeine to visual field loss in glaucoma patients, it is plausible that higher IOP with caffeine use would contribute to the onset of blindness.

While there may be a connection between caffeine intake and IOP in patients with pre-existing glaucoma, little data suggests that regular caffeine consumption increases risk for glaucoma. Data from the Nurses' Health Study and the Health Professionals Follow-up Study revealed that caffeine consumption was not prospectively linked to higher rates of POAG [481]. However, a significant relationship was found for those with a family history of glaucoma, suggesting that the effect of caffeine on glaucoma risk has a genetic component. It is plausible that the transient effect of caffeine on IOP is not sufficient to damage the retina, or that the IOP response is attenuated when caffeine is consumed habitually. More longitudinal research is needed to firmly establish the relationship between caffeine dose, IOP, and glaucoma risk, and to discern whether this relationship varies according to glaucoma diagnosis.

G Summary

There is considerable emerging evidence to suggest a link between pathological processes of glaucoma (oxidative stress, elevation of IOP) and diet components. Diet might also lower risk for the development of obesity and chronic diseases that are more common in people with glaucoma. The current body of scientific evidence on relationships of diet to glaucoma suggests that fruit and vegetable-rich diets may lower glaucoma risk through either or both means. However, the data are limited and insufficient to support the possibility that the intake of specific foods or dietary supplements is likely to lower glaucoma risk. At the current stage of knowledge, it is advisable that glaucoma patients, or those at high risk of glaucoma, eat healthy diets rich in fruits and vegetables.

VII CHAPTER SUMMARY

Scientific evidence suggests that *nutrition matters* in maintaining eye health, as with other parts of the body. That is, there is mounting evidence for substances in food which exert effects that are likely to promote or delay the development of the most common and costly causes of vision loss: age-related cataract and macular degeneration and DR. An emerging, but limited, body of evidence suggests that several specific aspects of healthy diets and lifestyles might lower glaucoma risk, as well. It is possible that healthy diets and lifestyles matter more (or less) in people genetically prone to these processes. Healthy diets, other healthy lifestyles, and genetic risk might work synergistically to lower risk for age-related eye diseases. However, the evidence is insufficient to make separate recommendations for individuals based on genetic risk.

Despite the evidence that *nutrition* matters, evidence that supplements of single or combination of nutrients slow age-related cataract, macular degeneration, glaucoma or DR is more limited. An exception is for the intake of high-dose antioxidant supplements and zinc in people with AMD, which is considered a standard of care for slowing the progression of AMD. There is no strong evidence that these or other supplements *prevent* this disease, or other age-related eye diseases. In most cases, nutrient-dense foods provide a larger array of potentially protective substances than pills. Increasing evidence suggests a larger impact of foods than supplements. An exception may be for vitamin D, which is sometimes hard to obtain from natural food sources. Vitamin D status might be most important in extreme northern and southern hemispheres which provide inadequate UV light in winter to permit the synthesis of this vitamin in skin.

Optimal ocular health may begin with gestation and infancy and continue into old age. Recent evidence has emerged to suggest a possible role of L and Z in gestation and infancy; a role in lifelong health has been proposed, but not studied. The most sustainable means of promoting eye health through nutritional means in populations over the long term may be to foster the ability to breast feed and assure access to a variety of foods, a large proportion of which are plant foods.

ACKNOWLEDGMENTS

This work is supported by NIH Grants from the National Eye Institute (EY0 16886 and 25292), the National Institutes of Aging (AG041776), the National Heart, Lung, and Blood Institute (HL103706), the Office of Dietary Supplements (HL103706-S1 and EY025292-S1). This work was also supported in part by an unrestricted grant from Research to Prevent Blindness, Inc. to the UW Madison Department of Ophthalmology and Visual Sciences, and in part by a National Eye Institute Vision Research Core grant (P30 EY016665) to the UW Madison Department of Ophthalmology and Visual Sciences.

Chapter 20

Phytochemicals in the Prevention and Treatment of Obesity and Its Related Cancers

Kee-Hong Kim[1] and Ki Won Lee[2]

[1]*Purdue University, West Lafayette, IN, United States,* [2]*Seoul National University, Seoul, Republic of Korea*

I INTRODUCTION

The prevalence of obesity is a significant global health problem. Obesity is the result of excess body fat due to an imbalance between energy intake and energy expenditure. Energy balance is influenced by numerous environmental factors (e.g., metabolic rate, exercise, and culture), and genetic factors (e.g., monogenic syndromes and susceptibility genes) (Fig. 20.1). Indeed, the excessive body fat accumulation in adipose tissue is a consequence of impaired energy expenditure, such as reduced physical activity, basal metabolism, and thermogenesis [1]. On the other hand, an increase in intake of foods with added sugars, less fiber, and/or elevated fat content impacts positive energy balance, resulting in an expansion of adipocyte size and weight, and an increase in number of new adipocytes. In addition, complex interactions among these variables contribute not only to individual differences in adipose mass gain, but also in the response to interventions and/or treatments of obesity. Brain and peripheral tissues such as adipose tissue, liver, and intestine play an important role in regulating systemic energy balance and, therefore the development and progression of obesity. Among these tissues, adipose tissue is known to play both causative and consequential roles in obesity. Although adipose tissue is traditionally known as an energy reservoir, storing lipids during periods of energy excess and positive energy balance, generation of new fat cells, and metabolic and endocrine changes in adipose tissue also contribute to metabolic dysfunction of other peripheral tissues and dysregulation of central signals of energy balance. This suggests that the generation of new adipose tissue and its metabolic and endocrine function could be preventive and/or therapeutic targets of obesity.

Despite many reported beneficial effects of dietary phytochemicals on health, less attention has been placed on the modulation of obesity and its associated diseases by phytochemicals. Thus, this chapter focuses largely on understanding the cellular processes involved in the generation and function of adipose tissue and obesity-related cancers. Furthermore, the current understanding of regulation of obesity by dietary phytochemicals found in fruits, vegetables, and edible plants (e.g., spices) is discussed.

II ROLE OF ADIPOSE TISSUE IN OBESITY

A Adipose Tissue Expansion

1 Hyperplasic Adipocytes

Adipose tissue develops as a result of hypertrophy (i.e., adipocyte size increase), hyperplasia (i.e., adipocyte number increase), or both. Adipocyte hypertrophy plays an important role in regulating the ability of cells' lipid storage and secretion of adipose-specific hormones/factors that contribute to the systemic energy balance, inflammation, and energy homeostasis. On the other hand, adipocyte hyperplasia, termed adipogenesis, is known to contribute to the generation of new adipocytes during childhood and adolescence in humans, as well as adipocyte turnover in adults [2]. This implies that adipogenesis could be as an effective cellular process for prevention of adipose tissue generation and, by extension, the development of

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00020-5

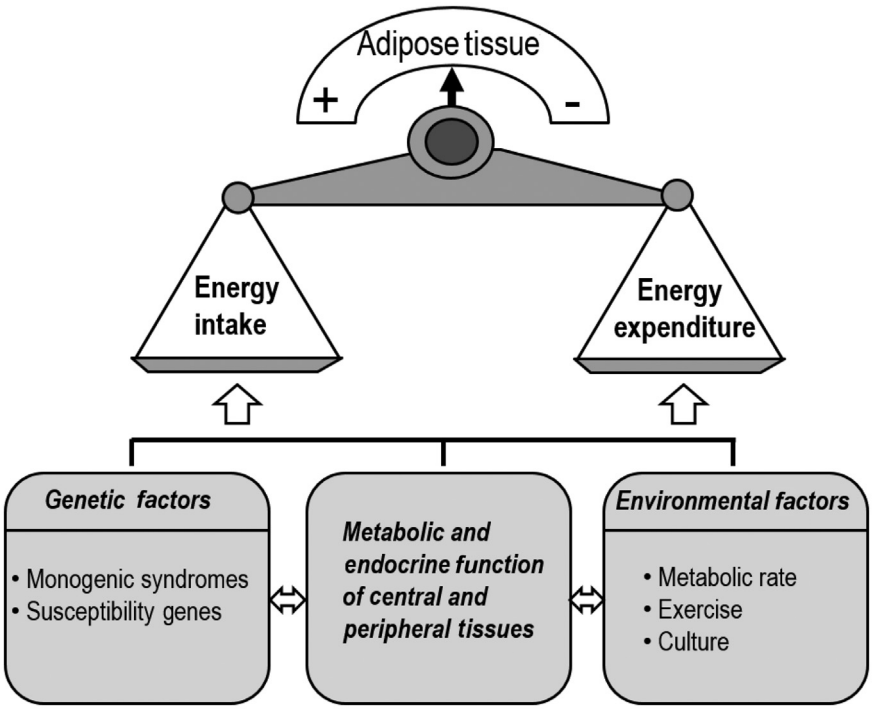

FIGURE 20.1 Factors influencing energy balance.

obesity in young adults. Mesodermal pluripotent stem cell driven preadipocytes undergo adipogenesis when cells are exposed to appropriate hormonal and nutritional signals. Adipogenesis consists of four distinct steps, including (1) early growth arrest of confluent preadipocytes, (2) mitotic clonal expansion (MCE), (3) transcription of adipogenic transcription factors, and (4) terminal cell differentiation [3]. Growth arrest of preadipocytes in the early phase of adipogenesis is coordinately regulated by transcriptional control of genes involved in the cell cycle by adipogenic transcription factors CCAAT/enhancer binding protein α (C/EBPα) and peroxisome proliferator-activated receptor γ (PPARγ) [3]. Upon exposure to mitogenic and adipogenic signals, the growth-arrested preadipocytes undergo at least one round of cell cycle with DNA replication and cell division. Although MCE appears to be required for promoting adipogenesis of most established preadipocyte cell lines in vitro, it is reported to be not necessary for adipogenesis of other cells such as primary human preadipocytes [3]. Nevertheless, inhibition of MCE by cell cycle inhibitors [4] and modulation of genes encoding cell cycle components [5,6] have been shown to impair adipogenesis. In addition, phosphorylational activation of the adipogenic insulin signaling pathway such as insulin receptor, insulin receptor substrate-1 and -2, phosphoinositide 3-kinase, and protein kinase B/Akt in the early phase of adipogenesis also participates in the promotion of adipogenesis. Some cell cycle regulators such as cyclin D, Rb, and E2Fs [7] appear to link between MCE and the transcriptional events in the early phase of adipogenesis. Concomitant with the MCE process, DNA binding ability of C/EBPβ, an early adipogenic transcription factor, and its transcriptional activity are acquired. This occurs through sequential phosphorylation of C/EBPβ by a cell cycle regulator cdk2/cyclinA, mitogen-activated protein kinase (MAPK), and glycogen synthase kinase-3β during MCE [8]. Phosphorylated C/EBPβ then subsequently induces its target adipogenic transcription factors C/EBPα and PPARγ.

Whereas C/EBPβ-induced expression of C/EBPα is required for promotion of adipogenesis and formation of white adipose tissue, PPARγ is reported to reverse the defective function of C/EBPβ and C/EBPα in adipogenesis [7], suggesting that PPARγ as the central regulator of adipogenesis. PPARγ forms a heterodimer with retinoid X receptor, and this heterodimeric complex binds to the PPAR response element located in the promoter regions of many genes involved in fat storage and adipokine production. Several agonists such as 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 and thiazolidinediones are also known to promote transactivation of PPARγ.

During the terminal phase of adipogenesis, genes encoding enzymes in lipid metabolism such as glycerol-3-phosphate acyltransferase (GPAT), glycerol-3-phosphate dehydrogenase, glyceraldehydes-3-phosphate dehydrogenase, fatty acid synthase (FAS), acetyl coenzyme A (CoA)

carboxylase (ACC), and stearoyl-CoA desaturase (SCD) are dramatically activated. Levels of genes involved in fatty acid update and transport, and lipid droplet formation, including an adipose-specific fatty acid binding protein (aP2), a fatty acid transporter (FAT/CD36), and perilipin, are also increased. In addition, mature adipocytes produce adipocyte-specific hormones such as leptin, adiponectin, resistin, adipsin, and plasminogen activator inhibitor-1, as well as a number of inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), IL-1α, and monocyte chemotactic protein-1. These adipocyte secreted factors are known to modulate peripheral and systemic energy balance.

Molecular and dietary regulation of adipogenesis is suggested to prevent the body weight gain and the development of obesity. However, it should be noted that inhibition of adipogenesis alone could possibly result in adipocyte hypertrophy and/or redirection of body fat to other nonadipose tissues, which increase the risk of the development of obesity-related diseases. Thus, additional approaches to improve whole-body energy expenditure possibly through activation of thermogenesis and/or fatty acid oxidation should be accompanied by the blockage of adipogenesis.

2 Hypertrophic Adipocytes

Adipose tissue is traditionally viewed as a storage organ of lipids. During approximately the past decade, adipose tissue has been further revealed as an endocrine tissue secreting a number of hormones and factors that modulate systemic glucose and lipid homeostasis. De novo lipogenesis plays a key role in adipocyte hypertrophy, as well as hepatic lipid synthesis. It was reported that the increase in adipose tissue in lean and obese adults is largely due to adipocyte hypertrophy since adipocyte hyperplasia is rather constant in adults [2]. This study indicates that adipocyte hypertrophy could play a key role in the development of adult obesity. The substrates for de novo lipogenesis are fatty acid esters and CoA. Transport of mitochondrial citrate to cytosol by tricarboxylate transporter initiates the generation of acetyl-CoA and malonyl-CoA by ATP-citrate synthase and ACC, respectively, followed by subsequent synthesis of fatty acids, mostly palmitate, by FAS. The most abundant saturated and unsaturated fatty acids found in adipocytes are stearate and oleate, respectively. A single *cis* double bond at the Δ^9 of oleate is introduced by SCD-1. Conversely, mice deficient in ACC [9] or SCD-1 [10] were found to be resistant to adiposity. Similarly, administration of an inhibitor of FAS such as a fungal-derived cerulenin and synthetic C75 promoted long-term weight reduction in obese animals [11,12], suggesting that FAS is an effective target protein for the control of de novo lipogenesis.

Triglycerides are synthesized by esterification of glycerol with three molecules of fatty acids. Thus, glycerol 3-phosphoate, a glycolytic metabolite, and fatty acyl CoAs are the key substrates for triglyceride synthesis. Fatty acids used for triglyceride synthesis are mainly derived from de novo lipogenesis, hydrolysis of triglycerides in the cell, or fatty acids transported from circulation. The first step of an esterification of a fatty acyl CoA to glycerol 3-phosphate is catalyzed by GPAT, and this is followed by subsequent esterification of two fatty acyl CoAs catalyzed by endoplasmic reticulum resident enzymes such as GPAT, *sn*-1-acylglycerol-3-phosphate acyltransferase, phosphatidic acid phosphatase, and diacylglycerol acyltransferase. The newly synthesized triglycerides in the endoplasmic reticulum are then coated by several lipid droplet envelope binding proteins, such as perilipin and adipose differentiation-related protein, which are required for the formation of triglyceride-enriched lipid droplets and an effective mobilization of lipid droplets under energy demanding condition. In supporting of the importance of these enzymes in triglyceride metabolism, genetic deletion of a gene encoding one of these enzymes in mice [13–16] and humans [17–19] with mutation of one of these genes have been shown to lower adiposity and/or energy balance. However, total inhibition of enzyme activities by genetic deletion of their corresponding genes is known to be associated with a number of side effects such as insulin resistance, skin-barrier abnormalities, and/or neonatal lethality [20]. This could be avoided if a selective and moderate inhibition of the function of enzymes involved in triglyceride synthesis could be achieved. In this regard, identification of natural phytochemicals that significantly, but not completely, inhibit activities of enzymes involved in triglyceride synthesis would effectively modulate the development of obesity [21].

Adipokines secreted from differentiated adipocytes regulate energy metabolism in peripheral tissues and brain in a paracrine and endocrine manner. Among the many adipokines, a significant amount of evidence suggests the important functions of leptin and adiponectin in the modulation of lipid metabolism both in adipose tissue and in nonadipose tissues such as liver and muscle. Leptin is a 16-kDa peptide that belongs to the cytokine class 1 superfamily. Leptin is encoded by *Lep* in mice and *LEP* in humans. Leptin exerts its biological functions by binding to its receptor encoded by *Lepr* in mice and *LEPR* in humans. Circulating leptin is correlated with body mass index (BMI), and defects in leptin and leptin receptor genes trigger the development of obesity and diabetes in both humans and animals [22,23]. The activated leptin–leptin receptor signaling pathway in peripheral tissues and in hypothalamus influences lipid metabolism and food intake, respectively. Leptin is known to induce mobilization of triglycerides in lipid droplets (i.e., lipolysis) by

activation of AMP-activated protein kinase (AMPK) and its-dependent fatty acid oxidation in skeletal muscle [24]. On the other hand, leptin is suggested to inhibit triglyceride synthesis and increase lipolysis in adipocytes through activation of leptin signaling pathway and suppression of genes involved in lipogenesis [25]. Although leptin not only appears to directly regulate the function of AMPK and its related triglyceride turnover, but it also indirectly modulates lipid metabolism through interference of insulin-induced lipogenesis and insulin-inhibited fatty acid oxidation, suggesting that leptin functions as a counter-regulatory hormone to insulin.

Adiponectin is a 244-amino-acid hormone mainly secreted from adipose tissue. Recent studies have further identified the expression of adiponectin mRNA in the liver and muscle tissues [26,27]. A number of animal studies indicated that adiponectin promotes fatty acid oxidation and suppresses gluconeogenesis in the liver, thereby promoting energy expenditure and protecting animals from high-diet-induced obesity and insulin resistance [28,29]. Conversely, obesity is associated with a low level of circulating adiponectin. Adiponectin-induced resistance to obesity and improvement of insulin sensitivity occur through interaction between adiponectin and the two receptors—a muscle-specific ADIPOR1 and a liver-specific ADIPOR2 [30]. The adiponectin-ADIPOR axis also appears to have direct and indirect effects on protection from obesity-related diseases such as atherosclerosis, cardiovascular diseases, and nonalcoholic steatohepatitis. These health benefits of adiponectin are exerted largely through allosteric activation of AMPK activity, and transcription of genes involved in fatty acid oxidation such as PPARα and PPARγ. Adiponectin expression and secretion is known to be modulated by various nutritional and inflammatory cues. For instance, fasting-refeeding [31], long-term caloric restriction [32], insulin treatment [33], and PPARγ agonists [34] induce adiponectin production, whereas inflammatory cytokines (e.g., TNF-α and IL-6) [35,36] and glucocorticoid [35] suppress adiponectin production.

During the development of obesity, hypertrophic adipocytes are known to display (i) increased basal lipolysis with elevated level of free fatty acid release, (ii) increased leptin secretion, (iii) deceased adiponectin secretion, (iv) increased expression and secretion of proinflammatory cytokines, and (v) impaired insulin-dependent glucose uptake (Table 20.1). Consequently, adipocyte hypertrophy is associated not only with adipose tissue expansion but also with impaired adipocyte function, thereby aggravating whole-body energy balance. On the other hand, hyperplasic adipocytes with relatively smaller cell size than hypertrophic adipocytes may counteract many detrimental effects of adipocyte hypertrophy in obesity (Table 20.1).

TABLE 20.1 Comparison of Adipocyte Hypertrophy and Hyperplasia in Obesity

Hypertrophy	Hyperplasia
Cell size (increased)	Cell number (increased)
Free fatty acid release (increased)	Free fatty acid release (decreased)
Leptin release (increased)	Leptin release (increased)
Adiponectin release (decreased)	Adiponectin release (increased)
Proinflammatory cytokine release (increased)	Proinflammatory cytokine release (decreased)
Insulin sensitivity (decreased)	Insulin sensitivity (increased)

B Function of Adipose Tissue in Energy Balance

Adipose tissue mass is closely associated with food intake regulation. As an endocrine organ, adipose tissue transmits a signal to the brain for central control of energy balance. Much attention has been given to the effect of an adipose-specific hormone leptin on central food intake. The interaction between leptin and its receptor expressed in hypothalamus is known to coordinately regulate central food intake signaling such as the proopiomelanocortin (POMC)-dependent anorexic pathway and the neuropeptide Y (NPY)/agouti-related protein (AgRP)-dependent hyperphagic pathway. Leptin-induced cleavage of POMC and its subsequent activation of α-melanocyte-stimulating hormone (α-MSH) and melanocortin receptor contribute to a decrease in food intake. On the other hand, reduction of circulating leptin level triggers the release of hyperphagic hormones NPY and AgRP in the hypothalamus. AgRP released under leptin deficiency in turn inhibits the anorexic function of α-MSH, resulting in stimulation of food intake [37,38]. Analogous to leptin, the level of plasma insulin, which is directly correlated with adipocyte hypertrophy, also modulates central food intake through the interaction with insulin receptor expressed in the hypothalamus for controlling anorexic and hyperphagic pathways [38,39]. Collectively, when adipose mass is reduced, low levels of circulating leptin and insulin are known to stimulate food intake and reduce energy expenditure. In contrast, increased levels of these hormones in circulation result in suppression of food intake and increased energy expenditure.

AMPK, a whole-body energy sensor protein, not only controls peripheral energy homeostasis but also integrates nutritional and hormonal signals in the brain to control central food intake and energy balance. Leptin-induced

dephosphorylation and inactivation of the hypothalamic AMPK has been shown to inhibit food intake. AMPK also plays an important role in hypothalamic de novo lipogenesis and its impact on food intake. AMPK activation in the hypothalamus under the insulin deficiency, for example, results in an inhibition of ACC activity with a reduced level of malonyl-CoA, which in turn modulates the function of hypothalamic neurons and increases food intake. On the other hand, inhibition of AMPK activity in the hypothalamus by central administration of glucose [40], metabolic intermediate citrate [41], or α-lipoic acid [42] resulted in the suppression of food intake. Moreover, inhibition of de novo lipogenic enzyme FAS activity by C75 [43] in the hypothalamus resulted in the accumulation of malonyl-CoA with an inhibition of food intake.

Central regulation of energy balance is also attributed by endocrine function of some intestinal hormones. Intestinal hormones such as cholecystokinin [44], peptide YY [45], and glucagon-like peptide-1 [46] are major representatives of endocrine-gut-brain communications that sense the size and frequency of meals in intestine. Thus, elevated levels of the release of these hormones from intestine are known to lower food intake, appetite, and weight gain through interaction with their specific receptors in the brain. Interestingly, some dietary compounds in coffee, such as chlorogenic acid and caffeine [47] and isoflavones [48], are known to modulate the release of intestinal hormones and lower satiety.

III OBESITY-RELATED CANCERS

Obesity is a global health crisis. Nearly 300 million adults are obese worldwide, and approximately two-thirds of U.S. adults are overweight or obese [49]. Obesity has been implicated in a number of chronic diseases, including diabetes and cardiovascular diseases [50]. As one of the life-threatening diseases, cancer has a high mortality rate. Increased cancer incidence has been observed in developing countries, as well as in developed countries, including the United States. Tobacco smoke, including secondhand smoke, exposure to sun, air pollution, exposure to toxic chemicals, infections, alcohol intake, and family history are responsible for cancer development. Obesity is a critical risk factor for developing specific types of cancers, as well. A cohort study estimated that 15−20% of deaths from all cancers are attributable to overweight and obesity in the United States [51]. Epidemiological studies have also suggested that greater BMI is associated with increased incidence and/or death from a few forms of cancer, including colon, breast, esophageal, and endometrial cancers [52]. However, studies of the associations between obesity and the mortality from cancers often yield inconsistent results, and the mechanisms by which obesity mediates tumor formation and progression are not clearly understood.

The World Cancer Research Fund has found that obesity is associated with greater risks from cancers of colorectal, breast (postmenopausal), endometrial, and esophageal, and probably other types of cancers [53]. In obesity, adipose tissue dysfunction is a key contributor to the development of hyperinsulinemia and insulin resistance. Insulin stimulates the production of insulin-like growth factor (IGF)-1 in adipose tissue, where it plays an important role in the cancer development by inducing cell proliferation and inhibiting apoptosis [54]. Binding of IGF-1 to its receptor (IGF-1R) activates multiple signaling cascades, including phosphatidylinositol 3-kinase (PI3K)-Akt and Ras/Raf/MAPK, which in turn lead to cellular growth, proliferation, differentiation, and motility [54].

Another mechanism associated with adiposity and carcinogenesis is the bioavailability of sex steroids [55]. Particularly, estrogen is mainly synthesized from adipose tissue, and its circulating level is directly associated with BMI in postmenopausal women [56]. Increased circulating levels and bioactivity of IGF-1 can decrease hepatic synthesis and circulating levels of sex-hormone-binding globulin (SHBG), which has a high affinity to testosterone and estradiol [57]. Indeed, in both men and women, decreased SHBG levels due to higher adiposity led to increased concentrations of free estradiol and testosterone [57]. After binding to their receptors, estrogen and testosterone can diffuse into the target cells, and subsequently promote cell proliferation and inhibit apoptosis [55].

A Colorectal Cancer

Colorectal cancer is the third most common type of cancer in the world. It is estimated that nearly 9.7% (1.23 million) of all commonly diagnosed cancers worldwide are attributed to colon cancer [58]. An epidemiological study has suggested that obesity is associated with an increased risk of colorectal cancer [59]. A prospective cohort study found direct associations between obesity measures such as waist circumference, waist:hip ratio, body weight, and BMI, and the risk for colorectal cancer in men [60]. Another clinical study performed in Japan found that colorectal cancer is significantly correlated with the accumulation of visceral fat, but not subcutaneous fat [61]. This study suggests that visceral adipose tissue accumulation is likely to be a stronger predictor for colorectal cancer development [61].

Although the mechanisms by which greater adiposity regulates colorectal cancer development are not clearly understood, increased circulating levels of leptin may be associated with obesity and colon cancer. A cohort study indicated that people with high leptin levels had an

approximately 30-fold higher risk of colon cancer [62]. Increased levels of leptin receptors have been found in colon tumors, polyps, and adjacent mucosa, as well as human colon cancer cells [63]. Obese mice also had greater body and epididymal fat mass, and increased levels of serum leptin and leptin receptor. An experimental study showed that obese mice fed a high-fat diet were more susceptible to carcinogen-induced colon tumorigenesis than normal diet fed mice [64]. This study suggests that obesity induced by high-fat diet stimulates colon tumor formation, which is likely mediated by increased levels of circulating leptin and its binding to the leptin receptor. Supporting to this notion, leptin is suggested to stimulate cell proliferation via activation of nuclear factor-κB (NF-κB) and extracellular signal-regulated kinase (ERK)1/2-mediated pathways in colonic epithelial cells [63,65]. Leptin is also known to induce angiogenesis [66], which results in tumor growth, invasion, and metastasis [67]. Moreover, recent study suggested a link between obesity and the silencing of colonic cell surface receptor guanylyl cyclase C (GUCY2C) in colorectal cancer. Their study suggested that caloric suppression of guanylin expression, silencing GUCY2C, disrupts the intestinal epithelial barrier, producing systemic genotoxic stress contributing to extraintestinal tumorigenesis in obesity [68].

B Breast Cancer

Breast cancer is the second most common cancer in the world, and it is the first leading cause of cancer-related mortality in U.S. women [69]. In particular, obesity increases the risk of breast cancer among postmenopausal women partially due to obesity-mediated upregulation of serum-free estradiol [70]. Whereas estrogen is produced mainly in the ovaries in premenopausal women, it is alternatively produced from adipose tissue in postmenopausal women [71]. Hence, the positive association between obesity and the risk of breast cancer among postmenopausal women is likely attributable to greater estrogen production from adipose tissue.

The mechanisms underlying the link between obesity and breast cancer risk are not fully understood. However, the potential mechanisms may involve obesity-mediated alterations in the levels of growth factors (i.e., IGF-1), subsequently modified sex hormones, and elevated levels of inflammatory cytokines and adipokines. Obesity is associated with increased levels of insulin and IGF-1, leading to the downregulation of circulating SHBG, which in turn increases bioavailability of free estradiol [57]. This increased amount of estradiol is considered to be a strong risk factor for the development of postmenopausal breast cancer [71].

Patients with breast cancer exhibited increased concentrations of plasma inflammatory cytokines, such as TNF-α, and IL-1β, -6, and -8 compared to their age-matched controls [72]. Conversely, elevated level of inflammation may also contribute to the increased risk of breast cancer. Indeed, obesity is considered to be a state with chronic low-grade systemic inflammation. Obesity-induced production of inflammatory cytokine TNF-α causes insulin resistance through activation of IκB kinase (IKK) complex, which in turn induces phosphorylation of serine residues of insulin resistance substrate [73]. In addition, other proinflammatory cytokine IL-6 activates Janus kinase (JAK)/the signal transducer and activator of transcription (STAT)-3 signaling pathways which in turn induce cancer cell proliferation [74].

Additionally, the positive relations between obesity and breast cancer development can be explained by obesity-mediated reductions in plasma levels of adipokines [75]. Among breast cancer patients, postmenopausal women exhibited significantly decreased serum adiponectin level compared to premenopausal women [76]. An in vitro study demonstrated that adiponectin suppresses cell proliferation and promotes cell growth arrest and apoptosis in MDA-MB-231 breast cancer cell [77]. The mechanism by which adiponectin prevents cancer progression is through the ADIPOR1 and R2-medicated activation of AMPK. Recent epidemiological studies have found a lower cancer incidence in the patients with type 2 diabetes after treatment with a metformin, an AMPK activator [78], indicating a key role of AMPK in cancer prevention. Interestingly, it was recently reported that obesity promotes cancer progression and metastasis by altering the biomechanical microenvironment of fatty adipose tissue in the breast [79]. Their findings suggest that obesity-induced interstitial fibrosis promotes breast tumorigenesis by altering mammary extracellular matrix mechanics.

C Endometrial Cancer

Endometrial cancer has the highest incidence rate in Western countries [80]. Case-control and cohort studies strongly suggested a positive association between overweight and/or obesity and endometrial cancer risk [51,81]. In particular, childhood BMI and height were shown to be associated with the risk of later development of endometrial carcinogenesis [82].

As with breast cancer, obesity-associated induction of circulating estrogen and reduction of SHBG level is likely to contribute to the development of endometrial cancer [83]. In addition, other studies have also found a close relation between obesity-caused induction of leptin and the risk of endometrial cancer [84]. Leptin has been shown to stimulate proliferation of human endometrial cancer cells through functional activation of cyclooxygenase-2 (COX-2), which is mediated via JAK2/STAT3, MAPK/ERK, and PI3K/AKT signaling pathways [85]. This finding

emphasizes the importance of leptin and leptin-mediated activation of COX-2 in obesity-triggered endometrial cancer development. It was also suggested that p27 is associated with the development of endometrial cancer in obesity. Indeed, loss of p27 was shown to be linked to the risk of endometrial cancer at the early progression stage [86].

D Esophageal Cancer

In addition to alcohol and tobacco uses, obesity is another critical risk factor for esophageal disorders: esophageal cancer, Barrett esophagus, and gastroesophageal reflux disease (GERD) [80], as supported by a recent meta-analysis that included 12 case-control studies and 2 cohort studies [87]. Among these disorders, esophageal cancer and GERD are reported to be positively correlated with obesity indices such as BMI and body fat distribution (i.e., abdominal body fat). Mechanisms underlying the relationship between esophageal cancer risk and obesity are not fully understood, but leptin is also suggested to play an important role in the development of esophageal cancer. Leptin promotes proliferation and mobility of human esophageal cancer cells [54] and this is likely through the activation of ERK and epidermal growth factor receptor (EGFR) [88]. Examination of the relationship between leptin receptor and adiponectin receptor (AdipoR1 and AdipoR2) expression in esophageal cancer and obesity status revealed that AdipoR1 is associated with obesity and is an independent predictor of patient survival [89]. In addition, both esophageal cancer and GERD are associated with systemic inflammation [90,91]. Because obesity is associated with a state of low-grade inflammation, obesity-induced systemic inflammation and elevated levels of secreted proinflammatory cytokines may promote the development of these esophageal disorders.

E Other Obesity-Related Cancers

Several studies have examined the potential relationship between obesity and the risk of other cancers such as bladder, prostate, and pancreatic cancers. However, the findings are not consistent. A case-control study has found a positive association between greater adiposity and the risk of bladder cancer [92]. However, a prospective cohort study of approximately 500,000 men and women has revealed a positive but modest correlation between adiposity and bladder cancer risk [93]. Although more than 40 studies, including various prospective and case-control studies, were conducted to examine the relationship between obesity and prostate cancer risk, the results were conflicting [94]. While several studies have suggested that increased BMI is likely to be associated with about twofold greater risk of pancreatic cancer in both men and women [95], but a meta-analysis using case-control and cohort studies did not find a weak relationship between BMI and pancreatic cancer risk [96]. Thus, whether obesity plays a role in the development and progression of bladder, prostate, and pancreatic cancers still remains inconclusive.

IV PHYTOCHEMICALS IN OBESITY AND ITS RELATED CANCERS

Currently a variety of approaches are used in the treatment of cancer including surgery, chemotherapy, and radiation therapies. While these treatments strive to decrease mortality rates and improve survival rates from cancers, they are associated with several side effects. Furthermore, patients undergoing typical treatment regimens often cannot be completely cured. It is reported that appropriate dietary modification contributes to an approximately one-third decrease in death rates for all cancers in the United States [97,98].

Natural bioactive compounds have been demonstrated to regulate a wide range of cellular and signaling processes in a variety of cancer cell types [99]. Fruits, vegetables, and edible plants (e.g., spices) are good sources of vitamins, minerals, and dietary fiber for basic nutrition. In addition, they are excellent sources of micronutrients, and natural bioactive phytochemicals such as polyphenols, phenolics, and alkaloids, are believed to contribute to many of the health benefits associated with fruits and vegetables. During the past several decades, a great deal of research has focused on characterizing which dietary phytochemicals are most effective in modulation of inflammatory, oxidative, and cell proliferative processes which substantially contribute to the initiation of many human diseases including cancer. Indeed, a number of epidemiological studies support the hypothesis that phytochemicals in fruits, vegetables, and plants reduce the risk of various forms of cancer [100–105]. Whereas many natural phytochemicals have been identified to be chemopreventive, efforts in identification of antiobese phytochemicals and their mode of actions have only more recently begun to emerge. Therefore, natural phytochemicals, which specially have both antiobese and chemopreventive properties, could be promising dietary approaches for the prevention of the development of obesity and its related cancer progression. The dietary phytochemicals reported to exhibit both potential antiobese and chemopreventive properties are summarized in Table 20.2 and discussed later.

A Curcumin

Curcumin (diferuloylmethane) is a natural yellow pigment and derived from turmeric, a powdered rhizome of *Curcuma longa* Linn (Table 20.2). Curcumin's protective

TABLE 20.2 Summary of Molecular Targets and End Point Modulation of Potential Antiobese and Chemopreventive Phytochemicals

Name	Structure	Molecular Targets and End Point Modulation	Reference
Curcumin		Lowered plasma triglycerides and VLDL levels, and liver triglycerides and cholesterol levels	[192]
		Lowered body weight gain, blood glucose and insulin levels	[108]
		Lowered body fat gain	[193]
		Reversed obesity-induced glucose and insulin tolerance	[194]
		Reduced lipid accumulation and inflammation	[114,194]
		Reduced body weight gain, adiposity, angiogenesis	[111–114]
		Activation of AMPK in adipose tissue	[116–118]
		Inhibited adipogenesis	[119]
		Reduced NF-κB activity and cell proliferation	[116,118]
		Induction of apoptosis of cancer cells	
		Inhibition of AP-1 activity	
Resveratrol		Decreased PPARγ expression	[129]
		Induced glucose uptake	
		Reduced de novo lipogenesis	[131,132]
		Induction of apoptosis	[133,134]
		Increased insulin sensitivity, AMPK function, PGC-1α expression	[135]
		Improved mitochondria function	[136,138]
		Reduced adiposity	[138]
		Suppressed leptin	
		Reduced EGFR, IGF1-R	
		Induced apoptosis and p53 signaling pathway	
EGCG		Decreased fat mass	[143,144]
		Reduced levels of serum lipid metabolites and/or body fat	[146–149]
		Increased thermogenesis and energy expenditure	[151–153]
		Inhibited gene expression and/or activity of lipogenic enzymes	[152,195]
		Activated AMPK	[152–157]
		Inhibited adipogenesis and adipocyte function	[161]
		Reduced the levels of IGF-1, IGFBP-3	[163,164]
		Suppressed TNF-α expression and NF-κB activity	[164,165]
		Induced apoptosis	
		Promoted cell cycle arrest	

(*Continued*)

TABLE 20.2 (Continued)

Name	Structure	Molecular Targets and End Point Modulation	Reference
Soy phytoestrogens	Genistein 	Lowered BMI	[174]
	Daidzein 	Improved insulin sensitivity and blood HDL level	[175,176]
		Reduced body and fat weight gain	[177]
		Suppressed de novo lipogenesis	[152]
		Stimulated lipolysis	[177–179]
		Inhibited adipogenesis	[179,180]
		Activated apoptosis and AMPK	[181]
		Inhibited apoptosis	[188]
		Inhibited hepatic triglyceride content and fatty acid synthesis	[189]
		Reduced sex steroid receptor protein expression	[190,191]
		Suppressed NF-κB activity	
		Inhibited ER-α, ER-β, and AR gene expression	
		Suppressed PTK activity	
		Inhibited TGFβ1-mediated cell growth	

activities against various diseases, such as diabetes, obesity, and cancers, have been intensively studied during the past several decades. Accumulating evidence suggested that curcumin exhibits antioxidant, antiinflammatory, anticarcinogenic, and cardioprotective properties [106], which are attributed to modulation of multiple targets in the cells and development of various diseases [99].

Curcumin has been reported to improve the profile of plasma lipid metabolites in obese animals. Curcuminoid-rich extracts [commercial-grade curcumin (~73%) mixed with demethoxycurcumin (~16%) and bisdemethoxycurcumin (~11%)] have been reported to lower liver triglyceride and cholesterol levels, and plasma triglycerides and VLDL fraction in animals fed a high-fat diet [107]. In diabetic mice, curcumin significantly suppressed body weight gain, blood glucose and insulin levels largely through lowering hepatic lipid metabolism [108]. The direct effect of curcumin intake on obesity has recently been addressed by Weisberg et al. who examined the therapeutic effect of curcumin on obese and diabetic animals [109]. Oral administration of 3% dietary curcumin to obese and diabetic mice for 6 weeks exhibited lower body fat gain and reversed obesity-induced glucose and insulin tolerance. Curcumin treatment also reduced lipid accumulation and inflammation in the liver, and macrophage infiltration of adipose tissue.

Curcumin has also been reported to prevent the development of obesity. A long-term feeding study showed that mice with high-fat diet supplemented with a low dose of curcumin (i.e., 500 mg/kg diet) at least for 12 weeks showed a reduction of body weight gain, adiposity, and angiogenesis in adipose tissue without affecting on food intake behavior [110]. This was associated with activation of AMPK, transcriptional suppression of genes involved in lipogenesis and angiogenesis in adipose tissue, and an increase in fatty acid oxidation. In addition, curcumin was demonstrated to have an antiadipogenic property both in vitro [111–114] and in vivo [110] through suppression of C/EBPα and PPARγ gene expression, and MCE, and activation of Wnt/β-catenin signaling, AMPK activity, and apoptosis of preadipocytes in the early phase of adipogenesis. Curcumin was also shown to induce brown fat-like phenotype in 3T3-L1 and primary white adipocytes. In this study, expression of UCP1 and other brown adipocyte-specific genes was found to be increased by

curcumin, which is likely mediated by curcumin-induced activation of AMPK [115].

Although the specific molecular mechanisms underlying curcumin's anticancer activities are not fully understood, several mechanisms underlying the chemopreventive function of curcumin have been proposed. Upon activation of cancer cells by free radicals, inflammatory mediators, carcinogens, or ultraviolet light, a transcription factor NF-κB senses these signals and induces expression of several genes involved in the cell survival, transformation, proliferation, and metastasis [116]. Curcumin is believed to suppress NF-κB activation by inhibiting the DNA binding ability of NF-κB, and reducing the activation of IKK complex, which in turn led to inhibition of inhibitory factor IκB phosphorylation, and subsequent translocation of NF-κB into the nucleus [117]. Curcumin-inhibited NF-κB activation results in the suppression of transcriptions of NF-κB-regulated genes involved in cancer cell proliferation such as COX-2, TNF-α, cyclin D1, adhesion molecules, and metalloproteinases [118]. The resulting impact is induction of apoptosis, programmed cell death. Curcumin has also been reported to promote cell cycle arrest in the G1/S phase in human colon carcinoma cells [119] by downregulating NF-κB-dependent cyclin D1 expression [118]. Curcumin also inhibits activity of a transcription factor activating protein-1 (AP-1). AP-1 regulates expression of several genes involved in apoptosis, cell proliferation, and progression. Importantly, AP-1 promotes tumor metastasis by repressing tumor-suppressor genes, including p53, p21, and p16 [116]. Curcumin suppresses AP-1 activation in the prostate cancer cell lines such as LNCaP, PC-3, and DUI145 [116]. Inhibition of AP-1 transcriptional activity may be attributed to curcumin-mediated inhibition of c-Jun N-terminal kinase phosphorylation [120] that otherwise leads to cell proliferation and tumorigenesis. In lung cancer, curcumin exhibited anticancer effect by suppressing the expression of enhancer of zeste homolog 2 (EZH2) in lung cancer cells which in turn decreased the expression of NOTCH1 [121].

Although curcumin is safe even at higher doses of 2 g/day in humans, the limited oral bioavailability of native curcumin has limited its therapeutic and/or preventive use in human diseases. Poor intestinal absorption of curcumin combined with its rapid hepatic metabolism and physiological clearance are hurdles that have served to limit its effectiveness as a chemopreventative agent in vivo. Developments of liposome, micelle, and phospholipid complex [122–125] with curcumin have long been studied and are promising approaches to improve bioavailability of curcumin. In addition, recently developed nanoparticle-based delivery of curcumin [126] and conjugation of curcumin with polyethylene glycol [111] could improve the bioavailability of curcumin, but the efficacy and safety of these complexes remain to be fully investigated and leveraged in a therapeutic approach.

B Resveratrol

Resveratrol (Table 20.2), a phenolic compound found in a diverse array of plants, has received much scientific interest throughout the years. A naturally occurring stilbenoid found in grapes, berries, peanuts, and sugar cane, resveratrol is best known from its association with the "French Paradox." Resveratrol has been reported to have a therapeutic potential against many chronic diseases. Its reported health benefits include hypolipidemic, chemopreventive, antiinflammatory, and antioxidant activities by largely targeting Sirtuin 1 (Sirt1) [127].

Resveratrol is reported to modulate adipose development and function via regulation of various cellular processes. As a dietary activator of Sirt1, resveratrol decreases lipid accumulation and promotes free fatty acid release from adipocytes through Sirt1-dependent repression of PPARγ function [128]. Resveratrol also inhibits adipogenesis of human adipocytes in a Sirt1-dependent manner through stimulation of basal and insulin-induced glucose uptake with reduced level of de novo lipogenesis in vitro [129]. Recent data showed that resveratrol inhibits lipogenesis of differentiating preadipocytes by inhibiting insulin signaling and mitochondrial biogenesis, and this contributes to adipose tissue weight loss in animals and humans [130]. In addition, Sirt1-independent function of resveratrol in fat cells has been proposed in which resveratrol regulates the number of differentiated human adipocytes through induction of apoptosis [131]. Indeed, resveratrol has been shown to be an effective proapoptotic agent both in preadipocytes [132] and in adipocytes, by which it controls, at least in part, the function and number of adipocytes. Nevertheless, mice administrated with a high-fat diet supplemented with resveratrol at 0.04% (w/w) of diet for 50 weeks [133] or at 0.4% (w/w) for 8 weeks [134] displayed enhanced insulin sensitivity, AMPK function, PPARγ coactivator-1α (PGC-1α) expression, and improvement of mitochondria function as well as reduced adiposity, suggesting a protective function of resveratrol against diet-induced obesity and its related metabolic disorders. However, more studies are needed targeting improved bioavailability of resveratrol to enhance circulating levels and presence in target tissues as a path to better translate these health benefits in humans.

Although the data are still insufficient to reach a conclusion, the protective actions of resveratrol against cancer development are likely attributable to the suppressions of leptin secretion [135]. Leptin acts as an important protein linking between obesity and cancer [62]. Indeed, a high-fat diet increases circulating levels of serum leptin, and leptin treatment has been shown to increase colonic cell proliferation in mice [64] and human colon cancer cells [63]. Given that resveratrol is known to suppress adipogenesis, resveratrol-mediated suppression of leptin secretion in adipose tissue likely contributes to prevent cancer development.

In addition, growth factor receptors are known to play an important role in the development and progression of colon cancer [136] via stimulating cell growth, angiogenesis, and metastasis. Accumulated evidence suggests that resveratrol-suppressed growth factor receptors, including EGFR and insulin-like growth factor-1 receptor (IGF-1R), also appear to mediate its chemopreventive function. In fact, animal experiment with Wistar rats has demonstrated that resveratrol administration for 30 weeks significantly attenuates colonic tumor incidence [137]. Resveratrol has been shown to suppress IGF-1-induced cell proliferation and induce apoptosis in human colon cancer cells by inhibiting IGF-1R/Wnt function and activating p53 signaling pathways [138].

C Tea Catechins

Consumption of teas, including green, black, white, and oolong, is commonly associated with a number of positive impacts on human health. The beneficial effect of consuming tea on body weight management appears to be largely through the modulation of whole-body energy balance. The potential mechanisms by which green tea regulates body weight and adiposity may be attributed to an increase in energy expenditure and fat oxidation, and a decrease in intestinal lipid absorption [139]. A long-term consumption of catechins (also known as flavan-3-ols or flavanols), which are natural phenolic antioxidants found in teas, is associated with reduction in body weight and body fat in humans [140,141]. Dietary catechins include: epicatechin, epicatechin gallate, epigallocatechin, and epigallocatechin gallate (EGCG). In particular, EGCG is the most abundant polyphenols found in green tea (Table 20.2), and it is most effective in preventing the development of various diseases, including obesity and type 2 diabetes [142]. EGCG decreases subcutaneous fat mass by an average of 55% and abdominal fat by an average of 28% in lean rats after 1 week of intraperitoneal injection of a dose of 70−92 mg EGCG/kg body weight [143]. A 4-day EGCG treatment also induced a 20% body fat loss in obese rats [144].

Although the antiobesity function of EGCG in humans is inconclusive yet, a number of human epidemiological studies suggest a possible benefit of EGCG and tea consumption in weight loss [101,103]. Consumption of high levels of green tea (more than 10 cups/day) [145], habitual tea consumption (more than 10 years) [146], and consumption of a bottle of oolong tea containing 690 mg catechins/day for 12 weeks [147] in different human populations resulted in lower levels of serum lipid metabolites and/or body fat, as well as a greater thermogenesis and energy expenditure [148,149]. It is important to note that other components of tea, such as caffeine, are also suggested to contribute, at least in part, to the health benefit of tea consumption [150].

Despite the important health benefit of EGCG, the detailed mechanism of its action in regulating body weight and adipose mass is relatively unclear. In general, EGCG and other catechins are known to inhibit gene expression and/or activity of lipogenic enzymes such as FAS, SCD-1, and glucose-6-phosphate dehydrogenase, thereby reducing fatty acid and triglyceride synthesis in adipose tissue and the liver [151−153] partly through activation of AMPK [152] and/or inhibition of adipogenesis of adipocytes. EGCG also displays a direct inhibitory effect on adipogenesis via regulation of multiple cellular processes and the transcriptional program in adipogenesis. In addition to its antiadipogenic property, EGCG has been reported to exhibit antimitogenic [154] and/or proapoptotic [155] effect, and to act as a transcriptional suppressor [156], and/or AMPK activator [157] during adipogenesis.

Numerous studies have suggested that EGCG may be effective in preventing cancer development [158]. A recent meta-analysis study showed a positive association between increased green tea consumption and a significant reduction of breast cancer risk [159]. An in vivo study using rats fed a high-fat diet supplemented with black tea has also found to have decreased tumor numbers, size, and multiplicity after the administration of a chemical carcinogen [160]. The chemopreventive mechanisms of catechins found in green and/or black tea have been proposed in a number of studies. Catechins appear to inhibit the function of growth factor receptors and their-downstream mediators, and NF-κB activation. Catechins also induce cancer cell apoptosis and cell cycle arrest. Oral administration of green tea polyphenol mixture to the transgenic adenocarcinoma of the mouse prostate (TRAMP) mouse model has been shown to inhibit the development and progression of prostate tumor by reducing the levels of IGF-1 and IGF-binding protein (IGFBP)-3, and its downstream signaling pathways in dorsolateral prostate [161]. The role of TNF-α is important in carcinogenesis because it acts as a growth factor for most of the tumor cells [162]. However, EGCG has been shown to suppress TNF-α expression [163] through inhibition of NF-κB activity [164]. On the other hand, EGCG induces apoptosis by stabilizing p53 in human prostate carcinoma LNCaP cells [165]. Likewise, promotion of cell cycle arrest through alteration of cell cycle regulatory protein expression by EGCG may be another molecular mechanism by which EGCG blocks carcinogenesis [164].

Antiobesity activities of EGCG have been well-defined. As discussed previously, green tea, and EGCG from tea in particular, has been suggested to decrease body mass and exert hypolipidemic activity. The potential mechanisms by which green tea regulates body weight

and adiposity may be attributed to an increase in energy expenditure and fat oxidation, and a decrease in intestinal lipid absorption [166–169]. Although it is not clear whether EGCG-lowered body weight and adiposity directly contribute to the prevention of the development of obesity-related cancers, based on the aforementioned studies, it is plausible to hypothesize that EGCG-mediated reductions in body and adipose tissue mass could contribute to the decreased risk of the development of various cancers. Hence, more studies are needed to address this hypothesis and to elucidate whether EGCG could be an ideal candidate to protect both obesity and its related cancers.

D Soy Phytoestrogens

Dietary phytoestrogens are reported to benefit human health [170]. The structural similarities between select phytoestrogens and estradiol have driven the notion that phytoestrogens are able to modulate cellular estrogenic processes through binding to estrogen receptors in various cell types. Indeed, phytoestrogens are largely known to have protective function against menopausal disorders, cardiovascular disease, cancer, and osteoporosis [171–173]. Isoflavones are the key phytoestrogens present in soy. Genistein and daidzein are the two most heavily studied forms (Table 20.2). Isoflavones are largely found in soybean and soybean products, and they are tightly associated with soy protein. In the past decade, a number of studies of humans and animals have provided evidence of a potential antiobesity function of soy protein and soy isoflavones including daidzein and genistein.

Consumption of soy isoflavones was associated with lower BMI, and improved insulin sensitivity, and blood high density lipoprotein (HDL) level in postmenopausal women of normal weight [174]. Moreover, soy protein isolate and its hydrolysate effectively reduced weight gain by lowering adipose tissue mass in genetically obese mice [175] and rats fed a high-fat diet [176]. Although the mechanisms underlying the antiobese function of phytoestrogens are largely unclear, the phytoestrogens appear to modulate systemic energy balance by targeting energy metabolism of a variety of cell types, including adipocytes and hepatocytes. Genistein is shown to suppress de novo lipogenesis and stimulate lipolysis in isolated adipocytes [177]. Moreover, genistein is known to inhibit adipogenesis by suppressing C/EBPβ activity [178], activation of AMPK [157], and apoptosis [179] in differentiating preadipocytes. Contrary to genistein's antiadipogenic effect, daidzein, an analogue of genistein, is reported to have proadipogenic property with improved PPARγ-mediated transcriptional activity and insulin-stimulated glucose uptake [180]. Genistein has also been reported to inhibit hepatic triglyceride content and fatty acid synthesis in the liver and adipose tissue [181]. In addition, administration of soy isoflavones to diet-induced obese male rats resulted in a decrease in body weight, and these effects were accompanied with suppressed lipogenesis and adipogenesis, as well as enhanced lipolysis and β-oxidation. This regulatory effect of soy isoflavones was reported to be mediated via inhibition of AKT/mTORC1 pathway [182]. Collectively, these phytoestrogens seem to have favorable actions on energy metabolism that could partly explain their protective and/or therapeutic effect on obesity and its related glucose disorders.

Epidemiological studies have suggested that increased consumption of phytoestrogens may contribute to a decrease in the rates of recurrence and mortality of breast and prostate cancers [183,184]. A cross-sectional study of 100 women, who had been treated for breast cancer and were in remission, reported that two-third of the patients have consumed some types of soy food with average daily intake of 11.6 mg genistein and 7.4 mg daidzein [185]. Among many other soy isoflavones, genistein has been studied extensively due to its abundance in soy foods, and its protective activities against hormone-dependent cancers [186]. Indeed, many animal studies suggest an anticancer property of genistein in prostate cancer. Dietary supplementation with genistein decreased the percentage of TRAMP mice that developed adenocarcinomas of prostate [187]. Consistent with this finding, supplementation with genistein and daidzein resulted in inhibition of chemical-induced prostate carcinomas in F344 rats [188]. Soy isoflavones are known to be converted to equol and 5-hydroxyl-equol by intestinal bacteria, which exhibit biological function that exceeds those of their precursors. Thus, soy isoflavones' antiobesity and anticancer properties are more likely to be attributed to equal-modulated estrogen- and androgen-dependent cellular conditions.

Although the mechanisms by which genistein protects against obesity-related cancer development have not been fully elucidated, downregulation of sex steroid receptor protein expression, suppression of NF-κB activation, and inhibition of tyrosine kinase in cancer cells by genistein and daidzein have been proposed. Because of the structural similarity between isoflavones and endogenous hormone 17β-estradiol, the potential chemopreventive function of genistein and daidzein is likely to be through modulation of estrogen receptor (ER) function and its related signaling pathways, and this could be mediated by the soy isoflavone metabolite, equol. In support, dietary genistein downregulates mRNA expressions of ER-α and -β as well as androgen receptor (AR) in the dorsolateral prostate of Sprague-Dawley rats [189]. This study suggests that dietary genistein may protect against prostate cancer due to its high affinity with sex steroid hormone receptor. These phytoestrogens also play an inhibitory role in the binding between NF-κB and DNA,

and in the protein tyrosine kinase (PTK) activity observed in prostate and breast cells [190]. In addition, genistein is suggested to target various cellular pathways such as transforming growth factor-β1 (TGF-β1) and its downstream pathways [191]. Collectively, the anticarcinogenic actions of genistein and daidzein are likely mediated through modulation of the functions of NF-κB and PTK, and also TGFβ1-dependent signaling cascades mostly in prostate and breast cancer cells, which otherwise are known to stimulate cancer cell proliferation.

V CONCLUSION

During the last several decades there has been a substantial increase in our understanding of the molecular basis of the development of obesity and obesity-related cancers. The identification of specific molecular targets that contribute to the incidence of these diseases provides the ability to screen new antiobesity and/or chemopreventive dietary components. The potential use of specific food components in the dietary prevention of obesity and its related cancers was discussed. Given the poor bioavailability of most of the aforementioned dietary components in physiological condition, further research should focus on developing new methods to enhance the efficacy and stability of these in circulation and/or target tissues. In addition, detailed preclinical studies and human studies should also be performed.

Chapter 21

Genetics of Nonsyndromic Human Obesity, With Suggestions for New Studies From Work in Mouse Models

Craig H. Warden and Janis S. Fisler
University of California, Davis, CA, United States

I INTRODUCTION

Complex and incompletely defined interactions between environment and genetics determine each individual's height and weight, as well as other human quantitative traits. The result is a population in which individuals vary widely for height and weight, but no one factor can be identified as controlling either trait in most people. In humans, long-term adult weight is relatively stable, as evidenced by the difficulty of sustaining intentional weight loss and the almost automatic return to previous weight following brief periods of overeating. This drive to constancy of body weight is due to both behavioral and physiological alterations that accompany weight change. Convincing evidence of the biological basis of the regulation of body fat stores comes from the identification of dozens of rare single-gene Mendelian mutations and syndromes that result in spontaneous massive obesity or in adipose tissue atrophy.

Most human obesity, however, is not due to mutations in single genes that have overwhelming effects, but is inherited as a complex, multigenic, quantitative trait influenced by many genetic and environmental variables. There are likely to be interactions among genes and between genes and environmental factors such that some alleles of one gene will not cause obesity unless specific alleles of another gene or environmental pressures are also present. Dietary effects on parents and parental genetics, independent of progeny genotype, also exert powerful but indirect effects on obesity. Genetic heterogeneity, where similar phenotypes are caused by more than one gene, and incomplete penetrance of the trait, where not all people with the gene develop the phenotype, also make dissection of complex phenotypes difficult. Expression of an obesity gene may also be age- or gender dependent. Thus, identification of all the genes promoting human obesity has not been, and will never be, a trivial task.

This chapter is not an exhaustive compendium of all things of genetics and obesity. This chapter does not include discussion of congenital lipodystrophies [1] nor rare genetic syndromes that include obesity in the phenotype, such as Bardet–Biedl and Prader–Willi, as these do not seem to contribute significantly to common causes of obesity and are reviewed elsewhere [2,3]. The present chapter is focused on human genetics, thus we do not plan to discuss the many effects of gut microbiota on metabolism and obesity [4]. The present chapter will discuss both monogenic and multigenic obesity, some of the techniques used to discover them, and general principles derived from these studies. We will list and discuss the most important known obesity genes, but we will not attempt to provide an exhaustive catalog of obesity genes (see [5,6]). Genetics is a rapidly progressing field, and knowledge of the genetic basis for obesity is expanding exponentially. Therefore, the reader should use this chapter to understand the most common genes and mechanisms, general ideas for finding more human obesity genes based on what has already been demonstrated in mice, and an appreciation of the wide variety of mechanisms by which genetics influences obesity.

II THE BIG PICTURE—HOW MUCH OBESITY IS DUE TO GENETICS

Genetic epidemiology of human obesity is the study of the relationships of the various factors determining the

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00021-7

frequency and distribution of obesity in the population. Such studies of obesity are limited in that they do not examine genetic variations and rarely directly measure the amount or location of body fat. However, genetic epidemiology studies do provide information as to whether there is a genetic basis for the trait, whether a major gene is involved in the population, whether inheritance is maternal or paternal, the relative importance of genes and shared or nonshared environment, and whether expression of the trait is gender or age dependent. Genetic epidemiology studies of human obesity employ a variety of designs and statistical methods, each giving somewhat different estimates for heritability of obesity. For a discussion of genetic epidemiology methods employed in the study of obesity, see [7].

The heritability estimates for human obesity are derived from a large number of studies of adoptees, twins, families, or communities. Population or family studies tend to have lower, and twin studies to have higher, heritability for body mass index (BMI). Heritability of BMI has been estimated from adoption studies to be as low as 10% and from twin studies to be as high as 85% [7,8] (Fig. 21.1). In a pediatric twin study, genetic influences contributed 75–80% in the percent of body fat [11]. The heritability for BMI in a study of childhood obesity in a Hispanic population was 40% and, in that study, heritability of diet and physical activity phenotypes ranged from 32% to 69% [12]. By using data from all types of studies, it is estimated that 40–70% of the within population variation in obesity is due to genetic variation [10] (Fig. 21.1). Most studies indicate that familial environment has only a minor impact on obesity.

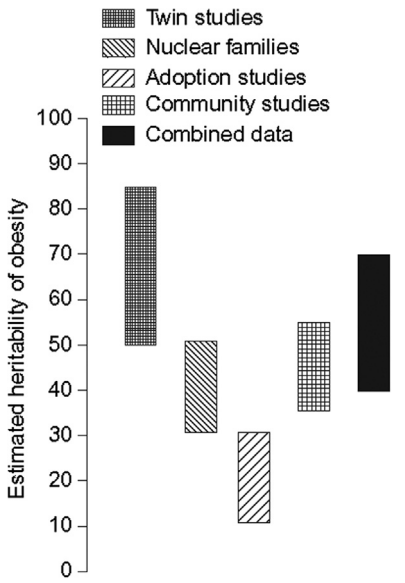

FIGURE 21.1 Heritability of obesity as determined by different study types. *Data for studies of twins, nuclear families, and adoption studies are taken from C. Bouchard, L. Perusse, T. Rice, D.C. Rao, The genetics of human obesity, in: G.A. Bray, C. Bouchard, W.P.T. James (Eds.), Handbook of Obesity, Marcel Dekker, New York, NY, 1998. Data for community-based studies are taken from A. Herbert, N.P. Gerry, M.B. Mcqueen, I.M. Heid, A. Pfeufer, T. Illig, et al., A common genetic variant is associated with adult and childhood obesity. Science 312 (2006) 279–283. Range of heritability estimated from all study types is taken from A.G. Comuzzie, D.B. Allison, The search for human obesity genes. Science 280 (1998) 1374–1377.*

III WHY FINDING OBESITY GENES MATTERS

During 2011–14, in the United States the prevalence of obesity in adults aged 20 years and over was 36% and in youths was 17% [13]. According to the World Health Organization in 2014 of the world population more than 1.9 billion adults were overweight (39%) and of these over 600 million were obese (13%). A total of 42 million children under the age of 5 years were overweight or obese in 2013 (http://www.who.int/mediacentre/factsheets). Obesity rates worldwide are predicted to rise to between 42% and 51% of the adult population by 2030 [14]. If obesity rates were to remain at 2010 levels the savings in medical expenditures over the next two decades could approach $550 billion.

Obesity is not just a financial burden. Sometimes the problems caused by obesity are social, such as discrimination, sometimes obesity influences quality of life by, for example, limiting physical activity, and sometimes obesity is associated with diseases that shorten lifespan, such as heart disease, type 2 diabetes, hypertension, and cancer. Additional obesity comorbidities include arthritis, limitations on mobility, sleep apnea, gallstones, and kidney disease. Until recently there was no way to determine if obesity caused these comorbidities or if they were simply correlated with obesity. Mendelian randomization, a study design that incorporates genetic information into traditional epidemiological methods, now provides a method to determine if genes simultaneously cause both obesity and comorbidity [15]. Causal relations then mean that treatment for obesity becomes even more urgent and that treatment can target specific genetic pathways that cause both obesity and comorbidity.

Studies of people who have lost weight by diet or bariatric surgery prove reduced mortality and improved quality of life. A person's genes influence weight gain, weight loss, and health consequences of obesity. Finding obesity genes may provide tools to improve health of people worldwide.

IV THE SEARCH FOR OBESITY GENES

A Lessons for Human Obesity From Genetic Studies in Mice

Although many decades ago genetic epidemiology studies provided evidence that obesity is highly genetic, there

was no understanding of the molecular basis for obesity until the identification of genes that cause Mendelian forms of obesity in mice. Five genes were known for many decades to cause monogenic obesity syndromes in mice. Positional cloning of the mouse obesity genes, *Lep*^{ob}, *Lepr*^{db}, *Tub*, *Cpe*^{fat}, and *A*^{y}, from naturally occurring mutant models between 1992 and 1996 led to an explosion of knowledge of the genetic causes of obesity [16]. When the third edition of this chapter [17] was published, human orthologs of three mouse obesity genes were known to cause obesity in humans and a fourth mouse obesity gene identified a pathway that caused human obesity. Subsequent studies have now demonstrated that human versions of all five mouse Mendelian obesity genes act in the brain to either directly cause obesity or identify a pathway that causes obesity. These mouse monogenic obesity genes in most instances are recessive and their human orthologs are expected to rarely cause obesity in the human population.

Mouse models of obesity provide information that often replicates causes of human obesity. Several hundred different knockout and transgenic mice have been developed where absence or replacement of a single-gene affects obesity or its phenotypes (for a listing of knockout and transgenic mouse models of obesity and related phenotypes see [6]). These are all possible human obesity genes. These and other genetic studies in mice also show that separate genes control (a) body weight, (b) BMI, (c) sizes of individual fat depots, and (d) responses of individual fat depots to dieting and exercise. Feeding different diets to mice revealed that some mice resist weight gain on diets that make other strains obese, indicating gene−diet interactions. These diet responsive genes are mostly separate from genes for spontaneous obesity on healthy chow diets. Human genetic studies have extensively investigated BMI, have produced smaller studies of overall fatness, but have produced virtually no data on genetics of individual fat depots, and despite many underpowered efforts, almost no significant results on gene−diet interactions.

Mice are valuable in the study of parental effects. Parents may exert indirect effects where female genotype influences progeny phenotype independent of progeny genotype [18,19] possibly by influencing milk composition or quantity, or quality of maternal care. Diets fed to male or female parents may influence weight and health of progeny through epigenetic effects that are heritable changes not due to changes in the underlying DNA sequence. Although similar maternal diet effects are well known in people, the paternal effects in mice have been a surprise as they occur through sperm. Recent evidence from mice suggests that RNA found in sperm can cause obesity and metabolic disorders in progeny of males fed high-fat diets [20]. No comparable studies exist for humans.

Although studies directly in humans have now successfully identified almost 200 obesity genes, taken altogether these account for a limited fraction of heritability and for only a few traits, such as BMI and overall fat distribution. The studies in mice and rats strongly suggest that work to find genes with similar effects on fat depots, diet, and parental effects in humans will identify entire new classes of human obesity genes. Doing so will likely increase the total heritability of obesity that can be explained in humans. Human geneticists have either not explored at all, or only begun to explore, these fundamental aspects of obesity that have been reproducibly demonstrated in mice and rats.

B Identification of Human Obesity Genes by Sequencing

Several approaches are currently used to find new human obesity genes, the most direct of which is to sequence DNA. One can sequence all DNA (whole genome sequencing), or only parts, such as the exome, the protein coding portion of the gene [21]. One recent paper used whole genome sequencing of Sardinians to identify genes influencing height, inflammatory markers, and lipids [22]. Although whole exome sequencing in obesity has been reported [23], no whole genome sequencing studies for obesity have yet been published.

Whether sequencing whole genome or whole exome, most investigators look for genes with mutations that obviously alter function such as stop codons, insertions, or deletions. One of the primary limitations of this approach is that missense mutations that substitute one amino acid for another in genes not previously known to cause obesity tend to be ignored, despite the fact that missense mutations can alter protein function. The practical problem is that each person has many thousands of missense variants and investigators cannot directly test functional effects of all to determine which of these are causal for obesity. Much effort is being devoted to methods to predict which missense mutations in protein coding regions will have functional effects on proteins, but at present there is no substitute for direct studies showing that a missense mutation alters protein function. And since many alleles that cause obesity are not in protein coding regions, ability to predict functional effects of these alleles ranges from nonexistent for alleles far from any gene to sometimes useful predictions for alleles in obvious gene promoter regions. Once again, there remains no convincing substitute for determining direct functional effects.

One exception is that some missense mutations in known obesity genes can be labeled as putative obesity causing. The most common results from sequencing are identification of novel mutations in known obesity genes,

for example, *LEP* [24,25], *LEPR* [24], and *MC4R* [25]. In ideal cases, investigators can show that missense mutations present in obese people will alter the function of a protein. For instance, missense mutations in *MC4R* may alter binding of α-melanocyte-stimulating hormone (α-MSH), localization on the cell surface, or production of cGMP on binding of α-MSH. Currently, mutations have been identified by sequencing in human orthologs of the known obesity genes *LEP* [24,25], *LEPR* [24], *MC4R* [25], *CPE* [26], *TUB* [27], and *PCSK1* [28]. New papers reporting discovery of mutations in these genes occur regularly, so we will not attempt to provide a comprehensive list.

Selected sequencing papers are presented in Table 21.1. Saeed and colleagues found that 30% of severe obesity in children in consanguineous or inbred families was due to variants in *LEP*, *LEPR*, or *MC4R* [24]. Philippe et al. [28] sequenced coding regions of 34 obesity genes in 201 individuals, including 126 who were obese. They report discovery of a nonsense loss of function mutation in *PCSK1* that causes a dominantly inherited familial obesity in a single three-generation pedigree. These investigators [28] also report finding another missense mutation in *PCSK1* and a missense mutation in *POMC* that were previously identified as putative obesity mutations but which are not associated with obesity in their study. This emphasizes the necessity for functional studies of missense mutations for putative obesity genes. Tan et al. [29] provide experimental evidence that exome sequencing did not identify all the obesity-causing mutations in *MC4R*, confirming prior hypotheses that whole genome sequencing will be needed to more completely catalog obesity-causing alleles.

TABLE 21.1 Sequencing Studies of Human Obesity

Gene	Protein Coded	Population	Method (Ref.)	Functional effects of variants confirmed	Comments
Mutations Identified by Sequencing Targeted at Known Obesity Genes					
LEP	Leptin	22 probands from consanguineous families	Targeted sequencing [24]	No	30% of severe obesity in children of consanguineous families due to *LEP*, *LEPR*, or *MC4R*
LEPR	Leptin receptor				
MC4R	Melanocortin receptor 4				
CPE	Carboxypeptidase E	1 individual from consanguineous family	Whole exome sequencing [26]	Yes	Obesity, intellectual disability, abnormal glucose, hypogonadism
TUB	Tubby bipartite transcription factor	1 individual from consanguineous family	Exome sequencing [27]	Yes	Frameshift mutation of *TUB* likely cause of obesity and retinal degeneration in humans Incomplete penetrance
PCSK1	Proprotein convertase subtilisin/kexin type 1	General population 206 of whom 126 obese	Sequenced coding regions [28]	No	One 3-generation family with dominantly inherited obesity
MC4R	Melanocortin receptor 4	267 obese children	Sequenced promoter region of *MC4R* [29]	Yes	Found novel promoter polymorphism that greatly reduced transcriptional activity in 1 child
Novel Obesity Genes Identified by Sequencing					
COA3	Cytochrome C oxidase assembly factor 3	1 obese adult	Whole exome sequencing [30]	Yes	Subject with exercise intolerance, obesity, neuropathy
DYRK1B	Duel specificity tyrosine-phosphorylation-regulated kinase 1B	3 multigenerational families 300 obese	Linkage analysis and whole exome sequencing [31]	Yes	Missense mutation associated with increase of BMI from 23 to 33. Separate variants associated with central obesity and metabolic syndrome

Several recent papers identify novel obesity genes and provide functional data demonstrating that the identified mutations have causal roles. Ostergaard et al. [30] studied a single subject with exercise intolerance, obesity, and neuropathy using whole exome sequencing and found compound heterozygous mutations in cytochrome c oxidase assembly factor 3 (*COA3*). *COA3* is an autosomal gene that is localized to mitochondria with expression highest in metabolically active tissues such as brain, liver, heart, kidney, and small intestine. Thus, effects of this mutation may be tissue specific which may explain the mild phenotype. Keramati et al. [31] used linkage analysis and whole exome sequencing to identify the gene *DYRK1B* as the cause of autosomal dominant coronary heart disease and metabolic syndrome in three multigenerational families. Initial studies identified significant logarithm of the odds (LOD) scores for linkage between markers in *DYRK1B* to BMI, blood pressure, and type 2 diabetes. Whole exome sequencing then identified a missense mutation in *DYRK1B* located in the LOD peak. In the families this mutation is associated with an increase of BMI from 23 to 33. The investigators screened 300 additional obese people and identified a separate variant that was also associated with central obesity. Subsequent letters to the editor by other groups confirmed that yet other missense mutations in *DYRK1B* influence metabolic syndrome.

Sometimes whole exome sequencing does not identify a mutation in a specific gene that causes Mendelian obesity but does identify susceptibility genes that increase risk. Pima Indians have one of the highest incidences of obesity and type 2 diabetes in the United States. They have been participants in, and subjects of, a long running study aimed at discovering if there is a genetic basis for this high incidence of obesity. Whole exome sequencing of 177 Pima Indians identified 31,441 coding variants, none of which had genome-wide significant association with adiposity or measures of type 2 diabetes [32]. A total of 345 of these variants that were predicted to have functional effects were genotyped in additional Pima Indians. *CYB5A* and *RNF10* showed significant association with adiposity and type 2 diabetes but the effects on type 2 diabetes were eliminated when the data were adjusted for BMI. Individuals with the risk allele of *CYB5A* were about 1 BMI unit heavier, while those with the risk allele for *RNF10* were about 3 BMI units heavier. Although these genes are risk factors for obesity, they cannot presently be considered as genes causing Mendelian forms of nonsyndromic obesity.

A small number of papers report the identification of novel genes through whole exome sequencing with possible causal mutations for obesity but do not demonstrate that the mutations identified influence function of the candidate obesity gene. Nevertheless, the utility of the sequence-based approach is likely to grow rapidly because costs are dropping and software for analyzing the results is improving [21]. Several low cost for-profit and nonprofit vendors already offer sequence-based diagnosis to primary care physicians with difficult to diagnose cases. However, most exome sequencing studies do not identify causal genes, and those that do, identify causal genes in only a fraction of the obese people studied. Thus, methods to determine causality of specific mutations remain essential. As discussed in Section IV-A, Lessons for Human Obesity from Genetic Studies in Mice, mouse genetic models often have phenotypes similar to those observed in humans with mutations in orthologous genes. Thus, one method to determine causality is to make the corresponding mutation in mice and then evaluate phenotype. Availability of clustered regularly interspaced short palindromic repeat (CRISPR)/Cas9 technology means that genetically engineered mice can be made and phenotyped much more quickly than was possible with traditional knockout or transgenic methods [33]. Characterizing the genetic basis of obesity will likely require much more than just exome sequencing.

C Genome-Wide Association Studies—Finding Most of the Common Disease Variants

Starting in 2005, human genetics entered a new era with the introduction of genome-wide association studies (GWAS) that examine many genetic variants in different individuals to see if any variant is associated with a trait. In one of the GWAS several hundred thousand single nucleotide polymorphism (SNP) markers, spread throughout the genome, are used to identify chromosomal regions influencing traits anywhere. GWAS owe their existence to several converging discoveries; sequencing of the human genome, identification of millions of naturally occurring SNPs, and discovery of technologies for determining which allele a person has for hundreds of thousands of SNPs in a single experiment.

One of the key analytical features of GWAS is that investigators do not need to use SNPs that cause disease; they only need to use SNPs that are near the disease-causing allele. More specifically, they need to be in linkage disequilibrium, or close, to the causal alleles. GWAS examine SNPs throughout the genomes of individuals to identify associations between those markers and diseases or specific traits, often comparing genomes of cases (disease) with controls (no disease). GWAS SNP panels are efficient at finding common variants that cause common diseases, but they cannot find rare disease-causing variants. The SNPs used are themselves ones where the minor alleles are relatively common, for instance many

have frequencies of 1−5%, meaning that there cannot be a unique association of any one common SNP with a rare allele. Rare allele discovery requires other methods, such as sequencing. Whole genome association studies have several other disadvantages. In some cases SNPs associated with obesity are located in introns of one gene but appear to act by influencing expression of an adjacent gene. In other cases SNPs associated with obesity are not located within a gene but are between genes.

Many GWAS have been performed for obesity [34,35]. The first obesity locus identified by GWAS was the fat mass and obesity-associated (*FTO*) gene [36], which has significant effects on feeding and on adipose tissue [37]. Although explaining only 1−3% of the variance in BMI, *FTO* polymorphisms have been found in multiple studies of populations worldwide.

The studies with the largest number of patients and providing higher statistical power are meta-analyses from the Genetic Investigation of ANthropomorphic Traits (GIANT) consortium that published several papers in 2015. One paper examined GWAS for BMI in adult men and women [38], while another examined GWAS for waist-to-hip ratio (WHR) after adjustment for BMI [39], and yet another examined the data stratified by gender and age [40].

The BMI study [38] identified 97 genome-wide SNPs, 56 of which were novel and 41 SNPs that had previously been significantly associated with BMI. Table 21.2 lists 13 of the 41 loci with significant association with BMI in multiple GWAS and highlights five of these genes that are components of the leptin-melanocortin pathway. When the data were stratified by gender and age, there was a larger effect in younger rather than older subjects at most of the loci [40]. There were no gender differences.

Estimation of overall heritability explained was conducted in two ways. First, just using genome-wide significant SNPs it was found that about 4% of heritability in BMI was explained. However, using all SNPs in the entire GWAS it was estimated that about 20% of heritability was explained. Of course, this would include some false positives, but may be a better estimate because it includes all the genes with very small effects on BMI.

A total of 35 of the BMI significant SNPs are also identified as associated with other diseases in the National Human Genome Research Institute (NHGRI) GWAS catalog. These include genes that are associated with cardiovascular disease, schizophrenia, smoking, irritable bowel syndrome, and Alzheimer's disease. As we will discuss later, these SNPs and traits are candidates for having causal relationships with BMI in Mendelian randomization studies.

Genes consistently and strongly associated with common obesity (Table 21.2), as measured by BMI in GWAS, include *FTO* (found only in GWAS), *MC4R* (identified as causing single-gene obesity, from sequencing studies, and from GWAS), *TMEM18*, *SEC16B*, and *TFAP2B* (all identified in GWAS), *BDNF* (identified as causing single-gene obesity and from GWAS), *NEGR1* and *FAIM2* (identified from GWAS), *SH2B1* (identified as causing single-gene obesity and from GWAS), and *GIPR* (identified from GWAS) [38,41,43,44].

The *FTO* was first identified through GWAS [45] and consistently shown to be associated with common human obesity across populations and ethnic groups [46]. The function of the FTO protein is unknown although mouse studies suggest it is a 2-oxoglutarate-dependent oxygenase that catalyzes nucleic acid demethylation [47]. *FTO* was recently found to interact with promoters of *IRX3* and *IRX5* that are involved in early neural development and may play a role in adipocyte, especially brown adipocyte, development [48]. *FTO* is highly expressed in the hypothalamus, a primary site for regulation of energy balance and satiety [45]. Risk alleles of *FTO* are associated with increased food intake, increased hunger, and reduced satiety [42], as well as with increased protein intake [49,50]. *FTO* variants interact with fat and carbohydrate intakes to affect BMI [51]. Individuals carrying homozygous *FTO* obesity predisposing alleles may lose more weight through diet or lifestyle intervention than noncarriers [52]. *FTO* variants have also been examined for interaction with physical activity, but the studies to date are not consistent [53].

MC4R, *BDNF*, *SH2B1*, *POMC*, and *TUB*, as components of the melanocortin pathway, contribute to single-gene obesity. However, variants of these genes also contribute to common obesity as measured by BMI in GWAS. Transmembrane protein 18 gene (*TMEM18*) expression levels are related to phenotypes of obesity and glucose metabolism [43,54]. *TMEM18* is widely expressed in the body, both centrally and in adipose tissue. However, its function in energy metabolism is not yet known. *NEGR1* codes for a neuronal growth-promoting factor which may be involved in synaptogenesis, neurite outgrowth, and cell-cell recognition/adhesion [43], and the gene is expressed in the hypothalamus and in peripheral adipose tissue and muscle. The gastric inhibitory polypeptide receptor (*GIPR*) gene codes for a receptor for an appetite-linked hormone, GIP, which is produced in the alimentary tract and mediates enhanced release of insulin from the pancreas. *GIPR* is also expressed in the hypothalamus and adipocytes.

Statistically significant SNPs are rarely causal for common diseases. Locke et al. [38] sought to determine if the significant SNPs were in linkage disequilibrium (close to) coding variants. They found coding variants predicted to have damaging effects on protein function in five genes in linkage disequilibrium with BMI SNPs; *ZNF142*, *STK36*, *TRIM66*, *BDNF*, and *GIPR*. Further study of these variants is needed to determine if they are

TABLE 21.2 Selected BMI Loci Identified in Multiple GWAS (Loci Listed in the Sequence of Strength of Association with BMI) [38]

Notable Gene	Gene Name	Chr	Function	Reference
FTO[a,c]	Fat mass and obesity associated	16	Catalyzes demethylation of RNA. Increased hypothalamic *FTO* expression associated with regulation of energy intake.	[38,41,42]
MC4R[a,b,c]	Melanocortin 4 receptor	18	MC4 protein binds α-MSH and is involved in regulation of feeding behavior and metabolism.	[38,41]
TMEM18[b,c]	Transmembrane protein 18	2	Transcription repressor. Cell migration modulator that enhances the glioma-specific ability of neuronal stem cells.	[38,41,43,44]
SEC16B[b,c]	SEC16 homolog B, endoplasmic reticulum export factor	1	Required for organization of transitional endoplasmic reticulum sites and protein export.	[38,41,44]
TFAP2B[c]	Transcription factor AP-2 beta	6	Transcription factor thought to stimulate cell proliferation and suppress terminal differentiation of specific cell types during embryogenesis.	[38,41]
BDNF[a,c]	Brain-derived neurotrophic factor	11	Helps support growth and differentiation of new neurons and synapses and support the survival of existing neurons.	[38,44]
NEGR1[b,c]	Neuronal growth regulator 1	1	May function as a trans-neural growth-promoting factor.	[38,43,44]
FAIM2[c]	Fas apoptotic inhibitory molecule 2	12	Protects cells from Fas-induced apoptosis.	[38,41]
POMC[a]	Proopiomelanocortin	2	Polypeptide hormone precursor that undergoes extensive, tissue specific, posttranslational processing to produce biologically active peptides, including α-MSH, important in regulation of appetite.	[38]
SH2B1[a]	SH2B adapter protein 1	16	The protein mediates activation of various kinases including *LEP* signaling and other genes of the leptin-melanocortin pathway.	[38,43]
GIPR	Gastric inhibitory polypeptide receptor	19	Stimulates insulin release in the presence of elevated glucose.	[38,43]
POC5	POC5 centriolar protein	5	Essential for the assembly of the distal half of centrioles, required for centriole elongation.	[38,43]
LINGO2	Leucine-rich repeat and Ig domain containing 2	9	unknown	[38,43]
TUB[a]	Tubby bipartite transcription factor	11	Plays a role in obesity and sensorineural degradation	[38]

[a]*Loci associated with genes involved in the leptin-melanocortin pathway. Each of these genes has variants that can cause single-gene obesity in humans.*
[b]*SNPs located near these genes have stronger association with BMI in younger versus older adults.*
[c]*SNPs located near these genes are significantly associated with BMI in children and adolescents.*

causal for the BMI effects. The authors also identified many genes where the BMI SNPs were associated with mRNA levels for adjacent genes, consistent with hypothesis that some of the SNPs influence BMI by altering mRNA levels.

The WHR GWAS, which focused on finding genes for upper versus lower body fat distribution rather than fat mass or mass of individual fat depots, showed several novel features [55]. Shungin et al. [55] found a total of 49 significant SNPs for WHR and another 19 associated with waist or hip circumference measures. Twenty of the SNPs showed strong gender dependence with 19 having stronger effects in women and only a one having stronger effects in men. When stratified for both gender and age, only gender differences were apparent in the data [40]. An additional GWAS paper focusing on adiposity or fat depots is consistent with the GIANT consortium findings. Sung et al. [56] identified multiple SNPs in several genes with gender-specific effects on visceral and subcutaneous adipose tissue.

Alternative measures of obesity may produce different GWAS results. Lu et al. [57] measured percent body fat in 100,716 people by either bioelectric impedance or dual-energy x-ray absorptiometry (DEXA) and found 12 genome-wide statistically significant SNP loci. Seven loci had larger effects on percent body fat than BMI. Five had larger effects on BMI than percent fat. None of the genes was significant for WHR adjusted for BMI. Thus, GWAS contrasting results for BMI and WHR adjusted for BMI, or examining percent body fat or different adipose depots, show different genes for weight and for individual fat depots and substantial genetic differences between males and females. The results are strongly consistent with mouse studies showing that body weight or BMI only partially overlap with percent fat and fat pad genetics.

Other GWAS examined children and various ethnic groups. Studies of children found that most genes for BMI are common with adults and only a few are child specific [41,44]. The results could mean that there are some different genetic controls between adult and childhood obesity, or they could mean that both adult and childhood obesity studies were underpowered and would find the same genes if enough people were studied. Also, most genes in other ethnic groups were the same as those observed in Caucasians; genes that were different may or may not indicate true ethnically different obesity pathways.

GWAS led to the development of genetic risk scores (GRS), multilocus profiles calculated by summing up the number of risk alleles for elevated BMI and obesity. GRS are very useful for studying effects of genetics on response to diet and exercise. They have also been used for the technique of Mendelian randomization, which determines if obesity has a causal effect on correlated comorbidities.

D Mendelian Randomization or Genetic Correlations and Causal Relationships

Obesity is correlated with many diseases, for example, hypertension, type 2 diabetes, cardiovascular disease, serum triglycerides, and more. Until recently there was no method to determine if obesity caused these other diseases, or if one or more other diseases caused obesity. Several methods have just recently become available to identify causal relationships between correlated complex traits. One method looks for genetic correlations. The method does not require individual genotypes, genome-wide significant SNPs, nor even measuring multiple traits for the same individuals. Thus, genetic correlations can be measured for large numbers of traits. Bulik-Sullivan et al. [58] estimated genetic correlations between 24 traits, including BMI. They report positive genetic correlations between BMI and type 2 diabetes, coronary artery disease, and serum triglycerides. They report statistically significant negative correlations between BMI and HDL cholesterol, age at menarche, height, and years of education. These results, and limitations, are quite similar to those observed using the technique of Mendelian randomization. Note that they did not have data on fat mass or fat distribution so comparisons of genetic correlations of BMI with fat mass or fat distribution were not possible.

Mendelian randomization combines genetics with traditional epidemiologic methods to provide causal information about correlated phenotypes, without conducting a randomized controlled trial. The Mendelian randomization approach limits both confounding and reverse causality errors, but assumes there is no linkage disequilibrium or pleiotropy where one gene has a primary effect on more than one phenotype.

A number of recent studies used Mendelian randomization to determine if obesity, as measured by BMI, is causal for disease. Using GRS generated from BMI risk alleles, Todd et al. [59] found evidence that obesity is causal for diabetic kidney disease in type 1 diabetes and Cole et al. [60] found evidence that obesity is a causal risk factor for coronary artery disease. On the other hand, Davies et al. [61] found little evidence that genetically determined BMI and height had influence on prostate cancer risk, but were associated with increased mortality in low-grade disease. Furthermore, Nordestgaard et al. [62] concluded that, although high coffee intake was correlated observationally with low risk of obesity, metabolic syndrome, and type 2 diabetes, there was no evidence to support a causal relationship.

Observational studies suggest that a leptin surge in the perinatal period may program the long-term risk of obesity. A study by Allard et al. [63] using DNA methylation levels near the *LEP* locus in a Mendelian randomization study supports causality between maternal hyperglycemia and epigenetic regulation of leptin in the newborn.

We expect to see more studies using Mendelian randomization to determine causal relations between obesity and disease and between environmental factors and obesity.

E The Problem of Missing Heritability

As much as 70% of any one person's risk for being obese may be heritable, that is, genetic. Yet, to date, less than 10% of that heritability has been identified. The gene most strongly associated with common human obesity, the fat mass and obesity-associated gene (*FTO*), only

contributes about 1% of the variance in BMI [36]. The problem of missing heritability is true not only for obesity but also for most common genetically complex traits and diseases. For example, height is estimated to be 80–90% heritable, yet large-scale population studies identify less than 10% of height's heritability [64].

This missing heritability may be due to the presence of rare variants, variants with low penetrance, copy number variants, epigenetic tags, numerous variants with small effects, or may be due to overestimation of heritability due to epistasis (gene–gene interaction), none of which are readily identified by GWAS.

Rare variants are likely to be missed by the GWAS approach despite the fact that they may have larger effects than common variants [65–67]. Rare variants with large effects seem to be more common in people with early onset or more severe obesity [68,69]. Indeed, sequence-based studies have already found that cohorts with extreme phenotypes of obesity are enriched with highly penetrant but rare alleles. It is likely that sequencing will continue to discover rare variants.

Copy number variation (CNV) is when the number of copies of a particular gene varies among individuals. CNVs comprise more total nucleotide content than SNPs and may encompass one or more partial or entire genes. Yet, in current SNP analytic methods homozygous (A/A), hemizygous (A/O), and duplicative (A/A/A) tend to be lumped. One study of CNVs showed that deletion at the 16p11.2 locus resulted in altered satiety response and subsequent obesity in children whereas duplication at that locus was associated with leanness [70]. Taking account of the structural dimension of the genome might recover some of the missing heritability for many traits [71,72].

Epigenetics refers to changes in gene expression that are not the result of DNA sequence, but can be the result of chemical modifications of DNA or of proteins that bind DNA. Common epigenetic tags are those resulting from DNA methylation or deacetylation of DNA-binding histones. These often occur as the result of early life environment. Evidence now suggests that epigenetic changes are important contributors to inheritance of obesity phenotypes. Since standard sequencing or GWAS techniques do not measure epigenetic tags, they may be a major component of missing heritability. Epigenetics will be discussed in more detail in Section V-A, Epigenetics.

Estimates of heritability assume that there are no gene–gene interactions (epistasis), a phenomenon found in all animal models of obesity. Epistasis is where a gene (or genes) masks or amplifies the effects of another gene (or genes). A classic example of the effect of gene–gene interactions on a complex trait comes from mouse studies. The severity of diabetes in both *Lep*^{ob} (leptin) and *Lepr*^{db} (leptin receptor) mutant mice is determined by the genetic background upon which the mutation is expressed. There are many different inbred mouse strains. These strains differ from each other at millions of places through their genomes. Thus, if the same mutation is moved from one strain to another by breeding, then one can determine if all these other variants influence the phenotypes produced by the mutation. Both *Lep*^{ob} and *Lepr*^{db} mutations in C57BL/6 strain mice result in hyperinsulinemia and obesity, whereas these mutations in C57BLKs strain mice result in severe diabetes and early death [73]. This means that genes other than *Lep*^{ob} and *Lepr*^{db} have dramatic effects on the phenotype that is observed. Characterization of epistasis influencing polygenic obesity in the BSB mouse model, produced by breeding C57BL/6J with *Mus spretus* (a different mouse species) F1 × C57BL/6J, found interaction between genes on different chromosomes that contributed significant variation to obesity and related phenotypes [74]. Each BSB mouse is genetically unique and weights, fat distribution, and fat mass vary widely from mouse to mouse. Quantitative trait locus mapping demonstrated both direct genetic effects and epistatic effects [74].

Gene–gene interactions are likely a universal phenomenon in common human diseases and may be more important in determining the phenotype than the independent main effects of any one susceptibility gene [75,76]. Zuk et al. [77] argue that a high proportion of heritability for certain traits could be due to genetic interactions. Gene–gene interactions are difficult to identify using traditional genetic studies in humans and studies searching for interactions of any gene with all genes are lacking for human obesity. Instead, investigators have performed more limited studies searching for epistasis of pairs of specific genes chosen by investigators. Gene–gene interaction effects have been shown on BMI and waist circumference [78], extreme obesity [79], abdominal fat [80], and on immune dysfunction in obesity [81]. Gene–gene interactions among variants of the β-adrenergic receptor genes (*ADRB1*, *ADRB2*, and *ADRB3*) contribute to longitudinal weight changes in African and Caucasian American subjects [82]. Epistasis affecting obesity was also found in African derived populations in Brazil where interactions between *LEPR* and *ADRB2* polymorphisms as well as a third-order effect between *LEPR*, *ADRB2*, and *INSIG2* were found [83]. In the study of Feitosoa et al., blood lipid profile and dietary habits were found to have confounding effects in the analysis [78]. It is possible to have both gene–gene and gene–environment interactions affecting the same pathway.

Zuk et al. [77] describe a method for estimating heritability not inflated by genetic interactions, but the method requires isolated populations.

V GENE–ENVIRONMENT INTERACTIONS

A Epigenetics

Epigenetics is the study of mitotic and/or meiotic changes due to environmental factors that switch genes on and off without changes in the DNA sequence [84]. Common epigenetic changes result from DNA methylation or histone deacetylation and often occur as the result of environmental exposure in utero, in the early neonatal period or early in life [85]. Epigenetic processes include genome imprinting, gene silencing, and noncoding microRNA, among other effects. Technically, the term epigenetics applies to only those changes that are stably inherited. However, the term epigenetics is also commonly used to describe processes that have not been shown to be heritable but that effect the development of the organism. There is increasing evidence that epigenetics is a mediator of gene–environment interactions underlying the development of obesity and comorbidities [86–90].

Nutrition and activity levels can both affect metabolism through epigenetic gene regulation. Studies that show epigenetic changes associated with weight regulation include studies of the Dutch winter famine that occurred in 1944 showing that children conceived during famine were small and underweight with increased risk for obesity and type 2 diabetes as adults [91,92]. In the Chinese famine of 1958–61, only females developed obesity in later life [93]. DNA isolated from individuals decades after the famine showed abnormal DNA methylation [94]. Studies of identical twins with discordant BMIs identified DNA methylation and expression differences in subcutaneous adipose tissue that distinguish one twin from the other, differences that tended to increase with diverging life experience suggesting that the difference in obesity is epigenetically regulated [95].

Epigenetic studies of human obesity are just beginning. A large-scale epigenome-wide study found significant associations between DNA methylation and BMI and waist circumference in European Americans, which was then replicated in two independent populations including both European and African Americans [96].

Studies showing inheritance of epigenetic changes have been done in rodents. Increased maternal energy intakes affect the epigenetic changes of rats [97]. Feeding a high-fat diet to female mice resulted in increased growth and insulin insensitivity in the progeny [98]. Wei et al. [99] found that prediabetes in male mice increased susceptibility to diabetes in progeny through gamete methylation changes. Mice with the Agouti viable yellow obesity mutation given dietary methyl group supplements have epigenetic changes that prevent passage of obesity to subsequent generations through the agouti viable yellow allele [100]. Integrating mouse to human approaches will be essential to the understanding of the epigenetic contribution to the current obesity epidemic.

B Genetic Effects on Weight Gain or Loss Due to Diet or Exercise

Why some people in modern societies become obese, despite considerable effort and expense to avoid this condition, whereas others stay lean without such effort, appears to have a genetic basis [101,102]. Chronic overfeeding studies by Sims and colleagues beginning in the 1960s showed interindividual differences in weight gain [103,104]. More recently, Bouchard and colleagues determined the response to changes in energy balance by submitting pairs of monozygotic twins either to positive energy balance induced by overeating [105] or to negative energy balance induced by exercise training [106]. Significant intrapair resemblance was observed for changes in body composition and was particularly striking for changes in regional fat distribution and amount of visceral fat. One explanation for these differences is that some twin pairs were better oxidizers of lipid, as evidenced by reduced respiratory quotient, during the submaximal work than were the other twin pairs [106].

Recent epigenome-wide association studies may help explain some of these interindividual differences in body weight response to diet or exercise [107,108]. Young men with low birth weight, suggesting in utero undernutrition, were compared to men of normal birth weight both on a control diet and after 5 days of a high-fat diet. There was no difference in skeletal muscle DNA methylation between low and normal birth weight cohorts on the control diet. However, after the high-fat diet the normal weight group had widespread skeletal muscle DNA methylation, whereas the low birth weight group had few methylation changes [108]. In obese adolescents DNA regions were differentially methylated consistent with weight loss response to diet [109].

Several papers now report DNA methylation changes as a result of acute [110] or chronic [107] exercise training including altered DNA methylation patterns in adipose tissue of healthy young men in candidate genes for obesity including *FTO*, *GRB14*, and *TUB* [107]. A meta-analysis of 10 studies found that individuals carrying homozygous *FTO* obesity predisposing allele lose more weight through diet or lifestyle intervention than noncarriers [52]. These studies are consistent with the hypothesis that exercise may modify DNA methylation, and thus gene expression, for many genes that influence BMI, fat mass, or fat distribution.

Other studies examined genes in the lipolysis pathway for influence on weight loss success but results are not consistent (see [111] for review).

C Genetic Effects on Weight Loss Due to Bariatric Surgery

Several studies with small numbers of subjects report on weight loss in individuals with *MC4R* mutations following bariatric surgery. Patients with *MC4R* mutations are able to lose as much weight as those without such mutations with bariatric surgery in children [112], adolescents [113], and adults [114]. GWAS-type studies with small numbers of subjects are just beginning to look at SNPs associated with weight loss success following bariatric surgery and need confirmation. At the present time, obesity GRS does not predict weight loss results following bariatric surgery [115].

VI GENETIC PATHWAYS OF OBESITY

The hypothalamus is of great importance in obesity as it integrates peripheral hormonal and neuronal signals of satiety and nutritional status, senses nutrients, controls glucose homeostasis and peripheral lipid metabolism, and functions to control whole body energy balance. Much of this control is through the leptin-melanocortin pathway in the hypothalamus. Recent studies also implicate adipose tissue as important in obesity, both as an active endocrine organ [116,117] and in regard to body fat distribution [55].

A The Leptin-Melanocortin Pathway in the Hypothalamus

The first five causal human obesity genes were identified using the mouse models Lep^{ob}, $Lepr^{db}$, *Tub*, Cpe^{fat}, and A^{y}. Once these genes were identified in mice, geneticists began searching for obese humans with mutations in these same genes. Study of the yellow obese A^{y} mouse led to the discovery of the leptin-melanocortin pathway, the primary pathway in the brain which functions in the regulation of body weight (Table 21.3). Searching in highly

TABLE 21.3 Single Gene Mutations Causing Uncomplicated Obesity in Humans and Confirmed in Mouse Models

Gene Name	Chromosomal Transmission	Function of Gene Product Relative to Obesity	Mouse Ortholog
Components of the Leptin-Melanocortin Pathway of the Hypothalamus			
Leptin (*LEP*) [118]	7q31.3 Recessive	Hormone secreted from adipocytes that plays a critical role in regulation of body weight by inhibiting food intake and stimulating energy expenditure. Deficiency causes hyperphagia, early onset obesity, hypogonadotropic hypogonadism, and altered carbohydrate metabolism.	Lep^{ob} cloned from the ob/ob mouse [154]
Leptin receptor (*LEPR*) [119]	1p31 Recessive	Receptor for the hormone leptin. LEPR deficiency causes same phenotype as LEP deficiency.	$Lepr^{db}$ cloned from the db/db mouse [120]
SH2B adaptor protein 1 (*SH2B1*) (155,156)	16p11.2 Recessive	Adaptor protein enhances intracellular leptin signaling in the brain. Loss of function mutation results in hyperphagia, childhood onset obesity, disproportionate leptin resistance, and reduced height as adult.	*Sh2b1* No obesity identified in homozygous null mice.
Proopiomelanocortin (*POMC*) [121]	2p23.3 Recessive	Located in centrally projecting neurons that contain peptide products of proopiomelanocortin (POMC) and cocaine and amphetamine-regulated transcript (CART). POMC is a precursor protein that is ultimately cleaved into ACTH, α-MSH, β-MSH, γ-MSH, and β-endorphin. Mutation causes hyperphagia, early onset obesity, hypocortisolism, and skin and hair hypopigmentation.	*Pomc* [157]
Tubby bipartite transcription factor (*TUB*) [27]	11p15.5 Recessive	Functions as a membrane-bound transcription regulator in the hypothalamus that translocates to the nucleus in response to phosphoinositide hydrolysis. Deficiency results in hyperphagia, obesity, altered glucose metabolism, and sensorineural degradation.	*Tub* cloned from the tubby mouse [158]

(*Continued*)

TABLE 21.3 (Continued)

Gene Name	Chromosomal Transmission	Function of Gene Product Relative to Obesity	Mouse Ortholog
Carboxypeptidase E (*CPE*) [26]	4q32.3 Recessive	Involved in the synthesis of most neuropeptides and peptide hormones. Deficiency results in severe obesity, type 2 diabetes, intellectual disability, and hypogonadotrophic hypogonadism.	Cpe^{fat}, cloned from the fat mouse [159]
Melanocortin 4 receptor (*MC4R*) [122,123]	18q22 Dominant	The encoded protein is a membrane-bound receptor and member of the melanocortin receptor family, interacts with adrenocorticotropic and MSH hormones, and is mediated by G proteins. Defects in this gene are a cause of hyperphagia, early onset obesity, increased height, and fasting hyperinsulinemia. MC4R mutations cause the most common form of human monogenic obesity ~ 5%.	*Mc4r* [160]
Proprotein convertase subtilisin/kexin type 1 (*PCSK1*) [161]	5q15-q21 Recessive	PC1/3 is a neuroendocrine convertase encoded by *PCSK1* that cleaves POMC and also proinsulin to insulin. Mutation causes hyperphagia, early onset obesity, hypogonadism, and altered carbohydrate metabolism.	*Pcsk1* mutation in the HRS/J inbred mouse results in late onset obesity
Melanocortin 2 receptor assembly protein 2 (*MRAP2*) [162]	6q14.2 Recessive	Regulates energy homeostasis through signaling of MC4R and PKR1.	*Mrap2* knockout produces severe early obesity [163]
Components of the Paraventricular Pathway of the Hypothalamus			
Brain-derived neurotrophic factor (*BDNF*) [124]	11p13 Recessive	Plays a role in the growth, maturation, and maintenance of cells in the brain and is active where cell-to-cell communication occurs. BDNF protein is found in regions of the brain that control eating, drinking, and body weight. Mutation causes hyperphagia, early onset obesity and cognitive impairment.	*Bdnf* [164]
Neurotrophic tyrosine kinase, receptor, type 2 (*NTRK2*) ([165,125])	9q22.1 Recessive	Receptor for BDNF. Mutation results in early onset obesity, hyperphagia, and developmental delay.	*Ntrk2* knock-in results in adiposity [166]
Single-minded homolog 1 (*SIM1*) ([167,126])	6q16.3 Recessive	Transcription factor that is essential for the development of the PVN of the hypothalamus. Haploinsufficiency causes hyperphagia, early onset obesity, altered carbohydrate metabolism, dysmorphic features, and mental retardation.	*Sim1* heterozygous mutants exhibit hyperphagic obesity [168]

consanguineous families including obese individuals, a mutation in the leptin (*LEP*) gene was discovered [118] and confirmed in additional homozygous *LEP*-deficient patients [25]. As with the *LEP* gene, homozygous leptin receptor (*LEPR*) deficiencies were found in severely obese siblings [119] and in families where severe obesity segregated with mutations in *LEPR* [127,128]. Individuals homozygous for mutations in either *LEP* or *LEPR* are hyperphagic and gain weight rapidly in the first year of life [118,129] and have delayed puberty due to hypogonadotropic hypogonadism [128]. Heterozygotes for *LEP* and *LEPR* mutations have increased fat mass but are not morbidly obese.

Borman et al. [130] identified a homozygous mutation in *TUB* in a child of consanguineous marriage. The 11-year old was identified with mild obesity and a 2-year history of deteriorating vision. Functional studies demonstrated that the mutated protein is expressed at low levels in the retina. Alsters et al. [131] identified a homozygous mutation in carboxypeptidase E (*CPE*) in a severely obese woman from a consanguineous marriage. The proband had severe obesity, intellectual disability, abnormal

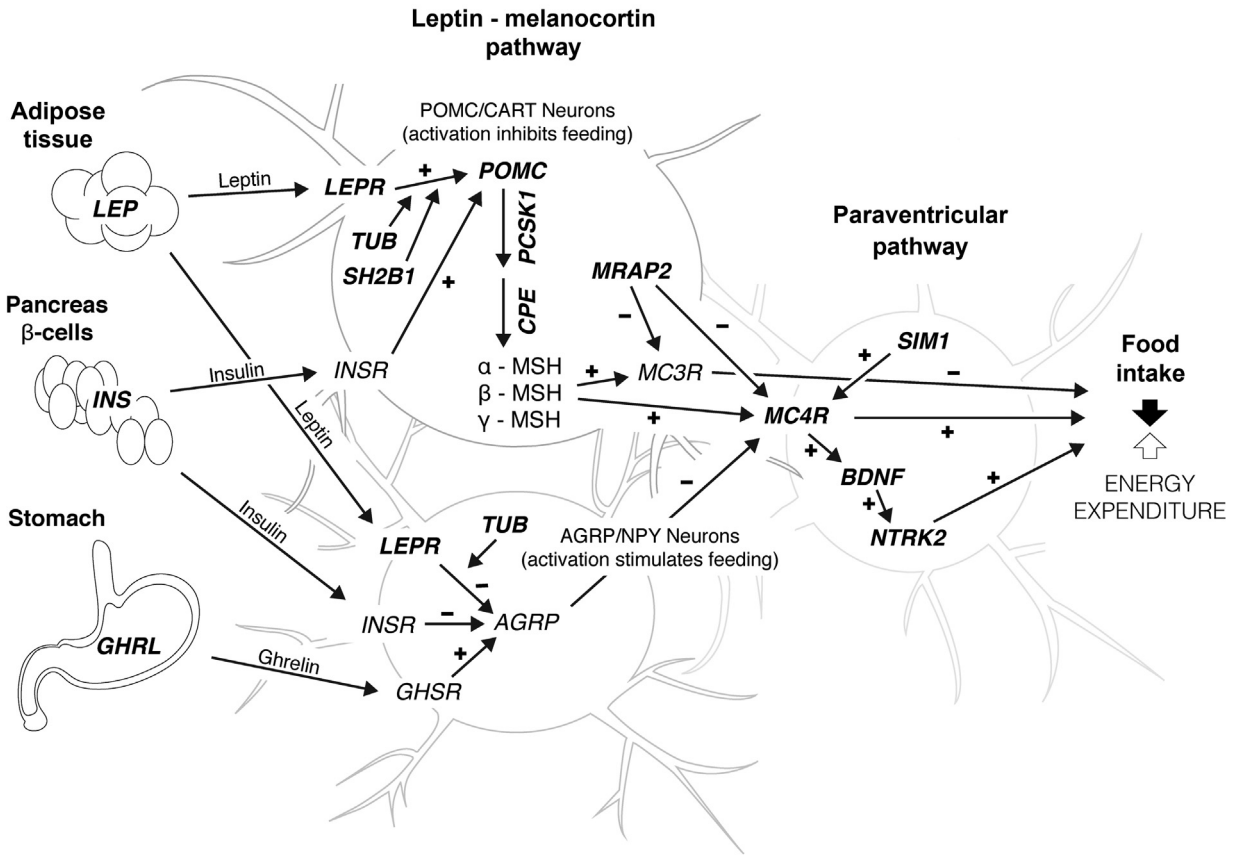

FIGURE 21.2 Simplified schematic of the genes involved in the leptin-melanocortin and paraventricular pathways in the hypothalamus. Mutations of genes in bold are known to cause monogenic obesity in humans. These pathways are essential components of the central control of energy homeostasis, propagating the signals that result in satiety and increased energy intake. Leptin is secreted from adipocytes, crosses the blood–brain barrier and activates leptin receptors. This activation, mediated by tubby bipartite transcription factor, stimulates POMC/CART neurons producing melanocortins that activate melanocortin 4 receptors in the paraventricular and ventromedial nuclei, resulting in satiety. *SIM1* is essential for development of the paraventricular nucleus. Brain-derived neurotrophic factor and its receptor, neurotrophic tyrosine kinase receptor, type 2, are part of the MC4R cascade leading to satiety. When stimulated by ghrelin receptors in the arcuate nucleus, agouti-related protein inhibits MC4R activity. AgRP, agouti-related protein; BDNF, brain-derived neurotrophic factor; CART, cocaine- and amphetamine-related transcript; CPE, carboxypeptidase E; GHSR, ghrelin receptor; INSR, insulin receptor; LEP, leptin; LEPR, leptin receptor; MC3R, melanocortin 3 receptor; MC4R, melanocortin 4 receptor; MRAP2, melanocortin 2 receptor assembly protein 2; α-MSH, α-melanocyte-stimulating hormone; β-MSH, β-melanocyte stimulating hormone; NPY, neuropeptide Y; NTRK2, neurotrophic tyrosine kinase receptor, type 2; PCSK1, proprotein convertase subtilisin/kexin-type 1; POMC, proopiomelanocortin; SIM1, single-minded homolog 1 of *Drosophila*. *Figure illustration by Venus Nguyen.*

glucose, and hypogonadotropic hypogonadism. The proband's symptoms closely match those of Cpe^{fat} mice.

To date, mutations in 12 genes, all components of the leptin-melanocortin or paraventricular pathways, have been reliably shown to cause spontaneous Mendelian increased BMI in humans; leptin (*LEP*), leptin receptor (*LEPR*), tubby bipartite transcription factor (*TUB*), SH2B adapter protein 1 (*SHR2B1*), proopiomelanocortin (*POMC*), proprotein convertase subtilisin/kexin type 1 (*PCSK1*), carboxypeptidase E (*CPE*), melanocortin 2 receptor assembly protein 2 (*MRAP2*), melanocortin 4 receptor (*MC4R*), brain-derived neurotrophic factor (*BDNF*), neurotrophic tyrosine kinase receptor type 2 (*NTRK2*), and single-minded homolog 1 (*SIM1*) (Table 21.3; Fig. 21.2). Mutations in these genes in humans are recessive, with the exception of *MC4R*, and therefore are rare, are associated with hyperphagia and severe obesity beginning in childhood, and may include developmental, endocrine, and behavioral disorders. (For a description of the most common single-gene obesity disorders and syndromes, see [132].)

Leptin (product of *LEP*) is secreted by adipocytes and its concentration in blood is proportional to fat mass. Leptin crosses the blood–brain barrier and activates leptin receptors (product of *LEPR*) on the surface of neurons in the arcuate nucleus of the hypothalamus. This activation, with the assist of the tubby bipartite transcription

factor (product of *TUB*) and SH2B adapter protein 1 (product of *SH3B1*), stimulates proprotein convertase (product of *PCSK1*) and carboxypeptidase E (product of *CPE*) to cleave proopiomelanocortin (product of *POMC*) into the melanocortins including α-MSH, the primary ligand for melanocortin receptors and activation of downstream signaling to regulate energy balance. (For reviews of the leptin-melanocortin pathway and downstream signaling in obesity see [6,133,134].) Activation of the agouti-related protein (AgRP)/neuropeptide Y (NPY) neurons in the hypothalamus stimulates feeding. Leptin binding inhibits the AgRP protein, thereby inhibiting feeding. Thus, leptin functions as an afferent signal in a negative feedback loop to maintain constancy of body fat stores.

Leptin acts through the leptin receptor, a single-transmembrane-domain receptor of the cytokine-receptor family [120]. The leptin receptor is found in many tissues in several alternatively spliced forms, raising the possibility that leptin affects many tissues in addition to the hypothalamus.

Leptin clearly has a broader physiological role than just the regulation of body fat stores. Leptin deficiency results in many of the abnormalities seen in starvation, including reduced body temperature, reduced activity, decreased immune function, and infertility. (For reviews of the physiological role of leptin see [135−137].) Leptin deficiency results in severe hyperphagia and early onset obesity. Replacement with human recombinant leptin in children with severe leptin deficiency normalizes food intake and body composition [136]. Studies of long-term replacement therapy in patients with congenital leptin deficiency show that leptin regulates many body functions including the endocrine system, energy balance, the adipoinsular axis, inflammation, and immunity [138].

Sequential cleavage of the precursor protein proopiomelanocortin (product of *POMC*) generates the melanocortin peptides adrenocorticotrophin (ACTH), the MSHs (α-, β- and δ-MSH), and the opioid-receptor ligand β-endorphin (for review see [139]). α-MSH plays a central role in the regulation of food intake by the activation of the brain melanocortin 4 receptor (product of *MC4R*). The dual role of α-MSH in regulating food intake and influencing hair pigmentation predicts that the phenotype associated with a defect in *POMC* function would include obesity, alteration in pigmentation (e.g., red hair and pale skin in Caucasians), and ACTH deficiency. The observations of these symptoms in two probands led to the identification of three separate mutations within their *POMC* genes [121]. Another *POMC* variant in a region encoding β-MSH results in severe early onset obesity, hyperphagia, and increased linear growth, a phenotype much like that seen with mutations in *MC4R* [140]. Heterozygosity for a *POMC* mutation having subtle effects on proopiomelanocortin expression and function was shown to influence susceptibility to obesity in a large family of Turkish origin [141].

A wide variety of hormones, enzymes, and receptors are initially synthesized as large inactive precursors. To release the active hormone, enzyme, or receptor, these precursors must undergo limited proteolysis by specific convertases. An example is the clipping of proopiomelanocortin by proprotein convertase subtilisin/kexin type 1, also known as prohormone convertase-1 (product of *PCSK1*). Mutations in *PCSK1* were found in individuals with extreme childhood obesity and elevated proinsulin and proopiomelanocortin concentrations but very low insulin levels (for review see [28]). Carboxypeptidase E (CPE) then removes a single basic amino acid from the C-terminus of many different hormones. For example, ACTH is produced from POMC by action of proteases, including PCSK1, then an intermediate product is produced by another protease, and finally α-MSH is produced when CPE removes a final C-terminal amino acid from this last intermediate. A recessive mutation of the gene producing carboxypeptidase E causes obesity in the Cpe^{fat} mouse. Since the human cases and the Cpe^{fat} mouse share similar phenotypes, it can be inferred that molecular defects in prohormone conversion represent a generic mechanism for obesity.

Several melanocortin receptors are highly expressed in the hypothalamus. Mutations in *MC4R* are found in various ethnic groups and cause the most common form of monogenic obesity in humans. The global presence of obesity-specific *MC4R* mutations is estimated to vary from 2% to 7% among population groups [139,142]. *MC4R*-linked obesity in humans is dominantly inherited with incomplete penetrance. Homozygotes have been observed in consanguineous families and have more severe phenotypes than heterozygotes. Subjects with *MC4R* deficiency are obese from an early age. Adrenal function is not impaired but severe hyperinsulinemia is present in the *MC4R*-deficient subjects. Sexual development and fertility are normal. Affected subjects are hyperphagic and have increased linear growth, similar to what occurs in heterozygous *Mc4r*-deficient mice. *MC4R*-deficient humans also have increased lean mass and bone mineral density and mild central hypothyroidism. Female haploinsufficiency carriers who have only a single functioning copy of *MC4R* are heavier then male carriers in their families, a pattern also seen in *Mc4r*-deficient mice. These data are strong evidence for dominantly inherited obesity, not associated with infertility, due to haploinsufficiency mutations in *MC4R*.

MC3R, while not known to cause single-gene obesity, acts as an autoreceptor indicating the tight regulation of the melanocortin system in energy balance. MC3R modifies energy balance by decreasing feed efficiency. Mutations in *MC3R* are not as common as in *MC4R* and

do not result in an autosomal dominant form of obesity, but may be important contributors to susceptibility to obesity. Two variants of the *MC3R* gene interacted with diet to affect weight loss success in an Italian clinic treating severe childhood obesity [143].

B The Paraventricular Pathway

Three genes important in downstream signaling of the melanocortin system have also been shown to cause single-gene obesities. Single-minded homolog 1, product of *SIM1*, is a regulator of neurogenesis and is essential to the development of the paraventricular nucleus of the hypothalamus [126]. Brain-derived neurotrophic factor, product of *BDNF*, and its receptor, neurotrophic tyrosine kinase receptor type 2, product of *NTRK2*, are involved in signaling in the ventromedial nucleus of the hypothalamus and contribute to memory and learning [125]. *BDNF*-deficient rodents are hyperphagic and obese. Case reports associate mutation in *BDNF* or *NTRK2* with massive obesity and impaired cognitive function [124].

C Genetic Pathways Involved in Common Obesity

Locke et al. [38], using data from all loci significantly associated with BMI in the GIANT Consortium GWAS meta-analysis, examined the data using pathway analysis. Biochemical analysis identified several gene sets with significant enrichment; neurotrophin signaling, general growth and patterning, basal cell carcinoma, acute myeloid leukemia, and hedgehog signaling. Pathway analysis showed that genes expressed in the nervous system were particularly enriched in the BMI GWAS, with genes expressed in the immune and hemic systems second most abundant. Genes for monogenic obesity, hypothalamic function, and energy homeostasis were frequently observed. Pathway analysis provided "strong support for a role of the central nervous system in obesity susceptibility and implicated new genes and pathways, including those related to synaptic function, glutamine signaling, insulin secretion/action, energy metabolism, lipid biology and adipogenesis" [38].

D Genetic Pathways Involved in Body Fat Distribution

Fewer studies have looked at body fat distribution by GWAS and, except for the GIANT study, sample sizes have been limiting. However, the GIANT consortium data showed that there was little or no overlap between genes associated with BMI and genes associated with WHR.

Pathway analysis also demonstrated that most WHR genes are expressed primarily in adipocytes and adipose tissue. Lack of evidence for association with brown adipose tissue and other adipose depots is likely due to absence of data for these traits. Using predefined gene sets Shungin et al. [55] observed enrichment for vascular endothelial growth factor (*VEGF*), phosphatase and tensin homolog (*PTEN*), insulin receptor (*INSR*), and peroxisome proliferator activated receptors (*PPAR*s). PPARs regulate expression of genes involved in, among other things, adipocyte differentiation, lipid metabolism, and energy balance. Pathway analysis implicated adipogenesis, angiogenesis, transcriptional regulation, and insulin resistance as processes affecting fat distribution. Of note, there was no overlap of these pathways with those identified for BMI.

VII CLINICAL IMPLICATIONS OF THE DISCOVERY OF OBESITY GENES

A Identification of Monogenic Causes of Obesity

Until recently, only the rare Mendelian syndromes, such as Prader–Willi and Bardet–Biedl, were known to cause heritable obesity. These disorders are easily recognized, both by a wide spectrum of phenotypes [132,144] and by the use of cytogenetics assays that are widely available. However, the Mendelian, nonsyndromic obesity disorders are not so easily diagnosed, because obesity is often the only apparent phenotype and clinical assays for known obesity gene mutations are rarely practical. It is estimated that 2–7% of morbidly obese patients have mutations in *MC4R* [122,123,145,146] and an unknown, but smaller, percent have mutations in other obesity genes, including *POMC* [147] and *NTRK2* [125]. Thus, only about 1 in 10 morbidly obese patient has a known mutation that explains the obesity, and molecular assays for the currently known Mendelian obesities would be negative in the majority of morbidly obese patients. Also, there are many known distinct mutations in each of these genes. Thus, no clinical laboratories yet provide diagnosis of these mutations, rather they have only been diagnosed by research laboratories. However, inability to make specific molecular diagnosis does not mean that one cannot identify people with increased risk for genetic obesity, and this may influence choices or approaches to treatment.

Several criteria can be used to estimate the probability that an individual's obesity has a genetic cause (Table 21.4). At the present time, due to the lack of data, these estimates do not produce any quantitative values revealing individual risk that obesity is monogenic, but rather just generic classification, such as likely genetic, uncertain, and likely not genetic.

TABLE 21.4 Suggestions to Evaluate Suspected Monogenic Etiology of Severe Obesity[a,b]

Phenotype	Phenotype Indicative of Genetic Etiology
Characteristic of All Genetic Obesities	
Family history	Having first-degree relatives with severe obesity
Age of onset	Normal birth weight but age of onset of obesity before age 10
Hyperphagia	Hyperphagia developing within first year of life
	Aggressive food-seeking behavior
Phenotype Associated with Specific Gene Mutation	
Very low leptin levels	Mutation in *LEP*
Hypogonadism, delayed puberty, lack of growth spurt	Mutation in *LEP* or *LEPR* or *PCSK1*
Disproportionate insulin resistance	Mutation in *SH2B1*
Developmental delay	Mutation in *SH2B1* or *SIM1*
Low ACTH or high proinsulin levels	Mutation in *POMC* or *PCSK1*
Frequent infections	Mutation in *POMC* (ACTH), *LEP* or *LEPR*
Defective prohormone processing	Mutation in *CPE* or *PCSK1*
Red hair segregating with obesity	Mutation in *POMC*
Severe hyperinsulinemia, acanthosis nigricans	Mutation in *MC4R*
Accelerated linear growth, increased bone mass	Mutation in *MC4R*
Delayed language skills, impaired short-term memory	Mutation in *NTRK2* or *BDNF*

[a]*Data adapted from ([169,170,155,161], [172], [171,128,132,148]).*
[b]*For a complete algorithm for the assessment of a severely obese individual, see [132].*
BDNF, brain-derived neurotrophic factor; *LEP*, leptin; *LEPR*, leptin receptor; *SH2B1*, SH2B adapter protein 1; *SIM1*, single-minded homolog 1; *MC4R*, melanocortin 4 receptor; *NTRK2*, neurotrophic tyrosine kinase receptor, type 2; *PCSK1*, proprotein convertase subtilisin/kexin-type 1; *CPE*, carboxypeptidase E; *POMC*, proopiomelanocortin.

Factors indicating a genetic basis for obesity are: (1) a family history of obesity is consistent with the presence of an obesity gene shared among family members; (2) early age of onset and extreme obesity indicate a genetic basis for obesity; and (3) children with single-gene obesity are normal weight at birth but severe early hyperphagia, often associated with aggressive food-seeking behavior, results in rapid weight gain, usually beginning in the first year of life. Severe obesity in children has been variously defined as a standard deviation score for BMI of more than 2.5 [148] or 3 [128] relative to the appropriate reference population. Extreme trait values are more likely to be genetic for many complex diseases, simply because extremes tend to result from the actions of severe mutations or from mutations in genes that have larger effects [149].

At present, a few diagnostic tools are available for the medical evaluation of patients suspected of having monogenic obesity. The only screening tests available are for those mutations that cause endocrine abnormalities. Serum leptin should be measured. Very low or very high serum leptin levels will indicate mutation in *LEP* or *LEPR*, respectively. However, lack of very high leptin levels cannot rule out homozygous mutations in *LEPR* [128]. A subset of obese individuals has inappropriately low leptin levels for their fat mass, suggesting a less severe defect in leptin regulation [150]. ACTH and proinsulin should be measured to indicate defects in *POMC* or in prohormone processing. Insulin should be measured to evaluate the appropriateness of the degree of hyperinsulinemia as this may indicate an *MC4R* mutation.

Physical appearance provides evidence of *POMC* mutations or the syndromic obesities. *POMC* defects can cause red hair and obesity [121], although most red hair results from mutations in melanocortin 1 receptor (*MC1R*) [151], which does not influence obesity. Thus, red hair is only informative when red hair, ACTH deficiency, and obesity cosegregate within a family.

Prader–Willi, Bardet–Biedl, and other syndromic obesities can be diagnosed by a variety of characteristic

phenotypes, such as small hands and feet, polydactyly, and mental retardation as well as by cytogenetic assays. Thus, one should rule out these diagnoses by phenotype determination and by absence of characteristic chromosomal abnormalities.

B Personalized Treatment Based on Genotype

At present the impact of genetics on diet effectiveness has been the subject of many papers, but all current studies have severe limitations. First, there are some large longitudinal or cohort studies that have reported statistically significant diet−genotype interactions. However, diet-based correlations have yet to provide evidence that stands the test of time. For example, correlations formed the basis for advice to avoid cholesterol and saturated fat, which have rarely been supported by randomized controlled trials. Second, all current randomized controlled trials are underpowered for genetics and thus find no or few significant results. Third, the underlying diet studies test too few diets for too short a time. Not even one large, well-powered study has examined diet−genotype interactions for diets that range from ketogenic to low carbohydrate or the typical U.S. diet to extreme low fat and vegan. Many basic questions are thus unanswered. For instance, does each person have one ideal diet for weight management or many possible equally healthy diets?

Matching diets to genotype is a goal for personalized medicine. Goals of personalized medicine are sometimes called P4; predictive, preventative, personalized, and participatory. The ability to calculate GRS is now well established but surprisingly, GRS may not predict weight gain or loss. Other components of P4 are not as advanced. Diet predictions based on questionnaire are flawed because diet questionnaires are unreliable. If people are resistant to trying new diets on their own, will they also resist when some professional or expert says "your obesity GRS means that you should be eating…?" One recent study reported that subjects told that they have higher genetic risk alleles of *FTO* had enhanced readiness to control weight but the knowledge of *FTO* status had no impact on behavior [152].

A 2016 NIH Working Group Report [153] on using genomic information to guide weight management pointed out that technologies are available for the fast characterization of the transcriptome, proteome, epigenome, and metabolome of an individual. But effective algorithms are yet to be developed to combine these data with classical medical and behavioral measures of the individual to personalize weight loss recommendations in the clinical setting.

Despite the ability to generate overwhelming amounts of genetic and other data for people, P4 recommendations for diet cannot be implemented. It is not known which of the many natural variants detected matter, nor do the diet studies needed to evaluate variants for causal effects on diet−genotype interactions exist. Thus, for a long foreseeable future, individuals will need to determine optimal diets by personally testing several different diets. The first step toward generalized discovery of personalized diets will require large highly powered randomized diet studies testing a full range of diets.

Chapter 22

Obesity: Overview of Medical Treatments and Interventions

Kenya D. Palmer and Caroline M. Apovian
Boston University School of Medicine, Boston, MA, United States

I INTRODUCTION

Obesity has reached pandemic proportion, despite efforts to reduce obesity since 2000 [1]. In the United States, almost 70% of the adult population is either overweight or obese, 35% of which are obese [2]. As of 2014, 1.9 billion adults are overweight, including more than 600 million adults who are obese; and 42 million children (<5 years old) [3]. Adult women are more effected by obesity than men; and minorities (black and Hispanic) more than whites [1]. Hispanic men are more likely to be overweight (80%) and obese (38%) than any other racial demographic, and non-Hispanic black women are more likely to be overweight (82%) and obese (58%) [4]. It is believed that with the current rate of growth, obesity will continue to increase to greater than 50% of the adult population [5].

Obesity is associated with several comorbid conditions, including type 2 diabetes mellitus (T2DM), dyslipidemia, hypertension (HTN), cardiovascular disease (CVD), stroke, gallbladder disease, obstructive sleep apnea (OSA), cancer, and osteoarthritis; as well as increased risk for all-cause and CVD mortality [6]. Considering the comorbid conditions associated with obesity it is not unimaginable that obesity would also be a costly disease. Although the economic burden of obesity is difficult to assess, given the comorbid conditions such as T2DM, it is possible that it costs the United States over $200 billion annually [7]. Given the health and financial consequences, obesity should be and is now considered a disease by the American Medical Association (AMA) [8].

Obesity is a chronic disease affecting adults and children of every race, socioeconomic and educational category. Every day those with obesity struggle to lose and maintain weight loss [9]. Given the comorbid diseases and potential complications, it is important for the health care provider (HCP) to understand how to approach and treat these patients successfully. Thus, the purpose of this chapter is to provide an overview of the clinical interventions available for the treatment of obesity. We will begin by taking the reader through the clinical assessment of the patients who are overweight and obese and evaluation of health risk.

II ASSESSMENT OF OVERWEIGHT AND OBESITY

The U.S. Preventative Services Task Force recommends screening all adults over the age of 18 years old for obesity [10]. The first guidelines for the management of obesity were developed in 1998 by the National Heart, Lung, and Blood Institute (NHLBI). Since 2010, several organizations have reevaluated how the adult with obesity is assessed clinically. In 2013 the American Heart Association (AHA), American College of Cardiologists (ACC) and The Obesity Society (TOS) gathered to update the NHLBI guidelines creating the "Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: The Evidence Report" for the management of adults with overweight and obesity [6]. Additionally, the American Association of Clinical Endocrinologist and the American College of Endocrinologists collaborated, developing the "Complications Centric Model for Care of the Obese Patient" [11]. Finally, in 2015, the Endocrine Society released clinical practice guidelines

TABLE 22.1 BMI, WC, and Cardiometabolic Disease Risk

BMI Classification			Cardiometabolic Disease Risk[a] (Relative to Normal Weight and WC[b])	
	BMI (kg/m^2)	Obesity class	Men (<102 cm)	Men (>102 cm)
			Women (<88 cm)	Women (>88 cm)
Underweight	<18	–	–	–
Normal weight	18–24.9	–	–	–
Overweight	25–29.9	–	–	High
Obesity	30–34.9	Obesity, Class I	High	Very high
Obesity	35–39.9	Obesity, Class II	Very high	Very high
Extreme obesity	>40	Obesity, Class III	Extremely high	Extremely high

[a]*Disease risk for developing T2DM, HTN, and CVD.*
[b]*Elevated WC also denotes increased risk, even in normal weight individuals.*
Source: M.D. Jensen, et al., 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and The Obesity Society, Circulation 129 (2014) S102–S138.

outlining the clinical approach to the assessment of patients with obesity [12].

The guidelines, regardless of the organization, call for the HCP to begin assessing patients based on their body mass index (BMI) and waist circumference (WC). Further assessment involves determining patients' actual, or risk for comorbid, condition. Treatment recommendations are based on the compilation of the aforementioned characteristics of the patient.

A Clinical Assessment of Body Fat

Obesity is not just excess weight, but an excess of body fat. Historically, obesity was defined according to the Metropolitan Life Insurance Company "ideal body weight" tables based on mortality data [13]. Given the controversy surrounding the utilization of obesity measures based on nongeneralizable data, new assessment tools were determined [14].

1 BMI and WC

Prior to 1985, the Metropolitan Life Insurance Company height–weight tables were used to identify health hazard based on ideal weight [15]. BMI, a closer estimation of body fat, has since replaced these ideal height–weight tables. Overweight is defined as a BMI 25–29.9 kg/m^2; and obesity as a BMI greater than 30 kg/m^2, which is further stratified into classes (Class I BMI 30–34.9 kg/m^2; Class II BMI 35–39.9 kg/m^2; Class III or extreme obesity: BMI greater than 40 kg/m^2) [6].

This measure and WC are recognized as the most convenient and expedient ways to identify body fat, morbidity, and mortality both in population-based research and the clinical setting. We know there is increased health risk associated with increased BMI (Table 22.1). Berrington de Gonzalez et al. [16] reported that in nonsmoking men and women, there is an increase in all-cause mortality with each 5 kg/m^2 increase in BMI; specifically, 30% in women (overweight, hazard ratio (HR) 1.13; obesity Class I, HR 1.44, CI 95%; obesity Class II, HR 1.88, CI 95%; obesity, Class III, HR 2.51, CI 95%). Similar risk increases were seen in men, however, the increase was greater than 30% for obesity classes II and III [16]. WC assesses risk for cardiometabolic disease in individuals with BMI 25–34.9 kg/m^2 [6]. It is assumed that in those with BMI greater than 35 kg/m^2 WC will likely be greater than 88 cm in women or 102 cm in men; and thus adds very little to the assessment of cardiometabolic risk.

Unfortunately, there are some variations in BMI and WC that make utilizing these measurements alone, inadequate [15]. When defining obesity according to percentage of body fat, %bf (25% in men, 30% in women), BMI often underestimates %bf in those with a BMI under 30 kg/m^2 [17] and may overemphasize body fat in women and minorities, making BMI most appropriate when gender and race of the individual is not considered [18]. Because of the greater prevalence of obesity among minorities, it is important that these discrepancies are not ignored.

Sharma and Kushner [15] suggest taking into consideration other individual attributes in addition to BMI and WC to guide clinical judgment for the treatment of obesity. The Edmonton Obesity Staging System (EOSS) (Table 22.2), an ordinal classification system, which

TABLE 22.2 Edmonton Obesity Staging System

Edmonton Obesity Staging System			
Stage	**Medical**	**Mental**	**Functional**
0	Absent	Absent	Absent
1	Preclinical/risk factors	Mild	Mild
2	Comorbidity	Moderate	Moderate
3	End organ damage	Severe	Severe
4	End stage	End stage	End stage

Source: Adapted from J.L. Kuk, C.I. Ardern, T.S. Church, A.M. Shamra, R. Padwal, X. Sui, S.N. Blair, Edmonton Obesity Staging System: association with weight history and mortality risk, Appl. Physiol. Nutr. Metab. 36 (2011) 570–576.

assesses comorbidity, functionality, and quality of life [15] in an effort to predetermine mortality [19], is a valuable adjunct to BMI and WC [19,20]. As the prevalence of obesity continues to grow, it is important that the HCP has a reliable way of assessing risk in this population. Although BMI and WC are widely accepted in the clinical setting, it is important to consider such tools as the EOSS when determining overall morbidity and mortality in the obese patient given the comorbidity.

B Assessment of Comorbid Conditions and Risk Factors

Obesity is a disease of excess fat. The fat cell, adipocyte, is a dysfunctional proinflammatory endocrine cell which leads to the cardiometabolic diseases associated with obesity. Even before obesity was recognized as a disease by the AMA, there was a known link between obesity and other diseases leading to a weight loss goal which is now increasingly relevant to the long-term survival of our population. The following is not a comprehensive review of all known comorbid conditions and risk factors associated with obesity, but some of the more common.

1 Cardiometabolic Disease Risk

a Type 2 Diabetes Mellitus

T2DM, characterized by hyperglycemia, insulin resistance, and/or impaired insulin sensitivity, affects over 300 million people worldwide and possibly 12–14% of adults in the United States [21]. T2DM may have the greatest association to obesity when compared to any other cardiometabolic disease [22]. The Nurses' Health Study and the National Health and Nutrition Examination Survey III (NHANES III) have provided a great deal of information regarding the relationship between T2DM and obesity. As BMI increases $>35\ kg/m^2$, the relative risk for T2DM increases significantly. This increased risk is closely related to the increase in visceral fat, as measured by WC [23].

Like obesity, T2DM is more prevalent among minorities (15.9% American Indian/Alaskan; 13.2% non-Hispanic blacks; 12.8% Hispanics) than non-Hispanic whites (7.6%) [24,25]. Over the past 20 years, both have increased in prevalence. Data collected from the Behavioral Risk Factor Surveillance System shows the rise in obesity and T2DM paralleled each other from 1990 to 2000, both increasing by almost 50% [22]. As HCP we know that diabetes, especially when uncontrolled, leads to poor long-term health outcomes. Given the relationship between the two, it is important that the HCPs (1) recognize this relationship and (2) provide the appropriate counseling to help patients lose weight and decrease their risk for developing diabetes.

b Hypertension

HTN, defined as a systolic blood pressure (SBP) greater than 140 and/or a diastolic blood pressure (DBP) greater than 90 is related to increased and elevated BMI. HTN is also most prevalent among minorities, specifically non-Hispanic blacks (42.4% men, 44% women) [26]. It is well-known that an increase in body weight is associated with increased HTN and other factors associated with heart disease [27]. Specifically, HTN is associated with weight at adulthood, weight gain throughout adulthood and obesity [28]. The rise in HTN risk as it is associated to weight gain is dose-dependent. This means the greater the weight gain, the greater risk (hazard ratio, 2.52; CI 95%), specifically among men [29]. Just as weight gain negatively affects BP, weight loss positively affects BP. We also know that weight loss is associated with decreased risk for HTN [28]. Weight loss can improve BP, which has been supported by countless studies on weight loss including pharmacotherapeutic randomized control trials. Losing as little as 5 kg can reduce both SBP and DBP, in a dose-dependent fashion [30].

c Cardiovascular Disease

BMI is strongly associated with risk factors such as T2DM, HTN, and dyslipidemia thereby increasing the risk of CVD [4,31]. CVD, including coronary heart disease (CHD) and stroke, poses great health risks for the patient with obesity, and is often complicated by T2DM, HTN, and dyslipidemia. The obese population will likely experience more T2DM (18.5%), HTN (35.7%), and dyslipidemia (49.7%) than their overweight or normal weight cohorts, according to NHANES data [4]. Obesity is a significant independent long-term predictor of CVD and weight gain after adulthood is associated with increased risk regardless of comorbid risk factors such as smoking

[32]. Long-term (26 years) data from the Framingham Heart Study revealed that a 10% increase in weight could increase the risk of developing CVD by 80% in men and 90% in women [32].

Obesity and CVD go hand in hand and there is increased mortality in those who live with both diseases. In discussing the relationship between these two diseases, it is important to mention the "obesity paradox" discussed by [33], as this may create some confusion in how to treat obesity in the presence of CVD. There is international research (Israeli) which has shown those with normal BMI and CHD/CVD are at greater risk for mortality than the mildly obese (BMI 30−35 kg/m^2) whereas those with moderate obesity (BMI >35 kg/m^2) have the expected increased mortality rate. Despite these unexpected findings, one should not forget that both T2DM and HTN risk increase with increased BMI thereby increasing risk of CVD; thus the HCP should not undervalue the benefits of weight loss [33]. As HCP we must appreciate the compounding effects of obesity when CHD, HTN, and T2DM are present. Data from the Framingham Heart Study revealing the relationship between BMI, HTN, and development of T2DM over 30 years leads us to understand the importance of early recognition of obesity and these comorbid conditions [34] and thus early treatment.

2 *Noncardiometabolic Disease Risk*

a Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is hepatic steatosis without cause of secondary hepatic accumulation of fat, further defined based on presence of hepatocellular injury with or without fibrosis or inflammation, which may ultimately lead to cirrhosis [35,36]. Just as population increases in obesity were noted, so have there been increases in the prevalence of NAFLD. From 1998 to 2008, the prevalence of NAFLD doubled (5.5−11%, respectively) [37]. Similar to obesity, NAFLD is most common among minorities, specifically Hispanics (45%) [38].

This hepatic metabolic disease, associated with insulin resistance, is most commonly seen in patients with diabetes and obesity; and may have a 100% prevalence in patients with Class III obesity [36]. Because of its relationship with increased insulin resistance, potentially atherosclerosis, and obesity, NAFLD is yet another weight-related comorbidity the HCP should be aware of when caring for the patient with obesity [22]. Weight loss is recommended as first line treatment for NAFLD by The American Association for the Study of Liver Diseases, the American College of Gastroenterology, and the American Gastroenterology Association [39]. In addition to improvements in liver enzymes alanine aminotransferase and aminotransferase with 4% weight loss [40], evidence suggests 75% remission of NAFLD with 5% weight loss [41].

b Obstructive Sleep Apnea

OSA is a syndrome characterized by repetitive episodes of upper airway obstruction occurring during sleeping hours. Obesity is the primary risk factor for OSA and more than 30% of the obese population has OSA, the majority of which have Class III obesity [42−44]. Although the relationship between OSA and obesity is recognized, causation is unknown. It is possible that obesity causes OSA, but it may be that OSA leads to obesity in some, as we know sleep deprivation is associated with weight gain [45,46]. An increase in weight of >10 kg also increases the risk of increasing severity of OSA, whereas weight loss reduces OSA severity [47].

c Polycystic Ovarian Syndrome

Polycystic ovarian syndrome (PCOS) is an endocrine disorder of reproductive health common among women of childbearing age, associated with chronic anovulation, infertility, and hyperandrogenism. Not only are these women suffering from reproductive abnormality, but they also have increased risk of several cardiometabolic diseases and often have obesity [11,48,49]. A meta-analysis of research evaluating the effects of obesity on PCOS showed that there was an insignificantly higher risk for impaired glucose and T2DM among women with overweight; however, women with obesity were significantly more likely to experience these metabolic changes associated with PCOS [49]. The reproductive differences (decreased sex hormone-binding globulin, increased total testosterone, free androgen index) excluding hirsutism are all exacerbated by obesity, whereas those women with overweight are not as affected [49].

Although the effects of lifestyle modification (discussed later in this chapter) on reproductive health are uncertain, lifestyle modification does improve cardiometabolic profile (fasting blood glucose, fasting blood insulin, decreased BMI) in women with PCOS [48,50]. There is some literature which points to improved reproductive outcomes with lifestyle modification for weight loss in the woman with obesity and PCOS [50−52]. The relationship between obesity, PCOS, and reproductive outcomes are important as the woman of reproductive age planning to conceive represents an opportunity for the HCP to positively affect two generations.

C Assessment of Readiness and Goal Setting

The weight loss process is physically, mentally, and emotionally demanding for most. In order to appropriately advocate for, educate, and treat the patient with

overweight or obesity HCPs must be able to assess the patients' stage of change and utilize motivational interviewing (MI) techniques to then evoke change within the patient.

1 The Transtheoretical Model of Behavior Change

According to Prochaska et al. [53], "any activity that you initiate to help modify your thinking, feelings or behavior is a change process" (p. 25). The transtheoretical model (TTM) of behavior change was initially utilized in psychotherapy to treat addictive behaviors by treating behavior change in a nonlinear, dynamic fashion [54]. The stages of change include precontemplation (no intention of changing), contemplation (thinking about change within the next 6 months), preparation (beginning to consider change more strongly, perhaps in the next 30 days), action (implementation of the behavior has occurred for the past 30 days), maintenance (behavior change has occurred for 6 months or longer), and termination [53] (Table 22.3). There are some that believe termination never occurs as the patient will always think about and/or struggle to be consistent with their new behaviors and thus, maintenance is often considered the final stage. Regardless, the patient attempting to change various behaviors in an effort to lose weight will "spiral" through these stages, and it is our job as HCPs to recognize where they are in this process in an effort to guide them into the next stage.

2 Motivational Interviewing

Obesity, like the cardiometabolic diseases associated, is a health condition amenable to the effects of healthy diet and regular exercise [55]. Discussing weight and need for weight loss with patients is difficult. Understanding obesity as a disease can potentially make this a less threatening topic for the HCP. MI, although time consuming, can be a useful skill to have when attempting to evoke change in patients, especially considering the intensity of change needed for weight loss and maintenance. It allows for constructive communication regarding the reduction of health risks and changing behavior. When talking with patients about their obesity, it should be discussed as a disease and related to any risk for or presence of comorbid conditions. MI allows the HCP to meet the patient where she or he is by identifying and discussing the difference between their current behaviors and their desired goals. When utilizing this form of communication with patients you want to discuss those discrepancies such that the patient begins to talk about the changes they want and need to make. This is done by establishing rapport with the patient and utilizing open-ended questions, and affirmation, reflection, and summarization of what the patient is saying [56].

TABLE 22.3 Stage of Change

Matching Interventions with Stage of Change	
Precontemplations	Provide knowledge, discuss pros and cons of change
Contemplation	There may be a balance between pros and cons, utilize MI
Preparation	Pros begin to outweigh the cons. Continue utilizing MI techniques.
Action	The pros outweigh the cons allowing the patient to actively begin to change.
Maintenance	Patient continues new behavior. Consistent work to avoid relapse.

3 Goal Setting and Clinically Meaningful Weight Loss

Understanding the TTM and utilizing MI skills gives the HCP a great advantage in coming to the aid of patients with obesity who are ready to make the changes necessary to promote weight loss. When caring for the patient with obesity, goal setting can be difficult. Many times patients are either unrealistic about the amount of weight they should lose, or often times the amount of time it should take to achieve such goals. Regardless, goal setting is imperative given it will direct your care plan. For example, a patient who wants to lose over 50% of their excess weight may be best served by referral to a surgical weight loss process. However, a patient determined to lose only 10% of their excess weight will likely be successful with lifestyle modification with or without the additional of antiobesity medications.

As the HCP and patient discuss weight loss goals, it is important to recognize and discuss the benefits of modest weight loss. Research has consistently revealed the clinical significance of modest weight loss of 5–10%. In fact, as little as 2% weight loss has shown to improve hemoglobinA1c (HgbA1c) [57,58]. Increasing weight loss from 2% to 5–10% can delay the progression from prediabetes (PreDM) to T2DM by 50% [58,59]. Decreases in SBP and DBP [58,60], total cholesterol and triglycerides, as well as increased high-density lipoprotein (HDLs) have also been noted with a modest weight loss of 5–10% [58,61].

Not only are there improvements in cardiometabolic risk factors and disease with modest weight loss, there are also improvements in biomechanical ailment and mental illness associated with obesity. The patient with obesity

may experience lower back pain, lower extremity arthralgia, gastroesophageal reflux disease, and mood disorders [62], symptoms which may improve with clinically significant and modest weight loss of 5−10%.

Once the appropriate stage of change is identified and the patient reports increasing motivation, a goal of 5−10% weight loss should be set. Additionally, lifestyle modification goals should be included. Goals should be SMART—specific, measurable, achievable, relevant/realistic, and time-based.

III SELECTING TREATMENT OPTIONS

According to the guidelines set forth by the AHA/ACC/TOS, obesity treatment should be based on patient BMI and cardiometabolic risk [6] (Table 22.4). As the BMI and cardiometabolic profile of the patient increases, the intensity and invasiveness of the treatment also increases. Generally, each patient should begin with lifestyle change, ideally for 6 months prior to initiation of pharmacotherapy [6] with antiobesity medications. For those who have tried and failed lifestyle modification, FDA-approved antiobesity medications should be initiated. If a patient has tried and failed lifestyle modification as well as pharmacotherapy, surgery and some devices are viable interventions.

A Lifestyle Modification

Lifestyle modification requires changes in two aspects of daily life. Patients need to modify their diet and increase physical activity/exercise. Over the past 10 years, there have been two important studies on the effects of lifestyle management in the obese population, specifically related to T2DM.

The Diabetes Prevention Program (DPP) lifestyle program, aimed at a 7% weight loss and150 minutes of physical activity weekly, effectively reduced the incidence of T2DM by 58% [63]. This was a culturally sensitive individually delivered program, involving frequent contact between the 1079 participants and coaches/case managers. The program included a 16 session core curriculum targeting diet, activity, and behavioral self-management topics, supervised physical activity sessions, and follow up weight loss maintenance interventions, with access to local and national networks [63]. The DPP shows us the level of intensity needed to achieve and maintain clinically meaningful weight loss, at least in the PreDM population.

The Look AHEAD (Action for Health in Diabetes) was another randomized controlled clinical trial evaluating the effectiveness of intensive lifestyle interventions (ILIs). This study evaluated people with obesity and T2DM and examined the effects of weight loss and increased activity on cardiovascular morbidity and mortality [64]. Approximately 5000 patients were randomized to either the ILI or a diabetes support and education program. The ILI was a three-phase group and individual intervention. Phase I comprised of two 6-month periods (1 year total), Phase II extended over 2 years (years 2−4), and Phase III began at year 5 and extended to the end of the trial. Sessions were initially delivered weekly in a pattern of three group sessions and one individual session per month for the first 6 months; then two group sessions and one individual session per month for the second 6 months; and then monthly individual sessions with 4- to 6-week refresher groups and campaigns two to three times per year for the remainder of the intervention. Participants received calorie targets based on initial weight and a physical activity goal of 175 minutes weekly and 10,000 steps daily [64]. Those randomized to the lifestyle intervention were able to achieve clinically meaningful weight loss ($>5\%$) within the first year (68%) [65] and maintain that weight loss through 8 years (50%) [66]. The ILI utilized in the Look AHEAD trial demonstrated that long-term weight loss is achievable with ongoing follow up and monitoring [66] and that weight loss is more likely to be maintained if achieved within the first 2 months of the weight loss process [67].

1 Dietary Modification

In order for patients to lose weight, a caloric (energy) deficit must occur. An energy deficit can be created through

TABLE 22.4 Criteria for Treatment of Obesity Based on Guidelines (Based on BMI and Comorbid Conditions)

BMI	25−26.9 kg/m^2	27−29.9 kg/m^2	30−34.9 kg/m^2	35−40 kg/m^2	>40 kg/m^2
Diet, exercise, behavior therapy	X	X	X	X	X
Antiobesity medication		X (in the presence of comorbidity)	X	X	X
Surgery				X (in the presence of comorbidity)	X

diet alone, exercise alone, or a combination of the two. For many, creating energy deficit through caloric restriction is the first step taken. Dietary energy deficits can be created for most women, by decreasing the daily caloric intake to 1200−1500 kcal/day; and for men, with a daily caloric intake of 1500−1800 kcal/day. Reducing a patient's daily intake by 500 kcal/day will create a deficit of 3500 kcal/week, leading to approximately 1 pound of weight loss per week. In order for this particular approach to be successful, one must first estimate the patient's current caloric intake or weight maintenance caloric requirement [6].

a Ad Libitum

For those patients who find structuring their daily intake to allow for accurate calorie counting tedious and time consuming, an ad libitum diet may be more realistic [6]. The ad libitum diet achieves caloric deficit through (1) decreasing portion size, (2) decreasing or eliminating a certain macronutrient like carbohydrates, (3) decreasing or eliminating high caloric, nonnutritional foods like potato chips and candy, or (4) decreasing or eliminating consumption of calorie-rich beverages, such as soda and juices.

b Very Low Calorie Diets and Low Calorie Diets

Very low calorie diets (VLCDs) restrict daily caloric intake to $<$800 kcal/day, whereas LCDs restrict daily caloric intake to $<$1200−1500 kcal/day. Protein shakes and other meal replacement (MR) smoothies or bars are often used to achieve the VLCD caloric requirements.

Given the extremely low daily caloric intake associated with the VLCD, this diet requires almost a full liquid approach. Patients are often on 3−5 shakes daily, with multivitamin and mineral supplementation. Side effects include fatigue, hair loss, dizziness, and constipation; and risk for cholelithiasis secondary to rapid weight loss. The VLCD usually results in $>$20% weight loss within the first 3−4 months [68]. Although rapid weight loss is seen, it is not usually well maintained with many patients gaining up to 50% of that weight back within the subsequent 12 months; and gaining all of the weight back in less than 5 years [69]. LCDs are not as extreme and with almost twice as many calories allowed (1200−1500 kcal/day), the weight lost is modest.

c Protein Sparing Modified Fast

The protein sparing modified fast (PSMF) diet is a 12 to 16 week very low calorie ketogenic treatment diet. Patients are advised to consume high bioavailable protein ideally from animal sources, specifically 1.5 g of protein per kilogram of ideal body weight, based on BMI of 22 kg/m^2 for women and 23 kg/m^2 for men. The PSMF also eliminates all carbohydrates and extra fats. Due to the restrictive nature of this VLCD, the PSMF also requires patients take a multivitamin and supplementation with sodium chloride, potassium, magnesium, and calcium [70] as needed. HCPs can confidently inform their patients that expected weight loss ranges from 1 to 3 kg weekly [70]. When combined with an intensive behavior program, 50% excess weight loss can occur [71]. Based on the findings of Palgi et al. [71] it is reasonable to utilize this diet in the treatment of patients with obesity, especially those that would benefit from significant weight loss but would prefer to avoid surgical options.

d Meal Replacements

MR diets allow the patient to replace one to two meals daily with either a shake (usually high protein) or protein bar. Ideally these MRs are fortified with vitamins and minerals to replace what would be consumed in normal meals. According to Heymsfield et al. [72], the partial meal replacement (PMR) diet can be more effective than reduced calorie diets (RCD) for weight loss. Those adhering to a PMR diet lost 7−8% of their body weight compared to those on the RCD (3−7%). The weight lost by those on a PMR diet was significant at both 3 months and 1 year [72]. This diet may be most effective for patients who (1) are not interested in calorie counting, (2) have difficulty restricting their favorite foods and therefore don't do well on ad lib diets, and/or (3) have hectic schedules which don't allow for food preparation and require eating on the go.

e Macronutrient Composition

Macronutrient diets determine caloric intake based on the percentage or total grams of protein, carbohydrates, and fat intake. Such diets are usually referred to as low-fat/high-carbohydrate diets, low-carbohydrate/high-protein diets, or moderate fat diets. These diets may range from 15% to 25% protein, 20% to 40% fat, and 35% and 65% carbohydrates.

Countless studies have been executed to identify which diet is best. Sacks et al. [73] looked at the results of various macronutrient compositions over the course of 2 years. During this time research looked at the effects of low versus high percentages of each macronutrient on weight and health outcomes. Within the first 6 months participants in all diet groups had clinically significant weight loss regardless of diet composition with weight regain over the next 2 years [73]. When comparing commercial diets, it has been noted that modest weight loss and improvements in cardiometabolic profile can be expected [74].

Research on the best diet for weight loss and the best diet for reducing cardiometabolic morbidity and mortality

is ongoing. What we know at this point is that (1) most calorie restrictive diets will produce weight loss within the first 6 months after which some weight regain will occur, (2) improvements in cardiometabolic profile are also likely to accompany weight loss, and (3) adherence to the diet of choice markedly improves the aforementioned results. Adherence may not only improve initial results, but it may in fact be the factor which increases the possibility of long-term success [74,75].

2 Physical Activity Modification

Dietary interventions alone can account for significant weight loss but results can be amplified and maintained with physical activity and exercise. The American College of Sports Medicine (ACSM) provides recommendations for physical activity based on desired goals. According to ACSM 150 minutes/week of physical activity will maintain or improve health. Initial weight loss is achieved with 150−250 minutes/week, whereas weight maintenance requires almost twice as much exercise (200−300 minutes/week) [76,77]. These recommendations include moderate-to-vigorous physical activity expending 1200−2000 kcal/week [78] (240−500 kcal/day for 5 days/week).

As important as it is for HCP to recognize the value of recommending physical activity, it is equally important that we are able to discuss the detrimental effects of physical inactivity with our patients. Physical inactivity (or sedentary behaviors) are associated with several negative health outcomes including increased risk for T2DM and CVD as well as premature mortality [79−81]. Creating a comprehensive treatment plan for the patient with obesity that discusses physical activity and exercise is imperative, given its known health benefits and potential effect on long-term weight management. When making recommendations to patients, it is important to understand the difference between physical activity and exercise.

3 Physical Activity

Physical activity can be defined as any bodily movement produced by skeletal muscle, ultimately leading to energy expenditure. It differs from exercise as it lacks structure and is typically not associated with fitness goals [82,83]. Examples of physical activity include activities of daily living, yard work, house cleaning, walking for transportation, and taking the stairs instead of the elevator.

We now know that physical inactivity is detrimental to health whereas physical activity improves health. Also, it is widely accepted that physical activity is important in improving the majority of risk factors associated with CVD, such as T2DM, regardless of age. Lifestyle interventions which include a calorie restricted diet, exercise, and weight loss show >50% reduction in developing T2DM [84,85]. Thus, regardless of overall fitness goals, the patient with overweight and obesity should be instructed to increase their overall physical activity and perhaps work toward the well-known recommendation of 10,000 steps/day.

4 Exercise

Physical activity is important, but exercise has significant contributions to overall health as well. Exercise is defined by ACSM as physical activity involving repetitive bodily movements that is planned or structured, with the goal of improving physical fitness (cardio, strength, flexibility, etc.). It includes aerobic training, often referred to as cardiovascular or cardio for short; resistance training (RT), often referred to as strength training; and flexibility training (FT), often referred to as stretching. It is not just enough to exercise, but one must consider the frequency, intensity, time (duration), and type of exercise while working toward goals.

Frequency refers to the number of days per week. As most know, both the CDC and ACSM recommend physical activity/exercise on most days of the week, or 5 days. Intensity refers to the level of difficulty. In much of the research, intensity effort is defined as the percentage of maximal volume of oxygen consumed ($VO2_{max}$), percentage of heart rate, or rate of perceived exertion (RPE). Intensity may be the confounding factor in translating exercise research to patient care and practice. Intensity for many will not be determined by their heart rate or $VO2_{max}$, but by utilizing tools such as the talk test and RPE (Table 22.5). Time refers to how much time in minutes is spent exercising. Lastly type includes aerobic, resistance, and flexibility exercises; and should always be considered fun.

a Aerobic Training (or Endurance Training)

The ACSM defines moderate intensity physical activity as 40−60% and vigorous physical activity as 60−90% of maximal heart rate or heart rate reserve. Moderate aerobic/cardiovascular training should be completed 5 or more days/week, 30−60 minutes/day (150−300 minutes/week),

TABLE 22.5 Comparison of Exercise Intensity, Talk Test, and RPE

Intensity	Talk Test	RPE
Very light	You can talk and/or sing	<3
Light		3−4
Moderate	You can talk, but NOT sing	5−6
Vigorous/hard	Difficult to talk or CANNOT talk	7−9
Very hard max		>10

whereas vigorous (>3 days/week; 20–60 minutes/day or 75–100 minutes/week) and moderate-to-vigorous (3–5 days/week; 20–60 minutes/day or 75–300 minutes/week) aerobic training can be done at a lower volume. Examples of aerobic/cardiovascular training include dancing, running/jogging, swimming, jumping rope; or playing sports like soccer or basketball [82,83].

As HCPs we should confidently tell our patients that improving their cardiorespiratory fitness (CRF) levels through aerobic activity will improve their overall health, especially for men with obesity [86] by decreasing mortality risk.

b Resistance Training

Resistance/strength training should occur at least 2–3 days/week, focusing on each major muscle group. Each muscle group should be stressed over 8–20 repetitions, 1–4 times (sets) with 1–3 minutes of recovery (rest) between sets. In general RT should be progressive, meaning there is some increase in the aforementioned variables with improvements over time [82,83,87].

Some research has noted that the greatest effect of RT on weight loss and conservation of fat-free mass (FFM) occurs with progressive, periodized programs which should thus be recommended more often to the patient with obesity. One practical limitation is that HCPs without the knowledge of exercise prescription/programming do not know how to progress RT routines for individual patients. Perhaps recommendations and guidance on exercise can occur seamlessly when HCP and exercise specialists through ACSM, strength coaches through the National Strength and Conditioning Association (NSCA) and certified personal trainers through various organizations collaborate to create an appropriate periodized program for their patients with overweight and obesity.

c Flexibility Training

Unlike aerobic and RT, FT does not have the same structured guidelines. If flexibility is an issue, daily stretching is considered most effective; otherwise each muscle group should be stretched for 2–3 days/week for at least 10–60 seconds, for 2–4 sets. Stretches can be static (held in place) or dynamic (moving) and should never cause pain [82,83].

5 Exercise and Weight Loss (With or Without Diet)

Physical activity and exercise have been touted as ineffective as a monotherapy for the treatment of obesity. Weight loss through exercise may only yield 0.1 kg/week [88]. Although the initial weight loss may be insignificant clinically, it is important to recognize the benefits of various forms of exercise on body mass, body composition, and cardiometabolic profile.

Clark [87] reviewed 66 studies, and pooled them to compare four specific subgroups including diet-only (D) interventions, combination endurance training (ET) and diet (ET/D), combined RT and diet (RT/D), and the combination of diet, RT, and ET (ET/RT/D). This meta-analysis and systemic review found ET/D versus D, to be more effective at decreasing body mass whereas RT/D was found to be more effective at preserving FFM while decreasing fat mass when compared to D. RT was favored over ET as a means of conserving FFM, alone or in combination with diet. Gender differences have also been noted in response to exercise, diet, and combination of exercise and diet. Women appear to respond to diet alone or in combination with ET, although this is only seen as a reduction in body mass and not conservation of FFM, whereas men tend to respond more so to diet with RT alone or a combination of ET/RT/D.

Although exercise alone may yield insignificant weight loss, we do know exercise is quite effective in weight maintenance or prevention of weight gain [89], even more so than just relying on diet to maintain weight [90].

6 Exercise and Cardiometabolic Improvements

Research repeatedly shows that diet and exercise improve the cardiometabolic profile of the patient [87]. In a study designed to evaluate the effects of physical activity on WC and CHD risk, physical activity, defined as activity at work and during leisure time, was shown to decrease WC independent of change in BMI. Inactive men with elevated WC had a HR for future CHD of 1.74 (95% CI); and women had a HR of 4.0 (95% CI) [91]. Following acute coronary events, cardiac rehabilitation and exercise training also reduce the prevalence of metabolic syndrome by 37% [92]. Despite research suggesting exercise-related improvements in cardiometabolic profile following a cardiac event, patients with obesity may not receive appropriate guidance, as clinicians ponder over which form of exercise should be promoted, RT, ET, or both.

a Resistance Training

RT with or without diet has been shown to improve total cholesterol and low-density lipoprotein (LDL) compared to ET which has shown no significant changes in lipid profile. Both RT and ET, with or without diet, have been shown to improve HDL. The only gender difference seen was related to improvements in HDL, which were in women engaged in ET and diet [87]. RT is noted to decrease the incidence of metabolic syndrome in those who practice, but research is confounding. A meta-analysis of 19 research articles evaluating RT only and its effects on metabolic syndrome, found RT significantly improves BP, fasting plasma glucose, HDL, triglycerides, and WC [93].

b Endurance Training

ET improves CRF. Zaccardi et al. [94] notes an inverse relationship between CRF and incidence of T2DM such that improvements in fitness decrease risk for T2DM by 5% per metabolic equivalent, but there was a wide range of variability in the percentage of T2DM reduction. These variations could be related to the diversity of the study population, but does not negate the positive effects of CRF on T2DM [94].

HCPs understand the value of diet, exercise, and physical activity not only in promoting weight loss but also in improving cardiometabolic profile. Although there is some confusion over what form of exercise to suggest, it is best to recommend a well-rounded, progressive program to our patients. Lifestyle changes incorporating both RT and ET in addition to calorie restriction can invoke the clinically meaningful weight loss associated with cardiometabolic improvements. Lifestyle modification, with behavior modification (BMOD), will serve as the backbone to any comprehensive program chosen for the patient with chronic obesity.

B Behavior Modification

Changing one's behavior is difficult. We know this from the extensive literature on weight loss and smoking cessation. The HCP can assess each patient's stage of change and identify change talk to assist the patient in recognizing where they are in their weight loss process; helping each patient with obesity transition through the stage of change process is vital to their success.

Considering patients with obesity are being advised to begin regular exercise programs, change their diet, perhaps start an antiobesity agent, and other behaviors (i.e., sleep hygiene), it is important to recognize that the stage of change approach may be different for each behavior change recommended. Marshal and Biddle [54] theorized that self-efficacy for change, decisional balance of perceived advantages and disadvantages of change, and the targets and techniques (the process of change) individuals use to modify their thoughts, feelings, and behavior are the main mediating factors in the change process. BMOD skills are likely best taught by a trained psychologist, psychiatrist, therapist, counselor, licensed social worker, or dietitian.

Thus, it is important that the HCP understand that diet, exercise, and behavior change are important parts of a comprehensive program which can illicit up to 10% weight loss and improve or prevent the cardiometabolic cormorbidities associated with obesity [95].

IV PHARMACEUTICAL INTERVENTIONS

A Background

Unlike comorbid diseases, obesity does not have an extensive list of options for pharmacotherapy; and the recognition of obesity as a disease has only modestly improved this. Antiobesity medications are an adjunct to lifestyle changes and ideally should only be initiated after a 6-month trial of diet and exercise [6]. The oldest medications (i.e., phentermine) have been FDA approved and available for almost 90 years. The first drugs, amphetamines, were used in the 1930s as anorexiants, but had to be reformulated because of addiction potential. Since then, several medications have been utilized, of which phentermine is the most often prescribed to date. In the late 1990s, a lipase inhibitor, orlistat, was FDA approved for weight loss. Since 1990 several medications have been developed for the treatment of obesity, but only four remain on the market, lorcaserin, liraglutide, and two combination medications phentermine/topiramate ER and bupropion/naltrexone [96].

Treating obesity, a chronic metabolic disease with cardiometabolic sequelae, is not like treating HTN or diabetes. First, it is important for the HCP to recognize the limited availability of antiobesity medications FDA approved for long-term management of obesity. Second, given the challenge of maintaining long-term compliance with the lifestyle changes, it is often difficult for patients to maintain the weight initially lost, validating the need for pharmaceutical interventions. Finally, when evaluating the cardiometabolic disease risk and medical history of the patient, often times the HCP's options for antiobesity medications are further limited.

B Antiobesity Medications Approved for Short-Term Use in Weight Loss

1 Phentermine Hcl

Phentermine Hcl is a noradrenergic sympathomimetic derived from amphetamine-based molecules, and the most commonly used anorexic agent by health care professionals (Table 22.6). Phentermine is FDA approved for short-term (3 months) use as a result of short-term studies completed during a time when obesity was not considered a disease, let alone a chronic disease. The exact mechanism of action (MOA) is unknown, but it is thought that Phentermine Hcl releases catecholamines in the hypothalamus [97] thereby suppressing appetite.

The most commonly reported adverse effects (AEs) are dry mouth, constipation, jitteriness, difficulty sleeping, and dizziness. Clinically, AEs such as elevated blood pressure and tachycardia should be evaluated at least monthly. Phentermine Hcl is a schedule IV, category X medication. It should be avoided if pregnant or lactating; women of childbearing age should be counseled on this matter. Phentermine Hcl is contraindicated for those with known hypersensitivity, known monoamine oxidase

TABLE 22.6 Long-Term Pharmacotherapeutic Intervention to Promote Weight Loss for the Treatment of Obesity

Agent	MOA	Cost	One Year Weight Loss (kg)	Common Adverse Effects	FDA Approval
Orlistat	Pancreatic lipase inhibitor causing excretion of ~30% of ingested triglycerides in stool	60 mg, $45120 mg, $207 wholesale	60 mg, −2.5 kg (−1.5 to −3.5) 120 mg, −3.4 kg (−3.2 to −3.6)	Oily spotting, flatus with discharge, fecal urgency, fatty oily stool, increased defecation, fecal incontinence	1999 orlistat2007 OTC
Lorcaserin	Highly selective serotonergic 5-HT2C receptor agonist causing appetite suppression	$240 Wholesale; Now $75	−3.2 kg (−2.7 to −3.8)	Headache, dizziness, fatigue, nausea, dry mouth, cough, and constipation; and in patients with type 2 DM: back pain, cough, and hypoglycemia	June 2012
Phentermine/ Topiramate-ER	Noradrenergic + GABA-receptor activator, kainite/ AMPA glutamate receptor inhibitor causing appetite suppression	$140−195	7.5 mg/ 46 mg − 6.7 kg (−5.9 to −7.5) 15 mg/ 92 mg − 8.9 kg (−8.3 to −9.4)	Paresthesias dizziness, taste alterations, insomnia, constipation, dry mouth, elevation in heart rate, memory or cognitive changes	July 2012
Bupropion/ naltrexone	Inhibitor of dopamine and noradrenaline reuptake + μ-opiate antagonist	$60−70 per month	6.2 kg 48 weeks	Nausea, constipation, headache, vomiting, dizziness trouble sleeping, dry mouth diarrhea	September 2014
Liraglutide	GLP-1 agonist	$1000 per month	6.2 kg 104 weeks	Nausea, vomiting, constipation, diarrhea, headache	December 2014

Source: From S.Z. Yanovski, J.A. Ynovski, Long-term drug treatment for obesity: a systematic and clinical review, JAMA 311 (1) (2014) 74−86. Modified from A.G. Powell, C.M. Apovian, L.J. Aronne, New drug targets for the treatment of obesity, Clin. Pharmacol. Ther. 90 (1) (2011) 40−51.

inhibitors (MAOi) use within 14 days, pregnancy, lactation, history of CVD, atherosclerosis, uncontrolled HTN, hyperthyroidism, and glaucoma.

Phentermine Hcl is dosed in 8−37.5 mg tablets, taken by mouth once daily (QD) 30 minutes prior to breakfast. When taken either continuously or intermittently for 36 weeks, phentermine results in greater weight loss compared to placebo. In fact, weight loss can be up to three times that seen with placebo alone (placebo—4.8 kg, continuous—12.2 kg, intermittent—13.0 kg) [98,99] making this antiobesity medication quite effective at producing significant weight loss in the short-term.

C Medications Approved for Long-Term Use

1 Orlistat (Xenical, Alli)

Orlistat, a pancreatic lipase inhibitor, has been FDA approved since 1959 for long-term weight management, at a dosage of 120 mg, three times daily (or 60 mg three times daily over the counter) taken with a fat-containing meal or 1 hour following the meal. Given orlistat prohibits the absorption of fat from the gut; the HCP should recommend a daily multivitamin containing fat-soluble vitamins.

The most common AEs associated with this medication include oily fecal leakage, fecal urgency, and fatty/ oily stool. There has been some postmarket incidence of liver damage and therefore liver function tests should be evaluated with initiation and dose adjustments [100]. Like phentermine and all other antiobesity agents, Orlistat is a schedule X medication, thus should not be taken while pregnant or breastfeeding. Orlistat is contraindicated for known hypersensitivity, pregnancy, chronic malabsorption syndromes, and cholestasis.

Orlistat was noted to have superior weight loss when combined with a lifestyle change program, compared to a lifestyle program alone. Torgerson et al. [101] conducted a 4-year, double-blind, prospective study with 3305 participants with BMI 30 kg/m^2 and normal (79%) or impaired (21%) glucose tolerance (IGT) randomized to (1) maximal dosage of orlistat as an adjunct to lifestyle changes or (2) lifestyle changes alone. After 4 years the group treated

with orlistat lost significantly more weight (5.8 kg) than the lifestyle alone group (3.8 kg) [101].

Within the group with obesity on orlistat, there was no significant difference in weight loss between those with normal or IGT. In addition to increasing weight loss, Orlistat was effective in decreasing the incidence of T2DM, evidenced by a risk reduction of 37.3%. The addition of Orlistat to lifestyle management increases weight loss compared to lifestyle alone, and more importantly it helps the patient with obesity to maintain clinically significant weight loss long-term (4 years) [101].

2 Phentermine/Topiramate ER (Qsymia)

Phentermine Hcl, already approved for the short-term treatment of obesity, was combined with topiramate, a dopamine/GABA inhibitor traditionally used to treat migraines and seizures, for the long-term (up to 1 year) treatment of obesity, and FDA approved in 2012. Phentermine Hcl/Topiramate ER dosages start at 3.75 mg/23 mg, respectively, and increase incrementally to a maximal dosage of 15 mg/92 mg, taken QD. The MOA of phentermine was discussed previously. The additional effects of topiramate ER involve several potential MOAs which effect GABA activity, AMPA/Kainite excitatory glutamate receptors, and carbonic anhydrase [97]. Combined, both centrally acting agents promote an anorexogenic effect leading to significant weight loss.

The most common AEs are paresthesia, dizziness, cognitive dysfunction, dysgeusia, insomnia, constipation, dry mouth, metabolic acidosis, and elevated creatinine [97]. Phentermine Hcl/topiramate ER is a scheduled IV drug, because of the potential addicting and stimulating effects of phentermine Hcl; and pregnancy category X due to teratogenic effects of topiramate. Topiramate causes cleft palate in the first trimester of pregnancy, thus all women of childbearing age should utilize some form of contraception prior to initiation and throughout continued use of the medication as recommended by the Risk Evaluation and Mitigation Strategy program. Phentermine Hcl/Topiramate ER is contraindicated for use with known hypersensitivity, MAOi use within 14 days, pregnancy, lactation, CVD history, hyperthyroidism, glaucoma, and agitation.

Phase II trials of phentermine Hcl/topiramate ER suggest the antiobesity medication effectively improves glycemic control in patients with obesity and T2DM and improves sleep apnea. EQUATE, a randomized, double-blind, placebo-controlled 28-week phase III trial, illustrated the superiority of monotherapy using phentermine Hcl/topiramate ER over the individual components. EQUIP, a 56-week phase III trial, demonstrated the dose-dependent effect of 1 year phentermine Hcl/topiramate ER use on weight loss (−5.1% 3.75/23 mg, −10.9% 15/92 mg) compared to placebo (−1.6%). More importantly, this trial shows us that those patients who qualify for bariatric surgery have a medical alternative which is also effective [97] as those with BMI >40 kg/m^2 were able to achieve weight loss greater than 10%, and with some greater than 15%.

CONQUER, which was the largest of the phase III randomized control trials, began to examine the effects of phentermine Hcl/topiramate ER on the cardiometabolic diseases associated with obesity. Again, phentermine Hcl/topiramate ER led to greater losses in weight, with many achieving 5% and 10% weight losses. More importantly, the use of phentermine Hcl/topiramate ER led to improvements in HTN, lipid profile, and glycemic control. Improvements were such that patients were able to decrease the use of medications to treat these cardiometabolic comorbidities associated with obesity [97].

The CONQUER trial was extended 52 weeks and became SEQUEL, a 108-week, phase III randomized control trial, which showed that the weight loss and cardiometabolic changes experienced within the first year of phentermine Hcl/topiramate ER use could be sustained through a second year, suggesting the value of long-term use of this antiobesity medications for the treatment of obesity [97].

3 Lorcaserin (Belviq)

Lorcaserin is a serotonin (5HT) agonist, FDA approved in 2012 for long-term (up to 2 years) management of obesity, taken as 10 mg tablets twice daily (BID). Lorcaserin is a 5HT2C-specific agonist, unlike previous nonselective agonists, fenfluramine and dexfenflurame, which activated 5HT2B receptors causing valvulopathy [102]. The MOA is not completely understood; however, it is thought to decrease food intake and increase satiety through the activation of the pro-opiomelanocortin (POMC) system of the hypothalamus.

The most commonly reported AEs are fatigue, constipation, dry mouth, headache, nausea, and dizziness. Due to the risk of serotonin syndrome, concomitant use with other serotonin agonists (i.e., selective serotonin reuptake inhibitors, SSRIs) should be avoided. Given lorcaserin is a 5HT-agonist and previous antiobesity agents with similar mechanisms of action led to valvulopathy, it is important to know that with serial echocardiograms, lorcaserin showed no increased risk of valvulopathy when taken BID [103]. In general this is a well-tolerated and safe antiobesity medication, which elicits clinically meaningful weight loss among patients with overweight and obesity, with or without diabetes [104]. Lorcaserin use should be avoided in those who have known hypersensitivity, during pregnancy or lactation, and in those who have decreased kidney function (creatinine clearance, CrCL <30).

When taking lorcaserin QD or BID compared to placebo, overweight and obese patients are more likely to achieve 5% (40.2%, 47.2%, 25%) and 10% (17.4%, 22.6%, 9.7%) weight loss. Following 1 year of treatment those patients who remain on the medication, even after reaching their nadir weight, experience less weight regain than those who discontinue medication use [103].

The BLOSSOM study was a randomized, placebo-controlled, double-blind parallel arm trial. Participants ($n = 4008$) with overweight and obesity were randomized to lorcaserin 10 mg BID, lorcaserin 10 mg QD or placebo groups. The primary outcome of this study was to evaluate the effectiveness of lorcaserin in promoting clinically significant weight loss compared to placebo. Participants receiving lorcaserin were significantly more likely to achieve 5% (47.2% BID, 40.2% QD) and 10% (22.6% BID, 17.4% QD) weight loss [103].

The BLOOM study was a 52-week, double-blind randomized control trial. During BLOOM, 3182 persons with overweight or obesity received lorcaserin 10 mg or placebo, BID. After 52 weeks those taking lorcaserin ($n = 1595$) either stayed on lorcaserin or were reassigned to placebo. Those on placebo ($n = 1587$) initially remained on placebo. At the end of the first year, those on lorcaserin were twice as likely to achieve clinically significant weight loss of 5% and three times likely to achieve 10% weight loss, compared to placebo. The weight loss achieved during the first year was maintained in those receiving lorcaserin during the second year. Whereas those who discontinued lorcaserin in the second year had weight regain.

Similarly to previously discussed antiobesity agents, lorcaserin improved the WC and cardiometabolic profile (fasting glucose, insulin, glycated hemoglobin levels, total cholesterol, LDL, triglycerides, high-sensitive c-reactive protein, fibrinogen levels, SBP, and DBP). Many of the improvements noted in year 1, diminished during year 2 if participants were randomized from treatment to placebo arm [105].

BLOOM-DM was a 52-week, randomized, placebo-controlled clinical trial, evaluating the effects of lorcaserin 10 mg QD, BID, or placebo on weight loss in participants with overweight, obesity, and T2DM. Including modified intent to treat and last observation carried forward data, this clinical trial supports previous findings suggesting taking lorcaserin 10 mg BID compared to QD or placebo, will elicit clinically meaningful weight loss. Unlike previous studies, those taking lorcaserin QD were more likely to achieve 5% (44.7%) and 10% (18.1%) weight loss compared to those on BID dosing (37.5% and 16.3%, respectively). Given this population with overweight and obesity also had T2DM, it is important to recognize the improvements noted in glycemic control for those in each group. As expected, those in the treatment arms were more successful at reducing their HgbA1c, fasting glucose, insulin, and calculated insulin resistance, compared to those in the placebo groups. Greater improvements in glycemic control also resulted in a decrease in use of oral antidiabetic medications [106].

4 Naltrexone Hcl/Bupropion Hcl (Contrave)

Naltrexone Hcl/Bupropion Hcl is a combination of an aminoketone antidepressant, and opioid antagonist provided in a fixed 8 mg/90 mg tablet, taken as 2 tabs, BID for a total 32 mg/360 mg dosage. Bupropion activates "hypothalamic POMC neurons, with downstream effects to reduce food intake and increase energy expenditure" (p. 225). Naltrexone "blocks opioid receptor-mediated POMC de-activation, augmenting POMC firing synergistically" (p. 225). Ultimately, central nervous system (CNS) reward pathways are altered such that the fixed dosage can stimulate weight loss [12].

The most common AEs noted are headache, constipation, dizziness, vomiting, and dry mouth. Although suicidality has not reported any side effect, the HCP should discuss this with patients given the potential mood changes secondary to bupropion use. Naltrexone Hcl/Bupropion Hcl is contraindicated for use with those who have known hypersensitivity, have used MAOi within 14 days, during pregnancy, and lactation, and with end-stage renal disease, uncontrolled HTN, history of seizures or seizure disorder, bulimia or anorexia, acute withdrawal from or dependence of opioids, active alcohol use, or abrupt discontinuation of known CNS depressants (i.e., benzodiazepines).

The Contrave Obesity Research I (COR-I), a double-blind, placebo-controlled, phase III trial, which evaluated the effectiveness of bupropion/naltrexone on weight loss in 1742 overweight and obese patients randomized to hypocaloric diet and exercise in addition to either placebo, NB32 (32 mg naltrexone Hcl/360 mg bupropion Hcl) or NB16 (16 mg naltrexone Hcl/360 mg bupropion Hcl), in BID fixed dose tablets. COR-I demonstrated a dose-dependent weight loss response with the placebo group losing the least amount of weight (−1.3%) compared to NB16 (−5.0%) and NB32 (−6.1%). Similar dose-dependent outcomes were seen in terms of the percent of participants who achieved clinically significant weight loss of 55−84 (16%), 186 (39%), and 226 (48%) for placebo, NB16, and NB32, respectively. Ultimately, COR-I illustrates the effectiveness of NB32 as a treatment option for obesity [107].

The COR-II, a double-blind, placebo-controlled study, expanded on the research done in COR-I to include the evaluation of 1496 patients with overweight or obesity, dyslipidemia, and/or HTN, randomized to either NB32 or placebo groups. Similar to COR-I, there was a statistically

significant difference in weight loss at 28 (6.5%) and 56 weeks (6.4%) in the NB32-treated patients compared to placebo (1.9%, 1.2%, respectively). In addition, there were improvements in WC, lipid profile, insulin sensitivity as well as food cravings, and overall hunger. This study suggests that great improvements in weight and cardiometabolic risk factors can be achieved within 28 weeks of initiating NB32 and be sustained throughout a year [108].

The COR-BMOD, a randomized, placebo-controlled trial, evaluated the efficacy and safety of NB32 plus intensive BMOD in 793 adults with obesity randomized to either NB32/BMOD or placebo/BMOD groups over 56 weeks. Participants were asked to follow a caloric-deficit diet and participate in 28 group BMOD sessions. After 56 weeks the NB32/BMOD group lost 4% more weight than the placebo/BMOD group (9.3%, 5.1%, respectively). When analysis included completers only the NB3/BMOD group lost 11.5% and the placebo/BMOD group lost 7.3% [109]. Additionally there were significant improvements in cardiometabolic disease risk.

COR-DM evaluated the efficacy of NB32 in 505 patients with obesity and T2DM over a 56-week, double-blind, placebo-controlled study, and assessed outcomes of 5% and 10% weight loss, and improvement in HgbA1c, WC, fasting blood glucose, and lipids. All participants received the same lifestyle intervention and were randomized to NB32 or placebo [110]. Those individuals in the treatment arm lost significantly more weight (25.0% NB32; 21.8% placebo). Of those on NB32 approximately 45% were able to lose 5% of their weight, compared to <20% in the placebo group. While on NB32 the participants with overweight or obesity and T2DM were able to reduce their HgbA1c, some to 7%, and improve their lipid profile [110]. Based on these findings, NB32 helps patients with overweight or obesity and T2DM lose weight and improve their cardiometabolic profile.

5 Liraglitide (Saxenda)

Liraglutide 3.0 mg is a glucagon-like peptide (GLP-1) agonist subcutaneous injection, FDA approved in 2015 for use in conjunction with an RCD and regular exercise to promote weight loss according to the AHA/ACA/TOS guidelines. Unlike liraglutide 1.8 mg, the 3.0 mg dosage is not indicated for management of glycemia in patients with T2DM. Liraglutide is an acylated human GLP-1 receptor agonist with >95% similarity to endogenous GLP-1. Glucagon like protein-1 regulates appetite and caloric intake, slows gastric emptying, promotes glucose-mediated insulin secretion, and down regulates glucagon secretion.

The most common AE is nausea, which is why this drug has a dose titration schedule over the course of a month. Patients should be instructed to start with 0.6 mg QD injection for 1 week. Each subsequent week there should be an increase in the dosage as follows: 1.2 mg, 1.8 mg, 2.4 mg, and concluding at the maximal dosage of 3.0 mg daily. Other AEs include vomiting, diarrhea, constipation, hypoglycemia (in patients with diabetes), and headache. Similar to all other antiobesity agents, liraglutide 3.0 mg cannot be taken during pregnancy or lactation. Liraglutide 3.0 mg is contraindicated in those who have experienced medullary thyroid carcinoma (familial or personal), multiple endocrine neoplasia syndrome type 2, or prior hypersensitivity.

SCALE Obesity and Prevention was a 56-week randomized, double-blind, placebo-controlled trial evaluating the effectiveness of Liraglutide 3.0 mg, in addition to diet and exercise in 3731 patients with obesity. Participants in the treatment arm lost almost three times as much weight (~8% liraglutide 3.0, ~3% placebo); and more participants taking this antiobesity agent were able to achieve >5% (~64%) and >10% (~33%) weight loss compared to placebo (~27% and ~11%, respectively). Similar to the results seen in research on other antiobesity agents, this study showed improvements in several cardiometabolic risk factors including WC, glycemia, blood pressure, and lipid levels [111].

SCALE Diabetes was a 56-week international, double-blind, placebo-controlled, parallel-group trial with a 12-week observational off drug follow up period, evaluating the effectiveness of liraglutide 3.0 mg in conjunction with a VLCD (500 kcal/day) and physical activity (>150 minutes/week) in participants with obesity and T2DM. Those receiving liraglutide 3.0 mg daily lost three times as much as those in the placebo group (6.0% vs 2.0%, respectively). Approximately twice as many patients in the treatment arm (~54%) were able to lose 5% of their initial weight compared to the placebo group (~21%); whereas there was almost a fourfold increase in the number of obese individuals able to achieve 10% weight loss on liraglutide 3.0 mg (25%) compared to placebo (~7%) [112].

SCALE Maintenance was a randomized, 56-week trial that evaluated the effectiveness of liraglutide 3.0 mg in maintaining clinically meaningful weight loss (>5%) in obese individuals following a calorically restricted diet. During the initial screening period, approximately 6% weight loss was achieved in all participants. Participants were then randomized to the treatment arm (3.0 mg liraglutide) or placebo for the 56-week study. Liraglutide 3.0 mg increased weight loss by an additional 6% compared to an additional 2% in the placebo group. More participants maintained their initial weight loss while on liraglutide (81%) compared to placebo (49%). Liraglutide 3.0 mg also effectively improved BMI, WC, and glycemic parameters [114].

Given the effectiveness of antiobesity agents in producing short-term weight loss, it is important to continue to work on medications that are capable of promoting

weight maintenance. Astrup et al. [113] evaluated the long-term efficacy of liraglutide 3.0 mg for sustaining weight loss over a 2-year period in a randomized, double-blind, placebo-controlled 20-week study. This European study showed that over the first year those participants on liralgutide 3.0 mg were able to lose almost twice as much weight as those on placebo (5.8 kg, 3.8 kg, respectively); and were able to maintain a 7.8 kg weight loss at 2 years, losing approximately 15.4% body fat. In addition, liraglutide 3.0 mg helps improve cardiometabolic profile (decreased PreDM and metabolic syndrome prevalence, blood pressure, lipid profile) [113].

Since patients often come to their HCP after experiencing multiple cycles of weight loss and subsequent weight regain from trying diet after diet, commonly referred to as "yo-yo" dieting, research to determine the effectiveness of antiobesity medications after initial weight loss with a LCD or intensive lifestyle program would be beneficial. Phase III trials for Liraglutide 3.0 mg have evaluated its efficacy in maintaining 5% weight loss achieved with a LCD. Following initial weight loss, participants with obesity were randomized to liraglutide 3.0 mg per day or placebo for 1 year. Wadden et al. [114] noted liraglutide 3.0 mg as an adjunct to diet and exercise was effective at maintaining initial weight loss seen with LCD. As HCPs and organizations such as TOS work to promote the treatment of obesity as all other chronic diseases, identifying antiobesity agents which improve long-term weight maintenance, such as liraglutide 3.0 mg, opens the door to improved interventions for this population [114].

D Medications Combined With Lifestyle Modification

Guidelines recommend that all patients begin with lifestyle management, including a calorie reducing diet, increased physical activity/dedicated exercise, and some behavior change [6]. Ideally this should begin 6 months prior to the initiation of antiobesity medications. Generally, one can expect about 3–5% weight loss with lifestyle modification alone. Combining antiobesity medications with intensive lifestyle treatment can increase weight loss by an additional 3–8%. Considering the recidivism seen in the weight loss process, having alternative antiobesity medications to combine with lifestyle interventions can only improve the long-term outcomes in the overweight and obese populations.

E Risk: Benefit Ratio

1 Selecting Pharmacotherapy for Patients

When determining the appropriate antiobesity medication for patients with obesity, the health care professional should bear in mind age, comorbid conditions, plans for conception, and initial BMI and weight loss goals of each patient prior to initiating pharmacotherapy.

a. Age: The upper age limit of the research evaluating antiobesity medications is 65 years of age. When prescribing antiobesity agents for your geriatric patients with overweight and obesity, it is important to keep this in mind. This does not mean that our older adult population should be ignored, but it may require more "finesse," and the HCP may want to "start low and go slow" when creating a comprehensive program which includes pharmacotherapy. The pediatric population, although affected by obesity, are not represented in research on anti-obesity medications. Although, not yet discussed, few antiobesity medications are FDA approved for the treatment of overweight and obesity in the pediatric population.

b. Comorbid conditions: Although diet, exercise, and weight loss are often principle concepts in the treatment of many of the health conditions associated with obesity, there are some details which should be noted when considering antiobesity medications for certain populations.

1. T2DM is not a contraindication to the use of any antiobesity medications. What must be considered is the potential for hypoglycemia. Thus, it may be necessary for patients to begin checking their blood sugars more often than they are accustomed, initially or throughout the weight loss process. This is especially important for those patients taking insulin or sulfonylureas.
2. HTN is not a contraindication, unless uncontrolled. For those patients interested in starting an antiobesity medication, controlling their HTN is essential prior to initiating treatment. Given that phentermine Hcl and phentermine Hcl/topiramate ER combination potentially increases BP, the HCP may want to avoid use of this medication in a patient with difficult to control HTN.
3. CVD is a contraindication for the use of phentermine and phentermine/topiramate ER.

c. Plans for conception and/or PCOS: Women of childbearing age and obesity are often counseled to lose weight to improve their chances of conception and outcomes during and after pregnancy. In this population avoiding the use of phentermine/topiramate ER would be advised; however, the use of other antiobesity medication options should be discussed with these patients. All antiobesity medications are contraindicated during pregnancy and lactation.

d. Initial BMI and weight loss goals: Often times patients will ask what their "ideal body weight" is. What we know is that there is increased risk of morbidity and

mortality with extremely low and extremely high BMI. Generally, a BMI of 22 kg/m^2 for a woman and 23 kg/m^2 for a male is considered "ideal" clinically. As a HCP one must be conscious of the patients' initial weight prior to determining and recommending achieving a particular BMI or weight. For example, a patient with a BMI >45 kg/m^2 may never achieve an "ideal" body weight, but may have a goal weight of 100-pounds less than his/her current weight. This is the time when patients need the most guidance and counseling around the medical and surgical options available to treat their obesity. Most importantly, this may be a time to address stages of change and barriers to weight loss, utilize MI, and set SMART goals. In general patients with a BMI >40 kg/m^2 may benefit most from a combination drug such as phentermine/topiramate ER as this drug was shown to successfully lead to 10−20% weight loss at maximal dosages.

V WEIGHT MAINTENANCE

What we really want for patients with obesity is not just weight loss, but weight loss maintenance. We know from countless studies that weight loss is in fact achievable within the first 6 months, but weight regain, ~30%, is likely to occur by the first year, especially when patients are lost to follow-up [115]. What may be the most discouraging fact for patients with overweight and obesity is that many will regain all of their weight, if not more within 3−5 years [116,117]. Thus weight maintenance is in fact the most difficult part of the treatment paradigm for the HCP.

Perhaps, the lower caloric needs following weight loss contribute to the weight regain seen in patients with obesity trying to successfully maintain their weight loss. We know that weight loss causes a decrease in FFM and a decrease in resting energy expenditure (REE). Schwartz and Doucet [118] reviewed 99 papers, from 1969 to 2008, totaling 2996 subjects to evaluate the effects of weight loss on REE and weight regain. This systematic review revealed that the decrease in REE was ~15 kcal/kg of weight lost, independent of intervention or gender and was not correlated to the amount of FFM lost. What was suggested was that exercise in addition to diet may minimize the changes in REE [118]. Although the data from the work of [118] is not comprehensive in explaining the biological basis of weight regain, it is beneficial to understand, but should not distract from the reality and challenges of weight loss maintenance.

The Look AHEAD study implemented the "longest, continuously implemented lifestyle intervention for weight management" [119]. Look AHEAD study identified several key factors related to successful weight loss maintenance. The greater the weight loss in the first year, the greater the long-term weight loss; those who lost 10% of their weight in the first year were 10 times more likely to achieve 10% weight loss in 4 years; and more likely to sustain a 5% weight loss [119].

If the Look AHEAD research gives us weight loss targets over the first year, there is still the question of how to coach patients to success. Given the prevalence of overweight and obesity, there are a great number of people in need of treatment and our most effective intervention is frequent contact [120−122]. Consistently seeing patients keeps them engaged and on track. Helping patients remain engaged by counseling them to record their dietary intake [123] and remain on a LCD [124]; promoting regular self-monitoring of weight [121,125]; and fostering engagement in consistent progressive physical activity/exercise [115−127] are important in aiding patients to adopt and successfully sustain a new lifestyle.

Can we create *Successful Losers*? The National Weight Control Registry, which has tracked over 10,000 people who have maintained a 30-pound weight loss over a year or longer [128] has shown that individuals who commit to 60 minutes of daily physical activity, maintain a low-calorie/low-fat diet weekdays and weekends, regularly have breakfast and monitor their weight [129] and have a greater chance of longer term success with weight loss. It is possible that after practicing these behaviors over time (2−5 years), individuals may have a greater chance at long-term success. Since we know that the faster and greater the weight loss in the first year increases the chances of weight loss at 4 years [119], HCPs can inform patients that they have a greater chance of long-term weight loss [129] when they start and adhere to a plan for the first year. Those with overweight and obesity have greater chances of weight loss and weight maintenance with the help of HCPs who are properly informed on the evidence-based interventions that can maximize initial weight loss and then sustain long-term weight loss maintenance.

VI PEDIATRIC AND ADOLESCENT OBESITY

Adults are not the only segment of the population affected by overweight and obesity. From 1980 to 2012, the prevalence of childhood obesity in the United States has more than doubled (from 7% to 18%) and it has more than quadrupled among adolescents (from 5% to 21%) [2]. Data from the 2013 Youth Risk Behavior Surveillance System (YRBSS) shows that over 13% of adolescents are overweight or obese (CCD, 2014). Children and teens with obesity are more likely to carry their excess weight into adulthood and increase their risk of the same comorbid conditions which affect adults with obesity [1]. Not only

are these children's health affected by excess weight, but they are also more likely to endure the negativity of social stigma and lower academic [1] performance. Given the potential for lower self-esteem, poor academic performance, social ridicule, and long-term health consequences, it is important that the HCP working with the pediatric population with overweight and obesity be prepared.

Childhood and adolescent obesity, like adult obesity, is pandemic and like the treatment paradigm of adults, our younger obese population's lifestyle modification should occur prior to initiation of pharmacotherapy or consideration of surgery [130]. The American Academy of Pediatrics recommends a stepwise care approach including 4 steps: prevention, structured weight management, comprehensive multidisciplinary intervention, and tertiary care intervention [131]. Despite limitations in the research, Spear et al. [131] suggest that lifestyle modification is warranted in this population and should include various diets, address food behaviors, physical activity, sedentary time, and utilize behavior change techniques. These recommendations do not differ from those made for adults. Pharmacological interventions should be left to the HCP in tertiary/specialty care clinics. Of the antiobesity agents once used for the treatment of obesity, orlistat (children >12 years old) and sibutramine were the only FDA-approved medications for use in the pediatric population [131]; however, the sibutramine has been discontinued from the U.S. market due to a cardiovascular incident.

Throughout the lifespan, morbid/severe obesity is difficult to treat, such that bariatric surgery is considered a better option for these patients. Despite the limitation in evidence supporting long-term outcomes, bariatric surgery should be reserved for the morbidly obese adolescent [130].

VII THE FUTURE OF OBESITY

As health care practitioners, our goal of decreasing morbidity and mortality is ignored when we ignore the weight of our patients and consider the treatment of obesity as a cosmetic disease only necessitating diet and exercise. We know that obesity is associated with higher rates of mortality than overweight or normal weight conditions [4]. Decreasing overall excess weight should be a priority. As research tells us that a BMI between 22 and 25 kg/m^2 is ideal, and an increase in BMI of 5 kg/m^2 is associated with a 30% increase in all-cause mortality (in nonsmokers) [4].

Fighting obesity requires that we abandon single-minded approaches and "understand that decisions are not made in a vacuum" ([1], p. 5). One must understand and accept that those communities greatly affected by obesity often lack access to nutritious foods or safe areas for physical activity and need more than just the help of the HCP. Efforts and collaborations among "the individual, family, schools, communities, businesses, government and obesity organizations" are needed ([1], p. 5).

Governmental changes have occurred over the past 5 years to improve the outreach to children and families affected by obesity. There has been an increase in nutrition education and support through the Special Supplemental Nutrition Assistance Program (SNAP-Ed), Supplemental Nutrition Program for Women, Infants, and Children (WIC), and the Child Care Development Block Grant (CCDBG) which offer nutritious food choices and promote physical activity within the communities served. One of the most proliferative governmental programs belongs to former First Lady, Michelle Obama. The Let's Move! program has enlisted the help of key stakeholders in the fight against obesity all across the United States [1] and under the Affordable Care Act, the focus on preventative health care has increased efforts to treat those with obesity.

International organizations such as the International Obesity Task Force (IOTF), TOS, the Obesity Action Coalition (OAC), and the World Obesity Federation (WOF), are dedicated to research and advocacy in obesity. Ultimately, the goal of all stakeholders should be to reduce the prevalence of obesity through prevention and treatment.

VIII CONCLUSION

Obesity is a pandemic, noncommunicable chronic disease, affecting all races, socioeconomic classes, and genders and this chapter only touches the surface of what is Obesity Medicine. This is meant to be an overview. We have come a long way, such that the AMA now recognizes obesity as a chronic disease with health consequences, thereby justifying assessment and treatment of this disease; but there is still much more work to be done.

After reading this chapter you as the HCP should understand the necessity of assessing for obesity by measuring weight, BMI, and WC. The degree of severity should be evaluated by identifying comorbidities and utilizing the EOSS as a way to identify those at risk for long-term health and physical consequences. The HCP should confidently motivate patients to pick any diet program that they can adapt to and be consistent with for life, for we now know adherence to lifestyle change is key [132]. Although the HCP may not be completely abreast of the latest exercise-related research, the basic exercise recommendations from ACSM are a good start. One should be able to assess each patient's stage of change and recognize the role of MI in communicating with and motivating patients to successfully incorporate the behavior changes that will help them accomplish their weight loss goals.

Utilizing the guidelines set forth by the Endocrine Society will allow the HCP educate and coach patients to make lifestyle changes related to diet and exercise. The results of the DPP and Look AHEAD ILIs provide guidance for what our patients should experience from a lifestyle/behavioral perspective. Finally, remember that there are pharmaceutical interventions effective in treating obesity and improving cardiometabolic comorbid disease.

As a nation, HCP, parents, educators, researchers, politicians, faith-based leaders, and the like, we have to understand, accept and implement a multipronged approach to treat and prevent obesity within our communities and rely on the current and up-and-coming research evidence to guide our patients and clinical decisions.

I INTRODUCTION

Bariatric (weight loss) surgery is considered as the most effective treatment for severe (morbid) obesity. According to a survey published by the International Federation for the Surgery of Obesity and Metabolic Diseases (IFSO), over 45,000 bariatric procedures were performed worldwide in 2013 [1]. In the United States, nearly 600,000 bariatric operations were performed over a 5-year period from 2008 to 2012 [2]. The average age of the US patient was 44 years old and approximately three-fourths were female. Surgeries performed include restrictive procedures such as laparoscopic adjustable gastric banding (LAGB), vertical sleeve gastrectomy (VSG), and restrictive-malabsporptive procedures such as the Roux-en-Y gastric bypass (RYGB), and biliopancreatic diversion (BPD and biliopancreatic diversion with duodenal switch, DS). Bariatric surgery is approved as a weight-loss option for two groups of patients: (1) those with a body mass index (BMI) $\geq$40 kg/m^2 (class III obesity) for whom surgery would not be associated with excessive risk, and (2) those with a BMI $\geq$35 kg/m^2 (class II obesity) with one or more severe obesity-related comorbidity, such as diabetes, cardiovascular disease, or obstructive sleep apnea [3–5]. According to the AHA/ACC/TOS 2014 Guideline for the Management of Overweight and Obesity in Adults [5], patients who are motivated to lose weight and who have not responded to behavioral treatment with or without pharmacotherapy with sufficient weight loss to achieve targeted health outcome goals should be advised that bariatric surgery may be an appropriate option to improve health. Furthermore, they should be offered referral to an experienced bariatric surgeon for consultation and evaluation.

Although the number of procedures performed annually has generally plateaued, the prevalence of severe obesity has steadily increased in the United States. Between 1986 and 2000, the prevalence of severe class III obesity (BMI $\geq$40 kg/m^2) quadrupled from approximately 1 in 200 adult Americans to 1 in 50; the prevalence of a BMI $\geq$50 kg/m^2 increased by a factor of 5, from approximately 1 in 2000 to 1 in 400 [6]. The latest available data from NHANES 2011–2012 shows that 6.4% of US adults are severely obese and 8.1% are moderately obese (BMI $\geq$ 35 kg/m^2) [7]. The prevalence of moderate and severe obesity combined is highest for non-Hispanic Black females, which reached 29.3% in the latest survey.

Although the clinical benefits of surgery are well documented, many of the weight-loss surgeries, most notably the combined restrictive–malabsorptive surgical procedures, place patients at high risk for development of both macro- and micronutrient deficiencies unless they are properly counseled and supplemented. Because most of the deficiencies can be identified early at a preclinical stage, early treatment will prevent or reduce symptoms and deficiency syndromes [8]. The role of the Registered Dietitian (RD) in providing medical nutrition therapy (MNT) to these patients is crucial. The dietitian's contribution to the success of the procedure involves practical nutrition knowledge, guidance and encouragement for diet, and behavioral changes. It is important that dietitians provide ongoing medical nutritional treatment, both preoperatively and postoperatively [9].

Although bariatric surgery does not cure obesity, it is considered a significant tool for weight loss and maintenance of weight loss. As such, patients are at risk to experience weight regain several years following surgery. This chapter reviews the most commonly performed weight-loss procedures, the importance of preoperative and postoperative management, the identification and management

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00023-0

of nutritional deficiencies that may occur following bariatric surgery, and factors associated with weight regain.

II BARIATRIC SURGICAL PROCEDURES

A Mechanisms of Action

Bariatric surgery results in weight loss and improvement of multiple comorbid conditions. Depending on the surgical procedure performed, weight loss primarily occurs by reducing caloric intake, altering gastrointestinal (GI) physiology, and gut–brain neuroendocrine signaling [10]. In contrast to popular perceptions, weight loss does not occur by producing significant macronutrient malabsorption. Instead, research over the past decade has identified multiple functional and hormonal changes involved in hunger, food intake, satiety, and glucose metabolism that occur as a result of the surgical procedures and further explain the differences in resultant weight loss and improvements in comorbid conditions. For this reason, bariatric surgeries are now more aptly referred to as "metabolic procedures." Depending upon the procedure performed, changes in some or all of the gut hormones include reduction in ghrelin, and increase in glucagon-like peptide-1 (GLP-1) and peptide YY_{3-36} resulting in significant changes in hunger, satiety, and food preferences [11,12].

The improvement in comorbid conditions that accompany weight loss is due to multiple interacting factors that effect changes in metabolism, pressure dynamics, and mechanics. Whereas some of the changes are brought about by diet and weight loss alone, others are the result of anatomical and physiological changes of the GI tract. The loss of fat mass, particularly visceral fat, is associated with multiple metabolic, adipokine, and inflammatory changes that include improved insulin sensitivity and glucose disposal, reduced free fatty acid flux, increased adiponectin levels, and decreased interleukin-6, tumor necrosis factor-α, and high-sensitivity C-reactive protein levels. Loss of visceral fat may also reduce intraabdominal pressure that may be related to urinary incontinence, gastroesophageal reflux, and hypoventilation [13]. Metabolic effects resulting from bypassing the foregut include altered responses of gut hormones involved in glucose regulation and appetite control [14].

Fluid and hemodynamic changes related to hypertension include diuresis, naturesis, reduced total body water and blood volume, and decreased indices of sympathetic activity. Mechanical improvements include less weight bearing on joints, improved lung compliance, and reduced bulky fatty tissue around the neck to relieve obstruction to breathing. More recent insights have shed light on altered bile acid metabolism and the role of gut microbiota on improving metabolic health. Depending on the comorbid condition, some or all of these changes may be responsible for improvement or resolution of the comorbidity.

III WEIGHT-LOSS SURGERIES

Weight-loss surgeries have traditionally been classified into three categories: restrictive, restrictive–malabsorptive, and malabsorptive. However, as noted above, newer understanding of the physiological and metabolic mechanisms of action have called this classification into question. Nonetheless, in order to appreciate the nutritional implications and consequences of the surgical procedures, using the traditional classification seems reasonable and will be used here. A diagram of the most commonly performed surgical procedures is shown in Fig. 23.1.

A Restrictive Surgeries

Restrictive procedures limit the amount of food the stomach can hold and slow the rate of gastric emptying. The vertical banded gastroplasty (VBG) is the prototype of this category but is no longer performed due to limited effectiveness in long-term trials. LAGB replaced the VBG and was responsible for a significant increase in the number of procedures performed after 2000. The first banding device, the LAP-BAND, was approved for use in the United States in 2001. A second device, the REALIZE band, was approved in the United States in 2007. In contrast to previous devices, the diameter of these bands is adjustable by way of their connection to a reservoir that is implanted under the skin. Injection or removal of saline into the reservoir tightens or loosens the band's internal diameter, respectively, thus changing the size of the gastric opening. Because there is no rerouting of the intestine with LAGB, the risk for developing nutritional deficiencies is entirely dependent on the patient's diet and eating habits. More recently, the laparoscopic sleeve gastrectomy (LSG) has replaced the LAGB as the most commonly performed operation among academic medical centers, accounting for 61% of all procedures in 2014 [15]. In this procedure, the stomach is restricted by stapling and dividing it vertically and removing approximately 80% of the greater curvature, leaving a slim "banana-shaped" remnant stomach along the lesser curvature. However, unlike the VBG or LAGB, removal of a portion of the stomach results in changes in hormonal metabolism that are similar to the restrictive–malabsorptive procedures described below.

B Restrictive–Malabsorptive Surgeries

The restrictive–malabsorptive bypass procedure combines the elements of gastric restriction and selective malabsorption. The RYGB is the most commonly performed procedure in this class. It involves formation of a 10- to 30-mL proximal gastric pouch by either surgically separating or stapling the stomach across the fundus. Outflow

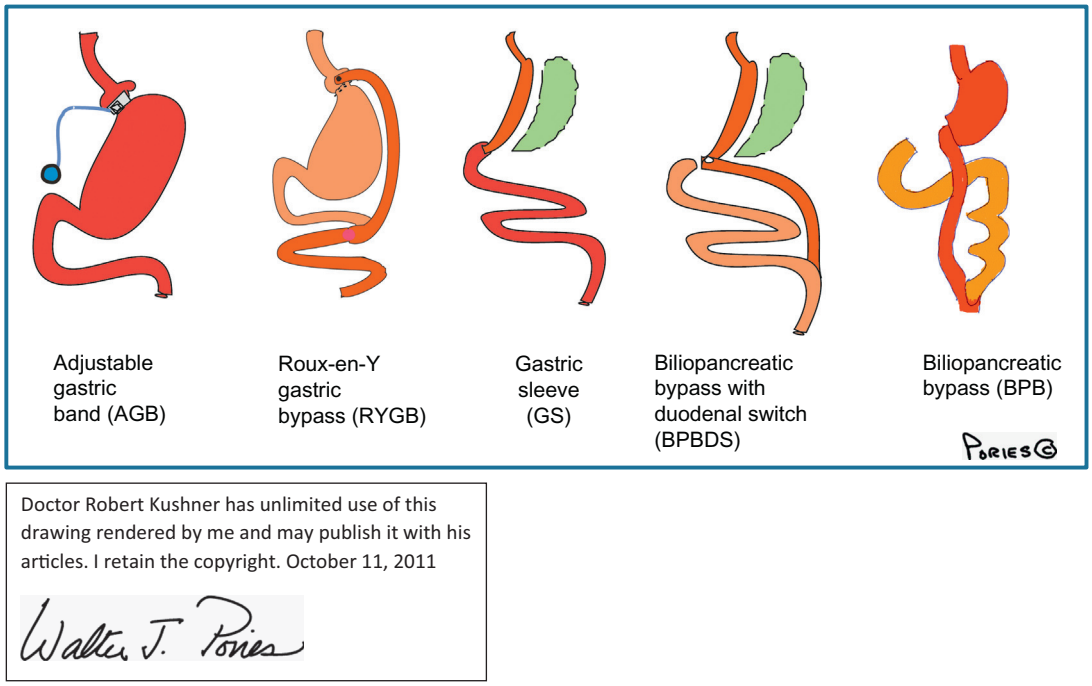

FIGURE 23.1 The five commonly accepted bariatric operations. *Reproduced with permission from Walter D. Pories.*

from the pouch is created by performing a narrow (10 mm) gastrojejunostomy. The distal end of jejunum is then anastomosed 50–150 cm below the gastrojejunostomy. "Roux-en-Y" refers to the Y-shaped section of small intestine created by the surgery; the Y is created at the point where the pancreobiliary conduit (afferent limb) and the Roux (efferent) limb are connected. "Bypass" refers to the exclusion or bypassing of the distal stomach, duodenum, and proximal jejunum. RYGB may be performed with an open incision or laparoscopically.

C Malabsorptive Surgeries

There are two malabsorptive procedures. In the BPD, a subtotal gastrectomy is performed, leaving a much larger gastric pouch compared with the RYGB. The small bowel is divided 250 cm proximal to the ileocecal valve and connected directly to the gastric pouch, producing a gastroileostomy. The remaining proximal limb (biliopancreatic conduit) is then anastomosed to the side of the distal ileum 50 cm proximal to the ileocecal valve. In this procedure, the distal stomach, duodenum, and entire jejunum are bypassed, leaving only a 50-cm distal ileum common channel for nutrients to mix with pancreatic and biliary secretions. The biliopancreatic diversion with duodenal switch (BPDDS) is a variation of the BPD that preserves the first portion of the duodenum. In this procedure, a vertical subtotal gastrectomy is performed and the duodenum is divided just beyond the pylorus. The distal small bowel is connected to the short stump of the duodenum, producing a 75- to 100-cm ileal–duodenal "common channel" for the absorption of nutrients. The other end of the duodenum is closed, and the remaining small bowel is connected onto the enteral limb approximately 75–100 cm from the ileocecal valve.

IV CLINICAL ASPECTS

A Weight Loss

Several meta-analyses and systematic reviews of bariatric surgery outcomes have been conducted [16–18]. In general, weight loss is greatest with the malabsorptive procedures (BPD and BPDDS), followed by the restrictive–malabsorptive procedure (RYGB), the LSG, and least with the restrictive LAGB procedure. As compared to standard care, differences in BMI levels from baseline at year 1 are $-11.3\ kg/m^2$ for BPD, $-9.0\ kg\ m^2$ for RYGB, $-10.1\ kg/m^2$ for LGS, and $-2.4\ kg\ m^2$ for LAGB [19]. Weight loss at 2–3 years following a surgical procedure varies from a mean of 20–34% of total weight depending on the procedure. The trajectory of weight loss also differs between procedure types. Whereas the rate of weight loss is slower with LAGB, with maximal weight loss achieved after 2 or 3 years, maximal weight loss with RYGB and LSG is achieved at 12–18 months [20,21].

B Effects on Comorbidities

A systematic review and meta-analysis of randomized controlled trials and nonrandomized controlled studies comparing bariatric surgery versus no surgery showed that surgery was associated with a reduced odds ratio (OR) risk of all-cause mortality (OR = 0.55), cancer (OR = 0.74), cardiovascular events (OR = 0.71), and stroke (OR = 0.66) [22]. Significant improvement in multiple obesity-related comorbid conditions has been reported, including type 2 diabetes, hypertension, dyslipidemia, obstructive sleep apnea, and quality of life [23]. The beneficial effect of weight-loss surgery on type 2 diabetes is particularly striking [24–26]. Several randomized controlled studies have demonstrated greater rates of partial or complete disease remission, and reduced use of antidiabetes medications after 3 years of follow-up [27,28]. Rates are greater following BPD, RYGB, or LSG than following LAGB, and the extent of remission is influenced by the amount of weight loss, weight regain, duration of diabetes, and the presurgery hypoglycemic therapy requirements [29]. The mechanisms of the greater antidiabetic effect following RYGB are primarily thought to involve caloric restriction and enhanced release of the incretins GLP-1 and glucose insulinotropic polypeptide, affecting both insulin secretion and sensitivity [30].

V PREOPERATIVE ASSESSMENT

A Overview

Guidelines for the perioperative nutritional, metabolic, and nonsurgical support of patients who undergo bariatric surgery have previously been published [8,31–33] along with "best practice" recommendations [34]. All patients who are considering weight-loss surgery should undergo a comprehensive assessment by a multidisciplinary team of health care providers that includes a physician, RD, and mental health care professional [8,31]. Preparation for surgery commonly spans 3–12 months depending on the patient's medical condition and criteria for insurance approval. During the preoperative process, patients are typically instructed on healthy eating and physical activity patterns, behavioral strategies to implement the lifestyle changes, and the importance of stress reduction and social support for long-term success. Specific dietary and nutritional recommendations pertinent to the surgical procedures include use of protein supplements, consumption of multiple meals and snacks, and slowing the rate of eating. Patients are seen either individually or in small groups. Many centers offer panel discussions between candidate patients and patients who have already undergone a procedure to provide a peer-to-peer discussion of risks, benefits, and challenges of life after bariatric surgery.

B Indications for Bariatric Surgery

According to the 1991 National Institutes of Health Consensus Development Conference Panel on bariatric surgery [3], patients with a BMI $\geq$40 kg/m^2 or those with a BMI $\geq$35 kg/m^2 who have associated high-risk comorbid conditions such as cardiopulmonary disease or type 2 diabetes could be considered surgical candidates. These indications have been reaffirmed by updated guidelines [8,31]. Consequently, Medicare and other third-party insurance payers have followed these criteria for reimbursement qualifications. The LAP-BAND system (Apollo Endosurgery, Inc, Austin, TX), one of the LAGB products used in the United States, has been approved by the US Food and Drug Administration for those with a BMI $\geq$30 kg/m^2 with a related health condition. In addition to BMI and the presence of comorbid conditions, other patient-related factors, such as psychosocial health, adherence, expectations, and past weight loss attempts, are taken into consideration. Contraindications include an extremely high operative risk, active substance abuse, or a major psychopathological condition such as major depressive disorder, schizophrenia, or bulimia.

C Medical Assessment

All patients need to undergo a comprehensive medical assessment prior to bariatric surgery. The purpose is to identify and optimally control medical problems prior to surgery. Patients with symptoms suggestive of obstructive sleep apnea (loud snoring, nighttime awakening, and morning and daytime sleepiness) should undergo a polysomnogram with initiation of continuous positive airway pressure (CPAP) if necessary. Patients with signs and symptoms of coronary artery disease or at high risk for cardiovascular disease should have a cardiac stress test performed. The two most common comorbidities that require preoperative control are diabetes and hypertension. Many patients may require initiation of medications to control blood glucose and blood pressure levels, respectively. Patients should discontinue cigarette smoking at least 2 months prior to surgery to reduce respiratory complications. Due to the rapid change in patients' medical conditions after surgery, patients need to be closely managed postoperatively for medication dose adjustments.

D Preoperative Nutrition Assessment

Dietary management of the bariatric patient begins preoperatively. All potential surgery candidates should meet with a RD to undergo a nutrition evaluation. The RD should determine if a patient meets the medically accepted criteria for bariatric surgery, educate the patient

on potential health and risk benefits of surgery, and determine the patient's ability to incorporate nutritional and behavioral changes. The nutrition evaluation is also used to determine a patient's education, existing medical conditions, and any potential physiological behaviors that could negatively impact the patient's weight loss after surgery. The RD should evaluate current diet, past weight loss attempts, nutritional deficiencies, or any disordered eating patterns including triggers to weight gain or challenges to following a healthy diet. Additionally, the dietitian should assess a patient's motivation for behavior change and social or economic concerns. Understanding the patient's expectations, knowledge, and self-efficacy regarding the postsurgery diet will also help the dietitian develop a nutrition prescription to set presurgery nutrition goals. The components of a nutritional assessment are outlined in Table 23.1.

Micronutrient deficiencies are common among patients with severe obesity [35,36]. Following a malabsorptive weight loss surgery, patients will be at higher risk for greater nutrient losses. Therefore, it is necessary to evaluate the patients' nutritional laboratory tests prior to surgery, specifically 25 (OH) vitamin D, calcium, thiamin, iron, and vitamin B_{12}. Deficiencies found in these nutrients should be corrected prior to surgery [8,31].

E Psychological Assessment

Psychological assessment should be performed by a licensed mental health professional prior to surgery. The evaluation serves two purposes: identification of potential contraindications to surgery, such as substance abuse or poorly treated depression or schizophrenia, and identification of potential postoperative problems, such as inability

TABLE 23.1 Presurgery Nutrition Evaluation

1. Reason for referral, anthropometric measures (weight/height/BMI)
2. Patient goals and expectation
   a. Patient's stated goals
   b. Reasons patient is seeking weight loss
   c. Patient's expectations regarding weight loss and surgery
3. Medications/abnormal nutrition labs
4. Weight history
   a. Onset of weight gain/onset of obesity
   b. Lowest/highest adult weight
   c. Family history of obesity
   d. Triggers for weight gain
      i. Life events, medications, postpartum weight retention, menopause, smoking cessation, work schedule, lack of nutrition knowledge, "emotional" eating behaviors
5. Prior weight loss efforts
   a. Commercial programs, medically supervised weight loss program, previous RD counseling, self-imposed diets, or previous history of bariatric surgery
6. Current diet intake
   a. Who shops/prepares food at home
   b. Diet recall: (24 h recall, food frequency)
   c. Food allergies/intolerances
   d. Supplement use
7. Patterns/habits
   a. Skips meals, unplanned snacks
   b. Fruit and vegetable intake
   c. Intake of highly processed foods or beverages
   d. Frequency of eating out/ordering in
8. Physical activity
   a. Time spent in sedentary actives (computer, TV, etc.)
   b. Work-related activity
   c. Planned exercise (type and frequency)
9. Assess
   a. Motivation for healthy eating
   b. Understanding of post-op diet, supplementation
   c. Ability and willingness to commit to all pre- and postsurgery appointments
   d. Need for additional nutritional education, support, pre-/post-op counseling
   e. Economic/financial ability for self-care following surgery (can the patient afford supplements, is access to healthy foods available?)

to adhere to behavioral changes needed for a successful outcome. Patients presenting with depressive symptoms, anxiety, low self-esteem, or relationship issues often benefit from preoperative intervention and/or a delay in surgery.

F The Role of Preoperative Weight Loss

In an effort to improve postoperative outcomes such as weight loss, diet adherence, and improved nutritional status, some bariatric surgery centers and insurance companies require patients to begin changing diet behaviors and striving for weight loss prior to surgery. The potential benefits of weight loss prior to surgery include acclimating to a restricted diet, increasing knowledge of healthy food choices, reduction in comorbidities, and a reduction in liver volume [37]. The purpose to reduce liver volume and intraabdominal fat is to help decrease surgery time and reduce comorbidities [38]. A 10% weight loss prior to surgery has been associated with decreased surgical complications and reduced hospital stays [39]. However, the research to support mandatory weight loss prior to surgery is limited and conflicting. The National Institute of Health does not require a mandatory weight loss for surgery.

VI POSTOPERATIVE MANAGEMENT

A Medical and Surgical Considerations

Patients who have undergone weight-loss surgery require ongoing postoperative care. Medical monitoring includes frequent assessment of preexisting comorbid conditions along with evaluation for postoperative complications. Patients with diabetes need to closely monitor their blood glucose levels because rapid resolution of diabetes frequently occurs following the RYGB, LSG, and BPDDS procedures. Antidiabetes medications are commonly reduced by half upon discharge from the hospital, and sulfonylurea agents—medications that may cause hypoglycemia—are discontinued entirely. Further reductions in antidiabetes medications are made based on glucose control. Similarly, antihypertensive medications may need adjustment as blood pressure falls. Diuretic agents are discontinued upon discharge from the hospital because they may lead to dehydration and electrolyte abnormalities. Patients with obstructive sleep apnea will frequently experience an improvement in sleep quality and reduction in the apnea hypopnea index. A repeat sleep study and retitration of CPAP is often performed 6–12 months postoperatively. Other preexisting medical problems, such as osteoarthritis, gastroesophageal reflux disease, urinary incontinence, asthma, heart disease, and hyperlipidemia, are managed according to symptoms or laboratory values [8,31].

Postoperative surgical care is necessary to ensure wound healing, surveillance for surgical complications, and, for patients who underwent LAGB, periodic tightening of the adjustable band. Food entrapment or vomiting suggests that the band is too tight and a need for loosening. Complications of the LAGB may include band slippage or erosion or fracture of the port and tubing. Complications from the RYGB procedure may include stenosis of the gastric outlet secondary to ulceration or scaring of the gastrojejunal anastomosis. These complications are routinely treated by prescription of an acid blocker and endoscopic dilation under light sedation. Intestinal obstruction can occur after the RYGB or malabsorptive operations and requires urgent surgical intervention. For these reasons, all patients should follow up with a physician who is knowledgeable about bariatric surgery.

B Nutrition Care

Follow-up of the nutritional status of the postbariatric surgery patient is essential for successful outcomes. Nutrition management after surgery has been shown to be a significant factor in postoperative weight loss. It is recommended that a follow-up period of up to 5 years is established to help prevent the development of nutrient deficiencies as well as weight regain [8]. Regular intervals of patient-provider contact can help patients achieve significant weight reduction and optimal health status. Conversely, failure to make follow-up appointments is associated with poorer weight loss and postoperative complications [32,40,41].

To ensure continuity of care for patients, it is important that dietitians provide ongoing MNT postoperatively. The primary focus of nutritional counseling following surgery is to facilitate weight loss while reducing nutritional deficiencies.

C Diet Progression Postsurgery

The postsurgery diet is a staged progression approach based on nutritional needs of the patient that will change according to the weight loss phase. This multiphase diet progression helps the patient transition from liquid to solid foods as nutritional needs and tolerances evolve. As there are a wide variety of diet protocols, there is no standardization of diet stages or diet progression. However, the general guidelines for diet stages post-RYGB and post-VSG are the same. Dietary guidelines for post-LAGB follows the same format, but progression through the diet stages and time spent on each diet phase may vary depending on surgery center. Therefore, it is crucial that all patients are followed frequently in the early

postsurgery months. Dietary progression is typically advised at the discretion of the dietitian [40].

Immediately following bariatric surgery, food intake is typically held until the GI tract function returns. When feeding is resumed, patients generally begin on a liquid diet before slowly progressing to solid foods as tolerated. Tolerance of food volume and consistency varies among patients who have undergone bariatric surgery, even among patients who have had the same procedure. It is important for all patients to be monitored frequently in the early stages after surgery.

1 Diet Stage 1: Liquid Diet

Clear Liquid Diet. The initial diet stage following the first 24–48 hours after bariatric surgery is a clear liquid diet. During this stage, GI motility is restored so these liquids must leave minimal residue in the GI tract. Patients are initially started on a clear liquid diet consisting of noncarbonated, sugar-free, or low sugar products such as water, coffee, tea, broth, sugar-free gelatin or ice pops, or any beverage sweetened with a sugar substitute [8,41].

Full Liquid Diet. Patients are progressed into a full liquid diet as tolerated. All liquids should remain noncarbonated, sugar-free, or low sugar. Patients may begin to incorporate beverages such as nonfat or low-fat milk, milk alternatives such as soy or almond milk, thin/strained soups with no solids such as tomato soup, protein drinks made with whey, whey isolate or soy protein powder, and yogurt. The progression into full liquids is intended to increase food tolerance as well as introduce texture and residue into the GI tract while providing patients with more energy and nutrients. Patients are encouraged to consume a minimum of 48–64 oz of fluids per day consisting of both clear and full liquids. Patients are advised to follow this diet stage for at least 10–14 days out of surgery [8,41].

2 Diet Stage 2: Pureed Diet

Approximately 2 weeks after surgery, patients will progress into a pureed food stage. Foods in this stage increase the gut tolerance of gastric residue from solute and fibers. Protein is emphasized and patients are encouraged to consume protein at three to six small meals over the course of the day. Protein supplements in the form of whey, whey isolate, or soy protein drinks are encouraged to further increase protein consumption. Tolerance for protein foods may be limited to only a few tablespoons at each meal or snack. Foods in this stage should be blended with water (or other liquid) to result in a pureed consistency resembling that of applesauce or baby food.

3 Diet Stage 3: Soft Diet

As pureed food is tolerated, patients are encouraged to incorporate soft foods. These soft foods are those that are easy to chew and will easily pass through the modified gastric pouch into the jejunum (RYGB) or flow easily through the modified stomach (VSG). Patients will continue to consume 48–64 oz of clear liquids per day, but will begin adding in soft, moist, diced, ground or pureed protein sources as tolerated. These foods include protein sources such as egg or egg whites, ground meats/ground poultry, soft fish, cooked beans, cottage cheese, low-fat cheese, and yogurts. This pureed and soft diet stage lasts approximately 10–14 days [33,40,42,43].

4 Diet Stage 4: Full or General Diet

After 2 weeks on the pureed/soft diet, patients are transitioned into a full or general diet as tolerated. If protein foods have been tolerated in the previous stages, patients are encouraged to add well-cooked or soft vegetables, soft and peeled fruits, and soft grains such as oatmeal or cooked cereals. In this stage, emphasis is placed on protein intake and restriction of certain dietary components such as concentrated sugar, fat, and refined carbohydrates such as pasta, rice, and bread. Throughout all diet phases, patients are encouraged to avoid eating and drinking simultaneously and to wait at least 30 minutes after meals to resume liquid consumption. A healthy diet consisting of lean proteins, fruits and vegetables, and whole grains should be consumed. Adequate hydration and fiber from sources such as fruits, vegetables, and whole grains will help prevent constipation [8,33,42,43].

D Nutrient Concerns and Supplementation

Nutritional deficiencies can and will occur in the bariatric patient for many reasons including inadequate food intake or poor food choices, malabsorption of nutrients from altered anatomy or persistent nausea, and vomiting that is common after all bariatric procedures in the early postoperative period. Nutrient deficiency will increase depending on the severity of the malabsorption. Due to the restrictive nature of LAGB and VSG surgeries, nutrition deficiencies are more like to occur due to inadequate or poor food choices. Because RYGB, BPD, and DS are malabsorptive, in addition to restrictive, micronutrient and macronutrient deficiencies are to be expected. Additionally, in these procedures, micronutrient deficiencies increase over time while the number of patients that are monitored decreases. Patients should also be made aware of additional deficiencies and concerns that may accompany poor attention to diet. Patients require lifelong vitamin and mineral supplementation regimes following

TABLE 23.2 Standard Postsurgery Supplementation and Dosage

Supplement	Recommended Dosage	
Multivitamin	1–2 daily	Should contain RDIs for all nutrients
		After 3 months, may switch to 1 daily
Calcium citrate	1200–1500 mg/day	Divided dose, do not exceed 600 mg in one dose
Vitamin D	3000 IU/day	Titrate to >30 ng/mL
Folic acid	400 mcg/day	Included in multivitamin
Elemental iron	18–27 mg/day	Not to be taken with calcium
		Taken with Vitamin C can increase absorption
Vitamin B_{12}	300–500 mcg/day	Oral, sublingual, or nasal
	1000 mcg/month	Intramuscular

Patients with deficiencies should be treated beyond these recommendations.
Source: From J.I. Mechanick et al., American Association of Clinical Endocrinologists, The Obesity Society, and American Society for Metabolic & Bariatric Surgery Medical guidelines for clinical practice for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient, 14 (Suppl. 1) (2008) 1–83; L. Allis et al., ASMBS Allied Health Nutritional guidelines for the surgical weight loss patient, SOARD 4 (2008) S73–S108.

these surgeries. It is essential that the multidisciplinary team provides guidance regarding nutritional supplementation to help patients maintain optimal health. A list of postoperative supplements and dosage can be seen in Table 23.2.

E Hydration

In the initial postoperative stages, some patients may find it difficult to adhere to the recommendation of 48–64 oz *of fluid per day. Due to decreased thirst, decreased appetite, and small pouch size, it may be difficult for patients to take in the necessary fluids, greatly increasing the risk of dehydration.* Patients should be aware of dehydration symptoms, including dark urine, headache, hard stools or constipation, dizziness, and extreme fatigue [8].

F Macronutrient Deficiencies

Macronutrients (protein, fat, and carbohydrates) supply energy and many essential nutrients and are needed in larger amounts in the diet to maintain homeostasis in the body. Nutritional deficiencies of macronutrients occurring in restrictive procedures such as VSG and LAGB are mostly a result of poor dietary intake as opposed to malabsorptive procedures such as BPD and DS, where as much as 25% of protein may not be absorbed [42,43].

Protein energy malnutrition (PEM) is the most severe macronutrient complication following malabsorptive procedures; protein malabsorption occurs in 7–21% of patients following BPD where up to 25% of protein is malabsorbed [43]. Reduced pouch capacity does not impact protein digestion as protein is digested in the small intestine; however, reduced capacity will impact overall protein intake. All bariatric patients are subject to increased PEM as a result of decreased dietary intake, anorexia, vomiting, food intolerance, fear of weight regain or decreased weight loss, and socioeconomic status [44].

PEM is typically detected 3–6 months following surgery and is mostly related to poor food intake and food intolerance to protein-rich foods. Patients should be regularly assessed for intake of protein-rich foods and protein supplements. Protein requirements for adults should be 10–35% of total energy. Patients who have undergone BPD or DS should consume 80–120 g protein per day. Patients who have undergone RYGB, VSG, or LAGB should be consuming at least 60 g or more per day [44].

Patients should be encouraged to consume protein-rich food sources as well as liquid protein supplements from whey, whey isolate, casein, milk, egg whites or soy protein sources. Patients should be cautioned that whey protein concentrates may contain significant sources of lactose that may not be tolerated among patients after RYGB. Lactose-free protein sources such as soy, egg whites, and whey isolates may be preferable to these patients [45]. Tolerance of protein foods tends to increase after the first year of surgery [42].

At this time, there are no specific recommendations for carbohydrate intake for the bariatric patient. Patients are encouraged to consume 50–130 g of carbohydrates daily to meet the requirements for brain activity and for glucose to fuel the central nervous system [42,46]. Patients should incorporate nutrient-dense, complex carbohydrates and fiber as whole grains, legumes and beans, low-fat dairy, and fruit. Patients should also be

encouraged to eliminate and avoid simple carbohydrates and concentrated sugars. Patients who have undergone RYGB may exhibit symptoms of dumping syndrome such as nausea, dizziness, perspiration, cramping, and diarrhea after consumption of refined carbohydrates [47]. Intake of some foods such as bread, rice, pasta, and soft-textured dough is typically difficult to tolerate following surgery [44].

As is the case with carbohydrates, there are no specific recommendations for fat intake after bariatric surgery. Overall, a low-fat diet is advised, and patients should be encouraged to consume unsaturated fats and essential fatty acids. Malabsorption of fat is greater in patients who have undergone BPD and DS, as these procedures can result in as much as 72% of fat being malabsorbed. Patients who undergo these malabsorptive procedures are at greater risk for deficiencies in fat-soluble vitamins such as vitamins A, D, E, and K.

G Micronutrient Deficiencies

Nutrient deficiencies can occur following malabsorptive and restrictive procedures. Following the RYGB, BPD, and DS procedures, key micronutrients are lost after bypassing the stomach, duodenum, and portions of the jejunum and ileum. Patients are at risk of depletion of thiamin, iron, folate, vitamin B_{12}, calcium, and vitamin D [48]. Along with supplementation of these nutrients, patients should also incorporate a daily multivitamin. Not all multivitamins are formulated the same, however. Recommendations postsurgery should include a daily multivitamin that meets the Daily Reference Intake (DRI) for adults. All postsurgery multivitamins should include 100% of the nutrients as listed in Table 23.3.

TABLE 23.3 DRI for Postoperative Multivitamins

	Adult Males	Adult Females
DRI		
Vitamin K (μg)	120	90
Biotin (μg)	30	30
Zinc (mg)	11	8
Thiamin (mg)	1.2	1.1
B_{12} (μg)	2.4	2.4
Folic acid (μg)	400	400
Iron (mg)	8	18
Copper (mg)	0.7	0.7

All multivitamins are not formulated similarly. All post-op multivitamins should contain 100% of these nutrients.
Source: From Dietary Reference Intakes (DRIs), www.nap.edu

Nutrient deficiencies may also emerge in LAGB or VSG procedures, though there are no changes to the absorptive pathway. Low nutrient intake, poor food choices, food intolerances, and limited portion sizes may contribute to micronutrient deficiencies in patients who undergo any bariatric surgery procedure. The absorption sites for micronutrients are shown in Fig. 23.2.

H Thiamin

Thiamin (vitamin B_1) is a water-soluble vitamin that is absorbed in the proximal small intestine. Thiamin deficiencies have been seen in up to 49% of patients following bariatric surgery [43]. Thiamin is not stored in large amounts in the body and levels can drop quickly from excessive vomiting, poor food choices, or limited food intake [48]. Deficiency in this vitamin mainly affects the central nervous system and can result in cardiac and neurologic complications resulting in the development of Wernicke's encephalopathy (leading to Wernicke–Korsakoff syndrome) and beriberi. Wernicke's encephalopathy is a neurologic complication characterized by ataxia, nystagmus, double vision, disorientation, and confusion. It can be seen in patients as early as 1 month postoperatively and is most commonly precipitated by intractable vomiting. Wet beriberi can affect the cardiovascular system and eventually lead to heart failure. Symptoms include tachycardia, shortness of breath, and swelling of the lower legs. Dry beriberi affects the nervous system and can lead to loss of muscle function, paralysis, and mental confusion.

All patients who have undergone bariatric surgery, especially those who have had malabsorptive procedures, should be monitored and supplemented with a B-vitamin complex or multivitamin as early as 2 weeks postoperatively to prevent thiamin deficiency [48,49]. Recommendations for maintenance of thiamin levels is 3 mg daily, which can be included in a multivitamin; patients who are experiencing extreme nausea and vomiting may require additional thiamin supplementation.

I Iron

Iron deficiency is more commonly found after RYGB and BPD/DS procedures due to the altered anatomy of the intestinal tract. Iron is absorbed throughout the small intestine, but is most efficiently absorbed in the duodenum and proximal jejunum, which is bypassed following these procedures. Deficiency can also result from decreased food intake and/or lack of gastric acid. The hypoacidic environment limits the conversion of iron into its absorbable ferrous form [42].

Malabsorption of iron coincides with a decreased intake of iron-containing foods, such as red meats, grains,

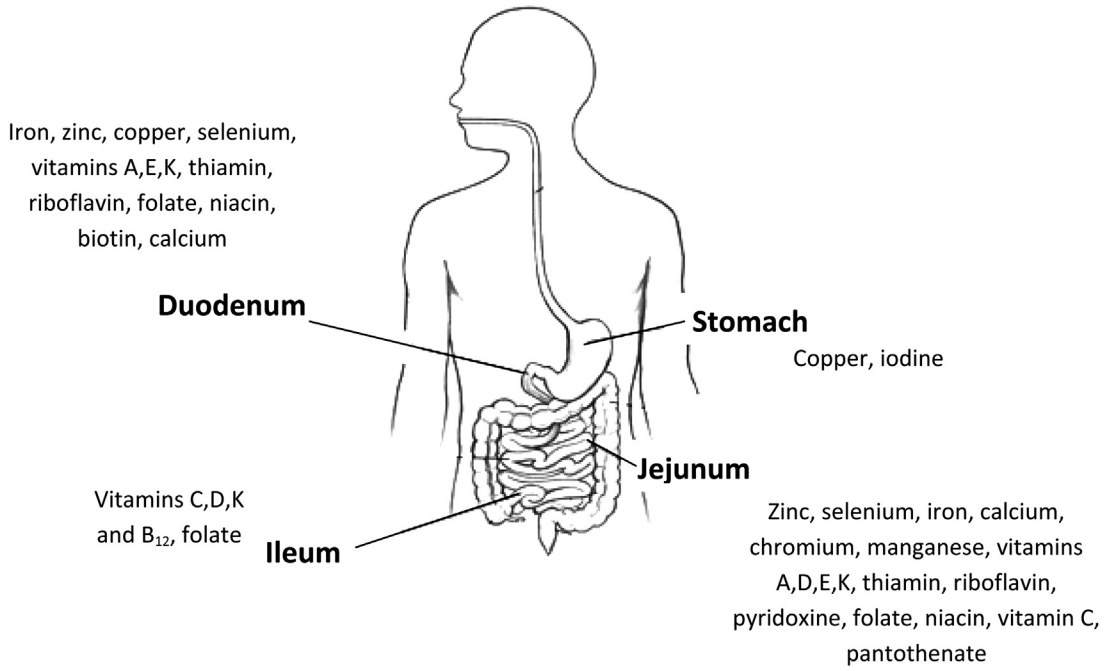

FIGURE 23.2 Micronutrient absorption sites within the GI tract.

and vegetables, which may be difficult for patients to tolerate and are typically avoided during the first few months following surgery. Iron deficiency is seen in 20–55% of RYBG patients, 0–18% of VSG patients, 13–62% of BPD patients, 8–50% of DS patients, and 14% of LAGB patients [50].

Iron deficiency is the main cause of anemia for bariatric surgery patients but anemia may also result from low levels of vitamin B_{12} and folate. Symptoms may include fatigue and reduced capacity for exercise tolerance. To prevent iron deficiency, all patients should be evaluated prior to surgery to determine any preexisting diminished iron stores as obesity-related inflammation interferes with iron availability [43,51].

Postsurgical patients should supplement with daily multivitamin–mineral supplements. It is recommended that 40–65 mg/day of elemental iron (alone or included in a multivitamin) is needed to maintain normal iron levels [8]. Menstruating women and those individuals who are at a higher risk of developing anemia should take an additional 50–100 mg/day [8,42]. Patients may find it difficult to adhere to oral supplementation due to GI side effects (constipation and cramping) or nutrient interactions. Iron supplementation can be inhibited in the presence of calcium supplementation, especially calcium carbonate, calcium citrate, or calcium phosphate. Vitamin C may increase the absorption of iron; patients should increase their intake of citrus fruits or vitamin C supplements. The risk for iron deficiency decreases over time as the patient is able to increase food intake and experience fewer food intolerances [8,42,43].

J Vitamin B_{12}

Malabsorptive and restrictive bariatric surgical procedures interfere with several key processes of vitamin B_{12} absorption. Due to changes in hydrochloric acid (HCl) production and reduced availability of intrinsic factor (IF), B_{12} absorption is impaired [42,43]. Post-RYGB, patients no longer have the ability to release vitamin B_{12} from protein foods because pepsinogen cannot be converted into pepsin due to the lack of HCl. Decreased production of IF by the parietal cells in the stomach will also prevent vitamin B_{12} from being absorbed. The parietal cells that excrete acid and IF, as well as the cells that excrete pepsinogen, are located primarily in the fundus and body of the stomach and is bypassed after RYGB.

Deficiency in vitamin B_{12} and folate is seen more prevalent with RYGB and BPD/DS patients than with VSG or LAGB patients. These procedures leave more of the stomach intact, producing more gastric acid and a subsequent increased availability of IF. However, these patients may still become deficient in B_{12} stores as a result of low tolerances of animal protein foods. Deficiency prevalence ranges from 7% to 70% by 3 years postoperatively [42,51]. Patients may begin to exhibit signs of B_{12} deficiency, including numbness or tingling in

the lower extremities, changes in gait or motor skills, loss of concentration, memory loss, or disorientation.

Typically, only those patients receiving RYGB and BPD/DS are supplemented with vitamin B_{12}, although all patients undergoing bariatric surgery should be routinely screened. Recommendation for maintenance levels of B_{12} is 1000 mcg/day. This can be given over a variety of courses (daily, weekly, or monthly) and across multiple administrative routes (oral, intramuscular, nasal, or sublingual) as recommended [8,42,43].

K Folate

Folate absorption occurs in the proximal small intestine. Folate deficiency is not as commonly observed as with B_{12} or iron deficiency, but patients who become anemic should be screened for a folate deficiency. Folate deficiency may occur as a result of inadequate dietary intake, nonadherence with multivitamin supplementation, or malabsorption. Folic acid stores can begin to diminish within a few months postoperatively and will present with symptoms such as macrocytic anemia and mental confusion (e.g., forgetfulness or paranoia). Prevalence of folate deficiency has been reported in 0−40% of patients following surgery, and has been reported in 22% of VSG patients and 12% of RYGB following surgery [51−53].

Multivitamin and dietary sources such as dark green, leafy vegetables, fruits, organ meats, and fortified grain products can replenish folic acid stores in the body. Supplementations of folic acid are recommended at 200% of the daily value (DV), between 800 and 1000 μg/day, which is commonly found in most multivitamins. This dose can correct or prevent folate deficiency in most patients [52]. Supplementation exceeding >1000 μg/day is not recommended as this can potentially mask a B_{12} deficiency. Folic acid deficiency in pregnant women is associated with an increased risk of neural tube defects in newborns. Women of childbearing age or who are seeking to become pregnant postbariatric surgery should monitor their intake of folic acid [54].

L Calcium and Vitamin D

Calcium and Vitamin D are typically grouped together, as a deficiency in one or both of these may lead to metabolic bone disease, increased bone turnover, secondary hyperparathyroidism, undermineralized bone, and bone loss [55]. A reduction in bone mineral density and bone mineral content generally accompanies weight loss; it is crucial to differentiate between the effects of weight loss compared to the malabsorptive consequences of bariatric surgery. A deficiency of calcium and vitamin D may result from a decrease in calcium and vitamin D rich dairy foods related to intolerance, or by a reduction in intestinal absorption resulting from surgical bypass of the duodenum, proximal jejunum, and ileum. Calcium is absorbed in the duodenum and proximal jejunum and is dependent on vitamin D levels. Vitamin D is absorbed in the small intestine, which is altered following RYGB and BPD/DS. Although calcium and vitamin D deficiencies are more prevalent in patients undergoing malabsorptive procedures, patients who had a VSG and LAGB can still experience calcium and vitamin D deficiencies due to poor food intake, usually related to intolerances to dairy products [42,43].

While calcium and vitamin D deficiency following malabsorptive procedures is predictable, patients often present with unrecognized deficiencies preoperatively. Patients with a high BMI may be subject to develop vitamin D deficiencies related to decreased bioavailability of vitamin D due to enhanced uptake and clearance by adipose tissues, or underexposure to the sun. Patients with severe obesity should be screened for vitamin D deficiency and abnormalities in bone density prior to bariatric surgery [42,43,56].

Oral supplementation should be given to support optimal bone health and to correct for deficiency. Recommended supplementation of calcium is 1200−1500 mg/day coupled with a calcium-rich diet [8]. Calcium intake poses many challenges for patients. A limit of 600 mg of calcium should not be exceeded in a single dose. Calcium supplements should be taken separately, ideally 2 hours apart, from iron or iron-containing multivitamins as calcium can interfere with iron absorption. Calcium citrate has been shown to be superior to calcium carbonate as it is absorbed better in the low acidic environment postoperatively [43,57]. With reduced calcium levels, patients are at greater risk of developing osteoporosis and fractures due to rapid weight loss and decreased absorption. Periodic measurements of 25 (OH) vitamin D, parathyroid hormone, and calcium should be obtained to screen for deficiency along with monitoring of bone density [43,47].

Patients with severe vitamin D deficiency should be supplemented at 50,000 IU of ergocalciferol orally once to twice per week for 8−12 weeks. Patients who underwent a BPD/DS procedure may require daily supplementation [8,42].

M Vitamins A, E, and K

Surgical procedures that alter fat digestion will result in differing absorption and transport of fat-soluble vitamins [42]. Following BPD/DS, intestinal dietary fat absorption is decreased as a result of the limited absorption areas, delays in the mixing of gastric and pancreatic enzymes with bile in the ileum. As fat-soluble vitamins are absorbed in the jejunum and ileum, this increases the risk of deficiencies for postsurgery patients. Additional

supplementation of vitamin A may be required after the BPD/DS procedures. Guidelines for vitamin A supplementation are 10,000 IU per day for BPD/DS patients followed by screening at 6 and 12 months postoperatively [8]. If deficiencies are discovered, plasma retinol should be assessed [42].

Vitamin K and vitamin E deficiencies are rare following bariatric surgery procedures, especially among patients who are taking a daily supplement regimen of 1−2 multivitamins that contain vitamin K and E [43]. Deficiencies of vitamin K are more prevalent in BPD/DS patients; these patients require an additional supplementation of 300 mcg vitamin K daily [42,43]. Levels should be assessed if the patient is experiencing hepatopathy, coagulopathy, or osteoporosis [8].

N Zinc, Copper, and Trace Elements

Zinc, copper, and iron compete for the same transport molecules in the body. Therefore, there can be an imbalance of these minerals following surgery. These trace minerals are absorbed in the jejunum, and absorption is compromised following RYGB and BPD/DS. Symptoms of zinc deficiency include alopecia, delayed wound healing, skin lesions, immune deficiencies, and hypogeusia. Impaired zinc absorption is also associated with intestinal diseases such as Crohn's disease or pancreatic insufficiency. Zinc is dependent upon fat absorption for metabolism and may be compromised after surgery due to poor dietary intake and/or poor fat absorption, especially as zinc is found in animal products including red meat and poultry as well as dairy products. A protein-rich diet promotes zinc absorption by forming zinc-amino acid chelates (the more absorbable form of zinc). There is insufficient research to support specific recommendations regarding zinc supplementation, but it is recommended for patients following RYGB and BPD/DS. A daily multivitamin supplement containing the DV of zinc (8−11 mg) is adequate in preventing zinc deficiencies [8,43].

Deficiencies in copper present similarly to deficiencies of B_{12} and can result in anemia and myelopathy. Copper is absorbed by the stomach and duodenum, and the risk of copper deficiencies is greater when this anatomy is bypassed. In addition to the malabsorption from these surgeries, diarrhea may also cause excess loss of copper. In patients who present with symptoms or neuropathy but have normal levels of B_{12}, copper levels should be examined. Currently there is no consensus for copper supplementation. Daily multivitamin supplements containing the DV (2 mg) should be adequate in preventing copper depletion in postsurgical bariatric patients [47].

There are insufficient data supporting the need to monitor trace elements (selenium, magnesium, chromium, sulfur, boron, iodine, and fluoride) after bariatric surgery. However, as selenium is absorbed in the jejunum, levels should be checked in patients that have undergone BPD/DS. Selenium deficiency has also been shown to occur in patients who have undergone RYGB and VSG as well. Patients presenting with unexplained anemia, fatigue, persistent diarrhea, cardiomyopathy, or metabolic bone disease should be examined for trace element deficiencies. Daily supplementation with a multivitamin that contains these trace elements should be sufficient to prevent any deficiencies of trace elements [8,43,47].

O Dumping Syndrome

Dumping syndrome occurs as a result of rapid gastric emptying and GI and systemic responses to a meal. More common with RYGB, dumping syndrome occurs after the ingestion of high-sugar or highly processed carbohydrates. Due to the lack of the pyloric sphincter, a hypertonic solution forms in the jejunum following the ingestion of sugar and or highly refined carbohydrates. This will lead to a sudden distention of the jejunum and result in symptoms of early dumping syndrome. These symptoms, including abdominal pain and cramping, nausea and vomiting, flushing, tachycardia, and syncope, can appear within 10−30 minutes after eating [58,59].

Late-stage dumping syndrome may occur anywhere from 1 to 3 hours after eating. Symptoms include perspiration, feelings of anxiousness or weakness, shakiness or hunger, and difficulty concentrating. These symptoms are a result of an excessive insulin release. This is a result of a rapid absorption of glucose which triggers an exaggerated insulin release and results in rebound or reactive hypoglycemia.

Dietary recommendations for patients experiencing dumping syndrome will vary depending upon each patient's diet and severity of symptoms. Recommendations to relieve symptoms of dumping syndrome include eating small meals spread throughout the day to improve absorption and to decrease dramatic fluid shifts. Meals should be high in protein, contain moderate levels of fat and should be devoid of refined or "simple" carbohydrates. Foods containing naturally occurring sugars, such as fruits and dairy, do not typically contribute to dumping syndrome. Proteins and fats are hydrolyzed more slowly into osmotically active substances whereas simple carbohydrates in the forms of lactose, sucrose, and dextrose are hydrolyzed rapidly. Complex carbohydrates and foods high in fiber content slow GI transit time and increase viscosity, but caution should be taken to avoid ingesting large amounts of high-fiber foods until tolerated. If fiber supplements are instituted, patients should be cautious with large supplements in the form of pills, as gastric narrowing, especially

following the LAGB procedure, may make it difficult for supplements to pass through narrowed gastric openings or if the patient is experiencing dysmotility [58,59].

VII LONG-TERM CONCERNS

A Weight Regain

Although clinicians commonly see bariatric surgery patients regain some weight postoperatively, the prevalence and incidence of weight regain has not been well characterized. The underlying factors that influence weight regain following bariatric surgery are multifactorial and include endocrine/metabolic alterations, anatomic surgical failure, nutritional indiscretion, mental health issues, and physical inactivity. The extent and significance of these factors is currently uncertain and likely varies between individuals and the operative procedure performed. Using cross-sectional data, weight regain has been estimated to occur in 20–35% of patients, depending on the procedure performed and duration of time following surgery [33]. Table 23.4 provides a categorical list of potential etiologies that should be explored with all patients who present with weight regain. The physiological and behavioral (diet and physical activity) causes are common to surgical and nonsurgical patients. Depending on the patient's age and gender, a thorough history should be performed that reviews all of these reasons followed by appropriate counseling. This section will focus on the dietary and nutritional considerations.

Immediately following surgery there is a reduction in a caloric intake due to a smaller gastric capacity, diminished hunger, and increased satiety brought about by the anatomical and metabolic changes discussed above. Over time, however, caloric intake is less restrained, which contributes to postoperative weight regain. In the Swedish Obese Subjects study [60], mean daily intakes of 2900, 1500, 1700, 1800, 1900, and 2000 kcal/day, respectively, were reported at baseline and 6 months, 12 months, 2 years, 3 years, and 4–10 years after surgery. These increases in caloric intake likely contribute to weight regain, which often begins in the second postoperative year. Dietary nonadherence, or the consumption of high calorie foods and beverages, may also contribute to the higher caloric intake. The results from a postoperative behavioral survey among 203 patients revealed a positive correlation between the magnitude of weight regain and consumption of large quantities of food in the evening or night, eating large quantities of high fat foods, and eating out more frequently [61]. In a case series of 289 patients who underwent RYGB, 23% of the population demonstrated dietary nonadherence and a continuation of presurgical eating patterns, leading to suboptimal weight loss, weight regain, or both [62]. These studies substantiate the importance of diet quality and caloric intake as causative factors for postsurgical weight regain.

TABLE 23.4 Etiological Factors for Weight Regain Following Bariatric Surgery

Anatomical
LAGB malfunction or mismanagement
Band or port breakage, band too lose
RYGB
Pouch enlargement
Gastrojejunal anastomosis dilation
Gastrogastric fistula
Physiological
Pregnancy
Menopause
Weight-gaining medications
Smoking cessation
Endocrine disorder: hypothyroidism, Cushing's disease
Intestinal or hormonal adaptation
Behavioral
Dietary
Unhealthy eating patterns, grazing, nibbling, mindless eating
Consumption of high-energy foods and beverages
Loss of dumping syndrome symptoms
Loss of control over urges, binges
Reduced vigilance
Physical activity
Reduced leisure time activity
Increased sedentary behaviors
Insufficient moderate- and vigorous-intensity exercise
Development of physical limitations to exercise

Grazing, defined as repeated episodes of consumption of smaller quantities over a long period of time with accompanying feelings of loss of control, has been identified as a common high-risk eating pattern after bariatric surgery [63,64]. Studies have shown that both preoperative and postoperative grazing behaviors independently predict poorer postsurgical weight loss [64].

Maladaptive dietary patterns have also been linked to other lifestyle behaviors that may impact eating habits among surgical patients. In data from the National Weight Control Registry collected at entry and 1 year follow-up,

surgical participants reported lower dietary restraint than nonsurgical participants [65]. Odom et al. [66] surveyed 203 patients (24.8% response rate) from a single center after a mean follow-up of 28.1 ± 18.9 months after RYGB. Seventy-nine percent of patients reported weight regain. Independent predictors of significant weight regain were lack of control of food urges (OR = 5.1), concerns over alcohol or drug use (OR = 12.74), lowest self-reported well-being scores (OR = 21.5), and no follow-up visits (OR = 2.60). In summary, attention to dietary nonadherence and maladaptive eating patterns is an important target to prevent postsurgery weight regain. Additional studies are needed to better understand the frequency, etiology, and treatment for weight regain.

VIII CONCLUSION

All bariatric surgeries have nutritional risks and consequences. The surgical multidisciplinary team is necessary to assess and prepare patients medically, nutritionally, and psychologically in an effort to reduce risks and improve outcomes following surgery. Bariatric surgery necessitates dietary modification of food texture, consistency, volume (both of solids and liquids), frequency and duration of meals, and adjustments for food intolerances, and potential nutrient deficiencies. Pre- and postoperative nutrition evaluations made by a RD will guide treatment recommendations and provide valuable information regarding both short- and long-term nutritional and behavioral treatment goals. All team members should be aware of postsurgery nutritional implications and environmental/behavioral factors that influence postsurgical weight loss, overall health and long-term weight maintenance.

Chapter 24

Behavioral Risk Factors for Overweight and Obesity: Diet and Physical Activity

Elisabeth M. Seburg[1], Melissa M. Crane[1,2] and Nancy E. Sherwood[1,2]
[1]HealthPartners Institute, Minneapolis, MN, United States, [2]University of Minnesota, Minneapolis, MN, United States

I INTRODUCTION

Understanding the determinants of obesity and developing appropriate prevention and treatment strategies require an in-depth examination of behavioral risk factors for obesity. The goal of this chapter is to review available data regarding the prevalence of overweight and obesity and the modifiable dietary and physical activity behavioral determinants of obesity that are potential targets for obesity prevention and treatment interventions. We begin with an examination of dietary factors that contribute to the development of overweight and obesity. Multiple factors that influence food intake will be discussed, including total energy intake, specific eating patterns, and environmental and societal influences. We then discuss physical activity factors, including exercise self-efficacy, social support, and access to exercise opportunities. The review will focus on behavioral risk factors for obesity in both children and adults.

II OBESITY AND OVERWEIGHT

Obesity is a significant problem that affects children, adolescents, and adults across gender, race, and socioeconomic strata [1–8]. As shown in Fig. 24.1, the prevalence of overweight and obesity provided by the objectively assessed weights during the National Health and Nutrition Examination Surveys (NHANES) show that the percentage of obese adults has increased over the last five decades [9]. Results from NHANES 2011–12 indicate that obesity rates may have stabilized with 68.5% of U.S. adults aged 20 years and over classified as either overweight or obese, with an estimated 34.9% considered obese (body mass index, BMI $\geq$30 kg/m^2), and 6.4% in the obese class 3 (BMI $\geq$40 kg/m^2) category [8]. Although there has been a stabilization of the overall prevalence of obesity, some groups including women over the age of 60 have seen continued increase in prevalence in recent years [8].

Prevalence of obesity among children and adolescents has also increased dramatically since the mid-1960s (Fig. 24.2) [9]. Results from NHANES 2011–12 indicate that 31.8% of U.S. children and adolescents aged 2 through 19 years are overweight ($\geq$85th percentile of BMI for age and gender), with 16.9% in the obese ($\geq$95th percentile of BMI for age and gender) category. Similar to trends in adult obesity prevalence, data from the past decade suggest that overall obesity prevalence among children and adolescents has remained high, but relatively stable [8,10]. NHANES data from 2003–04 through 2011–12 reveal small, but nonsignificant, changes in obesity rates among children aged 6–11 years (18.8–17.7%) and adolescents aged 12–17 years (17.4–20.5%) over this time period. A notable exception is among preschool aged children (aged 2–5 years), among whom obesity rates decreased from 13.9% in 2003–04 to 8.4% in 2011–12 [8]. A similar trend is observed in low-income preschool aged children (aged 2–4 years) monitored by the Pediatric Nutrition Surveillance System [11], with small declines in prevalence of obesity (15.2% in 2003 to 14.9% in 2010) and extreme obesity (2.2% in 2003 to 2.07% in 2010) [12]. The persistently high prevalence of obesity and overweight among children and adolescents remains of particular concern, given that childhood-onset overweight and obesity often tracks with adult obesity [13–15].

The prevalence of overweight and obesity has not increased consistently across racial, ethnic, and

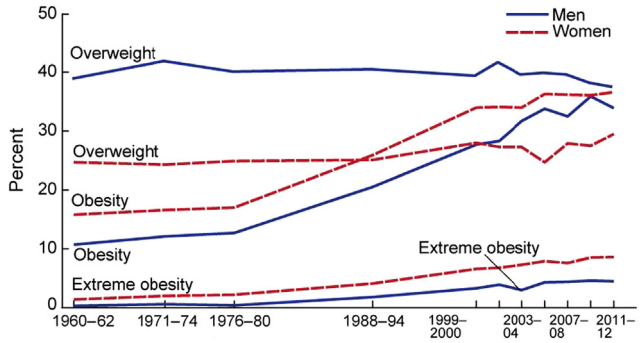

FIGURE 24.1 Trends in adult overweight, obesity, and extreme obesity among men and women aged 20–74: United States, selected years 1960–62 through 2011–12. *Notes*: Age-adjusted by the direct method to the year 2000 U.S. Census Bureau estimates using age groups 20–39, 40–59, and 60–74. Pregnant females were excluded. Overweight is BMI of 25 or greater but less than 30; obesity is BMI greater than or equal to 30; and extreme obesity is BMI greater than or equal to 40. *CDC/NCHS, National Health Examination Survey 1960–62; and NHANES 1971–74; 1976–80; 1988–94; 1999–2000; 2001–02, 2003–04, 2005–06, 2007–08, 2009–10, and 2011–12.*

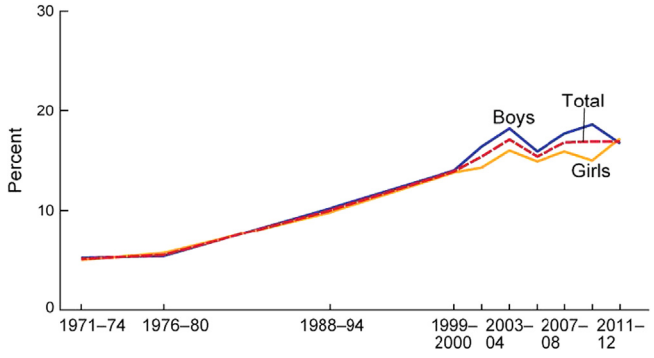

FIGURE 24.2 Trends in obesity among children and adolescents aged 2–19 years, by sex: United States, selected years 1971–74 through 2011–12. *Note*: Obesity is BMI greater than or equal to the sex- and age-specific 95th percentile from the 2000 CDC growth charts. *Fryar CD, Carroll MD, Ogden CL. Prevalence of Overweight and Obesity Among Children and Adolescents: United States, 1963–1965 Through 2011–2012. National Center for Health Statistics. September 2014. Available from: https://www.cdc.gov/nchs/data/hestat/obesity_child_11_12/obesity_child_11_12.pdf*

socioeconomic groups. Among both children and adults, Hispanic, non-Hispanic African American, and American Indian/Native Alaskan are at particularly high risk for obesity [10,16–20]. There is also evidence for an inverse relationship between socioeconomic status (SES) and obesity among women and children, although the relationship is not apparent among adult men [4,21,22]. In their recent systematic review of SES and overweight and obesity prevalence in children and adolescents in developed countries, Chung and colleagues conclude that there are significant differences in prevalence of overweight and obesity by SES group, with higher prevalence of overweight and obesity in low-SES children and adolescents in many countries [22]. In fact, several studies suggest the gap in obesity and overweight prevalence between U.S. children from low- and high-SES groups is widening [23–25]. Similarly, racial and ethnic disparities in obesity prevalence persist and may be increasing for some groups [26]. For example, among low-income preschool aged children, declines in obesity prevalence are seen for non-Hispanic White, non-Hispanic African American, Hispanic, and Asian/Pacific Islander children, but not for American Indian/Alaskan Native children [12,27].

The high prevalence of obesity and overweight among U.S. children, adolescents, and adults raises concerns about associated health risks across the lifespan [13], as well as intergenerational transmission of overweight and obesity risk [28]. There is substantial evidence of the persistence of overweight and obesity; childhood-onset of overweight and obesity tracks into adulthood, with youth who are overweight and obese more likely to be overweight and obese in adulthood [13,29]. Furthermore, parental obesity is a risk factor for obesity in childhood [30–33]. Sustained high levels of obesity and overweight in the U.S. population could lead to substantial increases in the number of people affected by obesity-related health conditions and premature mortality [34,35]. The health risks associated with obesity are numerous and include hypertension, type 2 diabetes mellitus, dyslipidemia, stroke, gallbladder disease, osteoarthritis, sleep apnea, respiratory problems, and certain cancers (e.g., endometrial, breast, prostate, and colon) [36–44]. In children and adolescents, obesity is associated with health risks, such as cardiovascular risks (e.g., dyslipidemia and endothelial dysfunction [45–50]), slipped capital femoral epiphysis [51], obstructive sleep apnea [52], and decreased quality of life [53]. Children and adults who are obese are also adversely impacted by social bias and discrimination [54,55].

In addition to the many health consequences of excess body weight, there is a sizeable obesity-related economic burden attributable to individual health, costs to society due to lost productivity, and premature mortality and treatment costs [56–61]. According to a recent systematic review and meta-analysis, the per-person direct medical cost of obesity is an estimated $1901 in 2014 U.S. dollars, with the aggregate national cost of obesity estimated at $149.4 billion [61]. Obesity-associated health care costs are not limited to adults [62–66]. The lifetime incremental direct medical costs for an obese 10-year old, compared to a normal weight 10-year old who remains normal weight through adulthood, are an estimated $12,660–$19,630 in 2012 U.S. dollars [66]. This translates to an additional $9.4–14 billion in lifetime direct medical costs for this age cohort. Other costs of obesity include an estimated loss of $8.65 billion annually due to obesity-related absenteeism [67].

Obesity and overweight are multidetermined chronic problems resulting from complex interactions between genes and an environment characterized by energy imbalance due to sedentary lifestyles and ready access to an abundance of food [68]. Genetic research holds considerable promise for understanding the development of obesity and identifying those at risk for obesity, including via low resting metabolic rate, low level of lipid oxidation rate, low fat-free mass, and poor appetite control [69–71]. Recent epidemiological trends in obesity have also been linked to behavioral and environmental changes that have occurred in recent years. The higher proportion of fat and the higher energy density of the diet in combination with reductions in physical activity levels and increases in sedentary behavior have been implicated as significant contributors to the obesity epidemic [68].

III DIETARY INTAKE FACTORS

A Energy Intake

Laboratory experiments in animals and human clinical studies have repeatedly shown that the level of fat and energy intake in the diet is strongly and positively related to excess body weight. Examination of secular trends in self-reported overall energy intake, eating frequency, and energy density of diets suggest that trends of food consumption roughly parallel the pattern of obesity observed in the United States over the past 40 years [72–74]. Examination of trends in energy intake from nine consecutive NHANES show that energy intake increased beginning in 1976–80, and peaked in 2003–04 for most groups (1946 kcal/day to 2269 kcal/day). Among men, average daily energy intake increased from 2401 kcal/day in 1976–80 to a peak of 2701 kcal/day in 2005–06 ($p < 0.01$). Among women, average daily energy intake peaked in 2003–04, increasing from 1521 kcal/day in 1976–80 to 1885 kcal/day in 2003–04 ($p < 0.01$) [72]. Declines in energy intake were observed between the 2003–04 and 2009–10 surveys, with average daily energy intake decreasing from 2269 kcal/day to 2195 kcal/day [72]. The decrease in energy intake seen in U.S. adults roughly aligns with stabilizing obesity prevalence among adults between 2003 and 2012 [8]; it is possible that these apparent declines in energy intake contribute to the recent leveling off of obesity rates.

Secular trends in energy intake of children and youth have also been examined [75–80]. Data from NHANES found that mean energy intake remained relatively stable from the 1971–74 to 1999–2000 surveys, except for an increase among adolescent girls of 80 kcal/day [76]. Similarly, examination of data from NHANES 1988–94 through 2003–08 showed no increase in total energy intake over time among children aged 2–19 years [78]. In contrast to analyses that use NHANES baseline data, comparisons of the 1977–78 Nationwide Food Consumption Survey and 1989–91 Continuing Survey of Food Intakes by Individuals with the 2003–06 and the 2005–10 NHANES surveys show increases in daily energy intake of 180 kcal/day [80] and 108 kcal/day [79] for children aged 2–18 years, respectively. The biggest increase is seen among preschool aged children (aged 2–6 years), whose daily energy intake increased from 1433 kcal/day in 1989–91 to 1664 kcal/day in 2003–06 [75]. Recently, Mendez and colleagues [77] compared energy intake across the 2003–10 NHANES. Results suggest differences in secular trends in energy intake by child age. Daily energy intake decreased between 2003–04 and 2009–10 among children aged 2–5 years (decrease of 220 kcal/day for boys and 132 kcal/day for girls) and 6–11 years (decrease of 230 kcal/day for boys and 142 kcal/day for girls). In contrast, for adolescents aged 12–18 years daily energy intake decreased between the 2003–04 and 2007–08 surveys, but increased between the 2007–08 and 2009–10 surveys (increase of 60 kcal/day for boys and 97 kcal/day for girls).

Changes and patterns in secular-trend surveys should be interpreted cautiously due to a number of limitations, including weaknesses in study design, methodological flaws, different survey methodologies, and random or systematic measurement error in the dietary data [81,82]. For example, the procedural changes between NHANES II and III in dietary survey methodologies, survey food coding, and nutrient composition databases have made comparisons between the two surveys difficult. These limitations could explain inconsistent results in secular-trend surveys.

B Calories From Beverages

The role of caloric beverages in the obesity epidemic has received considerable attention in recent years. In particular, researchers and policymakers have focused on sugar-sweetened beverage (SSB) consumption and its contribution to excess weight gain. SSBs are any beverages that contain added caloric sweeteners, including soda, fruit drinks, sport drinks, low-calorie drinks, and sweetened coffee and tea. National dietary intake data trends indicate SSB consumption by adults and children rose dramatically between 1970s and 2000s, but has decreased in recent years. French and colleagues [83] examined nationally representative data from the 1977–78 Nationwide Food Consumption Survey, 1994–96 Continuing Survey of Food Intake by Individuals, and 1998 Supplemental Children's Survey and found that among children aged 6–17 years, average soft drink consumption increased between 1977–78 and 1998 by 153% for boys and 91% for girls. Similarly, energy intake from SSB increased by

135% between 1977 and 2001 for children and adults [84]. More recently, data suggest decreases in overall energy intake from SSB among youth and adults [85–87]. Among children aged 2–19 years, the mean percentage of daily energy intake from SSB decreased from 13.5% to 10.3% between 2001 and 2010 [85]. Between 1999 and 2010, SSB intake fell for adults aged 20–39 years (from 12.8% to 9.3% of mean daily energy intake) and those aged 60 years and older (from 4.7% to 3.7%), while there were no significant changes for adults aged 40–59 years [87].

There is substantial empirical evidence linking consumption of SSBs to BMI in children and adults [88–91]. The majority of the findings derived from large cross-sectional studies and prospective cohort studies with long periods of follow-up indicate that there is a positive association between SSB intake and unhealthy weight gain and obesity in both children and adults [88,89,91,92]. Moreover, there is emerging evidence from randomized controlled trials that reducing consumption of SSBs may result in reductions in BMI in youth and adults [93–96].

Fruit juice is another caloric beverage that has been in the spotlight for its potential contribution to obesity. The American Heart Association and American Academy of Pediatrics (AAP) recommend limiting daily consumption of 100% fruit juice to 4–6 oz per day for children aged 1–6 years and 8–12 oz per day for children aged 7–18 years [97]. Many young children, however, exceed this recommendation [98–100]. NHANES data from 2007 to 2010 show that 32% of children aged 2–6 years exceed the recommended amount of juice [100]. The mean daily consumption of juice was 9.9 oz for children aged 2–8 years, and 11.2 oz for children aged 9–18 years [100].

There is much debate about the association of 100% fruit juice with obesity [101–103], with mixed findings on the relationship between fruit juice consumption and weight across studies [104]. Some in the field point to the nutritional benefits of juice, the contribution of juice to better diet quality, and the lower cost of fruit juice compared to whole fruit [100,102]. On the other hand, fruit juice consumption in early childhood may be associated with greater consumption of SSBs later in childhood [105] and drinking fruit juice may influence satiety less than consuming whole fruit [106] and contributes to excessive calorie intake [107,108]. The current evidence base and disparate findings makes it difficult to draw conclusions about the association of fruit juice consumption with obesity.

C Eating Away From Home and Fast Food

During the past 40 years, one of the most noticeable changes in eating patterns of Americans has been the increased popularity of eating out. Eating away from home includes foods obtained at restaurants, fast-food places, school cafeterias, and vending machines. The proportion of calories consumed away from home increased between 1965 and 2008 for adults across all income groups, though the percentage of calories eaten away from home is the lowest among low-income adults [109]. Between 1965 and 2008, the percentage of meals eaten or prepared at home decreased by 24.5% for men and 23.9% for women [109]. Frequency of eating away from home did not appear to change significantly after the recession of 2008 [110,111]; rather, data suggest shifts in the type of restaurants frequented, with more Americans choosing fast-food and fast-casual restaurants instead of sit-down restaurants [110–112]. Analysis of cross-sectional data from the American Time Use Study 2003–11 did not indicate changes in rates of eating away from home among adults, even after examining differences by SES [110]. A number of factors account for the increasing trend in eating out, including a growing number of women in the labor force, more two-earner households, a desire for convenience foods because of busy lifestyles and little time for preparing meals, more fast-food outlets offering affordable food, smaller families, and increased advertising and promotion by large food-service chains and fast-food outlets [113].

The trend toward eating away from home more frequently has also been observed among children and adolescents [80,114,115]. Data from the 1977–78 Nationwide Food Consumption Survey, 1989–91 and 1994–98 Continuing Survey of Food Intakes by Individuals, and 2003–06 NHANES for children aged 2–18 years suggest that the percentage of daily energy eaten away from home increased from 23.4% to 33.9% from 1977 to 2006 [80]. Of concern, the study authors also reported that the percentage of energy from fast food increased to surpass food intake in the school setting. By 2007–10, 50% of U.S. children consumed fast food on a typical day [115].

Trends in increased eating away from home may be related to observed increases in energy intake among Americans. Restaurant food is often high in energy, fat, and sodium [116] and food away from home has poorer nutritional quality than food prepared at home [117,118]. Many table-service restaurants provide 1000–2000 calories per meal, amounts equivalent to 35–100% of a full day's energy requirement for most adults [119]. In addition, consumers may view food differently when eating out than when eating at home. Meals or snacks eaten away from home may be seen as an exception to usual dietary patterns; in other words, it may be considered an opportunity to "splurge." Recent estimates from the USDA suggest that for the average adult, eating one meal away from home each week increases daily energy intake by about 134 calories and

translates to approximately two extra pounds each year [117]. Eating out in fast-food restaurants, specifically, has been implicated as a risk factor for obesity. In both youth and adult populations, frequency of fast-food consumption has been positively associated with BMI and obesity [120–123]. In an effort to provide consumers with information about the calories in the foods they are eating, the Food and Drug Administration recently released new guidelines that require calorie information to be posted at the point of sale for many restaurants and fast-food establishments [124].

D Portion Size

Portion sizes, both at home and at restaurants, have become larger over the past several decades [125–127], paralleling increases in obesity prevalence [128–132]. Many restaurants, especially fast-food restaurants, offer large and extra-large portion sizes of products and meals at low cost. The size of a "typical" portion has also increased. For example, Putnam [133] reports that the typical fast-food outlet's hamburger in 1957 contained a little more than 1 oz of cooked meat, compared with up to 6 oz in 1997. Soda pop was 8 oz in 1957, compared with 32–64 oz in 1997. A theater serving of popcorn was 3 cups in 1957, compared with 16 cups (medium size popcorn) in 1997. Analysis of nationally representative data shows that food portion sizes increased between 1977 and 1996 both inside and outside the home [125]. Energy intake and portion size of salty snacks, soft drinks, hamburgers, French fries, and Mexican food increased by 93 kcal, 49 kcal, 97 kcal, 68 kcal, and 133 kcal, respectively, with portion sizes the largest at fast-food restaurants.

Some hypothesize that bigger portion sizes are an important contributor to the obesity epidemic, with observational data supporting this perspective [122,129,130]. [57,58,61] While portion size has not been causally linked to obesity, studies conducted primarily in laboratory settings show that larger portion sizes are associated with greater energy intake [134]. In a meta-analysis of 104 studies, Zlatevska and colleagues [134] found that a 100% increase in portion size resulted in a 39% increase in consumption for adults and a 20% increase for children. Duffey and Popkin [122] examined the role of portion size, frequency of eating, and energy density in relation to change in total energy intake in adults over time. Using data from the Nationwide Food Consumption Survey (1977–78), Continuing Survey of Food Intakes of Individuals (1989–91), and NHANES (1994–98 and 2003–06), the authors found that portion size and number of eating and/or drinking occasions were the strongest predictors of total energy intake. Evidence from randomized controlled trials suggests that limiting portion sizes through portion-control tools (e.g., portion-controlled meals, portion-control plates) can be an effective weight loss strategy [135–137].

E Food Marketing

Although multiple factors influence eating behaviors, one particularly powerful influence is pervasive food marketing. Over the past 50 years, U.S. children and adolescents have increasingly been targeted with intensive and aggressive forms of food marketing and advertising practices [138–142]. Multiple techniques are used to reach children as young as toddlers to foster brand building and influence product purchasing behavior. Content analyses of various types of advertisements indicate that the majority of advertisements are for unhealthy foods [141,143–145]. A recent report found that in 2013, children and adolescents saw in average of 13.1 and 16.5 food advertisements per day on television, respectively [142]. Fast food was the most represented category of food in these advertisements (23% for children and 28% for adolescents), followed by cereal for children (16%) and candy for adolescents (14%). Restaurants (excluding fast food) comprised 12% of advertisements for children and adolescents, ranking third. Food marketing to children now extends beyond television and is expanding rapidly into ever-present and evolving "new media," including social media, apps, advergames, video games, and text messages [146–150].

The 2006 Institute of Medicine report on Food Marketing to Children and Youth concluded that food and beverage marketing practices geared to children and youth are out of balance with recommended healthful diets and contribute to an environment that puts youth's health at risk [151]. The report set forth recommendations to guide the development of effective marketing strategies that promote healthier food, beverages, and meals for children and youth. Among the major recommendations for the food, beverage, and restaurant industries was that the industry should shift their advertising and marketing emphasis to child- and youth-oriented foods and beverages that are healthier. The Children's Food and Beverage Advertising Initiative (CFBAI), a voluntary set of guidelines for marketing toward children, was created in 2006 as an effort in self-regulation by these industries. Despite industry claims (CFBAI 2013 Progress Report, 2014), research indicates that these voluntary guidelines have been largely unsuccessful in shifting the emphasis away from high-energy and low-nutrient foods and beverages to healthful foods and beverages in marketing targeting children [140,152,153]. The CFBAI does not apply to advertising directed at older children (aged 12 years and older), who are also susceptible to advertising and who may be unduly influenced by advertising techniques

that are more difficult to identify, such as social media marketing and product placements [154]. In addition, the CFBAI does not cover many types of child-directed advertising, including product packaging, in-store marketing, video games rated everyone, or PG and PG-13 movies [154].

To improve and limit food marketing viewed by children, experts recommend closing loopholes and expanding the scope of these guidelines [153,155] (Healthy Eating Research, Recommendations for Responsible Food Marketing to Children 2015). If industry-sponsored voluntary guidelines continue to result in only modest improvements in the content and reach of child-directed marketing, Congress should enact legislation mandating reforms. Advocacy and public health groups are also calling on the Federal Trade Commission, the Federal Communications Commission, and Congress to work together with industry to develop comprehensive and clear rules governing the marketing of food and beverages to children—rules that take into account the full spectrum of advertising and marketing practices across all media and apply to all children, including adolescents, as well as that address accountability shortfalls of current efforts [155].

F Eating and Dietary Practices

Much research examining the role of diet in the etiology of obesity has focused on associations between obesity and dietary intake (e.g., energy intake, portion size). As previously discussed, findings from this large body of research leave many questions unanswered. Research on eating practices and behaviors, such as meal patterns, dieting, and binge eating, provides insight on other factors that may influence dietary intake and weight status. In this section, we highlight some of the research that examines associations between specific eating practices and obesity and identify questions that remain unanswered, and make recommendations based on this body of research for future studies.

1 Meal Patterns

Research examining the pattern and timing of eating suggests that the timing and frequency of daily eating occasions may be associated with the development of overweight and obesity, as well as with weight loss [156,157]. Much attention has been paid to the importance of breakfast and the impact skipping this meal on weight gain and weight loss efforts [158–160]. In observational studies, skipping breakfast has been found to be higher among overweight adolescents and adults [159]. In a cross-sectional study of more than 8000 adolescents, usual breakfast consumption was reported by 53% of normal weight youth, 48% of overweight youth (85th–95th percentile), and 43% of obese youth (BMI > 95th percentile) [161]. In addition, several cross-sectional studies report associations between eating breakfast and better nutritional profiles [162] and increased physical activity levels [157] in children and adolescents. Breakfast eaters generally consumed more daily energy, yet were less likely to be overweight [162]. The quality of the breakfast meal is a key consideration, with consumption of ready-to-eat or cooked cereal typically associated with better nutrition and weight outcomes [163,164].

There is, however, relatively little evidence of a causal relationship between eating (or skipping) breakfast and obesity, and randomized trials investigating the impact of skipping breakfast on energy intake and weight loss are limited and report mixed findings [157,158,160]. Because of the cross-sectional nature of the evidence, it is not clear whether breakfast eating or skipping leads to obesity (e.g., it may be associated with higher energy intake at later times in the day) or whether it is a consequence of obesity (e.g., meals are skipped for weight-control purposes). Additional high-quality, randomized studies testing the relationship between breakfast and obesity are needed.

Meal skipping is frequently used as a weight-control method. Among adolescents and adults trying to control their weight, Neumark-Sztainer and colleagues [165] found that skipping meals was commonly reported; 18.6% of adult males and females, 22.8% of adolescent females, and 14.1% of adolescent males trying to control their weight reported skipping meals. An important question relates to the impact of skipping meals on overall energy and diet quality. In a study of women participating in a weight gain prevention study, skipping meals for weight-control purposes was not associated with overall energy intake [166]. However, meal skippers reported higher percentages of total energy intake from fat and from sweets, lower percentages of total energy intake from carbohydrates, and lower fiber intakes than women who did not report meal skipping [166]. Similar to the evidence on skipping breakfast, it is not clear whether meal skipping plays a causal role in the onset of obesity. Additional prospective studies and evaluations of interventions aimed at decreasing meal skipping are needed to assess causality. However, in light of the inverse associations between meal skipping and nutrient intake, and the potential for leading to uncontrolled eating due to hunger, meal skipping should not be recommended as a weight-control strategy. Rather, careful planning of meals with nutrient-dense foods that are low in fat and energy should be encouraged.

Similar to meal skipping, snacking behavior also has an inconsistent relationship with obesity [167,168]. While snacking behavior and the prevalence of obesity increased

simultaneously in the past several decades [74,169], recent studies suggest that relationships between snacking and weight may vary by gender and overweight status [170] and by the types of foods eaten as snacks [170–172]. Chapter 25, Snacking and Energy Balance in Humans, of this volume includes a more detailed discussion of this topic.

2 Dieting Behaviors and Dietary Restraint

Research findings clearly indicate that overweight individuals are more likely to report engaging in dieting and other weight-control behaviors than healthy weight individuals. For example, in a large cross-sectional study of adolescents, dieting behaviors were reported by 17.5% of underweight girls (BMI <15th percentile), 37.9% of healthy weight girls (BMI 15th–85th percentile), 49.3% of overweight girls (BMI 85th–95th percentile), and 52.1% of obese girls (BMI >95th percentile) [173]. In 5- and 10-year follow-ups of the same population, adolescents who reported dieting and unhealthy weight-control behaviors were found to be at increased risk for weight gain and for being overweight over time, even after adjusting for baseline weight status [174,175]. Adolescents who reported dieting and unhealthy weight-control behaviors at baseline had greater increases in BMI over the 10-year period, compared to peers who did not engage in these behaviors at baseline [175]. BMI increases were even greater for those young people who reported persistent dieting and unhealthy weight-control behaviors (i.e., reported at both baseline and the 5-year follow-up). Among persistent dieters, BMI increased by 4.33 for females and 6.96 for males over the 10-year study period, compared to increases of 2.38 and 3.45 among nondieters, respectively. For both females and males, persistent engagement in unhealthy weight-control behaviors predicted greater increases in BMI, compared to participants who did not engage in these behaviors (4.63 vs 2.29 for females and 5.42 vs 3.65 for males, respectively) [175]. Similarly, in a prospective study on adolescent girls by Stice and colleagues [176], baseline dieting behaviors and dietary restraint were found to be associated with obesity onset 4 years later. After controlling for baseline BMI values, the hazard for obesity onset over the 4-year study period was 324% greater for baseline dieters than for baseline nondieters. For each unit increase on the restraint scale, there was a corresponding 192% increase in the hazard for obesity onset [176].

These findings suggest that for some individuals self-reported dieting may be associated with a higher energy intake, and not a lower energy intake as intended. One explanation for this is that self-reported "dieting" may represent a temporary change in eating behaviors, which may be alternated with longer term eating behaviors that are not conducive to weight control. Another explanation is that self-reported dieting and dietary restraint may be associated with increased binge-eating episodes resulting from excessive restraint, control, and hunger. Indeed, Stice and colleagues did report positive, albeit modest, associations between binge eating and both dieting behaviors ($r = 0.20$) and dietary restraint ($r = 0.20$). In an analysis aimed at addressing the somewhat perplexing question as to why dieting leads to weight gain, Neumark-Sztainer and colleagues found that binge eating was an important mediating variable between dieting and weight gain over time in adolescents [174]. Other researchers have also suggested that dietary restraint may lead to binge-eating behaviors [177], thereby placing individuals at risk for weight gain, rather than the intended weight loss or maintenance [178].

3 Binge Eating

Lifetime prevalence of binge-eating disorder in the United States is estimated to be 2.6% [179]. In a cohort of adolescents followed from age 16 to 24 years, 2.3–3.1% of young women and 0.3–1.0% of young men reported binge eating [180]. Overweight individuals are more likely to engage in binge-eating behaviors than their normal weight counterparts among youth and adults [181–183]. In a nonclinical sample of adult women enrolled in a weight gain prevention program, binge eating was reported by 9% of normal weight women and 21% of overweight women [181]. Furthermore, binge eating tends to be more prevalent among overweight individuals seeking treatment for weight loss. It is estimated that about 30% of participants seeking weight loss counseling engage in binge eating [184], with about 3.5–5% meeting clinical criteria for Binge-Eating Disorder, the majority of whom are overweight or obese [185,186].

Success in weight loss efforts may be influenced by binge-eating behaviors, though previous studies report mixed findings. While most studies show that binge eating at the commencement of weight loss treatment does not influence weight loss success [187–191], several studies have found that baseline binge-eating status is related to program compliance and attrition [189,190] and may be related to weight loss maintenance [192–194]. Previous research has found that behavioral weight loss programs may positively impact binge-eating behaviors [193,195,196], with improvements in binge eating associated with better weight loss outcomes and maintenance [192,195–197]. In a weight loss maintenance study of adult women and men who had previously lost at least 10% of their body weight, prevalence of binge eating at any point during the study period was 30.1% [192]. Results from this study suggest that consistency of binge

eating may be important to weight loss maintenance; binge eating at baseline was not associated with weight regain, but those adults who reported binge eating during the study period had a higher rate of weight regain than those who did not report binge eating at any time point.

In working with overweight individuals within health care and other settings, it is essential to be sensitive to the daily struggles overweight clients may face within thin-oriented societies. Risk factors for binge eating include the internalization of negative weight stereotypes and thin-ideals, perceived pressure to be thin, and body dissatisfaction [198–201]. Overweight clients may be reluctant to share their binge-eating experiences; therefore a nonjudgmental attitude on the part of the health care provider is critical. For some individuals, hunger resulting from dieting or meal skipping may be a cause of binge eating, while for others binge eating may be a response to stress. Some individuals may be experiencing cyclical patterns; for example, emotional stress leads to binge eating, which leads to further emotional stress, which leads to further binge eating. Strategies for avoiding binge eating should be linked to factors that appear to be leading to binge eating for each individual.

4 Family Influences on Dietary Intake and Eating Practices

A considerable amount of research has been devoted to the role of the family in the etiology, prevention, and treatment of childhood obesity [202–204]. Family-based obesity treatments are rooted in the premise that the home environment and parenting practices are critical to the eating and activity behavior changes needed to successfully promote and sustain healthful body weight for children [205–207]. Epstein's parent-family-based obesity treatment produced impressive results. At the 10-year follow-up, 33% of all children decreased their BMI by 20% or more from baseline, and 30% were no longer obese. Other work supports the idea of parent-focused child-obesity treatment. After 7 years of follow-up, children whose parents received a parent-targeted intervention were significantly less likely to be obese compared to children who were themselves the target of the initial intervention (30% and 69%, respectively) [207]. These results suggest that targeting parents is of critical importance.

With regard to dietary intake and eating practices, questions arise as to how the family environment influences individual family members' eating behaviors and what parents and family can do to support healthy eating behaviors. The aim is to provide an environment in which healthful food is available, eaten in an enjoyable manner, and consumed in appropriate amounts. Most of the research in this area has focused on the influence of parents on their children's eating behaviors. Parents/caretakers may influence their children's dietary intake and eating practices via numerous channels. Some of the key channels include the home food environment [208–211] (including food availability, preparation, and accessibility), family meal patterns [212], infant and child feeding practices [213,214], and role modeling of eating behaviors and body image attitudes [215]. Research in the arena of adolescent health indicates that general family context variables are strongly associated with the emotional well-being of adolescents and with eating and other health-related behaviors [216].

The role of parenting in the promotion of healthy eating behavior and activity patterns has received increased attention in recent years. Research has focused on the role of domain-specific parenting styles, such as parent feeding practices, as well as the role of more general parenting styles and practices, such as authoritative versus permissive parenting. Food-specific parenting practices have been shown to be related to eating patterns, with some practices linked to healthy eating behaviors and others to unhealthy eating behaviors [217–220]. For example, restrictive feeding practices have been found to be associated with decreased fruit and vegetable intake [221] and greater child interest and desire for restricted foods [222], suggesting this may be a counterproductive strategy. For general parenting styles, the literature is more mixed; some studies do not support an association between parenting style and child dietary intake, while others have found that certain parenting styles, particularly authoritative parenting, are associated with healthier eating patterns [223]. Further research is needed on the relationship between general parenting styles and child dietary intake to provide a better understanding of how and through what mechanisms general parenting may affect child eating patterns. There is significant evidence of an association between family meals and child and adolescent dietary intake [212,224]. Previous research on children and adolescents has found that eating together with family is associated with greater intake of healthy food and lower intake of unhealthy food [212]. There is, however, inconsistent evidence linking family meals to child and adolescent weight status. Most research to date has been cross-sectional; several studies have found no association between family meals and child and adolescent BMI, while others have found that greater frequency of family meals is inversely associated with child BMI [225]. A recent longitudinal analysis provides evidence of a relationship between family meals during adolescence and weight status as a young adult. Berge and colleagues [226] examined 10-year weight outcomes of adolescents enrolled in Project EAT I and Project EAT III and found that those participants who reported having family meals at baseline had lower odds of overweight or obesity in

young adulthood, compared to those participants who reported no family meals. The association was strongest among African American participants, though results were significant among all racial and ethnic groups.

Although there is ongoing work in this area, research to date suggests that providing a healthy home food environment and healthy routines, such as family meals, are important. This allows children to make choices within their environment regarding exactly what and how much to eat and allowing for the development of internal regulation of food intake.

IV PHYSICAL ACTIVITY

Prominent among the health benefits associated with a physically active lifestyle is the protective effect of physical activity on obesity. Cross-sectional research shows that lighter individuals are more active than heavier individuals and prospective research indicates that changes in physical activity level are associated with changes in body weight in the direction predicted by the energy balance equation [227–230]. The majority of studies conducted in children also find that physical activity levels and body weight are negatively associated [231–233]. Exercise has also been shown to improve short- and long-term weight loss in experimental studies in both children and adults [234–236] and is a key factor in successful weight loss maintenance [237–239]. Despite these relationships, the weight losses achieved through changes in physical activity alone are often minimal. Therefore, recommendations for weight control include changes to both diet and physical activity [239].

A Prevalence of Leisure-Time Physical Activity in Adults

The 2008 United States Department of Health & Human Services Physical Activity Guidelines recommend that adults engage in 150 minutes a week of moderate-intensity, or 75 minutes a week of vigorous-intensity aerobic physical activity (or an equivalent combination of moderate- and vigorous-intensity aerobic physical activity) to obtain substantial health benefits. An approximate doubling of these amounts is recommended to obtain additional health benefits and two or more weekly muscle-strengthening activities are recommended in addition to aerobic activity. In order to achieve weight loss and weight maintenance, higher levels of moderate-to-vigorous physical activity (MVPA) (150–250 minutes per week) are recommended [239].

Despite the benefits of physical activity for body weight regulation and health, many individuals in the United States are insufficiently active or inactive. Using self-reported measures of physical activity, data from the BRFSS survey indicated that only 20.6% of American adults met guidelines for physical activity in 2011 [240]. Similar to prevalence with overweight and obesity, there are differences in physical activity by sex, race/ethnicity, age, and education: men tend to be more active than women; younger adults are more likely to be active than older adults, with the lowest levels of activity observed among those 65 years and older, and non-Hispanic whites report the least leisure-time physical activity compared to other racial and/or ethnic groups [240,241]. Socioeconomic disparities in physical activity are also observed, with education and income positively associated with leisure-time physical activity level [242,243]. However, when considering total physical activity (including household and occupational activity), many of these disparities are decreased or reversed [244].

B Prevalence of Leisure-Time Physical Activity in Youth

Although estimates of physical activity levels among youth tend to be higher than self-reports by adults, the prevalence of regular physical activity is still surprisingly low. Current physical activity guidelines for children suggest that children should get 60 minutes of activity daily which should include muscle-strengthening activities at least 3 days per week and 3 days bone strengthening activities [245]. Parent-reported data from the NHANES suggest that 70% of children aged 9–11 were meeting these recommendations in 2009 [246]. The availability of data on physical activity patterns and prevalence varies as a function of child age group. Representative survey data on the physical activity patterns of young children are not available, in part because of methodological difficulties in collecting such data from children. Young children are limited in their ability to accurately recall their activity patterns, and the unplanned, unstructured nature of children's physical activity patterns does not lend itself well to the self-report format employed in large-scale surveys. Increasingly, accelerometry is used to estimate children's physical activity levels, with Actigraphs used to measure physical activity in NHANES beginning in 2003.

According to data from the CDC's Youth Media Campaign Longitudinal Survey (YMCLS), a nationally representative survey of children aged 9–13 years and their parents was conducted between 2002 and 2006 [247,248]. Data from the 2002 survey found that 61.5% of children aged 9–13 years did not participate in any organized physical activity during their nonschool hours and that 22.6% did not engage in any free-time physical activity. Between 2002 and 2006, physical activity levels reported on the YMCLS remained stable or slightly increased. Examination of 2003–04

and 2005–06 NHANES physical activity data measured by accelerometry among 6- to 19-year olds showed that 6- to 11-year olds spent over twice as much more time (88 minutes per day) engaged in MVPA compared to 12- to 15-year olds and 16- to 19-year olds who engaged in 33 minutes/day and 26 minutes/day, respectively [249]. Data from the Youth Risk Behavior Surveillance Surveys (YRBS) among U.S. high school students showed that in 2007, just over one-third of youth reported any kind of physical activity that increased their heart rate and made them breathe hard some of the time for a total of at least 60 minutes per day on 5 of the 7 days preceding the survey [250]. The 2007 YRBS data also showed that just under one-third of adolescents participated in insufficient amounts of physical activity. Similar to patterns observed among adults, across multiple national surveys, physical activity levels tend to be higher among boys compared to girls and higher among non-Hispanic White youth compared to Black and Hispanic youth [251]. Moreover, activity levels predictably decline as children transit into adolescence.

C Determinants of Physical Activity

In addition to the demographic determinants of physical activity, including age, gender, race/ethnicity, etc., there are important modifiable determinates of physical activity that can be leveraged to enhance physical activity and weight-control interventions. Although there are numerous potential determinants to consider (e.g., see Ref. [252]), a selection of impactful determinants will be presented here for consideration.

1 Self-Efficacy

Self-efficacy is an individual's belief in his or her ability to successfully engage in a given behavior which may influence the activities that individuals choose to approach, the effort expended on such activities, and the degree of persistence demonstrated in the face of failure or aversive stimuli [253]. Exercise self-efficacy is the degree of confidence an individual has in his or her ability to be physically active under a number of specific/different circumstances or, in other words, efficacy to overcome barriers to exercise [254]. Exercise self-efficacy is one of the strongest and most consistent predictors of exercise behavior in adults [255–260]. Self-efficacy is particularly important during challenging transitions such as beginning a physical activity routine [257] or when faced with barriers to remaining active [260]. Self-efficacy has also been shown to be highly related to physical activity in youth [261–264]. Perceived competency, an aspect of self-efficacy, is predictive of maintaining activity during the transition from adolescence to adulthood, specifically among females [265].

2 Social Support

Social support is another strong correlate of physical activity for both youth [266–275] and adults [276–283]. Adults who engage in regular exercise report more support for activity from people in their home, work, and social environments. Instrumental support may be particularly important for initiation efforts among sedentary adults [284]. Carron et al. [285] examined six major sources of social influence on physical activity, including important others such as physicians or work colleagues, family member, exercise instructors, or other in-class professionals, co-exercisers, and members of exercise groups, in a comprehensive review. In studies testing how social support may influence physical activity, social support has been found to influence self-regulation behaviors associated with higher levels of physical activity, both directly and indirectly, through self-efficacy [286] and through motivational variables [287]. Further investigation of the pathways through which social support influences physical activity is important for developing effective interventions that capitalize on social influences.

Positive family environments and family support for physical activity is a robust correlate of physical activity for both boys and girls [267,269–272,274,275]. A comprehensive review examining the relationship between parental social support and youth physical activity identified two overarching categories of support, tangible and intangible [288]. Within these overarching categories, subcategories were identified. Tangible support included instrumental support, such as purchasing equipment, payment of fees, and transportation and conditional support which included either involvement of the parent in the activity or being physically present, but not directly participating in the activity. Intangible support included motivational support such as providing encouragement and praise, and informational support. Across the 80 reviewed studies, the majority demonstrated positive associations between the various types of parental support and physical activity. Peer support has also been shown to be a strong correlate of youth physical activity level with the influence of peers increasing over time [267,268,273,289].

The use of online social networks has grown in recent years: currently 65% of American adults regularly use online social networks [290]. With this growth, there is also growing acknowledgment of the role online social support can play in supporting health behaviors such as physical activity. While this is a newer area of research, there is evidence that individuals who use online social networks seek and gain social support for physical

activity and other health behaviors [291,292]. These platforms can be harnessed to enhance social support during intervention (e.g., see Ref. [293]) and may be especially useful when intervening with individuals whose unique social support needs may not be fulfilled through traditional social support networks. As an example, online social support was utilized to help improve physical behaviors of young adult cancer survivors, a group for whom social support is vital but difficult to create through traditional means [294].

3 Overweight and/or Discomfort With Physical Activity

Clearly, body weight and physical activity are inextricably linked. Although it is clear that increasing physical activity is an important factor in regulating body weight, weight status may serve as a barrier to physical activity. This is due in part to physical activity being less pleasurable (e.g., it is uncomfortable for people to exercise when they are heavier), and in part because of embarrassment (e.g., individuals report feeling embarrassed about being seen in public in exercise clothes, at gyms, due to weight status and societal reactions toward overweight individuals) [295] or due to body dissatisfaction [296]. However, weight status can also be a motivator for initiating exercise. One of the most common reasons adults give for exercising is weight control, and physical activity is one of the strongest correlates of successful weight loss and maintenance [297]. Physical activity promotion programs, however, need to be modified to address the needs of overweight youth and adults. Longitudinal data on adolescents indicate that body dissatisfaction predicts lower levels of physical activity, suggesting a need for physical activity interventions that help individuals feel more comfortable with their bodies, regardless of their weight status [298].

4 Exercise History

Prior history of physical activity should positively influence future physical activity behavior by promoting and shaping self-efficacy for exercise and by developing physical activity skills. The observed relationship between exercise history and exercise behavior varies, however, depending on how exercise history is defined and the time period over which physical activity behavior is assessed. Physical activity has been shown to track moderately well across childhood and adolescence [299] and in adulthood [300]. A systematic review of 27 papers from 16 different cohorts that included baseline age ranges from 8 to 10 years, with follow-up duration ranging in length from 5 to 55 years suggested that physical activity tends to track more strongly in boys compared to girls, at older ages, and tracks less strongly with increasing years of follow-up [301]. Youth who participate in sports tend to be more likely to be physically active as young adults [302,303]. Interestingly, there is an emerging literature suggesting that sedentary activities such as television viewing and video game use also track across childhood [304]. The perception of the exercise experience as a child may be as important as amount of childhood exercise. One recent study found that recalling being forced to exercise as a child was associated with lower levels of physical activity in adulthood [305]. A child's enjoyment of physical activity [306,307] and enjoyment of physical education experiences [308] are significant predictors of physical activity levels. Creating positive environments for physical activity for youth is likely a key factor in promoting higher levels of physical activity as a lifestyle habit.

5 Time

Among adults, time constraints are the most frequent barriers to exercise and are reported by both sedentary and active individuals across diverse populations with respect to age, race/ethnicity, and gender [309–315]. Even among regular exercisers, scheduling efficacy remains an important and significant predictor of adherence [254]. Therefore, to maintain exercise adherence, regular exercisers have to become adept at dealing with time as a barrier. The time barrier may be a particular problem for certain population subgroups. For example, time spent caring for children may make it difficult for parents to maintain a regular physical activity program [315].

Several physical activity intervention approaches geared toward addressing the time barrier have been developed in recent years. These include strategies to help people fit exercise and physical activity into their lives without necessarily having to engage in center- or gym-based activities, such as home-based programs, using either phone- [316–318], mail- [319,320], or technology-based [319,321–323] delivery modalities (e.g., web-based options, smart phones). Another strategy to address the time barrier has been to focus on the potential health benefits of integrating multiple short bouts (<10 minutes) of physical activity across the day. A recent systematic review of the evidence for the effectiveness of short activity bouts that are incorporated into organizational routines in schools and work settings concluded that interventions that integrate physical activity into organizational routines have shown modest but consistent benefits [324]. Even shorter bouts of high-intensity training of <5 minutes have received growing attention and is a potential intervention approach to offset the perception of limited time [325].

6 Access and Environmental Factors and the "Built Environment"

Another barrier that has received increasing attention in recent years is access to exercise facilities, including parks and recreational facilities and safe and attractive places to walk and play outside. The burgeoning literature on the linkages between the built environment and physical inactivity and obesity has increasingly recognized the complexity in measuring the various aspects of the environment that are thought to be important. Brownson and colleagues [326] categorize measurement of the built environment in the following three ways: (1) perceived measures obtained by telephone interview or self-administered questionnaires; (2) observational measures obtained using systematic observational methods (audits); and (3) archival data sets that are often layered and analyzed with geographic information systems. An extensive review of this literature is beyond the scope of this chapter; however, recent comprehensive reviews are available [327]. Distance between individuals' homes and recreational and exercise facilities and/or density of such facilities has been shown to be negatively correlated with exercise behavior in adults [328]. Depending on an individual's activity preference, access to exercise facilities may or may not be related to exercise levels. For those individuals who prefer exercises such as walking or running, which can be done anywhere, access to facilities may be less relevant. Additionally, for those who exercise with home equipment, which could include stationary bikes, treadmills, and even exercise videos, access to facilities may also not affect exercise adherence. Regardless, the extent to which environments are conducive to physical activity likely has a strong impact on population activity levels (e.g., walking/biking paths, safe streets). In addition to objective measures of availability, perceived availability and perceived safety are important [327].

Physical activity among youth appears to be particularly strongly influenced by environmental factors [327,329,330]. The amount of time children spend playing outside has been shown to be a strong correlate of physical activity levels in some [331,332], but not all [333]. Children who live in neighborhoods where play spaces are not adequate are going to have more difficulty achieving recommended levels of physical activity. Further, both child and parent perceptions of neighborhood safety influence children's levels of physical activity [334]. Inequality in availability of physical activity facilities and access to safe play spaces may contribute to ethnic and socioeconomic disparities in physical activity and overweight patterns among youth. Use of after-school time for sports and physical activity, access to community sports activities, and frequency of parents transporting children to activity locations have all been shown to be correlates of physical activity in boys and girls [335–339]. The extent to which families have time and resources to support their children in physical activity pursuits will also have a strong impact on children's activity levels. Anecdotal reports suggest that children spend less time in unstructured physical activities (e.g., neighborhood pick-up games, hide and seek, tag) than in previous years. In contrast, there appears to have been an increase in community-organized sports (e.g., traveling soccer and basketball teams) that require increased parental time, involvement, and financial resources. These factors may potentially contribute to decreases in physical activity and increased socioeconomic differences in physical activity and obesity risk among youth and is an area worthy of further exploration.

a Sedentary Behavior

A related but separate concern from physical activity is the rise of sedentary behavior. Although low levels of leisure-time physical activity likely contribute to the epidemic of obesity, leisure-time activity has remained stable or increased since the mid-1980s, the period during which the prevalence of obesity increased [340]. The past century, however, machines with motors have replaced human labor in virtually every aspect of life, so that the energy expenditure now required for daily life is a fraction of what it was a generation or two ago. Recent examination of data from the U.S. Bureau of Labor Statistics and NHANES estimates that over the last 50 years occupation-related energy expenditure has decreased by more than 100 calories per day [341]. Simultaneous with this change, technology has increased opportunities for sedentary leisure-time activities as well, including television, personal computer use, and mobile devices. This combined change has led to an increase in sedentary activity. Objectively assessed data from NHANES suggest that American adults are sedentary 7.7 hours per day [342] and children are sedentary for 5.5–8.5 hours [251]. Sedentary behavior has recently received growing attention as a separate risk factor for mortality above and beyond physical activity [343].

Television viewing is a major source of inactivity and has received considerable attention as a risk factor for obesity. In addition to contributing to sedentary behavior and displacing time potentially spent in more active pursuits, television viewing has been hypothesized to contribute to excess energy intake [344] and can serve as a cue for eating high-fat, high-energy foods [345]. According to data provided by A.C. Nielsen Company, the average household television set is turned on for more than 7 hours per day [346]. Survey data estimating the frequency of television watching are necessary, however, because television viewing is not necessarily the primary

activity when the television set is turned on. Data from the Americans' Use of Time study show that free time spent watching television increased from about 10.4 hours per week in 1965 to about 18.9 hours in 2010 [347]. Nielsen data indicate that the amount of time per day adults spend watching television is closer to 5 hours per day. Increasingly, adults are watching "time shifted" television and simultaneously watching television while using the Internet.

The high frequency of television viewing and other "screen time" among youth is disturbing. A recent review of the literature indicates that boys and girls are watching 1.5−3.7 hours and 1.4−3.0 hours of television per day, respectively [348]. The AAP recommends that children over the age of 2 watch no more than 2 hours of "screen time" per day. Recent examination of NHANES data (2001−06) indicated that nearly half (47%) of the children and adolescents spent ≥2 hours per day total screen time, largely driven by time spent viewing television [349]. Examination of media use data in younger children, including toddlers and infants, is also concerning. Despite the fact that the AAP discourages media use and screen time for children under the age of 2, a telephone survey conducted in Washington and Minnesota indicated that about 40% of children regularly watched television, DVDs, or videos by 3 months of age, with about 90% of children regularly experiencing screen time by 24 months of age [350]. Examination of data from the National Longitudinal Survey of Youth (1990−98) indicated that almost one-fifth of 0- to 11-month olds and almost half of 12- to 23-months olds watched more television than the AAP recommends [351]. Demographic factors associated with higher screen time in younger children include lower levels of parent education [351] and race/ethnicity with African American and Hispanic children tend to watch more television than non-Hispanic White children [351,352].

Cross-sectional research has shown that there is a consistently strong positive relationship between television watching and obesity in children [333,345,353−358] and adults [359−363]. Although it has been hypothesized that television watching influences obesity by replacing time that could otherwise be spent engaging in more active pursuits, data suggest that this relationship may not always be so simple (i.e., increases in sedentary behavior may result in decreases in physical activity, but physical activity does not necessarily increase in the context of reductions in sedentary activity) [364] and that physical activity and television viewing are often independent predictors of obesity [353]. Additional hypotheses regarding associations between television watching and obesity implicate increases in energy intake linked with television watching. The 2005 Institute of Medicine report focused on food marketing to children concluded that there is strong evidence that television advertising influences children's food preferences and requests, short-term food consumption patterns, and possibly usual dietary intake, and that exposure to advertising is associated with adiposity in children [365].

V CONCLUSION

We have reviewed the literature on key diet and physical activity related risk factors for obesity in children and adults. Highlights related to dietary intake include (1) recognizing the contribution of total energy intake to energy regulation; (2) the influence of eating practices such as eating out, breakfast skipping, restrained eating, and binge eating on obesity; and (3) social and environmental factors that promote excess energy intake. Highlights of the review from the physical activity domain include (1) the importance of addressing the influence of both leisure-time physical activity and sedentary behavior to total energy expenditure; (2) the importance of fostering both self-efficacy and social support for physical activity to promote higher levels of physical activity; and (3) the influence of environmental factors on physical activity levels. To effectively combat the public health problem of obesity, interventions and policies that target change in dietary intake and physical activity are necessary. Intervention efforts must take into account that dietary intake and physical activity are complex, multidetermined behaviors influenced by individual, social, and environmental factors [366].

The etiology of obesity is complex and encompasses a wide variety of social, behavioral, cultural, environmental, physiological, and genetic factors. To effectively address the obesity epidemic in the United States, considerable effort must be focused on helping individuals at the population level to modify their diets and increase their physical activity levels, key behaviors involved in the regulation of body weight. Educational and environmental interventions that support diet and exercise patterns associated with healthy body weight must be developed and evaluated. Prevention of obesity should begin early in life and involve the development and maintenance of healthy eating and physical activity patterns. These patterns need to be reinforced at home, in schools, and throughout the community. Public health agencies, communities, government, health organizations, the media, and the food and health industry must form alliances if we are to combat obesity.

Chapter 25

Snacking and Energy Balance in Humans

V. Drapeau, S. Pomerleau and V. Provencher
Laval University, Quebec, QC, Canada

I INTRODUCTION

Increasing rates of overweight and obesity over the past decades have coincided with changes in dietary patterns. Snacks have become a major source of the daily energy intake in the population. Despite the vast body of existing evidence studying the impact of snacking on energy balance in humans, it remains unclear whether snacking contributes to overweight or whether it can help with weight management.

Although this chapter reviewed studies involving adults and children, it is not a systematic review of the literature. It first presents the current definitions that describe snacking and how these definitions influence results observed throughout the literature. The prevalence of snacking and the types of food consumed as snacks are detailed in order to get a broader picture of the situation. Thereafter, evidence showing the effects of snacking on energy balance is presented and highlights both the beneficial/neutral and the negative impacts of snacking on energy balance. For a better understanding of why snacking may be seen as beneficial or as a risk factor, possible mechanisms are also explained. At the end, some recommendations are presented on how snacks can be integrated into a healthy diet.

II DEFINITION OF SNACKING

The impact of snacking on energy balance is a significant source of controversy in the literature. Snacking has been recognized to have positive outcomes such as the contribution of nutrients to the diet, lower body mass index (BMI) and greater weight loss, but it has also been associated with negative outcomes such as weight gain and obesity. Defining snacking is not a simple task as it includes different dimensions such as "what," "how much," "when," and "how" foods are eaten and is influenced by cultural norms. These differences likely explain why no consistent definition has been adopted among researchers in the field (Fig. 25.1).

The different definitions of snacking used in the literature have been recognized as the principal factors influencing the link between snacking and energy balance. Many definitions have been proposed, which all have strengths and weaknesses. The most common definitions are based on (1) time of day food is consumed, (2) portion size, (3) time and portion size, (4) number of eating events per day, (5) self-reporting, (6) type of food and its nutrient profile, (7) where eating occurs, and (8) physiological responses. The first four criteria—which seem to be favored in clinical trials—can be objectively defined and measured. The subsequent three are more subjective and frequently employed in large research surveys in which collecting detailed snacking data may not be feasible. Although often used interchangeably, these definitions address different dimensions of snacking with some overlap between them. Besides these definitions based on observations and reporting of eating behaviors, another interesting definition founded on physiological responses was proposed. This definition is related to the presence or absence of a triggering physiological stimulus. However, this method has been less commonly used so far. Thus, at this time, it is critical that the strengths and weaknesses of different definitions be understood so that appropriate inferences can be drawn from the data collected from each. Moreover, since no single definition adequately covers the different dimensions, these definitions should be used to derive a global definition. Table 25.1 presents the different definitions with their strengths and principal limitations.

In summary, there is no single, widely accepted definition of snacking. Each approach holds advantages and inconveniences. It is also noteworthy that most of these

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00025-4

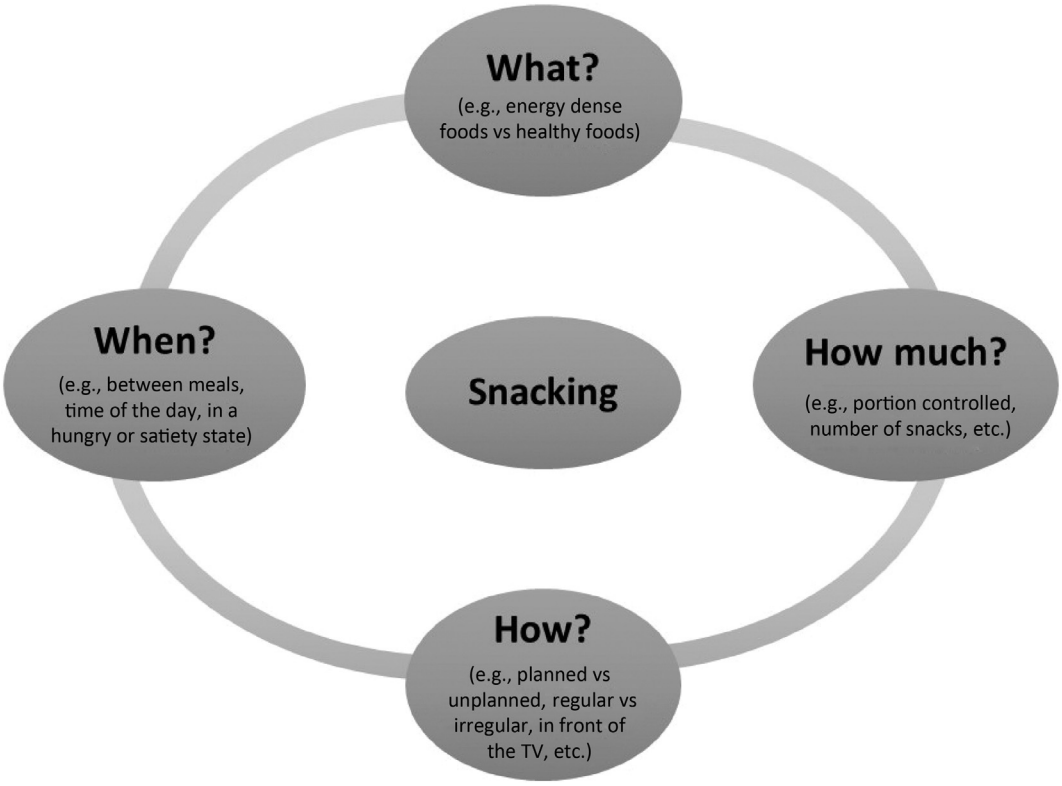

FIGURE 25.1 Dimensions of snacking patterns. *Adapted from C. Berg, H.B. Forslund, The influence of portion size and timing of meals on weight balance and obesity, Curr. Obes. Rep. 4 (2015) 11–18 [1].*

definitions are subject to underreporting as they are usually assessed with 24-hour dietary recalls, food diaries, or food frequency questionnaires. This limitation will be further discussed in another section. The selection of a definition depends on the study objectives and the feasibility of collecting different types of information. It is important to note that findings based on one definition are difficult to interpret and to compare with other results not using the same definition. Another critical point—there is no single measure that is broadly representative of all snacking dimensions. Perhaps, the combination of more than one definition could represent an avenue to adequately assess snacking behaviors.

III PREVALENCE OF SNACKING

In the United States, data from National Health and Nutrition Examination Survey (NHANES) showed that snacking behaviors have changed over the last four decades [3]. In comparison to the 1971–74 surveys, results from 2007 to 2010 revealed a greater proportion of adults eating snacks. Overall, 90% of the population consumed snacks in both genders. These results are based on participant self-reporting where snack was defined as "any eating event identified as snack, drink, between meals, extended consumption." Furthermore, data from 2007 to 2010 indicated that approximately 66% of US adults consumed two or more snacks per day compared to 63% in 1971–74. Consequently, the percentage of people consuming more than 50% of daily energy intakes from snacks has significantly increased among men and women. Interestingly, while the interval between breakfast and lunch remained unchanged, the interval between lunch and dinner was slightly longer, which has resulted in a shorter interval between dinner and after-dinner snacks over the decades.

Similar results have also been observed for adults in Europe (France [4], United Kingdom [5], and Finland [6]) and in Latin America (Brazil [5] and Mexico [7]). While trends showing higher rates of snack consumption over the last years have also been noted in China, the proportion of snackers remains smaller (37% of adults consuming snacks) than other countries [8]. Although cultural differences may be seen among countries (e.g., number and times of daily eating episodes), trends showing an increase of eating patterns that include snacks remain constant around the world [9]. Incidentally, a "snack-dominated eating pattern" has been described among Finnish population representing the habit of consuming a majority of daily energy from snacks [5]. A similar pattern was

TABLE 25.1 Different Snacking Definitions

Snacking Dimension	Definition	Strengths	Limitations
1. Time of the day	Based on the consumption of foods at specific times of day (mid-morning, mid-afternoon, and evening)	Convenient for data analysis by avoiding ambiguous or arbitrary food attribute quantification such as form, nutrient profile, or portion size	Subject to error due to different lifestyles and eating patterns, for example, cross-culturally, the main eating event in the North America tends to occur at approximately 6 p.m. versus 10 p.m. in some European countries; eating early or late in response to working schedule may shift meals to snacks and vice versa
2. Portion size	Based on the consumption of a snack with a portion size smaller than that of a meal. Can be calculated by summing the calories from two or more foods consumed together	Avoid limitations attributable to defining what time of day a snack or meal occurs	Still requires an arbitrary criterion for differentiating meals from snacks; Difficult to assess cultural practices; Subject to time trends, that is, portion size of snacks may increase with rising daily energy intakes and portion sizes complicating the interpretation of findings from the literature
3. Time and portion size	Based on foods or a group of foods, with a predetermined portion size, consumed after a specific period of time following other eating events with a defined portion size	More objectively measured data because it considers the intervals between two eating occasions and the energy content of the foods consumed within an eating event	Based on arbitrary criteria defined by the researcher versus observed cultural patterns
			Not applicable for large surveys because the necessary level of time and portion size detail is often not available (e.g., with food frequency questionnaires)
4. Number of eating events	Based on the number of eating events which usually includes regular meals and snacking	Provides more flexibility than the "time of day" definition because meals do not have to be eaten within specific times of the day	Eating events usually self-defined by the respondents, which can result in different definitions applied across individuals or cultures, hampering comparative analyses
	Meals are expected to follow a relatively fixed routine, especially during the week (breakfast, lunch, and dinner), whereas snacking is assumed to be less structured and regular and thus may occur at different times and places	Can be used for individuals with different lifestyles and cultural backgrounds	Requires a researcher-imposed set of criteria, and no consensus on metrics exists
5. Self-reporting	Based on self-reported foods that are consumed as part of a meal or snack	Commonly used approach in epidemiological studies	Based on self-reported data which can be significantly affected by cultural norms and perceptions, for example, if the participant criterion to identify a snack was based on food type or portion size, it is unclear how this respondent would report the same food eaten as a meal or how another participant would classify the same food as a snack
		Has strong cultural connotations but largely defies objective documentation	

(*Continued*)

TABLE 25.1 (Continued)

Snacking Dimension	Definition	Strengths	Limitations
6. Types of food and nutrient profiles	Based on the nutrient profile of foods snacks can be classified according to nutrient density; several classification systems identifying high-quality snacks exist, but criteria vary, with little congruence between systems	Could help to identify specific foods associated with better outcomes on energy balance and health	Subject to misclassification of snack food items. Some foods have mixed profiles providing important nutrients and high energy density (e.g., ice cream) and/or can have other properties that do not promote positive energy balance or weight gain (e.g., nuts)
7. Where snacking occurs	Based on the place where snacking occurs. In this case, meals are assumed to be eaten at a fixed place such as a table at home or at a restaurant, whereas snack foods are, by default, consumed elsewhere	Avoid issues related to food type, nutrient content, time of day, and portion size and is easily distinguished from a meal	Cannot easily be distinguished from secondary eating and drinking, that is, when individuals indicate another activity as their primary focus, for example, eating while driving, etc.
8. Physiological response	Based on the presence or absence of a triggering physiological stimulus, that is, drop in blood glucose, a snack would be defined as an eating event not triggered by hunger, but instead elicited by an external nonphysiological stimulus	Objective measure	Does not consider time of consumption or nutrient profile Does not consider differences in metabolic status before a meal or a snack, which can influence substrate oxidation

Source: Adapted from R. Mattes, S.Y. Tan, Snacking and energy balance in humans (Chapter 27), in: A. Coulston, C. Boushey, M. Ferruzzi (Eds.), Nutrition in the Prevention and Treatment of Disease, third ed., Academic Press, New York, NY, 2013 [2].

noted in Brazil where nearly 23% of the population reported eating more than three snacks per day (defined as heavy snackers) [6]. The average number of snacks reported was 1.6 snacks per day. This average was nearly the same in Mexico [7] while it was a little over two snack episodes per day in the United States [3,10].

Nationally representative survey data indicated that the contribution of snacks to the overall dietary intake of U.S. children and adolescents also increased over the past few decades [11,12]. The prevalence of snacking, that is, at least one snack over two recall days, increased from 74% in 1977–78 to 98% in 2003–06 [11]. Over the same period, the average frequency of snacking increased by one occasion per day to reach an average of two snacking occasions per day in 2003–06 and the contribution of snacking to total energy intake increased to 27% in 2003–06. Analyses of trends in dietary intake in U.S. children have also shown that there was a significant increase in the contribution of energy-dense foods, nutrient poor foods, and beverages to the total daily energy over the past decades [13].

Overall, snacks represent roughly 20–25% of daily energy intake for both adults and children [3,7,11,14,15]. In Canada, snacks now provide more calories than breakfast [14]. American data from 2003 to 2006 showed an increase in the daily energy intake coming from snacks for children (from 244 to 496 kcal/day) and adults (from 196 to 472 kcal/day) when compared to data from 1977 to 1978 [16]. Energy per snacks has also risen from 502 to 634 kcal/snack among men and from 296 to 438 kcal/snack among women in the United States over the last 40 years [3]. In Norway, energy content per snack was slightly lower with 406 and 430 kcal for women and men, respectively [15] and in Mexico, total energy per snack was even lower with an average of 178 kcal for both genders and all ages [7]. In Brazil, light snackers (one to two snacks per day) consumed more calories per snack when compared with heavy snackers (280 vs 233 kcal, respectively) [6]. However, heavy snackers consumed almost twice as many calories per day from snacks compared with light snackers (832 vs 422 kcal, respectively). In the case of the heavy snackers, energy from snacks accounted for 35.5% of the daily energy intake, while it was 21.7% for light snackers. Among Brazilians, the largest number of snacks was consumed in the afternoon or early evening whereas the largest volume (grams/snack) and energy content per snack were reported in the late morning and late at night [6]. In China, the most popular time for taking a snack was the evening [8] while it was mid-morning and mid-afternoon in Mexico [7]. It should be noted that

in Great Britain, snacking peaks at three moments during the day, which are usually 2−3 hours after breakfast, lunch, and dinner [17]. These data show cultural differences that are mostly explained by the time of the day meals are consumed and, consequently, may affect the timing of snacks [9].

IV SNACKING AND TYPE OF FOOD CONSUMED

For both adults and children, compared with foods eaten at meals, foods consumed as snacks are often lower in fat and protein while being higher in carbohydrates, added sugars, and fiber [6,13,15,18]. Another study demonstrated that most snacking patterns among adults were correlated with higher intakes of potassium, calcium, fiber, vitamin A, and magnesium [19]. Similar results have been observed among older adults (over 65 years old) where snacking frequency was positively correlated with daily intakes of vitamins A, C, and E, magnesium, copper, potassium, and beta-carotene [20]. In order to take into account the overall diet quality, some studies have used the U.S. Department of Agriculture's Healthy Eating Index (HEI). Data from NHANES 1999−2004 showed that snacking was modestly but significantly associated with higher HEI scores and a slightly more nutrient-dense diet [21]. When analyses are made by studying the snacking patterns, results reported that several snacking patterns were associated with better diet quality than those consuming no snacks [19]. The only snacking pattern significantly inversely correlated with diet quality was the soft drink pattern. In terms of food groups, results from a cross-sectional study reported that only the percentage of energy from nuts, fruits, and juices was significantly positively associated with diet quality [10]. Conversely, snacking energy coming from desserts, sweets, and sugar-sweetened beverages was significantly inversely correlated with diet quality. When comparing snack choices between genders, it was noted that women were more likely to choose healthier snack foods while men were more likely to choose unhealthy snack foods such as sweets and savories [22].

In China, the most common snacks were fruits, grains, and beverages over all age groups [8]. Interestingly, the increase in snacking observed over the two last decades seems to be explained by a high consumption of fruit as snacks. In the Mexican population, fruit was also the most common snack among adults [7]. Otherwise, salty snacks, sweet snacks, sugar-sweetened beverages, and milk were frequently consumed as snacks. Similar results were reported in an article studying a population from Brazil [6]. The most commonly consumed snacks were sweets and desserts, fruit, sugar-sweetened beverages, and also sweetened coffee or tea and a typical Brazilian snack (*salgados*, which is a high-calorie fried/baked dough). While fruit is also a common snack in Great Britain, the most common snacks are confectioneries such as chocolate and biscuits [17]. It was noted that the most popular snacks are those which can be easily transported. In Canada, data demonstrated that more than 41% of the calories eaten between meals were coming from the "other foods" category such as high-fat and/or high-salt snack foods or beverages [14]. In Spain, results from a survey revealed that snacking was positively associated with regular consumption of salty and fatty foods [23]. In the United States, total fruit, whole fruit, whole grains, milk, oils, and sodium component scores were positively associated with snacking frequency [21]. In the United Kingdom, an interaction between BMI and snacking frequency has been noticed [4]. Thus, differences in the types of snacks consumed were examined by BMI. Results showed that overweight individuals had higher intakes of crisps, chocolates, ice cream, and sweets and lower intakes of yoghurt and nuts when compared with normal-weight individuals.

Regarding the food forms, data from NHANES 2006 showed that food-only snacks increased by 180 kcal per day for both children and adults while adults only consumed on a daily basis approximately 100 kcal more from snack beverages when compared to 1977 [16]. Over the years, the percentage of snack calories coming from beverages remained essentially the same for all age groups. However, this percentage was lower in children (∼25% of all snack calories) than in adults (∼35% of all snack calories). As for the energy density coming from snack beverages, it has increased over the years in all adults [24]. Moreover, it has been noted that the number of snack episodes and the duration of each eating period increased with the daily energy intake from beverages [25]. Consequently, beverage-only snacking episodes tended to result in increased energy intake over the day.

Results from these studies suggest that snacking may be compatible with an adequate diet quality [9]. However, snacks are increasingly considered as an important part of eating patterns, which may involve either favorable (healthy and/or nutrient-dense) or less favorable (unhealthy, low nutrient, and/or high energy-dense) foods [15,22].

V SNACKING AND ENERGY BALANCE

Over the last decades, eating frequency and energy intake from snacks have both increased and obesity has been on an upward slope. On a theoretical basis, daily total energy intake varies according to eating events as well as energy intake and/or energy density during these eating occasions. That said, a high number of eating events may not

necessarily promote a positive energy balance if they are low in energy content. Nevertheless, it has been shown that caloric intake within an eating occasion is influenced by the portion size in both children and adults leading to overconsumption [1,26]. Therefore, even though it is widely assumed that larger portion sizes contribute to high rates of overweight and obesity [27], it is not clear whether or not caloric compensation (e.g., reduction of intake in main meals) occurs when snacks are consumed.

For both adults and children, studies reported that a greater eating frequency or a "snacking pattern" may promote a positive energy balance [13,19,28–31]. The number of snacks was directly related to the daily energy intake indicating that snack consumption is not entirely compensated by reduced food intake during main meals [28]. Among adolescents and adults, an increase in energy intake from snacks was a result of greater snacking frequency and also, larger snack portion size [32,33]. However, eating frequency was also negatively associated with energy intake per eating occasion [6,31] and greater eating frequency was reported to not correlate with a higher BMI in adults [22,31,34] and children [35].

The first part of this section [Beneficial Effect or No Effect of Snacking on Energy Balance (Weight Management) and Negative Effect of Snacking on Energy Balance (Overweight and Obesity)] presents more detailed studies that investigated the association between snacking and body weight or BMI. A more important focus was directed toward data published after 2010 within this section, but results from older studies can also be found in Tables 25.2 (children) and 25.3 (adults). The second part of this section (The Benefits and Risks of Snacking: Possible Explanations and Proposed Mechanisms) presents factors explaining why snacking may be perceived as both beneficial and deleterious for weight management.

A Beneficial Effect or No Effect of Snacking on Energy Balance (Weight Management)

Several studies reported a beneficial role of snacking on energy intake and thus on energy balance suggesting that snacking may be helpful in the context of body weight management. Most of these studies used a cross-sectional or prospective design but there are also a few intervention studies supporting this outcome.

Adult cross-sectional studies have reported either beneficial or neutral roles of snacking on energy balance. One of these studies verified dietary patterns and their associations with BMI [34]. The "snack pattern" was significantly correlated with a lower BMI. Another group of researchers compared normal-weight individuals to weight loss maintainers and overweight individuals [55]. It has been observed that self-reported eating frequency—including meals and snacks—was higher among normal-weight and weight loss maintainers than in overweight participants and there were no differences in the number of meals consumed. Authors further concluded that eating frequency may be an important aspect for weight loss maintenance. Differences between obese and nonobese individuals have also been noticed through another cross-sectional study showing that normal-weight subjects consuming additional snacks were associated with lower body fat [4]. Hence, these results suggest a beneficial impact of snacking on weight management both for obese and nonobese individuals.

Neutral effects of snacking on energy balance have also been reported. Data from a food panel questionnaire completed by more than 6000 participants evaluated the association between snack frequency (number of additional food items consumed between main meals) and BMI [22]. Results indicated that there was no association between snack frequency and BMI. Among women 40–60 years old, a study revealed that eating frequency which included meals and snacks was not associated with overweight and was not different between BMI groups [31]. Conversely, eating frequency was positively associated with total energy intake but negatively associated with energy intake per eating occasion regardless of BMI. Another cross-sectional study investigated dietary patterns at two different European universities and their relationship to BMI [58]. There were no general relationships between BMI and snacking regardless of the country. Thus, results from these cross-sectional studies in adults demonstrated that consumption of snacks is not associated with a higher BMI and might help individuals maintain their weight loss.

The beneficial or neutral impact of snacking on energy balance observed in adults has also been observed among children and adolescents. For example, Snoek and colleagues [37] noticed that high snacking frequency was associated with a lower risk of being obese compared to low snacking frequency in children or adolescents. Another cross-sectional study performed in 5811 American adolescents showed that snacking frequency and percent energy from snacks were associated with a lower prevalence of overweight/obesity regardless of reported efforts to lose weight in some adolescents [41]. Kelishadi and colleagues observed similar results in another cross-sectional study done in 14,880 children and adolescents [47]. In this study, snackers versus nonsnackers were less likely to be overweight/obese and to present abdominal obesity. This is in agreement with two other studies, which demonstrated that obese children were more likely to be nonsnackers compared to the normal-weight children [43] (done in 4262 Chinese children and adolescents) or to have no morning snacks [45]. Other results even showed that meal

TABLE 25.2 Association Between Snacking and Body Weight in Children/Adolescents

Study	Population	Design	Snacking Definition[a]	Summary of the Results	Impact on BW[b]
Crooks [134]	U.S. elementary school children ($n = 54$), grades 3–5	Cross-sectional	Type of food and its nutrient profile	High average daily snack consumption was reported in boys "at risk" for overweight, but not girls (probably because of the small number of participants)	+
			Measures: four 24-hour dietary recalls		
Kant [36]	American children and adolescents ($n = 4852$), aged 8–18 years	Cross-sectional	Type of food (i.e., low-nutrient-density foods) and its nutrient profile (e.g., visible fat; table sweeteners, candy, and sweetened beverages; baked and dairy desserts; salty snacks; and miscellaneous)	High amounts of low-nutrient-density food intake was related to higher energy intake and lower amounts of the five major food groups and most micronutrients but not body weight	≠
			Measures: 24-hour dietary recall		
Nicklas et al. [135]	Euro-American and African-American children ($n = 1562$), aged 10 years	Cross-sectional	Type of food and its nutrient profile (e.g., salty snacks, candy, desserts, fats/oils, and sweetened beverage groups)	Total amount of food consumed, notably from snacks, was positively associated with overweight status	+
			Measures: 24-hour dietary recall		
Huang et al. [136]	U.S. children ($n = 1995$), aged 3–19 years	Cross-sectional	Type of food and its nutrient profile	Percent energy from snacks was not associated with BMI in plausible reported energy intake from children	≠
			Measures: two 24-hour dietary recalls	Energy intake and meal patterns were associated with BMI only in plausible reported energy intake from children (compared to the total sample)	+
Snoek et al. [37]	Dutch adolescents (girls $n = 4581$; boys $n = 4430$), aged 11–16 years	Cross-sectional	Number of eating events (snacks)/day	Frequent snacking (three or more snacks per day) was associated with a lower risk of being overweight compared to less frequent snacking	−
			Measures: self-reported	No association between snacking and overweight was found in multivariate analyses, which included all eating and lifestyle behaviors in girls	≠
Lioret et al. [38]	French children ($n = 748$), aged 3–11 years	Cross-sectional	Type of food and its nutrient profile (e.g., French fries, soft drinks, sweetened beverages, low consumption of yogurt/cottage cheese)	The "snacking and sedentary pattern" was positively associated with childhood overweight in the youngest children	+
			Measures: parents for children >10-years old or self-reported 7-day dietary recall		

(*Continued*)

TABLE 25.2 (Continued)

Study	Population	Design	Snacking Definition[a]	Summary of the Results	Impact on BW[b]
Dubois et al. [39]	French Canadian children ($n = 1549$), aged 4–5 years	Cross-sectional	Eating frequency (snacks) and watching TV behavior Measures: maternal self-administration questionnaire	Snacking while watching TV on a daily basis was associated with higher average BMI than snacking less frequently in front of the TV	+
Macdiarmid et al. [40]	Scottish children ($n = 156$), aged 5–17 years	Cross-sectional	Eating frequency and food items (core food groups, e.g., pasta, bread, eggs, etc., vs noncore food groups, e.g., biscuit, pudding, yogurt, soft drink, etc.) Measures: 4-day unweighted dietary recalls	Meal and snack frequency was not different between BMI groups (normal weight vs overweight/obese)	≠
Kerr et al. [33]	Britain adolescents ($n = 434$) and Northern Ireland adolescents ($n = 47$), aged 13–16 years	Cross-sectional	Eating frequency outside three regular meals Measures: 7-day dietary recall	Snack energy intake, percent of energy from snack or frequency of snack was not different between normal weight and overweight/obese adolescents	≠
Keast et al. [41]	U.S. adolescents ($n = 5811$), aged 12–18 years	Cross-sectional	Number of eating occasions or the time of day food was consumed	Increased snacking frequency and increased percentage of energy from snacks was associated with a lower prevalence of overweight or obesity and abdominal obesity	−
		Data from NHANES	Measures: self-reported 24-hour food recall	Snackers, compared with nonsnackers, were less likely to be overweight or obese and less likely to have abdominal obesity	
Mushtaq et al. [42]	Pakistani primary school children ($n = 1860$), aged 5–12 years	Cross-sectional	Type of food consumed as snacks and its nutrient profile Measures: self-reported (interview)	Eating snacks and fast food ≥ once a week (43%) was more likely to be associated with overweight and obesity	+
Guo et al. [43]	Chinese children and adolescents ($n = 4262$), aged 5–18 years	Cross-sectional	Type of food consumed as snacks Measures: self-reported	Obese participants were more likely to be nonsnackers compared to the normal-weight ones	−
Jennings et al. [44]	UK children ($n = 2064$), aged 9–10 years	Cross-sectional	Time of day food is consumed, that is, foods or drinks consumed at any time other than meal periods Measures: self-reported 4-day dietary journal with parental assistance	Increased snacking frequency was favorably associated with adiposity, diet quality, and activity behaviors in healthy weight children but not centrally obese children	−

(*Continued*)

TABLE 25.2 (Continued)

Study	Population	Design	Snacking Definition[a]	Summary of the Results	Impact on BW[b]
Thibault et al. [45]	French children ($n = 4048$) aged 5–7 years and ($n = 3619$) aged 7–11 years	Cross-sectional	The time of day food is consumed Measures: self-reported or parents report morning snack yes/no	No morning snack was associated significantly and independently with higher overweight or obesity prevalence (as well as female gender, low or medium parental SES, never or sometimes having breakfast, never eating at the school canteen) in 7 to 11 years old	−
Murakami and Livingstone [46]	British children ($n = 818$) aged 4–10 years and adolescents ($n = 818$) aged 11–18 years	Cross-sectional	Eating frequency, that is, the number of eating events per day, except for those providing <210 kJ of energy Measures: self-reported and/or parent reported, 7-day diary	A higher eating frequency is associated with a higher BMI z-score in adolescents but a lower total cholesterol and LDL-cholesterol concentrations in children	+
Kelishadi et al. [47]	Iran children and adolescents ($n = 14,880$), aged 6–18 years	Cross-sectional	Eating frequency, that is, the number of eating events per day including snacks (e.g., cakes, chips, sugar-sweetened beverages, milk and dairy products, and sausages) Measures: parents report FFQ and self-reported FFQ for snack items	Higher eating frequency was associated with lower mean values of anthropometric measures (e.g. weight, BMI, WC)	−
Murakami and Livingstone [137]	British children ($n = 818$), aged 4–10 years and adolescents ($n = 818$), aged 11–18 years	Cross-sectional	Eating frequency and time of the day (meal = eating episode comprising ≥15% of TEI); snack = all other eating episodes (except food items <210 kJ of energy) Measures: self-reported and/or parent report, 7-day diary recall	Measures of meal frequency and snack frequency showed no association with adiposity measures in both children and adolescents; however, they were all associated with unfavorable dietary intake patterns Decreasing the number of small eating occasions regardless of the time of day may be important to improve diet quality but not adiposity	≠
Locard et al. [138]	French children obese ($n = 327$) and nonobese ($n = 704$), 5 years	Case–control	Not specified Measures: parents report	Snacking was identified as an environmental factor, which contributes to child obesity (along with southern European origin of the mother, excessive TV viewing and more importantly, short sleep duration)	+

(*Continued*)

TABLE 25.2 (Continued)

Study	Population	Design	Snacking Definition[a]	Summary of the Results	Impact on BW[b]
Tanasescu et al. [48]	Puerto Rican children ($n = 53$), aged 7–10 years	Case–control	Eating (snack) frequency (e.g., sweets and snacks: candy, chocolate, milk custard, jello, ice cream, sugared cookies, chips, peanuts, peanut butter, popcorn)	Snack consumption (i.e., sum of frequency of chips, peanuts, peanut butter, and popcorn consumption) was positively associated with BMI	+
	Obese ($n = 29$) and nonobese ($n = 24$)		Measures: self-reported FFQ and assisted 24-hour recall		
Field et al. [49]	Children (girls $n = 8203$ and boys $n = 6774$), 9–14 years of age	Prospective	Portion size and food items (e.g., one pop tart, one snack cake, three cookies, one small bag of popcorn)	Snack food intake was a significant, but weak, inverse predictor of annual changes in BMI z-score among the girls but not in boys (after controlling for Tanner stage of development, age, height change, activity, and inactivity)	−
			Sugar-sweetened beverages (e.g., soda) were not included as servings of snack foods	The authors conclude that although snack foods may have low nutritional value, they were not an important independent determinant of weight gain	
			Measures: self-reported FFQ (YAQ)		
Phillips et al. [50]	Adolescents (girls $n = 196$), aged 8–12 years	Prospective	Portion size and food items (e.g., baked goods, ice cream, chips, sugar-sweetened soda, candy)	Energy-dense snack food consumption was not associated with body weight status or fatness changes over the adolescent period	≠
			Measures: self-reported FFQ (Willett)	Soda consumption was the only snack food positively associated with body weight status changes (but not fatness)	
				Energy-dense snack food consumption was positively associated with TV viewing	
Thompson et al. [51]	American girls ($n = 101$) aged 9–15 years	Prospective	Time of the day and eating frequency	Eating frequency was significantly associated with change in BMI z-score during weekdays. Girls eating 4.0–5.9 times per day exhibited a smaller increase in BMI z-score than girls eating 6.0 or more times per day	+
			Measures: two 7-day dietary records	Eating frequency in the evening/night during weekdays also was significantly associated with change in BMI z-score	

(*Continued*)

TABLE 25.2 (Continued)

Study	Population	Design	Snacking Definition[a]	Summary of the Results	Impact on BW[b]
Li and Wang [52]	Low-income African-American adolescents ($n = 181$), aged 10–14 years	Prospective	Portion size and food items (e.g., one pop tart, one snack cake, three cookies, one small bag of popcorn)	High intake of snacks (as well as energy, fiber, fried food) was less likely associated with high BMI (same quartile at baseline and 1-year follow-up)	−
			Measures: self-reported FFQ (YAQ)	Decreases in snack intake (as well as energy) was negatively related to high BMI (same quartile at baseline and 1-year follow-up)	
Ritchie [53]	American girls ($n = 2372$) aged 9–10 to 19–20 years	Prospective	Eating frequency and time of the day (meal = eating episode comprising ≥15% of TEI); snack = all other eating episodes	Less frequent eating predicts a greater gain in adiposity in adolescent females	−
			Measures: self-reported 3-day diary recall each year except years 6 and 9		
Shroff et al. [54]	Colombian children ($n = 961$), aged 5–12 years	Prospective	Portion size and food items (e.g., candy, ice cream, packed fried snacks, soda, and sugar-sweetened fruit-flavored drinks)	Snacking patterns tend to be positively associated with BMI and adiposity changes	+
			Measures: self-reported FFQ	Soda intake was the only food pattern positively and significantly associated with BMI changes	

[a]*Snacking definition: (1) time of day food is consumed, (2) portion size + food items, (3) time and portion size and food items, (4) the number of eating events per day (or eating frequency), (5) consumer self-report, (6) type of food and its nutrient profile, (7) where eating occurs, and (8) physiological responses.*
[b]*Impact of body weight (BW): ≠, no association; +, positive association; −, negative association.*
BMI, body mass index; FFQ, food frequency questionnaire; YAQ, Youth Adolescent Questionnaire; TEI, total energy intake.

and snack frequencies were not different between normal-weight or overweight/obese children [40]. Although less numerous, some longitudinal studies showed that high snack food intake [49] or high eating frequency [53] were significant inverse predictors for BMI changes, although these were not strong relationships [49]. Increased snacking has been associated with lower BMI at baseline and 1-year follow-up in 181 low-income African-American adolescents [52]. A review of 32 cross-sectional and longitudinal studies investigating the association between snack consumption and energy balance concluded that most studies (21 out of 32 studies) found either a beneficial or a neutral impact of snacking on energy balance [13]. This is also concordant with a meta-analysis, which established that eating frequency was associated with lower body weight status in children and adolescent boys ($n = 3408$) and girls ($n = 3462$) [35]; however, this meta-analysis included some studies that considered only formal meals and not snacking in eating events.

Overall, these cross-sectional and longitudinal results support the notion that snacking in adults, children, and adolescents could be part of a healthy lifestyle with neutral or even beneficial effect on energy balance. However, given the nature of the studies, no causal relationships can be concluded. There are only few intervention studies, which evaluated the association between snacking and energy balance in adults. One of them verified the long-term (12 weeks) impact of three different snack foods, that is, nuts, chocolate, or chips (vs no snack food) on energy compensation and food habits among adult nonobese participants [64]. Results showed that energy compensation occurred for all types of snack food. Similarly, an intervention study also involving nonobese subjects evaluated the impact of an 8-week protocol of snack

TABLE 25.3 Association Between Snacking and Body Weight in Adults

Studies	Population	Design	Snacking Definition/ Measures[a]	Summary of the Results	Impact on BW[b]
Bachman et al. [55]	Weight loss maintainers ($n = 96$), normal weight ($n = 80$) and overweight ($n = 81$), aged ≥ 18 years	Cross-sectional	Consumers' self-report Measures: 24-hour dietary recalls	Eating frequency was higher in weight loss maintainers and normal-weight individuals than in overweight individuals	−
Barnes et al. [10]	Adults ($n = 233$), aged 18–60 years	Cross-sectional	Consumers' self-report Measures: three telephone-administered 24-hour dietary recalls	Snacking energy or frequency of snacking was not significantly associated with BMI	≠
Basdevant et al. [139]	Obese women ($n = 273$), aged 18–65 years	Cross-sectional	Time of day food was consumed Measures: dietary histories performed by trained dietitians	Snackers had higher total daily energy intakes compared to nonsnackers because of greater consumption of food at meals and between meals	≠
Cho et al. [34]	Adults ($n = 1118$), aged 30–70 years	Cross-sectional	Type of food and its nutrient profile, that is, three dietary patterns (e.g., vegetable-seafood, meat-fat, and snack) Measures: validated self-administrated food frequency questionnaire aimed at foods consumed during the previous year	Snack dietary patterns showed no association with obesity	≠
Drummond et al. [140]	Women ($n = 47$), aged 20–55 years	Cross-sectional	Time of day food was consumed	Women who ate most frequently also had the highest energy intakes, although this did not lead to higher BMI	≠
	Men ($n = 48$), aged 20–55 years		Measures: food diary, unweighted, recorded for seven consecutive days	In men, there was a significant negative correlation between eating frequency and body weight or BMI. As energy intake did not increase with eating frequency, men appeared to have compensated by reducing the mean energy consumed per eating episode	−
Edelstein et al. [141]	Adults ($n = 2034$), aged 50–89 years	Cross-sectional	Consumers' self-report Measures: short mailed questionnaire asked "How many meals and/or snacks do you eat in a usual day?"	Eating frequency was not associated with BMI	≠
Fabry et al. [142]	Men ($n = 379$), aged 60–64 years	Cross-sectional	Time of day food was consumed and consumers' self-report Measures: interview with a trained dietitian	Men who ate three meals a day (or less) were more susceptible to have an excessive weight than those who ate five meals (or more)	−

(*Continued*)

TABLE 25.3 (Continued)

Studies	Population	Design	Snacking Definition/ Measures[a]	Summary of the Results	Impact on BW[b]
Hampl et al. [143]	Men ($n = 1756$) and women ($n = 1511$), aged 18–65 years	Cross-sectional	Consumers' self-report and time of day food is consumed Measures: two nonconsecutive, multiple-pass 24-hour dietary recalls	Snacking patterns have some effects on energy and nutrient intakes but not on BMI	≠
Hartmann et al. [22]	Adults ($n = 6189$), aged 20–99 years	Cross-sectional	Consumers' self-report Measures: food frequency questionnaire	No association between snack frequency and BMI	≠
Howarth et al. [144]	Adults ($n = 2685$), aged 20–90 years	Cross-sectional	Consumers' self-report Measures: two 24-hour dietary recalls	Eating frequency may play a role in increasing overweight and obesity	+
Kant et al. [145]	Men ($n = 2580$) and women ($n = 4567$), aged 25–74 years	Cross-sectional	Number of eating events per day (or eating frequency) Measures: one 24-hour dietary recall administrated by a trained dietitian at baseline	Eating frequency and BMI were inversely correlated in both men and women	−
Kant and Graubard [56]	Adults ($n = 39,094$), aged 25–74 years	Cross-sectional	Number of eating events per day (or eating frequency) Measures: 24-hour recall administered by a trained dietary interviewer	Number of eating and snack episodes were significant independent predictors of higher energy intake in both men and women. There was an inverse association between the number of eating and snacking episodes and obesity but that was not significant after adjustment for low-energy reporting	≠
Ma et al. [146]	Adults ($n = 499$), aged 20–70 years	Cross-sectional	Number of eating events per day (or eating frequency) Measures: three 24-hour dietary recalls	Greater number of eating episodes each day was associated with a lower risk of obesity	−
McCarthy et al. [147]	Adults ($n = 1379$), aged 18–64 years	Cross-sectional	Type of food and its nutrient profile, that is, 28 food groups such as savory foods, cheeses, beverages, etc. Measures: 7-day food diary	Greater consumption of savory snacks was associated with an increased likelihood of being classified as obese	+
Metzner et al. [148]	Men ($n = 948$) and women ($n = 1080$), aged 35–69 years	Cross-sectional	Number of eating events per day (or eating frequency) Measures: 24-hour dietary recall	Frequency of eating was inversely related to the adiposity index for men and women separately	−
Mills et al. [31]	Overweight and obese women ($n = 1099$), aged 40–60 years	Cross-sectional	Consumers' self-report Measures: one mailed 1-day food record	Eating frequency was not associated with overweight/ obesity but related to energy intake	≠

(*Continued*)

TABLE 25.3 (Continued)

Studies	Population	Design	Snacking Definition/ Measures[a]	Summary of the Results	Impact on BW[b]
Murakami and Livingstone [57]	Men ($n = 678$) and women ($n = 809$), aged 19–64 years	Cross-sectional	Type of food and its nutrient profile (<15% of total energy intake) and time of the day food was consumed Measures: 7-day dietary record	Higher snack frequency was associated with higher adiposity measures	+
Neuhouser et al. [149]	Adults ($n = 982$)	Cross-sectional	Type of food and its nutrient profile, that is, high-fat snacks, reduced-fat snacks, or free-fat snacks Measures: food frequency questionnaire and snack-food questionnaire	There was no significant correlation between snack intake and BMI	≠
Ruidavets et al. [150]	Men ($n = 330$), aged 45–64 years	Cross-sectional	Number of eating events per day (or eating frequency) Measures: 3-day food record	Number of eating occasions was negatively associated with BMI	−
Scherwitz and Kesten [151]	Adults ($n = 5256$)	Cross-sectional	Type of food and its nutrient profile ("Task Snacking" includes such behaviors as eating while working, in front of the computer or TV, driving, reading, talking on the phone, or walking) Measures: 80-item questionnaire, designed to measure food, nutrition, and eating themes	The results show that eating style "Task Snacking" was predictive of BMI	+
Spanos and Hankey [58]	University students ($n = 160$), aged ≤24 years	Cross-sectional	Consumers' self-report Measures: food frequency questionnaire comprised 16 questions assessing meal and snacking habits	No relationships were found between BMI and snacking	≠
Summerbell et al. [59]	Adults ($n = 187$), aged 17–91 years	Cross-sectional	Time of day food is consumed Measures: 7-day weighed dietary records	Feeding pattern was not related to BMI within the working age or elderly groups. In the middle-aged group, lower energy intakes during the evening were associated with lower BMI	≠
Titan et al. [152]	Women ($n = 7776$), aged 45–75 years	Cross-sectional	Consumers' self-report	Increased eating frequency was weakly but significantly and positively associated with BMI	+
	Men ($n = 6890$), aged 45–75 years		Measures: food frequency questionnaire	Increased eating frequency was weakly but significantly and negatively associated with BMI	−

(*Continued*)

TABLE 25.3 (Continued)

Studies	Population	Design	Snacking Definition/ Measures[a]	Summary of the Results	Impact on BW[b]
Wahlqvist et al. [153]	Men ($n = 145$) and women ($n = 148$), aged 70 years and over	Cross-sectional	Number of eating events per day (or eating frequency) Measures: diet history	Consumption of a greater number of meals/snacks was negatively associated with the body fatness	−
Whybrow and Kirk [154]	Women ($n = 44$), aged 17–26 years	Cross-sectional	Number of eating events per day (or eating frequency) Measures: 7-day weighed food diary	There was a significant negative correlation between eating frequency and BMI	−
Zizza and Xu [21]	Adults ($n = 11,209$), aged 20 or older	Cross-sectional	Consumers' self-report Measures: 24-hour dietary recall	Snacking frequency was inversely associated with BMI	−
Berteus Forslund et al. [155]	Obese ($n = 83$) and lean ($n = 94$) women, aged 37–60 years	Case–control	Consumers' self-report Measures: meal pattern questionnaire	The number of reported intake occasions across a usual day was higher in obese women compared with controls and the timing was shifted to later in the day	+
Berteus Forslund et al. [156]	Obese men ($n = 1891$) and women ($n = 2368$), aged 30–60 years versus lean men ($n = 505$) and women ($n = 587$), aged 37–60 years	Case–control	Consumers' self-report Measures: self-administered meal pattern questionnaire	Obese subjects were more frequent snackers than lean subjects and women were more frequent snackers than men. Snacks were positively related to energy intake. Sweet, fatty food groups were associated with snacking and contributed considerably to energy intake	+
Bes-Rastrollo et al. [60]	University graduates ($n = 10162$)	Longitudinal prospective	Consumers' self-report Measures: semiquantitative food frequency questionnaire	Between-meal snacking was significantly associated with a higher risk of substantial weight gain. Usual snackers presented an adjusted 69% higher risk of becoming obese during follow-up	+
Keski-Rahkonen et al. [157]	Men ($n = 2060$) and women ($n = 233$), aged 16 years (T1), with follow-ups at 17 years (T2), 18.5 years (T3), and at 22–27 years (T4)	Longitudinal	Consumers' self-report Measures: eating style questionnaire at T4	Frequent snacks were significantly associated with obesity	+
Cameron et al. [61]	Obese men ($n = 8$) and women ($n = 8$), aged 18–55 years	Intervention	Number of eating events per day (or eating frequency) Measures: snacks included through a meal plan (three meals + three snacks per day vs three meals no snack)	Increasing meal frequency does not promote greater body weight loss during an 8-week energy-restricted weight loss program	≠

(*Continued*)

TABLE 25.3 (Continued)

Studies	Population	Design	Snacking Definition/ Measures[a]	Summary of the Results	Impact on BW[b]
Fay et al. [62]	Adults ($n = 50$)	Intervention	Type of food and its nutrient profile (e.g., M&Ms and Maltesers) Measures: snack provided by the research team	After eating until satiation, participants who initiated another snacking episode, their intake was predicted by higher BMI	+
Kong et al. [63]	Overweight or obese women ($n = 123$)	Intervention	Consumers' self-report Measures: food records and 24-hour recalls	Mid-morning snackers had a lower weight loss after a 12-month weight loss intervention when compared to nonmid-morning snackers	+
Pearson et al. [64]	Nonobese adults ($n = 102$), aged 18–65 years	Intervention	Type of food and its nutrient profile (e.g., hazelnuts, chocolate, potato crisps, or no added snack food) Measures: snacks provided by the research team for a 12-week period	Energy compensation occurred for all three snack conditions in this nonobese population	−
Piehowski et al. [65]	Overweight and obese women ($n = 26$), aged 25–45 years	Intervention	Type of food and its nutrient profile, that is, dark chocolate snack or a nonchocolate snack (e.g., nonchocolate sweet snack of fruit-flavored licorice) Measures: snacks provided by the research team for a 18-week period	Improvements in anthropometric and body composition measurements were achieved with a reduced-calorie diet including a snack	−
Viskaal-van Dongen et al. [66]	Nonobese men ($n = 16$) and women ($n = 66$), 18–35 years	Intervention	Time of day food was consumed + type of food and its nutrient profile, that is, snacks consumed with or between meals and snacks having a low (e.g., fruits or dairy products) or high (e.g., cereal products or savory snack) energy density Measures: snacks provided by the research team for a 8-week period	Consuming snacks did not contribute to weight gain. Healthy, nonobese young adults were able to maintain a normal body weight through an accurate compensation for the consumption of snacks	≠

consumption on changes in body weight [66]. There were four parallel groups: snacks consumed with or between meals and snacks having a low or high energy density. No differences were noted in body weight between the four groups. In this study, moment of consumption and energy density did not influence body weight. Thus, this finding suggests that snacks (high or low in energy density) do not contribute to weight gain among nonobese young adults. In this situation, it is possible that nonobese adults were able to maintain a normal body weight through an accurate caloric compensation.

Among obese individuals, a study investigated whether having greater meal frequency (three meals + three snacks per day) could lead to a greater weight loss in

comparison with lower meal frequency (three meals per day) within an energy-restricted diet of 8 weeks [61]. In this case, increasing meal frequency did not compromise body weight loss compared with a no-snack pattern. Moreover, there were no significant differences between both groups for adiposity indices, appetite measurements, and gut peptides. Data collected from another intervention study among overweight adults aimed to verify the effects of a reduced-calorie diet including two different types of snacks, that is, chocolate or a nonchocolate snack on body composition [65]. This 18-week study showed a reduction in estimated daily energy intake for both groups. The intervention also led to a decrease in body weight, hip and waist circumferences, and fat mass with no change in lean mass. Authors then concluded that improvements in anthropometric and body composition can be achieved with a reduced-calorie diet even if snacks are included. These results suggest that snacking can be part of a weight loss program since energy restriction seems to be the primary independent determinant of weight loss in this context. Unfortunately, intervention studies investigating the impact of snacking restriction and/or mandatory snacking on total energy intake and body weight are clearly lacking in children and adolescents.

In summary, for both adults and children, there is evidence to support the notion that snacks may have a beneficial and/or neutral effect on energy balance. Studies presented in this section suggest that energy compensation occurs in response to snacking and that benefits of snacking can be observed in normal-weight individuals or in overweight and obese individuals on a calorie-restricted diet. Thus, conclusions suggest that it is possible to integrate snacks to a healthy lifestyle.

B Negative Effect of Snacking on Energy Balance (Overweight and Obesity)

Despite a certain number of studies showing a beneficial role of snacking on energy regulation and weight control, other data suggest that snacking contributes to weight gain and obesity [9,29]. It has been stated that regardless of the time of consumption or macronutrient composition, snacks exerted a weak satiety effect [29]. Thus, the energy intake related to snacks was not compensated for over the next meal and led to a positive energy balance compared with no-snack conditions. This is particularly true when snacking occurs in a nonhungry state or in nonusual snackers [67].

A cross-sectional study examined the associations between meal and snack frequency with dietary intakes and adiposity measures [57]. After adjustment for potential confounders, meal frequency, using a definition based on time, was positively associated with BMI and waist circumference (WC) in men only while there were no associations when a definition based on energy contribution was used. Snack frequency was correlated with both BMI and WC regardless of the definition of snacks in both men and women. Similarly, another cross-sectional study examining associations between snacking frequency and adiposity measurements observed an increased WC when overweight participants consumed higher quantities of snacks [4]. Similarly, a longitudinal study verified the association between snacking and weight gain and obesity in a middle-aged population [60]. At the beginning of the study, all participants were classified as normal-weight; however, after a mean follow-up of 4.6 years, 2.7% of the sample developed obesity (BMI over 30 kg/m^2). Usual snackers presented a 69% higher risk of becoming obese during follow-up. Thus, eating snacks has been considered as a potential risk factor for obesity. A cross-sectional study has found associations between unhealthy snacking and BMI [68] while another has shown that energy intake from snacks was not compensated for during main meals; however, the association with BMI has not yet been verified [28].

In children and adolescents, although more studies seem to demonstrate a beneficial or neutral effect of snacking on energy balance, some evidence also suggests that snacking promotes a positive energy balance. Accordingly, cross-sectional or case−control studies found that frequency of snacking [46], percentage of energy consumed as snacks or greater consumption of energy-dense snacks [42,48] were associated with overweight and obesity among some groups. Prospective studies have also shown that snacking frequency was associated with greater changes in BMI [51,54]. Among adults and children, although some cross-sectional and longitudinal studies have shown associations between snacking frequency and a greater BMI, the evidence remains inconclusive. Thus, larger trials and intervention studies must be done to confirm these effects.

Only a few intervention studies support the notion that snacking results in a positive energy balance and these have been done in adults. In this regard, an intervention study in overweight and obese women investigating the associations between snacking and weight loss during a 12-month weight-loss program found that the percentage of weight loss was significantly lower among mid-morning (10:30 to 11:29 a.m.) snackers compared to nonmid-morning snackers [63]. However, there were no significant differences in the percentage of weight loss when measured by snacking frequency. Authors concluded that future weight loss programs should consider not only snacking frequency, but also the timing and quality of snacks. In another intervention study, Fay et al. observed that among individuals who initiated snacking (after already having reached satiety), the intake of

calories was associated with a higher BMI [62]. This finding suggests that snacking initiation in the absence of hunger could be an important contributor to overconsumption.

To our knowledge, intervention studies supporting the notion that snacking results in a positive energy balance in children are not common, yet, some observation studies document the influence of environment. Accordingly, some environmental stimuli seem to influence the impact of snacking on diet quality and adiposity in children. For example, at least two studies have shown that an increase in snacking in front of the TV was associated with an increased risk of obesity in early childhood [39,69]. One of these studies, performed in 1549 children aged 4−5 years in Quebec, Canada, found that children who ate their snack in front of the TV once daily or more (17% of the sample, based on parental reports) had higher BMIs than those who ate while watching TV less than once a day; however, there was no association between hours of daily TV viewing and BMI [39]. Another study observed that snacking and sedentary patterns were positively associated with childhood overweight in the youngest when compared with the oldest [38] suggesting that sedentary behaviors could represent another stimuli influencing the associations between snacking and energy balance.

In summary, the literature presents evidence supporting that snacking can have both beneficial/neutral and negative impacts on energy balance. The evidence seems to be more controversial in adults than in children and adolescents. In younger children, more evidence seems to point in the direction of a beneficial or neutral effect of snacking, yet, to our knowledge no intervention studies have specifically addressed this issue in this population. Additional research is needed to identify possible explanations or mechanisms linking snacking with body weight.

C The Benefits and Risks of Snacking: Possible Explanations and Proposed Mechanisms

Many factors may explain why snacking can be viewed as both beneficial on body weight control and as a risk factor for weight gain and obesity. The first and probably the most obvious factor is related to variations in the definition and assessment of snacking used in studies. This issue has been discussed in the second section of this chapter (Section II: Definition of Snacking). In line with the definition issue, the diversity of variables used as an indicator of snacking pattern represents another factor. Studies reported outcomes such as the time of eating, percentage of energy consumed as snacks, nutrient composition of snacks, and the types of foods consumed as snacks (see, e.g., Tables 25.2 and 25.3). These variable descriptors may not be capturing the same eating patterns, and correlations among them are unknown. Others issues include concerns with "when" snacking occurs, "what" is eaten, "how" the snack is perceived, and "what" is done while snacking. These issues are described here.

1 Timing of Meals

The timing of snacking refers not only to when to consume the snacks between meals but also the overall distribution of snacking over the day. It has been proposed that providing snacks to offset variations in glucose and insulin, two well-known biochemical parameters affecting appetite control [29], may prolong the intervals between eating events and reduce energy intake at eating events. Although this hypothesis is interesting, it has not been validated in well-controlled experimental studies. Accordingly, Marmonier and colleagues [70] demonstrated that eating at different time points after a meal (i.e., 5 minutes before blood glucose peaked; 40 minutes after blood glucose peaked; or 2 hours before usual dinner time) had no impact on subsequent energy intake. Thus, in this study, snacking timed to match biochemical indices failed to decrease hunger, delay subsequent meal, and reduce dietary compensation for the snacks under all conditions.

Another aspect that has not been extensively studied related to the timing of snacking and energy balance in the timing of the snacking occasions. Hence, there is more and more evidence to identify the timing of food intake (i.e., when we eat, as a novel factor that promotes weight gain or resistance to weight loss). A study demonstrating that mice fed during the light phase (i.e., mice biological night phase) gained more weight on a high-fat diet than mice fed the same diet, but during the nocturnal phase, largely contributes to the demonstration of the effect of timing of food intake on body weight [71]. In humans, observational studies have shown that greater food intake in the evening was associated with an increased risk of overweight and obesity [72] and was positively associated with BMI, even after controlling for sleep duration and energy intake [73]. In line with this, a review highlighted that obese individuals are consistently characterized by a delayed pattern of eating [74]. More recently, two weight loss interventions with cross-over designs showed less body weight loss in the late eating condition compared to the early eating condition [75,76]. In another study, individuals who ate their largest meal after 3 p.m. lost less weight during a weight-loss trial than individuals who ate their largest meal before 3 p.m. [77].

Research on the Night Eating Syndrome (NES), an extreme example of delayed food intake, also supports the findings that late eating could be involved in obesity. NES is a disorder characterized by excessive evening and nighttime eating and is associated with insomnia, a

depressed mood and distress. Although, this problem is also observed in normal-weight individuals, the prevalence of NES is higher among overweight and obese individuals [78]. In line with this, results revealed that individuals characterized by night-eating behaviors (i.e., excessive evening eating and night-eating, but not presenting clinically with NES) have higher BMI and poorer metabolic health [79]. When examined prospectively, these individuals (normal-weight) tended to have a higher increase in BMI over 2 years [80]. Among night-eating symptoms, nocturnal ingestion and morning anorexia were the two symptoms that predicted an increase in percent change in BMI and WC, respectively. Other studies have shown that night-eating can lead to weight gain (4.3−4.5 kg over 3−6 years) [81−83].

Taken together, observational and experimental studies suggest time of snacking could influence the impact of snacks on energy balance. In line with this hypothesis, some observational studies indicated that snacking often occurs in the evening [6,8]. Only a few cross-sectional studies reported timing of snacking, yet, Thompson and colleagues presented some results which support the idea that late snacking is linked with body weight gain [51]. Accordingly, in their prospective study in 101 young girls, only the mean percentage of daily energy consumed in the evening/night was positively associated with change in BMI z-scores ($p = 0.039$) after controlling for baseline BMI.

To our knowledge there are very few intervention studies which have evaluated the impact timing of snacking per se on energy balance. In one study, eleven women were invited to change the timing of their snacking without changing total caloric intake or meal frequency for a 13-day period. More specifically they had to consume either a morning (10 a.m.) or evening (11 p.m.) snack in addition to their three regular meals, which they had to eat at their usual times [84]. Even though the conditions did not impact body weight or glucose metabolism, the evening snack condition decreased fat oxidation and increased total and low density lipoprotein (LDL) cholesterol. In another study, LeCheminant et al. used a randomized cross-over study to examine the effects of restriction of energy intake at evening/night (from 7 p.m. to 6 a.m.) among 27 healthy young males [85]. Each condition was maintained for a 2-week period. The results showed a significant decrease in energy intake (− 244 kcal) in the energy-restricted condition and a significant difference in weight change between the two conditions: a small body weight reduction (− 0.4 kg) was observed in the energy-restricted condition whereas weight gain was observed in the usual condition (+ 0.6 kg). Although these results provide some preliminary evidence that late snacking may contribute to weight gain or resistance to weight loss, other results do not support this hypothesis. In the intervention by [63], where weight loss was significantly less among mid-morning snackers compared to nonmid-morning snackers, eating snacks was related with a diet higher in fruits, vegetables and fiber-rich foods, which was also part of the dietary recommendations in this study.

It is important to note that these studies were not all well controlled for energy intake, physical activity, sleep, and other factors and had substantial methodological differences (e.g., energy restriction vs no energy restriction). Even though more research is needed to confirm the impact of timing of snacks on body weight, these results suggest that timing of snacking should be considered more when studying the impact of snacking on energy balance.

The mechanisms that drive the association between timing of food intake and energy balance are not well understood but changes in appetite control over the course of the day have been suggested as one factor. Accordingly, studies from De Castro et al. proposed that intake in the morning is associated with a lower total daily energy intake, while intake at night is associated with greater overall daily energy intake [86]. This phenomenon was explained by the fact that satiating properties of ingested nutrients decline over the course of the day, with foods eaten in the morning producing greater satiety as shown by a greater satiety ratio (i.e., duration of the after meal interval in minutes divided by the energy content of the meal) than foods eaten later in the day [86,87]. In addition to appetite control, other mechanisms involving sleep, metabolism, circadian rhythms, and genetic factors have also been proposed [77,88]. The possibility that snack quality of late-eaters may be a factor involved in these relationships may not be excluded. In line with this, results from the QUALITY cohort [89] showed that children with delayed meal-related distribution of energy intake also reported less healthy eating habits such as a greater percent of fat and sodium intakes, fewer servings of fruits and vegetables and a higher occurrence of unhealthy snacks (high sodium, high saturated fat, low fruits and vegetables, etc.) compared to children with more normal meal-related distribution of energy intake [90]. Snack quality will be further discussed in the next section.

2 Type of Snacks and Food Quality

The quality of snacks consumed may also explain the inconsistent results observed between snacking and body weight. Although snacking can improve diet quality by contributing to the intake of several vitamins and minerals such as vitamin A, potassium, magnesium [19,20] and increasing fruits, whole grains, and fibers [33,44], snacking has also been associated with less desirable dietary intake patterns such as higher total energy intake and higher added sugar in adults and children [15,57]. It is

also noteworthy that the type of snack has been associated with overall diet quality [10,33]. In terms of food groups, results from a cross-sectional study reported that only percentage of energy from nuts, fruits, and juices was positively associated with diet quality [10]. In contrast, snacking energy coming from desserts, sweets, and sugar-sweetened beverages was inversely correlated with diet quality. In the same study, general snacking behaviors (intake or frequency) were not associated with BMI. Percentage of snacking energy from vegetables was however significantly correlated with a lower BMI whereas percentage of snacking energy from desserts and sweets was positively associated with a higher BMI. In a study done in the United Kingdom, an interaction between BMI and snacking frequency was observed [4]. Thus, results revealed that overweight individuals had higher intakes of crisps, chocolates, ice cream, and sweets and lower intakes of yogurt and nuts when compared with normal-weight individuals. These foods generally have a higher energy density (kJ or kcal per gram), a food characteristic well known to influence energy intake. Foods that have a high energy density increase energy intake and vice versa [91]. This is concordant with the results of a review, which found that, in some groups of children, the percentage of energy consumed as snacks, or the consumption of energy-dense snack foods, was associated with a higher BMI [13].

Healthy snacking such as an increased intake of fruits, whole grains, and fiber could promote satiety and thus help body weight control. One example of that is the study of Waller et al. where 58 overweight/obese males and females with self-reported night snacking behaviors were randomized into a cereal group (CR) and no-cereal group (NC) for a 4-week period [92]. Compared to baseline, the CR group reduced their total daily caloric intake by almost 400 kcal whereas the NC experienced a small but nonsignificant reduction of energy intake during the same period. This study suggests that providing a structured healthy snack rich in fiber in the form of a "ready-to-eat" breakfast cereal can help to regulate energy intake and contribute to weight loss. Moreover, other studies showed that, compared with foods consumed at meals, snacks are actually higher in carbohydrates and lower in fat [15]. Higher eating frequency and replacement of fats by carbohydrates has been shown to be a successful weight management strategy [93].

It is also interesting to note that liquid snacks, more specifically consumption of sweetened beverages such as soda and juices, represent a type of snack that is more consistently associated with weight gain and obesity. According to one prospective study, energy-dense snack food consumption was not associated with body weight status or fatness over the adolescent period in girls [50]. However, soda consumption was the only snack food positively associated with body weight changes. More recently, Shroff et al. also observed that among all of the foods considered, soda was the only one that was positively associated with BMI changes in children whereas overall snacking patterns only tended to be associated with BMI and adiposity changes [54]. These results are concordant with a recent randomized trial among school-aged children which showed that sugar-sweetened beverages led to greater gains in BMI and WC compared with unsweetened beverages [94]. This suggests that liquid snacks could promote a greater risk of positive energy balance than solid snacks [95]. Although this hypothesis is still controversial, failure to compensate for energy from sugar-sweetened beverages at the subsequent meal compared to solid foods can be involved in this effect [96,97]. Moreover, it has been hypothesized that sugar-sweetened beverages bypass intake regulatory systems compared with solid foods and thus result in different physiological responses [96]. This will be discussed in the Section VI, Snacking as Part of a Healthy Diet.

Overall, these results suggest that high energy or low nutrient-dense snack foods promote body weight gain and obesity whereas low energy or high nutrient-dense snacks could help body weight control. Altogether, the evidence emphasizes the importance of considering the snack quality to identify the impact of snacking on energy balance.

3 Perceptions About Foods (Cognitive Bias/Cues)

Snacks foods are not equally viewed by everyone, and how a specific food is described can influence an individual's perception. A recent qualitative study reported that snack foods were not always perceived as "real food" by mothers [98]. In fact, when serving snacks, mothers more often attempt to manage their children's behavior rather than consider snacking as a way to provide nutritious foods. Different cognitive representations about what is a meal versus a snack may also influence intake. Capaldi et al. showed that when isocaloric preloads were given to participants, but presented either as a snack or as a meal, a lower intake was observed following the preload described as a meal than when described as a snack [99]. With regards to healthy eating, findings, from the literature that we recently reported in a review, suggest that various cognitive factors, such as type of food and branding, can significantly influence perceived healthiness of food via judgmental bias. However, impacts on food choice and intake are not always observed [100]. A study showed that perceiving a snack food (i.e., oatmeal-raisin cookies) as healthy significantly increased undergraduate female students' intake of that food by 35% (i.e., 56 kcal) during an ad libitum single meal in comparison to a condition in which the same food was perceived as

unhealthy [101]. The "healthy" snack was also seen as not only healthier but also more appropriate to eat. No differences between measured and self-reported snack intakes were observed which suggest that participants generally regarded it as normal to have a high intake of healthy foods. On the other hand, in a larger study conducted among men and women, verbal nutrition claims significantly influenced perceived healthiness of the snack food, but no impact was observed on food intake [102]. Wansink and Chandon have also addressed this issue, and reported an increased caloric intake of 28% among participants when chocolate candies were labeled as low in fat than when labeled as regular [103]. Overweight participants also appeared to be more inclined to eat in the low-fat labeling condition compared to the normal-weight participants, as their intake increased by 47% (vs 16% for normal-weight participants). A recent systematic review reported that attentional bias toward food cues varied between individuals, with an enhanced reactivity to food cues observed among overweight and obese individuals compared to normal-weight ones [104]. We are currently surrounded by numerous nutrition claims and logos that appear on food labels and advertising as well as by information published by the media or on various websites. All of these cognitive influences, often identified by the concept of "health halos," could positively influence energy balance while snacking. In fact, various food marketing strategies, such as branding, food claims, or food pricing, can bias food consumption and lead us to eat more than expected [105], and possibly without being aware of these overeating habits.

4 Attention Versus Mindless Eating

Recent work conducted by Susan Higgs suggests that when individuals' attention during eating is distracted by different factors, such as TV watching or computer games, their later snack intakes can be significantly increased [106]. On the other hand, when they are prompted to pay attention while eating, later snacking would decrease. This impact on snack intake can be explained by an impairment in the meal memory caused by the distractor, which is not observed when paying attention to eating [106]. In a recent systematic review and meta-analysis, evidence indeed support that being distracted while eating can have an impact on food intake, and positively influence energy balance [107]. While distraction induced moderate increases in immediate intake, the positive impact on later intake was greater. In another study, Robinson et al. examined if attentive eating could lead to reduced intakes among overweight and obese individuals [108]. In comparison to a control condition (neutral audio book), participants in the focused-attention condition, who ate their lunch meal while listening to audio instructions guiding them in eating attentively, ate 30% less when invited to snack 2–3 hours later. Behavioral strategies promoting greater attention while eating thus appear to be promising for appetite regulation. Altogether, these findings suggest that a snacking context that impedes the ability to pay attention while eating could be a potential risk factor for overconsumption. However, when eating attentively, snacking could be considered as a beneficial factor by enhancing reductions in energy intake.

5 Other Concerns

Besides different snacking definitions and assessments, timing, food quality, food perceptions, and level of attention while snacking, many other issues related to methodology and analysis could explain the discrepancy between studies investigating the impact of snacking on energy balance.

a Underreporting

Underreporting, particularly for foods rich in fat, sodium, or sugar, has been identified as one important issue in this regard. This occurs frequently in overweight and obese individuals and those involved in a weight loss program [109–111]. There is some evidence, which indicates that underreporting is especially common for snacks [112]. In a cross-sectional study conducted in American children and adolescents ($n = 4408$), different relationships were observed between snacking and BMI in plausible versus nonplausible reported energy intakes. For example, some relationships were found between the portion size of snacks (boys) or snack frequency (girls) and BMI percentile in the total sample whereas total snack consumption (frequency or size) was not significantly related to BMI percentile in the plausible sample. Similar results have been reported for eating frequency in studies examining adults as well [56]. When underreporters were excluded from studies, the originally reported inverse association between eating frequency and BMI was decreased or even reversed [8,59]. These findings suggest that excluding implausible energy intake reporters may be necessary when exploring the relationships between snacking and energy balance in both children and adults.

b Planned Versus Unplanned

The idea that the context of snacking "planned versus unplanned" may influence the effects of eating frequency and snacking on energy regulation has been proposed in a symposium on the subject in 2011 [30]. This theoretical model hypothesized that the inclusion of snacks may pose a moderate to high risk of overeating when a diet is not planned. Within a planned-diet, the risk of overeating remains low even when the snacking frequency is higher. The study of Waller et al. represents a good example [92].

In this study, overweight/obese males and females consumed either cereal as a snack or no cereal for 4 weeks. Total daily caloric intake was reduced by 400 kcal in the snack group while no significant reductions in energy intake was observed in the no cereal group suggesting that providing a structured snack in the "ready-to-eat" form would contribute to appetite control and body weight regulation.

This concept is also in line with the notion that compensation for energy intake is more often seen in habitual snackers (i.e., where a snack is usually planned in the daily eating pattern). In a 3-week intervention study where habitual/regular snackers were asked to consume several snacks up to 25% of their total energy intake, adequate energy compensation was observed [113]. This was more specific to low-fat snacks compared to high-fat snacks. In contrast, another experimental study showed that participants who never typically eat a snack in their daily routine and who were invited to eat a snack during the usual satiety period (i.e., when not hungry), snack intake did not lower hunger ratings, delay dinner request, and reduce energy intakes at dinner, leading to a higher total energy intake over the whole session [70]. Marmonier and colleagues showed that the absence of a satiety effect in individuals who never or rarely snacked could be biologically driven: usual snackers showing a decrease in hunger and lower glucose and insulin before snacking versus nonsnackers [70,114]. The evidence suggests that planned/regular eating habits may facilitate energy balance, while unplanned/irregular snacking, also characterized by eating in the absence of hunger, seems to be unfavorable to maintain energy balance [1]. Since the context of snacking, "planned versus unplanned," influences the impact of snacking on energy intake regulation, more studies should be done to assess this topic.

c Location

Another factor to consider is the location where the snack is consumed. Accordingly, the odds of eating an unhealthy snack appear to be 1.5 times greater when snacking occurs at places other than the home [68]. Furthermore, snacks taken from home were more often low-nutrient foods such as sugar-sweetened beverages. Indeed, snacks consumed during visits to private households and at restaurant outlets contained more energy, had a higher percentage of energy from fat and lower fiber density than snacks consumed at home [15]. Therefore, the place where a snack is consumed seems to influence the quality of the food eaten at these events.

d Physical Activity Level

Other factors identified which could explain mixed results around snacking and body weight regulation is related to the physical activity level (PAL) of snackers versus nonsnackers. This is supported by cross-sectional studies which have found either no relationship or a negative relationship between snacking and body weight and even if snacking was also related to higher energy intakes [36,41]. It is possible that snacking is associated with increased PAL, especially if sport supplements such as protein bars and sports drinks are considered as snacks [93]. The absence of a positive association between snacks and BMI could thus be explained by higher energy needs in more physically active individuals (lean or obese) that are met by a higher frequency of snacking. Besides PAL, this suggests that snacking is also associated with a more active lifestyle, which influences energy balance. Physical activity has not been considered in all snacking studies, and thus, results in this context should be interpreted with caution.

The results presented above emphasize the need to carefully interpret literature related to snacking and body weight regulation. Without knowledge about these potential factors, that is, underreporting, PAL, planned/regular snackers versus unplanned/irregular snackers combined with different population subgroups (e.g., lean vs obese), it is likely that associations between snacking and BMI will be variable.

VI SNACKING AS PART OF A HEALTHY DIET

Snacking represents one common eating pattern in many populations. Although some evidence suggests that spontaneous snacking increases the risk for weight gain, others indicate that snacking is associated with lower body weight and/or that it provides a substantial proportion of nutrients to the diets of both children and adults. In this context, it becomes important to identify how snacks can be integrated into a healthy diet. This will present some considerations related to each snack dimension in order to promote healthy snacking. Moreover, recommendations/strategies, which aimed to improve appetite control and to prevent overeating episodes, will be presented. These aspects could help health professionals in their interventions with their clients/patients to favor healthy snacking.

With respect to healthy eating, the composition of snacks is probably the most important aspect of snacking because this can have an impact on both appetite sensations and energy intake. Snack composition should be designed to increase satiation and satiety and help to regulate energy intake. Many food properties have been identified to influence appetite control. Accordingly, macronutrients have differing effects on satiety; protein being the most satiating and fat the least [115]. Preloads high in protein, when compared to meals lower in protein,

prolong satiety and reduce energy intake at a subsequent meal [116]. It seems that a minimum of 20 g of protein 30 minutes before a meal is necessary to represent the most effective strategy to enhance satiety [117]. Although there is evidence supporting the satiating effects of protein, studies that compare the satiety effects of snacks of various macronutrient compositions are limited. Marmonier et al. performed two experimental studies comparing the impact of isoenergetic high-protein, -carbohydrate, or -fat afternoon snacks on short-term appetite control [114,118]. They showed that although high-protein snacks prolonged the interval between preload ingestion and the subsequent meal (dinner), energy was not compensated, resulting in higher total energy intake. It must be noted that the snack items differed between conditions and thus different sensory characteristics or perceptions could have influenced the results. It is also unknown if the high protein satiating effect could have influenced long-term energy intake. Macronutrient composition is thus likely influenced by a snack's satiety properties, but additional studies are required to determine how to optimize these effects in the long term.

When considering carbohydrates, evidence has also shown that low glycemic index foods also improve appetite control [119], although this effect could also be due to other food properties such as energy density. Accordingly, as described earlier, high energy density increases the risk of overeating and favors a positive energy balance [120]. Thus, favoring low energy-dense snacks seems to represent one important strategy, which could help to achieve healthy eating. The mechanisms underlying the response to variations in energy density are not well understood but could involve sensory factors related to food volume, which influences gastric distension and gastric emptying rate, and/or cognitive factors, such as beliefs about the satiating capacity of different foods.

Decreasing the energy density of snacks can be easily achieved by including fruits or vegetables into a snacking episode. Besides their high content of water and fibers, fruits and vegetables are also high in nutrients. This is supported by studies, which showed that eating low energy-dense foods such as a salad or a soup before a meal (15−20 minutes) helps to reduce food intake during the meal [121,122]. Other long-term intervention studies showed that increasing fruits and vegetables as a nonrestrictive weight loss strategy over a 6-month period leads to a modest but significant weight loss [123]. This is concordant with a systematic review and meta-analysis revealing that increasing vegetable or fruit consumption tends to result in either a small reduction in body weight or reduced weight gain relative to the control group [124]. Yet, other studies indicate that advice to increase intake of fruits and vegetables can increase weight gain [125], weight regain [126], and more specifically in the overweight/obese population [127]. Increasing fruits and vegetables has been shown to be an effective strategy to decrease the consumption of unhealthy snacks among children [128]. Taken together, there is more evidence which support the recommendation of fruits and vegetables as a strategy to decrease energy density of snacks. However, it will be important to advise that this must be done in the context of energy balance where snacking is planned in the daily diet and this is probably more relevant in some populations (e.g., obese).

Formulating recommendations based on energy density to promote healthy snacking has some limitations. Accordingly, sweetened beverages such as soda are low energy-dense foods, yet it has also been associated with a positive energy balance and weight gain [96]. In contrast, nuts are high energy-dense foods due to their high fat and low water content. However, due to their strong satiety properties and the fact that their energy is not efficiently absorbed, evidence does not support their role in the risk of weight gain [129,130]. Moreover, advising the inclusion of low energy-dense foods as part of snacking without consideration for portion size can also promote a positive energy balance. It has been shown that portion size and energy density both influence energy (i.e., high energy density and larger portion size) and result in higher energy intakes [120]. Therefore, recommendations based on energy density should mostly consider foods that are relatively high in water and fiber as well as high in nutrients. Fresh fruits and vegetables, which usually come in reasonable portion sizes, meet these considerations.

The positive relationships between energy-containing beverage consumption and body weight and BMI in most epidemiological and intervention studies [96,131] highlight another important aspect related to the physical characteristics of the snack: solid versus liquid form. Although the exact mechanism is still being studied, solid seems to be more satiating than liquid especially among overweight individuals. This is also true when referring to fruits and vegetables. Accordingly, Houchins et al. compared the impact of energy matched liquid versus solid forms of fruits and vegetables in lean and obese individuals in randomized cross-over controlled trials [127,132]. They showed lower satiation when fruit beverages were consumed at a lunch visit compared with when solid fruits were consumed under comparable conditions, especially in the overweight/obese participants [132]. Moreover, the solid forms of fruits and vegetables improved dietary compensation and no weight change in the lean group whereas the overweight/obese group had lower compensation and significant weight gain. In contrast, liquid forms of fruits and vegetables induced incomplete dietary compensation and weight gain in both the lean and overweight/obese individuals [127]. Thus, evidence suggests that solid foods

instead of liquid foods should be recommended when snacking is planned. Again, increasing fresh fruits and vegetables consumption represents a strategy in line with this recommendation.

Besides energy density, studies related to timing of food intake suggest that limiting food intake or snacking later in the day (i.e., after dinner) could help to maintain or favor a negative energy balance. Of course this recommendation must be adapted according to cross-cultural differences (i.e., limiting "snacking" later in the day will not be the same in the United States vs Spain where the main eating event is around 6 p.m. in United States vs 10 p.m. in Spain). As explained in the previous section (Section V: Snacking and Energy Balance), timing of a given snack could influence its impact on energy balance. Timing is another factor to consider in favor of healthy snacking (Fig. 25.2).

Lastly, considering that perceptions and distractions can influence the amount of food eaten, it is important to include behavioral strategies that promote greater attention while eating and thus, appear to be promising for appetite regulation. These behavioral strategies are aimed to improve control around food selection and quantity [133]. Moreover, behavioral strategies should increase individual awareness about the impact of health or satiety claims on their behavior. Table 25.4 presents considerations and recommendations related to healthy snacking.

VII CONCLUSIONS

Given the important contribution of snacking to total energy intake and the need to develop more effective strategies to improve healthy eating habits and body weight management, it is important to better understand the impact of snacking on energy balance. Overall, the literature presents evidence that snacking is associated with both beneficial/neutral and negative effects on energy balance adults and children. Thus, the existing evidence does not clearly indicate that snacking is related to obesity and weight gain nor does it indicate that snacking is a good strategy for body weight control. Whether or not snacking influences energy balance requires considerations to numerous methodological issues such as snacking definitions and assessments, timing, food quality, food perceptions, and level of attention while snacking, underreporting, and other lifestyle habits. Future studies should consider the harmonization of the snacking definition as well as draw attention to better assess or control for these methodological issues. Because most of the studies have cross-sectional or prospective design, there is an urgent need to design intervention studies aimed at identifying the most optimal intervention strategies to promote healthy snacking patterns with a specific attention of snacking in children.

Although more studies are needed, the literature supports some strategies that can help to integrate snacking into a healthy diet without promoting positive energy balance. These strategies include the consumption of low energy and high nutrient-dense, solid snacks, such as fruits and vegetables, which are planned in the daily schedule and eaten in optimal environmental conditions. Even if they seem to be simple recommendations, significantly improving snacking patterns will likely require combined efforts of health professionals in the field of behavior modifications as well as those working in industry, schools, and other public health and community settings.

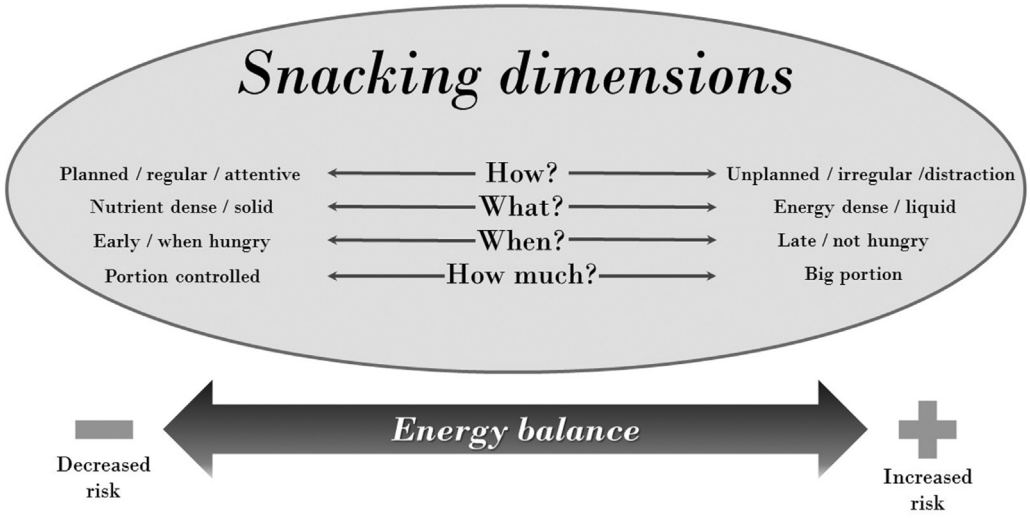

FIGURE 25.2 Summary-dimensions of snacking patterns.

TABLE 25.4 Considerations and Recommendations to Promote Healthy Snacking

Snacking Dimensions	Considerations	Recommendations
What?	What kind of food is usually eaten as snack? Is it usually low energy-dense and high nutrient-dense?	• Favor fruits and vegetables • Limit sweetened beverages as a snack • Other protein and nutrient-rich foods such as nuts
When?	When a snack is usually consumed?	• Limit snacking after dinner or in improper places • Do not store (tempting) foods in several places such as in the glove compartment of the car or the desk drawer at work. Keep these places snack-free • Do not snack if you are not hungry
How much?	Is a snack portion controlled? What is the number of snacks per day versus meals?	• Limit to one regular portion. Do not automatically use the suggested industry portion or whole package, but take your energy needs into account • Do not consume the total amount of a package or container of food but determine the amount of a "normal" serving size to eat • When there is a choice of portion size, pick the smallest one
How?	Is a snack planned in the diet? Is a snack consumed regularly? In a hungry state? How does snacking occur? Describe the context: In front of the TV? In the car? Is the person usually snacking? Is snacking part of an active lifestyle?	• Do not snack if it was not planned in your daily eating pattern unless the meal is delayed • Do not eat directly from the refrigerator or pantry • When preparing a snack, do not snack on the ingredients • Notice when you are satisfied and make it a habit to leave something on your plate when you are satisfied (satiated) • Avoid other activities such as watching TV, reading, or driving a car when eating • Avoid eating during work-related activities such as meetings, working at your desk, or making telephone calls • Take your time when eating your meal • Take time to appreciate the snack in a quiet environment

Chapter 26

Genetic Influences on Blood Lipids and Cardiovascular Disease Risk

Toni I. Pollin[1], Jose M. Ordovas[2,3] and Martha Guevara-Cruz[4]

[1]University of Maryland School of Medicine, Baltimore, MD, United States, [2]Tufts University, Boston, MA, United States, [3]Centro Nacional Investigaciones Cardiovasculares (CNIC), Madrid, Spain, [4]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán (INCMNSZ), Mexico City, Mexico

I INTRODUCTION

The major public health concerns in the developed world (i.e., cardiovascular disease (CVD), cancer, and diabetes) have both genetic and environmental causes. The interface between public health and genetics involves working toward an understanding of how genes and the environment act together to cause these diseases and how the environment (e.g., diet), rather than genes, might be manipulated to help prevent or delay the onset of disease.

CVD, the leading cause of mortality in most industrialized countries, is a multifactorial disease that is associated both with nonmodifiable risk factors, such as age, gender, and genetic background, and with modifiable risk factors, including elevated total and low-density lipoprotein cholesterol (LDL-C) and triglyceride (TG) levels, as well as reduced high-density lipoprotein cholesterol (HDL-C) level. Heritability estimates for blood lipids are high—approximately 40−60% for HDL-C, 40−50% for LDL-C, and 35−48% for TG [1].

Traditionally, the major emphasis of public health measures has been on lowering serum cholesterol, which has long been recognized as an important risk factor for the development and progression of atherosclerotic vascular disease; multiple clinical studies for the past 30 years have demonstrated the benefits of this approach. In view of these findings, the National Heart, Lung, and Blood Institute convened the National Cholesterol Education Program Adult Treatment Panel I (NCEP ATP I) [2]. This panel and similar panels throughout the world have set the standards for lowering lipid profiles in clinical practice. Subsequent revisions of these standards (NCEP ATP II and III) [3,4] have placed a greater focus on LDL-C, and target LDL-C levels are based on patient risk of subsequent coronary disease events. Since the publication of the NCEP ATP III guidelines, several large-scale clinical trials of cholesterol-lowering treatments have been conducted, the findings of which may be used to further refine current clinical practice standards [5,6]. Although most of the evidence that lowering serum LDL-C can reduce CVD morbidity and mortality comes from pharmacological interventions, the NCEP has emphasized that therapeutic lifestyle change should be the primary treatment for lowering cholesterol, and drug therapies should be reserved for cases in which lifestyle modification is ineffective. The lifestyle modifications advocated include dietary changes, increased physical activity, and weight management. The recommended dietary changes to reduce LDL-C include restriction of saturated fat to less than 7% of total caloric intake, restriction of cholesterol to less than 200 mg/day, increased viscous fiber intake (10−24 g/day), and increased plant stanol/sterol intake (2 g/day) [4]. However, it is not known how many individuals can achieve the recommended levels of serum lipids using this approach, in large part because it is currently impossible to predict plasma lipid response to dietary changes in individual patients [7,8].

Other pharmacological approaches to CVD risk reduction have been investigated, including treatments to lower serum TG and raise HDL-C. Fibrate drugs are most commonly used to lower TG. Fenofibrate therapy has been associated with changes of −25 to −59% in TG, −33 to +1% in LDL-C, and +1 to +34% in HDL-C in CVD

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00026-6

patients [9]. The largest reduction of CVD risk by fenofibrate has been detected in patients with marked dyslipidemia, a feature of metabolic syndrome (MetS), in whom a 27% relative risk reduction was found in the Fenofibrate Intervention and Event Lowering in Diabetes study [10,11]; therefore, fenofibrate would be expected to have large beneficial effects in MetS patients. The use of fenofibrate in the management of lipoprotein disorders dates back to the mid-1960s. However, their prominence has lessened throughout the years because of unimpressive results in major clinical trials, safety concerns, and the emergence of 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins). Moreover, the general trial results with these agents have been confusing, with varying cardiovascular benefits [12–14] depending on the dyslipidemia status [15].

The epidemiologic, experimental, and circumstantial evidence implicating low HDL-C as a major risk factor for CVD has driven considerable research on this lipoprotein fraction; it is hoped that raising HDL-C may further reduce CVD risk beyond what can be achieved with the use of statins. However, doubts about the clinical benefits of treatments to enhance plasma HDL-C levels have been raised by the premature termination of a large phase III trial with torcetrapib, the most potent and furthest-developed HDL-C-raising compound, which was discontinued because of excess mortality in patients receiving the drug [16]. The causes of torcetrapib failure are unknown and may be related to the drug's mode of action, to toxic off-target effects of the drug, or both. However, the failure of torcetrapib does not mean that targeting HDL in CVD prevention is no longer a research goal. Other HDL-C-raising therapies that act through similar or disparate molecular mechanisms are in various stages of preclinical and clinical development [17,18].

The considerable interindividual variation in lipid response, cardiovascular event response, and adverse events observed following these therapies has brought considerable attention to the concept of more targeted therapies based on genetic information. Pharmacogenomics (or pharmacogenetics) involves the search for and identification of genetic variants that influence patient response to drug therapy. During approximately the past decade, some progress has been made in our understanding of the variable efficacy of statin therapy [19]. Similarly, there is evidence that fenofibrate treatment improves the lipid profile, but there is significant interindividual variability in lipid response to fenofibrate, which may be mediated by specific genes [20,21]. Important limitations and issues in pharmacogenetics have been raised, however, which need to be resolved before its clinical application.

Regarding the connection between diet and plasma cholesterol concentration, several studies during the first half of the 20th century demonstrated that serum cholesterol could be modified by the composition of dietary fat [22,23]. Studies by Keys and colleagues [24] and Hegsted et al. [25] provided the first quantitative estimates of the relative effects of the various classes of dietary fatty acids and the amount of dietary cholesterol on serum cholesterol changes. Later, other predictive algorithms were developed, including predictions of LDL-C and HDL-C responses [26–28]. The relationships between dietary changes and serum lipid changes are well founded and predictable for groups. However, a striking variability in the response of serum cholesterol to diet between subjects was reported as early as 1933 [29], and this variability has been the subject of multiple reports. In some individuals, plasma total lipid and LDL-C levels dramatically decrease following the consumption of lipid-lowering diets, whereas they remain unchanged in others [27,30–34]. Multiple studies in animal models and in humans have shown that serum lipoprotein response to dietary manipulation has a significant genetic component [35–40]. Genetic variability could therefore have a significant impact on the success of public health policies and individual therapeutic interventions. Moreover, it could be partially responsible for the apparent lack of hard endpoint benefits shown by many dietary studies aimed at decreasing CVD [41–43].

As indicated previously, the success of CVD risk-reducing strategies has traditionally been measured based on their effects on plasma lipids and, specifically, lipoprotein levels. Lipoproteins are macromolecular complexes of lipids and proteins that originate mainly from the liver and intestine and are involved in the transport and redistribution of lipids in the body. Lipid and lipoprotein metabolism can be viewed as complex biological pathways containing multiple steps. Lipid homeostasis is achieved by the coordinated action of hundreds of gene products, including nuclear factors, binding proteins, apolipoproteins, enzymes, and receptors. Lipid metabolism is also closely linked to energy metabolism and is subject to many hormonal controls that are essential for adjustment to environmental and internal conditions. Genetic variability within candidate genes involved in lipoprotein metabolism has been associated with abnormal lipid metabolism and plasma lipoprotein profiles that may contribute to the pathogenesis of atherosclerosis. This complex regulatory network can be dissected into three major pathways (Fig. 26.1). The exogenous lipoprotein pathway describes the metabolism of lipoproteins synthesized in the intestine following dietary fat intake, the endogenous pathway involves the metabolism of lipoproteins involved in the transport of liver lipids to peripheral tissues, and the reverse cholesterol transport pathway describes the process by which excess peripheral lipids (primarily cholesterol) are transported to the liver for catabolism. Our knowledge about how variants in candidate genes

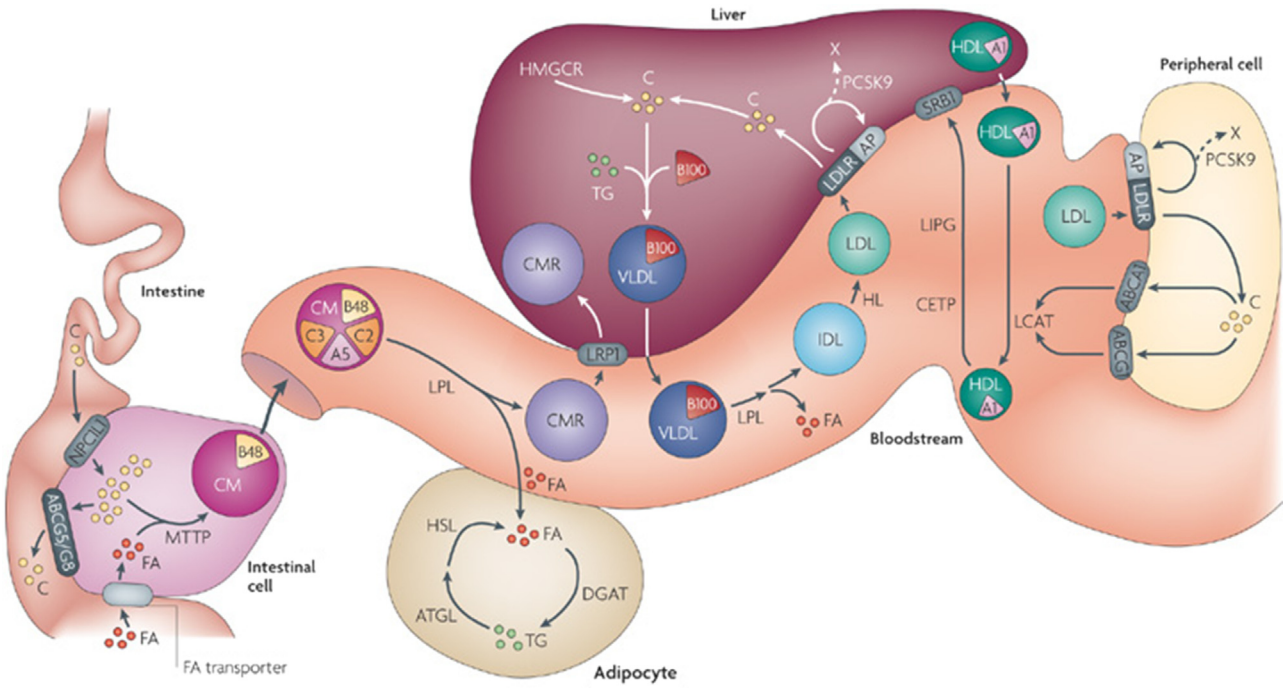

FIGURE 26.1 The main lipids in lipoproteins are free and esterified cholesterol (C) and TG. The metabolism of TG, LDL cholesterol, and HDL cholesterol is shown. In TG metabolism, hydrolyzed dietary fats enter intestinal cells (enterocytes) via fatty acid (FA) transporters. Reconstituted TG is packaged with C ester and the apolipoprotein B (APOB) isoform B48 into chylomicrons (CMs) by microsomal TG-transfer protein (MTTP) through a vesicular pathway. CMs, secreted via the lymphatic system, enter the vena cava and circulate until they interact with LPL, the secretion of which depends on lipase-maturation factor 1 (not shown), and which is secured to endothelium by proteoglycans and glycosylphosphatidylinositol-anchored HDL-binding protein 1 (not shown). CMs contain apolipoproteins, including APOA5 (A5), APOC2 (C2), and APOC3 (C3). Released free FAs incompletely enter peripheral cells. In adipocytes, enzymes including acyl CoA:diacylglycerol acyltransferase (DGAT) resynthesize TG, which is hydrolyzed by adipose TG lipase (ATGL) and hormone sensitive lipase (HSL). CM remnants (CMRs) are taken up by hepatic LDL receptor (LDLR), in the absence of LDLR they are taken up by LDLR-related protein-1 (LRP1). In liver cells (hepatocytes), TG is packaged with cholesterol and the APOB isoform B100 into VLDL; the TG contained in VLDL is hydrolyzed by LPL, releasing FAs and VLDL remnants (IDL) that are hydrolyzed by hepatic lipase (HL), thereby yielding LDL. In LDL cholesterol metabolism, sterols in the intestinal lumen enter enterocytes via the Niemann-Pick C1-like 1 (NPC1L1) transporter and some are resecreted by heterodimeric ATP-binding cassette transporter G5/G8 (ABCG5/G8). In enterocytes, cholesterol is packaged with TG into CM. In hepatocytes, cholesterol is recycled or synthesized de novo, with 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR) being rate-limiting. LDL transports cholesterol from the liver to the periphery. LDL is endocytosed by peripheral cells and hepatocytes by LDLR, assisted by an adaptor protein (AP). Proprotein convertase subtilisin/kexin type 9 (PCSK9), when complexed to LDLR, short-circuits recycling of LDLR from the endosome, leading to its degradation (X). In HDL cholesterol metabolism, HDL, via APOA-I (A1), mediates reverse cholesterol transport by interacting with ATP-binding cassette A1 (ABCA1) and ABCG1 transporters on nonhepatic cells. LCAT esterifies cholesterol so it can be used in HDL cholesterol, which, after remodeling by CETP and by endothelial lipase (LIPG), enters hepatocytes via scavenger receptor class B type I (SRB1). *Reprinted by permission from Macmillan Publishers Ltd. R.A. Hegele, Plasma lipoproteins: genetic influences and clinical implications, Nat. Rev. Genet. 10 (2009) 109–121, copyright 2009.*

involved in each of these three interrelated processes affect dietary response and cardiovascular risk is discussed next.

A Exogenous Lipoprotein Pathway

The exogenous lipoprotein pathway begins in the enterocyte with the synthesis of chylomicron particles. Dietary fats absorbed in the intestine are packaged into large, TG-rich chylomicrons for delivery to sites of lipid metabolism or storage. During their transit to the liver, these particles interact with lipoprotein lipase (LPL) and undergo partial lipolysis to form chylomicron remnants. These chylomicron remnants pick up apolipoprotein E (APOE) and a cholesteryl ester from HDL, after which they are taken up by the liver in a process that is mediated by the interaction of APOE with hepatic receptors. In most people, this occurs quickly, and chylomicrons are not usually present in the blood after prolonged fasting. However, there is dramatic variability in postprandial lipoprotein metabolism, which is determined in part by genetic factors, and this variability could be highly relevant to achieving a more precise definition of individualized CVD risk [44,45]. The most relevant candidate genes involved in

this metabolic pathway and their known associations with plasma lipid levels and dietary response are described later.

B Endogenous Lipoprotein Metabolism

Hepatocytes synthesize and secrete TG-rich very low-density lipoprotein (VLDL), which may be converted first to intermediate-density lipoproteins and then to LDL through lipolysis by a mechanism involving LPL, similar to that described for the exogenous lipoprotein pathway. The excess surface components are usually transferred to HDL. Some of these remnants may be taken up by the liver, whereas others are further lipolyzed to become LDL, which, in humans, contains APOB as its primary apolipoprotein. This pathway uses many of the same genes as the exogenous pathway. The LDL receptor is primarily responsible for the catabolism of LDL particles in the liver and peripheral tissues. Another important factor in endogenous lipoprotein metabolism is the HMG-CoA reductase gene, which encodes a key enzyme in de novo cholesterol synthesis.

C Reverse Cholesterol Transport

Both the liver and the intestine synthesize HDL. In its precursor form, HDL is disc-shaped, and it matures in the circulation as it picks up unesterified cholesterol from cell membranes (see the later discussion of the ATP-binding cassette-1), other lipids (phospholipids and TG), and proteins from triglyceride-rich lipoproteins (TRL) as these particles undergo lipolysis. The cholesterol is esterified by lecithin−cholesterol acyltransferase (LCAT), and the small HDL3 particle becomes a larger HDL2 particle. The esterified cholesterol is either delivered to the liver or transferred by the action of the cholesterol ester transfer protein (CETP) to TRL in exchange for TG. The liver may then take up cholesterol via receptors specific for these lipoproteins, or it can be delivered to the peripheral tissues. The TG received by HDL2 is hydrolyzed by hepatic lipase, and the particle is converted back to HDL3, completing the HDL3 cycle in plasma. In the liver, cholesterol can be excreted directly into bile, converted to bile acids, or reused for lipoprotein production.

However, CVD has a multifactorial etiology in which a complex combination of environmental, genetic, and clinical risk factors seem to play determinant roles [46,47]. The complex architecture of this disease and its genetic basis [48] are still poorly understood, and some discrepancies remain in estimates of the heritability of numerous CVD-related quantitative traits (QTs) [49]. The identification and validation of genetic variants that promote CVDs and related QTs may lead to a better understanding of the pathogenesis of these diseases and to the identification of novel disease-associated biological pathways and risk factors.

During approximately the past two decades, the genetics of chronic diseases and related QTs have been assessed by candidate gene approaches [50] as well as linkage approaches, which were successful in families with Mendelian (single gene) forms of dyslipidemia, but less so in examining polygenic sources of lipid variation in the population. Twin and family studies have been used to estimate heritability, whereas population-based studies are used to identify variants that are associated with specific phenotypes and to explore interactions between genetic and environmental factors. Candidate genes are those considered to influence complex phenotypes due to their participation in related biological pathways or due to their location near a region of interest [50]. This hypothesis-driven research has provided the foundation for the development of genetic CVD risk profiles [51]. However, since 2007, genome-wide association studies (GWAS) have revolutionized the research of chronic diseases such as CVDs and their associated QTs [52−54]. Recent technological advances have enabled the rapid and accurate assessment of millions of single-nucleotide polymorphisms (SNPs) in large populations, and many new GWAS have been conducted for different CVD phenotypes and related traits. These studies have identified hundreds of largely common genetic factors, some of which have been frequently replicated, albeit with small individual effects. Moreover, GWAS have revealed previously unsuspected pathological pathways [55,56]. Nevertheless, the causal variants identified by GWAS are insufficient to explain the high heritability of different CVD phenotypes. Additional studies are required to further refine the prevention, diagnosis, treatment, and prognosis of CVD patients based on genetic factors [57]. For example, the decreasing costs of DNA sequencing technologies are enabling large-scale sequencing studies, including the entire genome or exome (region of the genome containing all protein coding genes), to emerge and identify rare and low frequency variants generally not identifiable via GWAS and likely to have larger individual effects.

II REPRESENTATIVE GWAS

Lipid measures represent excellent secondary phenotypes for the genetic investigation by many GWAS of CVD, and relatively large sample sizes can be obtained to study these traits. Here, we discuss the main features of several GWAS using lipid measures.

Sabatti et al. [58] reported GWAS results for nine quantitative metabolic traits (HDL-C, LDL-C, TG, glucose, insulin, C-reactive protein, body mass index, and systolic and diastolic blood pressure) in the Northern

Finland Birth Cohort of 1966 (NFBC1966), which was drawn from the most genetically isolated regions of Finland. This study replicated most previously reported gene associations and identified nine new associations, several of which highlighted genes with metabolic functions: HDL-C with *NR1H3* (LXRA), LDL-C with *AR* and *FADS1−FADS2*, glucose with *MTNR1B*, and insulin with *PANK1*. Two of these new associations emerged after adjusting results for body mass index. Gene−environment interaction analyses suggested additional associations that will require validation in larger samples. These loci, even when combined with quantified environmental exposures, explain little of the trait variation in NFBC1966. However, the association between LDL-C and an infrequent variant in *AR* suggests that cohort studies have the potential to identify associations with both common, low-impact and rare, high-impact QT loci.

In another study, Aulchenko et al. [59] reported the first GWA analysis of loci affecting total cholesterol (TC), LDL-C, HDL-C, and TGs sampled randomly from 16 population-based cohorts and genotyped using mainly the Illumina HumanHap300-Duo platform. Their study included a total of 17,797−22,562 persons aged 18−104 years and from geographic regions from the Nordic countries to southern Europe. They established 22 loci associated with serum lipid levels at a genome-wide significance level, including 16 loci that had been identified by previous GWAS. The six loci newly identified in this cohort were *ABCG5*, *TMEM57*, the *CTCF−PRMT8* region, *DNAH1*, *FADS3−FADS2*, and the *MADD−FOLH1* region. The effect sizes differed significantly by sex for three loci. Genetic risk scores based on lipid loci explained up to 4.8% of the variation in lipid profile and were associated with increased intima media thickness and coronary heart disease incidence.

To dissect the polygenic basis of these traits, Kathiresan et al. [60] conducted GWAS in 19,840 individuals and replicated it in up to 20,623 individuals. They identified 30 distinct loci associated with lipoprotein concentrations, including 11 loci that reached genome-wide significance. The 11 newly defined loci include common variants associated with LDL cholesterol near *ABCG8*, *MAFB*, *HNF1A*, and *TIMD4*; with HDL cholesterol near *ANGPTL4*, *FADS1−FADS2−FADS3*, *HNF4A*, *LCAT*, *PLTP*, and *TTC39B*; and with TGs near *AMAC1L2*, *FADS1−FADS2−FADS3*, and *PLTP*. The proportion of individuals exceeding clinical cutoff points for high LDL cholesterol, low HDL cholesterol, and high TGs varied according to an allelic dosage score. These results suggest that the cumulative effect of multiple common variants contributes to polygenic dyslipidemia.

Ma et al. [61] reported single-locus and epistatic SNP effects on TC and HDL-C using Framingham Heart Study (FHS) data. Single-locus effects and pairwise epistasis effects of 432,096 SNP markers were tested for their significance on log-transformed TC and HDL-C levels. Twenty-nine additive SNP effects reached single-locus genome-wide significance ($p < 7.2 \times 10^{-8}$), and no dominant effect reached genome-wide significance. Two new gene regions were detected: the *RAB3GAP1−R3HDM1−LCT−MCM6* region of chr02 for TC was identified by six new SNPs, and the *OSBPL8−ZDHHC17* region (chr12) for HDL-C was identified by one new SNP. The remaining 22 single-locus SNPs identified confirmed previously reported genes or gene regions. For TC, three SNPs identified two gene regions that were tightly linked with previously reported TC-associated genes, including rs599839 10 bases downstream of *PSRC1* and 3.498 kb downstream of *CELSR2*, rs4970834 in *CELSR2*, and rs4245791 in *ABCG8*. The association of HDL-C with *LPL* was confirmed by 12 SNPs 8−45 kb downstream, with *CETP* by two SNPs 0.5−11 kb upstream, and with the *LIPG−ACAA2* region by five SNPs in this region. Two epistasis effects on TC and 13 epistasis effects on HDL-C reached the significance of "suggestive linkage." The most significant epistasis effect ($p = 5.72 \times 10^{-13}$) was a dominant × dominant effect of HDL-C between *LMBRD1* (chr06) and the *LRIG3* region (chr12) and was close to reaching "significant linkage"; this pair of gene regions had six other D × D effects with "suggestive linkage." Genome-wide association analysis of the FHS data detected two novel gene regions with genome-wide significance, detected epistatic SNP effects on TC and HDL-C with the significance of suggestive linkage in seven pairs of gene regions, and confirmed the association of some previously reported gene regions with TC and HDL-C.

Teslovich et al. [62] identified additional common variants associated with plasma TC, LDL-C, HDL-C, and TG concentrations. They performed a meta-analysis of 46 lipid GWAS. These studies together comprised more than 100,000 individuals of European descent from the United States, Europe, and Australia. They reported 95 significantly associated loci ($p < 5 \times 10^{-8}$), with 59 showing genome-wide significant association with lipid traits for the first time. The newly reported associations include SNPs near known lipid regulators (e.g., *CYP7A1*, *NPC1LA*, and *SCARB1*) and in many loci not previously implicated in lipoprotein metabolism. The 95 loci contribute not only to normal variation in lipid traits but also to extreme lipid phenotypes, and they affect lipid traits in three non-European populations (East Asians, South Asians, and African Americans). That study also identified several novel loci associated with plasma lipids that are also associated with CVD. Finally, it validated the functions of three novel genes—*GALNT2*, *PPP1R3B*, and *TTC39B*—with experiments in mouse models. Taken

together, Teslovich et al.'s findings provided the foundation for a broader biological understanding of lipoprotein metabolism and identify new therapeutic opportunities for the prevention of coronary artery disease (CAD).

Lettre et al. [63] identified common genetic polymorphisms associated with CVD and its risk factors (LDC and HDL-C, hypertension, smoking, and type 2 diabetes) in individuals of African ancestry through a GWAS in 8090 African Americans from five population-based cohorts. They confirmed 17 loci that had previously been associated with CVD or its risk factors in Caucasians. For five of these regions (CHD: *CDKN2A/CDKN2B*; HDL-C: *FADS1−FADS3*, *PLTP*, *LPL*, and *ABCA1*), the authors were able to use the distinct linkage disequilibrium patterns in African Americans to identify DNA polymorphisms that were more strongly associated with the phenotypes than the previously reported index SNPs found in Caucasian populations. They also developed a new approach for association testing in admixed populations using allelic and local ancestry variation.

GWAS have identified a number of SNPs associated with serum lipid level in populations of European descent. The individual and the cumulative effects of these SNPs on blood lipids are largely unclear in the U.S. population. Chang et al. [64] used data from the second phase of the Third National Health and Nutrition Examination Survey (NHANES III), a nationally representative survey of the U.S. population, to examine associations of 57 GWAS-identified or well-established lipid-related genetic loci with plasma concentrations of HDL-C, LDL-C, TC, and TG. They used multivariable linear regression to examine single SNP associations and the cumulative effect of multiple SNPs on blood lipid levels. Analyses were conducted in adults for each of the three major racial/ethnic groups in the United States: non-Hispanic whites ($n = 2296$), non-Hispanic blacks ($n = 1699$), and Hispanics ($n = 1713$). The allele frequencies of all SNPs varied significantly by race/ethnicity, except rs3764261 in *CETP*. Individual SNPs had small effects on lipid levels, but the effects were consistent across racial/ethnic groups for most SNPs. More GWAS-validated SNPs were replicated in non-Hispanic whites (<67%) than in non-Hispanic blacks (<44%) or Hispanics (<44%). Genetic risk scores were strongly associated with increased lipid levels in each race/ethnic group. The combination of all SNPs into a weighted score explained no more than 11% of the total variance in blood lipid levels. The authors concluded that the combined association of SNPs, used to generate a genetic risk score, was strongly correlated with blood lipid measures in all major race/ethnic groups in the United States and that this knowledge could help in identifying subgroups of patients at high risk for an unfavorable lipid profile.

GWAS were never designed to interrogate actual underlying causal variants; rather, they are used to "tag" the approximate locations of disease variants, typically down to a few hundred kilobases. The development of GWAS methodology may have transformed our ability to discover key genetic factors that are involved in the pathogenesis of CVD, but this only represents the first step in a much longer process. The genes and pathways uncovered using the GWAS approach are likely to be fundamental to disease biology, so it will be crucial to determine how these variants affect the expression and function of the gene products through molecular biology approaches. Therefore, we compiled a list of genes identified by GWAS and additional evidence of their association with lipids. We found 118 loci potentially associated with serum lipid levels that were identified in different GWAS and were also implicated in previously known Mendelian forms of lipid disorders, previously published in candidate gene association studies, or identified through the examination of metabolic phenotypes of knockout mice maintained by the Jackson Laboratory. These genes are described in Table 26.1.

We (JMO and MG-C) identified 118 loci that showed genome-wide significant associations with at least one of the four traits tested (LDL-C, TG, HDLC, and TC). Among these loci, 53 demonstrated genome-wide association with LDL-C, 45 with TG, 56 with HDL-C, and 57 with TC. Only two genes in all GWAS had the same effects on HDL-C—the *LPL* and *CETP* genes. The genes most frequently identified in GWAS for LDL-C were *PCSK9*, *CELSR2*, *APOB*, *ABCG5/8*, *HMGCR*, *LDLR*, *APOE−APOC1−APOC4−APOC2*, and *NSRF*; *CILP2* and *NCAN* were also identified in multiple LDL association studies. The genes most frequently identified in GWAS for TG were *APOB*, *GCKR*, *ANGPTL3−DOCK7−ATG4C*, *MLXIPL*, *LPL*, *FADS1−FADS2−FADS3*, and *APOA−APOC3−APOA4*. The genes most frequently identified in GWAS for HDL-C were *GALNT2*, *LPL*, *ABCA1*, *FADS1−FADS2−FADS3*, *MVK*, *LIPC*, *CETP*, *LCAT*, and *LIPG*. Finally, the genes most frequently identified in GWAS for TC were *CELS42*, *APOB*, *ABCA5G/8*, *LIPG*, and *LDLR* (Table 26.2).

Waterworth et al. [67] conducted a meta-GWAS to identify novel genetic determinants of low LDL-C, HDL-C, and TGs. They combined GWAS data from eight studies, which included up to 17,723 participants and associated information on circulating lipid concentrations. They performed independent replication studies in up to 37,774 participants from eight populations and also in a population of Indian Asian descent. They also assessed the associations between SNPs at lipid loci and CVD risk in up to 9633 cases and 38,684 controls. They identified four novel genetic loci that showed reproducible associations with lipid levels, including a potential functional SNP in the *SLC39A8* gene for HDL-C, an SNP near the *MYLIP/GMPR* and *PPP1R3B* genes for LDL-C, and an

[a]*Each gene listed in the "locus" column is either a plausible biological candidate gene in the locus or the nearest annotated gene to the lead SNP.*
Chr, chromosome; GWAS: 1, Teslovich et al. [62]; 2, Aulchenko et al. [59]; 3, Kathiresan et al. [60]; 4, Sabbatti et al. [58]; 5, Waterworth et al. [67]; 6, Lettre et al. [63]; 7, Ma et al. [61]; and 8, Chang et al. [64].

SNP at the *AFF1* gene for TGs. SNPs at the *CELSR2−APOB−APOE−APOC1−APOC4−APOC2* cluster, *LPL−ZNF259−APOA5−APOA4−APOC3−APOA1* cluster, and *TRIB1* locus showed strong statistical association with one or more lipid traits and were also associated with CVD risk.

Most recently the Global Lipids Genetics Consortium [66], in a worldwide meta-analysis expanded to 188,577 European individuals genotyped either on GWAS or specialized Metabochip arrays, identified and annotated 157 loci associated with lipid levels at genome-wide significance ($p < 5 \times 10^{-8}$), including 62 not previously reported. Diverse (European, East Asian, South Asian, and African ancestry) populations comprising 7898 were used to narrow the signals in 12 loci. Of the 62 novel loci, which identified 240 genes within 100 kb, the role of 38 in lipid regulation was supported by previous evidence as reported in the literature or curated pathway databases, and the other 24 had no such evidence. Several other analyses were performed to gain insight into the role of these variants, including analysis of the relationship with CAD risk and lipid subfractions, providing evidence that LDL-C and TG but not HDL-C levels are causally related to CAD risk [66]. Because of the complexity of the analyses and combination of platforms used, these results have not been included in Tables 26.1 and 26.2.

These increasingly large GWAS studies and meta-analyses have made possible the identification of numerous common variants with increasingly smaller effect sizes that were not investigated by previous candidate gene studies. Ultimately, one of the major challenges going forward will be to determine how these recently uncovered variants affect the expression and function of gene products using molecular biology approaches. Detailed genotype−phenotype studies will be required to determine the mechanisms involved and how these loci potentially interact with and are involved in other disorders. Only by continuing to uncover the functional context of these genetic variants and understanding their interactions can these findings be truly translated into meaningful benefits for patient care. Further understanding of the effects of low frequency and rare variants in these and other genes likely to have larger effects will also be important for clarifying the genetic contributions to lipid level variation. As GWAS generally only tests for common variants, such large effect variants have not been accessible in population studies. Identifying these will require large, high-throughput sequencing efforts involving thousands of DNA samples, which is becoming increasingly possible with the advent of next-generation sequencing technologies and decreasing costs. Studying founder populations, in which frequencies of otherwise rare variants can be dramatically increased, also offers the opportunity to be able to characterize phenotypic effects of rare variants.

A Founder Populations

While GWAS in outbred populations are generally not powered to detect rare variant associations, the founder effect enables a rare variant to reach a high frequency in a closed population such that it can be tagged by a common variant at the lower end of the frequency spectrum. In 2008, we (TIP and colleagues) [68] performed a GWAS for TG levels before and after a high fat meal in 806 Pennsylvania Old Order Amish individuals. An SNP on the array near the *APOA1/C3/A4/A5* region showed genome-wide significant association with lower fasting ($p = 4 \times 10^{-14}$) and postprandial ($p = 2.8 \times 10^{-10}$) TG levels. Sequencing of the APOC3 gene revealed a previously unreported loss-of-function mutation R19X to be present in approximately 5% of the Amish population. In addition to being associated with a cardioprotective lipid profile including low TG, high HDL-C, and low LDL-C, the variant was also associated with less coronary artery calcification, a subclinical measure of CVD. [68] Interestingly, we also found that the Amish also have a dramatically elevated carrier frequency (12%) of an otherwise rare APOB variant R3527Q causing familial hypercholesterolemia; our large sample of carriers showed that

mutation carriers had more coronary calcification even after adjusting for LDL-C levels, suggesting an effect of lifelong exposure to elevated LDL-C and/or other mediating factors [69] and on a practical level suggesting that genetic testing may offer benefits for prediction and management of CVD risk beyond cholesterol level measurement.

B High Throughput Sequencing

In 2014, The Exome Sequencing Project [70] reported on efforts to better understand the role of rare variants in the population in TG levels and cardiovascular risk. They sequenced protein coding regions of 18,666 genes in 3734 individuals with European or African ancestry and analyzed the association of groups of rare variants within each gene with TG levels. The gene most strongly associated with TG levels was *APOC3*, resulting primarily from four mutations, including R19X, found in five or more individuals each. Genotyping these variants in 41,671 additional European/African ancestry participants yielded association with 39% lower TG, higher HDL-C and a trend toward lower LDL-C. Importantly, genotyping these four in 110,970 individuals revealed that carriers, comprising 1/150 individuals, had a 40% lower risk of coronary heart disease and no evidence of increased hepatic fat, providing clinical confirmation that loss of apoC-III is cardioprotective. A separate study reported at the same time by Jørgensen et al. [71] confirmed these findings: in 75,725 individuals, sequencing of the coding and flanking regions of *APOC3* was conducted and three LOF *APOC3* mutations were found in 1/290 individuals and were associated with 44% lower TG levels and 41% and 36% lower risk of ischemic vascular disease and ischemic heart disease, respectively [71]. Together these findings along with previous findings regarding apoC-III function have helped to establish a primary role for TG variation in CVD etiology. Further studies of individuals with these variants is underway and expected to increase our understanding of the etiology of CVD and specifically increase our understanding of apoC-III function; meanwhile, clinical trials of strategies to reduce CVD risk by directly interfering with apoC-III production are already underway [72] and may offer improvements in CVD prevention over existing therapies which act in part through apoC-III. In a similar manner, gain of function mutations in *PCSK9*, encoding an inhibitor of the LDL receptor, were first identified as a cause of familial hypercholesterolemia (elevated LDL-C) through a linkage and fine mapping study in families [73]; subsequently, studies of individuals with very low LDL-C levels revealed cardioprotective loss-of-function mutations reducing LDL-C and CVD risk in 2% of African Americans and $<1\%$ of European Americans [74] that have led to the development of commercially available *PCSK9* inhibitors to treat hypercholesterolemia [75,76].

III DEVELOPMENT OF CARDIOVASCULAR SCORE

Measures of cardiovascular risk, such as the Framingham score, have long been used in public health research and practice [77–80]. These risk scores play an important role in screening programs to identify susceptible individuals before the onset of clinical symptoms and facilitate primary prevention [81]. Cardiovascular risk scores are also used in epidemiological research, namely as measures of exposure, as stratification variables, or as measures of potential confounders [82,83].

The predictive ability of existing cardiovascular risk scores varies greatly between populations and is particularly low for ethnic minorities [84]. This variability merits further investigation; most current cardiovascular risk measures are based on cohorts from high-income Western countries [85,86], and their generalizability to populations from low- or middle-income countries or ethnically and economically diverse communities in high-income countries is limited.

In addition, low LDL-C and high HDL-C, TG, and TC concentrations are important and heritable risk factors for CVD. Although GWAS of circulating lipid levels have identified numerous disease-associated loci, a substantial portion of the heritability of these traits remains unexplained. Evidence of unexplained genetic variance can be detected by combining multiple independent markers into additive genetic risk scores. These polygenic scores, which were constructed using results from the ENGAGE Consortium GWAS on serum lipids [59], were used to predict lipid levels in an independent population-based study, the Rotterdam Study II. This study also tested for evidence of a shared genetic basis for different lipid phenotypes. The polygenic score approach was used to identify an alternative genome-wide significance threshold for subsequent pathway analysis, and the results of that analysis were compared with those based on the classical genome-wide significance threshold. Demirkan et al. [87] provide evidence suggesting that many loci that influence circulating lipid levels remain undiscovered. Cross-prediction models suggested a small overlap between the polygenic backgrounds involved in determining LDL-C, HDL-C, and TG levels. Pathway analysis utilizing the best polygenic score for TC uncovered extra information compared with a model that used only genome-wide significant loci.

Using prediction modeling, Demirkan et al. [87] explain up to 4.8% of the variance in HDL-C, 2.6% in LDL-C, 3.8% in TG, and 2.7% in TC. However, these proportions are much lower than those identified by the Global Lipid Genetics Consortium, which were estimated to explain 12.4% (TC), 12.2% (LDL-C), 12.1% (HDL-C), and 9.6% (TG) of the variance in the FHS sample, as reported by

Teslovich et al. [62]. This is expected because increases in sample size lead to better estimation of SNP effect sizes.

GWAS have yielded a wealth of information about the pathogenesis of dyslipidemia. Even as we continue to use these studies to uncover novel protein and gene variants involved in lipoprotein metabolism, a significant investment of effort and resources needs to be made to fully exploit the findings of these important studies. Further research facilitated by availability of large-scale high throughput genome-wide sequencing as underway in the T2D-Genes Consortium, including in founder populations, is expected to include the identification of additional less frequent variants with large effects, which may help us narrow down the genetic loci of interest and provide proof-of-concept of the potential benefits of modulating the functions of these proteins as in the case of *PCSK9* [75,76,88] and *APOC3* [68,70–72].

The GWAS and sequencing studies reviewed here represent the culmination of years of groundwork, but the studies and results reported in this chapter only scratch the surface of the true potential of this approach. In addition to the obvious next steps of replication, signal refinement, and identification of additional causative variants, the definition of the biological roles of GWAS- and other identified genes in metabolic pathways will require substantial further research, including studies of these genes in model systems.

ACKNOWLEDGMENTS

Chapter 27

The Role of Diet in the Prevention and Treatment of Cardiovascular Disease

Chesney Richter[1], Ann Skulas-Ray[1] and Penny Kris-Etherton[2]
[1]The University of Arizona, Tucson, AZ, United States, [2]Pennsylvania State University, State College, PA, United States

I INTRODUCTION

Cardiovascular disease (CVD) still remains the leading cause of death in the United States despite steady declines in prevalence due to decades of research and many advances in pharmacological and surgical treatments [1]. Health care costs for CVD in the United States were estimated to be over $315 billion in 2011−12 (including both direct medical costs and indirect costs, such as lost work days and productivity) [1], and are expected to exceed $1 trillion annually by 2030 [2]. Thus, there remains a need for effective CVD prevention strategies and improvements in current standard-of-care pharmaceutical interventions to reduce CVD risk. CVD risk factors are characterized as nonmodifiable (e.g., age, ethnicity, sex, and family history) or modifiable [3]. The traditional modifiable risk factors include elevated total cholesterol (TC), low-density lipoprotein-cholesterol (LDL-C), and hypertension. It is also generally agreed upon that elevated triglycerides (TGs), reduced high-density lipoprotein-cholesterol (HDL-C), type 2 diabetes, and overweight/obesity also increase CVD risk [4,5]. Most interventions target the traditional modifiable risk factors, but it is important to note that other factors also contribute to the development of CVD. For instance, it has been estimated that determining risk solely on cholesterol screening would fail to identify approximately half of the 1.3 million individuals who develop myocardial infarction (MI) each year [6]. There is growing evidence to support the role of new and emerging CVD risk factors, including inflammation, oxidative stress, the omega-3 index, central blood pressure, arterial stiffness, and postprandial derangements in metabolism or altered lipoprotein properties (e.g., particle size) that are not assessed in a standard lipid panel. Both traditional and emerging risk factors can be modified by dietary and/or lifestyle changes, and a healthy diet has long been a cornerstone for the management of CVD risk factors.

The American Heart Association (AHA) and other organizations, such as the U.S. Department of Agriculture (USDA), U.S. Department of Health and Human Services, and Academy of Nutrition and Dietetics (AND) regularly issue diet and lifestyle recommendations to reduce chronic disease risk, including (or specific to) CVD. Historically, these dietary recommendations have focused on macronutrient targets (e.g., <7−10% of calories from saturated fat). Recently, recommendations have shifted toward a whole food, dietary pattern approach. This change is evident in the 2015−2020 Dietary Guidelines for Americans (2015−2020 DGA) and the 2013 American Heart Association/American College of Cardiology (AHA/ACC) Guideline on Lifestyle Management to Reduce Cardiovascular Risk [7,8]. Thus, this chapter briefly reviews the current dietary guidelines for minimizing CVD risk, and discusses the role of both macronutrients and evidence-based dietary patterns in preventing and treating CVD.

A Dietary Guidelines and Recommendations

The 2015−2020 DGA [7] and the 2013 AHA/ACC Guideline on Lifestyle Management to Reduce Cardiovascular Risk [8] are the most recent dietary guidelines for reducing the risk of CVD (and other chronic diseases). The 2015−2020 DGA encourages the consumption of nutrient-dense foods, including a variety of vegetables, fruits (especially whole), grains (with at least

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00027-8

half being whole grains), fat-free or low-fat dairy, oils, and a variety of protein foods (e.g., seafood, lean meats, eggs, legumes, nuts, seeds, and soy products) [7]. Foods high in saturated fatty acid (SFA), *trans* fatty acid (TFA), added sugars, and sodium should be limited. The recommended intakes of nutrient-dense foods that are associated with reduced CVD risk—when not exceeding energy needs—are presented in Table 27.1. The 2015−2020 DGA recommends consuming <10% of calories from SFA [7]. The AHA/ACC Guideline recommends an even greater reduction to 5−6% of calories [8]. Both recommend that TFA consumption be limited [7,8]. For adults who choose to consume alcohol, consumption should be limited to one drink per day for women and up to two drinks per day for men [7]. The calorie content of alcohol should also be considered so as to ensure that daily energy needs are not exceeded. The 2015−2020 DGA recommends that sodium intake be limited to <2300 mg/day [7]. The AHA/ACC Guideline further specifies that sodium intake be reduced by at least 1000 mg/day and that intake should not exceed 2400 mg/day, with a sodium intake of 1500 mg/day being optimal [8]. Although these recommendations are based on current evidence, our understanding of how macronutrients, micronutrients, and other dietary bioactives affect CVD risk is a continually evolving process; thus, it is likely that dietary approaches for reducing CVD risk will also continue to advance and become even more effective as our knowledge evolves.

II EFFECTS OF MACRONUTRIENTS ON CVD RISK FACTORS

Different macronutrients have very specific effects on CVD risk factors; thus, although current dietary guidelines for reducing CVD risk now place greater emphasis on the overall dietary pattern, target ranges for macronutrient intakes remain an important element of nutrition interventions. Historically, nutrition recommendations have focused on dietary fat and reducing SFA and TFA intake. Recently, more attention has been directed toward the effect of modifying the type and/or amount of carbohydrates (CHO) and protein, as well. For instance, the importance of whole grains versus refined CHO are now well recognized. Potential differences between the effects of dietary protein from plant versus animal foods on CVD risk have also generated much interest. The following sections discuss each macronutrient and their effects on CVD risk.

A Dietary Fat

The role of dietary fat in the onset and progression of CVD has been studied extensively, and determining the ideal quantity and quality of dietary fat is an important consideration for CVD prevention and treatment. Table 27.2 summarizes the dietary fat recommendations issued by several expert organizations, as well as the average daily intake of the U.S. population. The 2015−2020 DGA [7], the joint report by the Food and Agriculture Organization and the World Health Organization [12], and the AND [13] all recommend 20−35% of energy from fat but differ with regard to specific fatty acid (FA) recommendations. However, the recommendation to restrict total fat intake is an area of controversy, and may not be as beneficial for reducing chronic disease risk as it was once thought. For instance, in the Women's Health Initiative Dietary Modification Trial [14], there was no reduction in the risk of CVD (including specifically coronary heart disease [CHD] and stroke) in women instructed to follow a low-fat diet (20% of calories from fat), despite a 4 mg/dL reduction in LDL-C [14]. However, it should be noted that although the women in the low-fat intervention group reduced their percent of energy from total fat by 8.2-percentage points compared to the control group after 6 years (37% vs 28.8%), the 20% goal was not met. Dietary intake data demonstrate that many Americans are not consuming recommended amounts and types of dietary fat (Table 27.2). However, the type of nutrient used to replace fat, and the type of FA consumed markedly affects CVD risk and may be more meaningful than a total dietary target. For instance, certain SFAs and TFAs adversely affect lipid and lipoprotein levels, whereas unsaturated FAs (monounsaturated fatty acid [MUFA] and polyunsaturated fatty acid [PUFA]) are beneficial. Thus, emphasis should be placed on optimizing types of dietary fat and other macronutrients rather than reducing total fat. Based on this evidence, the AHA/ACC 2013 Guideline focuses exclusively on SFA [8].

1 Saturated Fatty Acid

Reducing SFA intake is a common component of dietary guidelines for CVD risk reduction (Table 27.2), and is supported by evidence from epidemiologic, clinical, and animal studies demonstrating that SFA generally increases lipid and lipoprotein levels. Early predictive equations developed by Keys et al. [15] and Hegsted et al. [16] demonstrated that SFA raised TC levels compared to CHO and MUFA (which both had neutral effects), whereas PUFA lowered TC levels. Moreover, SFA was twice as potent in raising TC as PUFA was in lowering TC. Several predictive equations reported that every 1% increase in energy from SFA increased LDL-C levels by approximately 1.28−1.74 mg/dL and HDL-C levels by 0.43−0.50 mg/dL [17−19]. However, individual SFAs may have different effects on lipids and lipoproteins [20]. For instance, stearic acid (18:0) has been shown to have a neutral effect on TC, LDL-C, and HDL-C [21], whereas

TABLE 27.1 Key Recommendations for Foods to Consume More of and Foods to Limit in Order to Achieve a Healthy Dietary Pattern and Reduce CVD Risk[a]

Consume More	Target Servings[b]	Serving Descriptions	Beneficial Components
Vegetables	2½ servings per day[d]	1 cup raw or cooked vegetables or 100% juice; 2 cups leafy salad greens; ½ cup dried vegetable[e]	Fiber, potassium, magnesium, B vitamins, vitamin C, and other phytochemicals
Fruits	1½ servings per day	1 cup of fresh, canned, or frozen fruit; 1 cup 100% fruit juice; ½ cup dried fruit	Fiber, potassium, vitamin C, phytochemicals, and many other nutrients[f]
Whole grains	3 servings per day	1 slice of bread; ½ cup cooked rice, pasta, or cereal; 1 oz. dry pasta or rice; 1 oz. ready-to-eat cereal	Fiber, B vitamins, iron, zinc, phosphorous, riboflavin, vitamin A, phytochemicals, and other micronutrients
Dairy (fat-free or low-fat)	3 servings per day	1 cup milk, yogurt, or fortified soymilk; 1½ oz. natural cheeses such as cheddar cheese; 2 oz. of processed cheese	Calcium, phosphorous, vitamin A, vitamin D (if fortified), fatty acids, protein, magnesium, and other micronutrients
Protein foods	5 servings per day	1 oz. lean meat, poultry, or seafood; 1 egg; ¼ cup cooked beans or tofu; 1 tbsp peanut butter; ½ oz. nuts/seeds	B vitamins, selenium, choline, phosphorous, zinc, copper, vitamin D, and vitamin E
Seafood	8 servings per week	Preferably oily; avoid deep fried or breaded fish	Omega-3 fatty acids, selenium, magnesium, vitamin D, and other nutrients
Meats, poultry, eggs	26 servings per week	Should be consumed in lean forms	Heme iron; meats provide the most zinc; poultry provides the most niacin; eggs provide the most choline
Nuts, seeds, soy products	5 servings per week	Should be unsalted	Nuts/seeds provide the most vitamin E; soy products and legumes are a source of copper, manganese, and iron
Oils	2 servings per day[g]	1 tablespoon of oil; avoid tropical oils with a higher percentage of SFA (e.g., coconut and palm)	Polyunsaturated fats and vitamin E
Consume Less	**Target**	**Strategies to Reduce Intake**	**Beneficial Effects of Reduction**
Solid fats (i.e., SFA and TFA)	Limit intake	Avoid soft margarines with partially hydrogenated vegetable oils, butter, cream, beef tallow, and lard	↓ LDL-C Potentially improves other risk factors
Sodium	Limit to 2300 mg per day	Avoid the "salty six" (i.e., bread and rolls, cured meats, pizza, poultry, soup, and sandwiches)	↓ blood pressure Potentially improves other risk factors
Added sugars	Limit intake	Avoid sweetened beverages, candies, grain-based and other desserts	↓ consumption of empty calories and refined carbohydrates
Alcohol[c]	Up to 2 daily for men; 1 daily for women	Avoid excessive alcohol consumption (1 serving = 5 oz. wine, 12 oz. beer, or 1.5 oz. spirits)	Excessive alcohol intake ↑ blood pressure Moderate alcohol intake ↑ HDL-C and potentially improves other risk factors
Discretionary calories (% total calories)	270 kcal (14%)	If all food choices to meet recommendations are nutrient-dense, a small number of calories (up to the specified limit) can be used for added sugars, refined starches, solid fats, alcohol, or to eat more than the recommended amount of a food group	Maintain energy balance and limit consumption of solid fats, added sugars, and sodium

[a] *Adapted from D. Mozaffarian, L.J. Appel, L. Van Horn, Components of a cardioprotective diet: new insights, Circulation 123 (24) (2011) 2870–2891. [9] and based on the 2015–2020 DGA.*
[b] *Based on a 2000 kcal/day diet. Servings should be adjusted accordingly for higher or lower energy intake.*
[c] *Excessive alcohol consumption increases the risk of alcohol-related accidents, homicides, suicides, and increases chronic disease burden [10]. Thus, alcohol use is not advisable as a population-based strategy to reduce cardiovascular risk and has an overall net adverse effect on population mortality [11]. For adults who already consume alcohol, no more than moderate use should be encouraged, and only when there is no risk of a health condition, drug–alcohol interaction, or adverse effects on work situations.*
[d] *Should include a variety of vegetables from all of the five vegetable subgroups—dark green, red, and orange, legumes (beans and peas), starchy, and other.*
[e] *Should be consumed in a nutrient-dense form, with limited addition of salt, butter, or creamy sauces. When selecting frozen or canned vegetables, choose those lower in sodium.*
[f] *Whole fruit maximizes nutrient intake; fruit juice is lower in fiber and can contribute excess calories.*
[g] *Should replace solid fats rather than being added to the diet.*

TABLE 27.2 Recommended Dietary Fat Intake for Adults (> 19 Years of Age) Compared to Current U.S. Intake

Type of Fat	Recommended Intake (% of Daily Calories)[a]				U.S. Adult Intake (% of Daily Calories)[a]
	2015–2020 DGA	AHA/ACC 2013	FAO/WHO 2005	AND 2007	
Total fat	20–35	–[b]	20–35	20–35	33–34
SFA	<10	5–6	10	Goal of <7; 10% maximum	11
TFA	–[c]	–[c]	<1	<1	<1
MUFA	–[d]	–	–[e]	15–20	12–13
PUFA	–[d]	–	6–11	–	7–8
Omega-3	–	–	0.5–2	0.5–2	<1
Omega-6	–	–	2.5–9	5–10	7

myristic acid (14:0) is more hypercholesterolemic than lauric acid (12:0) and palmitic acid (16:0) [22]. Despite these differential effects, recommendations targeting individual FAs are not practical because people generally consume SFA as a blend in food sources. SFA intake may also adversely affect other CVD risk factors, such as inflammation [23,24] and vascular function as assessed by flow-mediated dilation [25,26], but clinical evidence is limited and inconsistent [25,27].

Despite many decades of dietary guidelines advising reduced SFA intake, the association between dietary SFA and CVD risk remains controversial and highly debated. Although SFA intake has been associated with greater CVD incidence in some epidemiological studies [28–30], many systematic reviews and meta-analyses have found no association for CVD risk [31–34]. For instance, in a meta-analysis of prospective cohort studies evaluating FAs and CHD risk, Skeaff and Miller found no association between SFA intake and the risk of CHD death or events [31]. Table 27.3 shows the estimated relative risk associated with each FA in this analysis. Subsequent meta-analyses have similarly questioned the association between dietary SFA intake and increased CVD risk [32–34]. However, it should be noted that a major limitation of these studies is that they failed to evaluate nutrient substitutions for SFA (discussed further below).

Importantly, decreasing SFA intake is typically accompanied by an increase in another macronutrient and this has a substantial effect on lipid/lipoprotein responses, and thereby influences overall CVD risk. For instance, substituting SFA with MUFA, PUFA, or CHO consistently lowers both LDL-C and HDL-C [8]. However, the replacement of SFA with CHO or MUFA raises TG, whereas replacement with PUFA lowers TG [8]. Thus, the lack of association between SFA and CVD risk in some meta-analyses may be due to insufficient consideration of the type of macronutrient used to replace SFA. For instance, in a pooled analysis of 11 cohort studies from both the United States and Europe [35], replacing 5% of energy intake from SFA with PUFA reduced the risk of CHD death (hazard ratio, HR: 0.74; 95% CI: 0.61–0.89) and CHD events (HR: 0.87; 95% CI: 0.77–0.97). In contrast, substitution with MUFA was not associated with CHD, and substitution with CHO was associated with a modest increased risk of CVD events (HR: 1.07; 95% CI: 1.01–1.14), but not CVD death. However, it should be noted that there was no discrimination between CHO sources in this study [35], which can significantly affect CHD risk (discussed further in following sections). Furthermore, in a 2015 analysis of 84,628 women in the Nurses' Health Study and 42,908 men in the Health Professionals Follow-up Study, isocaloric (5%) substitution of SFA with PUFA, MUFA, and CHO from whole grains was associated with a 25%, 15%, and 9% lower risk of CHD, respectively (Fig. 27.1) [36]. It has also been estimated that each 5% energy increase in

TABLE 27.3 Estimated Relative Risk of CHD Death and CHD Events for Individual Fatty Acids in Prospective Cohort Studies[a]

Type of Fat	Relative Risk (95% CI)				Mean Intake in Low and High Categories Among Cohorts (% Total Energy)	
	CHD Death	*p* Value	CHD Events	*p* Value	Low Intake	High Intake
Total fat	0.94 (0.74–1.18)	0.583	0.93 (0.84–1.03)	0.177	23–30	38–47
TFA	1.32 (1.08–1.61)	0.006	1.25 (1.07–1.46)	0.007	0.8–2.4	1.6–6.4
SFA	1.14 (0.82–1.60)	0.431	0.93 (0.83–1.05)	0.269	7–11	14–18
MUFA	0.85 (0.60–1.20)	0.356	0.87 (0.74–1.03)	0.110	9–11	16–20
PUFA	1.25 (1.06–1.47)	0.009	0.97 (0.74–1.27)	0.825	3–4	6–10
n-3 LC-PUFA	0.82 (0.71–0.94)	0.006	0.87 (0.71–1.10)	0.066	0–0.3 g/day	0.37–2.5 g/day

PUFA as a replacement for SFA decreases CVD events by 10% [37].

More research is needed to clarify discrepancies about the association between SFA intake and CVD risk among epidemiologic studies. Particular focus on evaluating the specific nutrients (i.e., types of fat and CHO) replacing dietary SFA intake would help to more accurately determine effects on CVD risk. Although the macronutrient substitution for SFA was not evaluated in the previously mentioned meta-analyses that found no association between SFA intake and CVD risk [31–34], these analyses may also be limited by inconsistent and/or imprecise dietary assessment methods, the potential for regression dilution bias, underestimation of an association due to variability, and/or measurement error. There is also growing evidence that the food source of SFA may influence CVD risk [27,38,39]. Furthermore, there is still debate about whether MUFA, PUFA, or complex CHO are the optimal replacement for SFA.

2 Trans *Fatty Acid*

TFAs are classified as unsaturated FAs that have at least one nonconjugated double bond with *trans*

stereochemistry. Dietary TFA is primarily a result of industrial production (e.g., partially hydrogenated oils), although some *trans* isomers are produced by ruminant animals. The adverse effects of TFA on cardiovascular health have been demonstrated in both clinical and epidemiologic trials. TFA intake consistently increases TC, LDL-C, and the TC/HDL-C ratio, and decreases HDL-C [40,41]. Moreover, there is substantial evidence that TFA increases the risk of CVD death and CVD events more than any other type of FA [31,42,43]. In 2003, based on widespread scientific agreement regarding the adverse effect of TFA consumption on CHD risk, the Food and Drug Administration issued a final rule requiring the declaration of the amount of TFA present in foods and dietary supplements [44]. Labeling requirements and growing public awareness have also led to efforts to reduce TFA content in restaurant foods and reformulate food products to eliminate or substantially reduce TFAs.

The naturally occurring TFA in ruminant meat and dairy products is predominantly composed of vaccenic acid (C18:1 *trans*-11) and the isomer of conjugated linoleic acid (CLA; C18:2 *cis*-9, *trans*-11). It has been proposed that the structure of bonds in CLA may confer different physiological effects compared to industrial TFA, but this remains unclear in both epidemiological and clinical studies. In two quantitative reviews of randomized controlled trials (RCTs), Brouwer et al. [45,46] found that gram for gram, all types of TFA have largely the same unfavorable effect on LDL-C, the LDL-C/HDL-C ratio, and the TC/HDL-C ratio. However, it should be noted that the amount of ruminant TFA provided in the majority of clinical studies greatly exceeds the amount typically consumed (<2%) [47]. The amount of ruminant TFA in the diet is also minimal relative to industrial TFA, and it is much more likely for industrially produced TFA to be consumed at amounts that adversely affect CVD risk factors. Maintaining a low-SFA intake is likely to ensure that ruminant TFA is minimal [47]. Therefore, while it is possible that industrial and ruminant TFA have different metabolic effects, there is currently no conclusive evidence to justify excluding ruminant TFA from the recommendation to reduce total TFA consumption as much as possible [7,8,47].

3 Monounsaturated Fatty Acid

MUFAs are classified as FAs containing a single double bond. The most predominant MUFA in the diet is oleic acid (18:1*n*-9), which is a primary component of vegetable oils (e.g., olive oil) and nuts. There is a large body of evidence demonstrating that the replacement of SFA with MUFA improves multiple CVD risk factors [48–50]. For instance, using MUFA to isocalorically replace SFA reduces TC, LDL-C, and the TC/HDL-C ratio [8,51,52]. As a SFA replacement, MUFA also tends to preserve HDL-C to a greater extent than PUFA [49]. Furthermore, when CHO are isocalorically replaced by MUFA, HDL-C is increased while LDL-C and TG are lowered [8,17,52]. MUFA intake may also lower systolic and diastolic BP [50] and improve insulin sensitivity and the glycemic response [49]. Some have challenged the cardioprotective effects of MUFA based on results from animal studies [53,54], but no detrimental effects have been reported in human studies [55].

Many epidemiological studies support cardioprotective benefits of MUFA for CVD risk [29,56,57], but not all studies have been consistent [35,58]. In a systematic review of prospective cohort studies, Mente et al. [56] reported an inverse association between MUFA and CHD risk (risk ratio (RR): 0.80; 95% CI: 0.67–0.93). Moreover, a 5% isocaloric replacement of MUFA for SFA has also been associated with lower CVD risk [29,57]. In contrast, the pooled analysis of prospective cohort studies by Jakobsen et al. [35] found that substituting MUFA in place of SFA was associated with an increased risk of CHD events (HR: 1.19; 95% CI: 1.00–1.42). However, these positive correlations may be due to confounding with SFA intake as food sources of MUFA in the United States tend to also be high in SFA (e.g., meat and dairy) [35,58].

Dietary guidelines for reducing CVD risk now increasingly recommend MUFA (and PUFA) as a replacement for SFA [7]. Higher-MUFA intake is also a key component of the Mediterranean-style dietary pattern due to the emphasis on olive oil over other fats. In the United States, MUFA intakes are typically ~13–14% of energy, whereas they comprise ~16–29% of energy in Mediterranean-style diets—largely at the expense of SFA [59]. The particular food source of MUFA is also an important consideration when considering CVD risk. For instance, the predominant sources of oleic acid in the typical American diet are grain-based desserts, meat, and poultry [60]. It is unlikely that greater MUFA intake would result in cardioprotective effects in this context. If MUFA intake is increased, it should be obtained from MUFA-rich vegetable oils, such as olive or canola oil, and/or nuts. Current clinical evidence indicates that MUFA is a suitable substitution for SFA, TFA, and/or CHO; however, there are considerably fewer studies that have investigated the effects of MUFA on CVD risk compared to the number on PUFA and no RCTs have been conducted to evaluate the effect of MUFA on CVD morbidity and/or mortality.

4 Polyunsaturated Fatty Acid

There are two major classes of PUFA, and they are defined by the position of the first double bond relative to the methyl terminus: omega-6 (*n*-6) and omega-3 (*n*-3) FA.

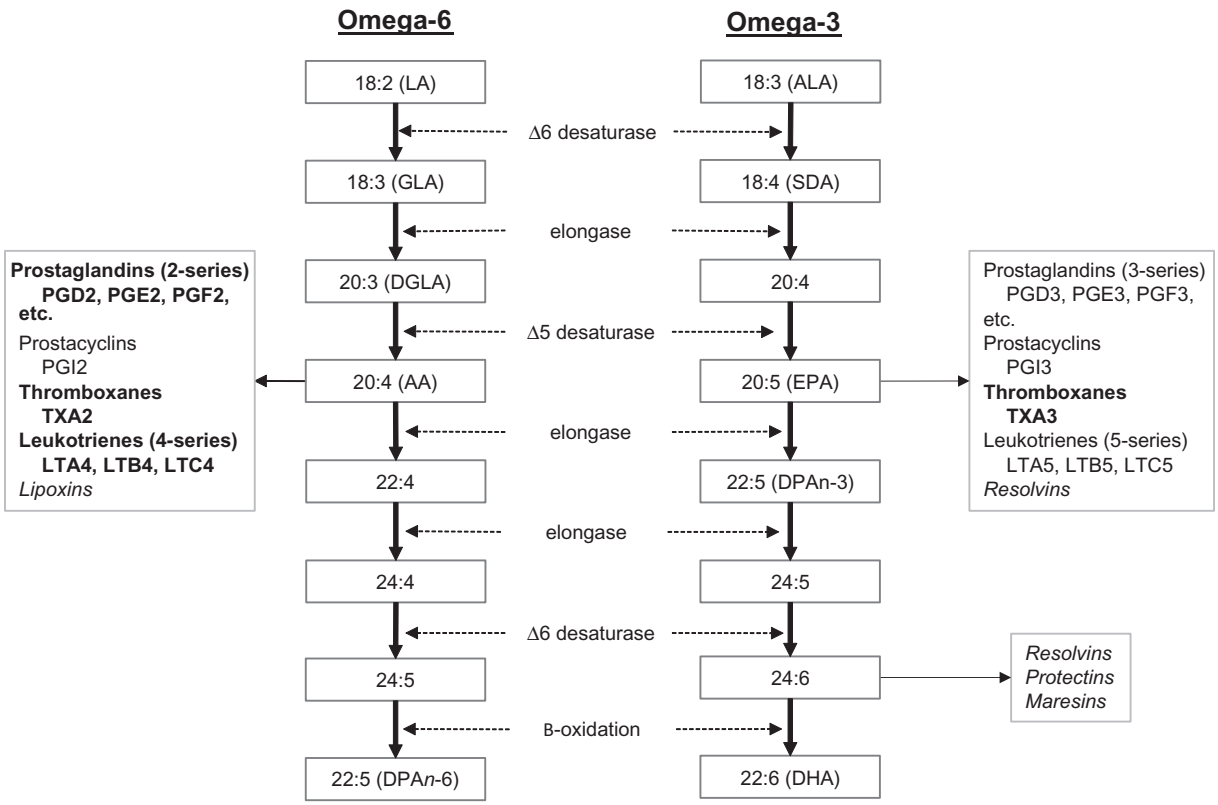

FIGURE 27.2 Biochemical pathway for the interconversion of *n*-6 and *n*-3 FAs. AA, arachidonic acid; ALA, α-linolenic acid; DGLA, dihomo-γ-linolenic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; LA, linoleic acid; SDA, stearidonic acid. Bold text = proinflammatory; normal text = less inflammatory; and *italicized* text = proresolving.

Linoleic acid (LA; C18:2*n*-6) and α-linolenic acid (ALA; C18:3*n*-3) are the essential *n*-6 and *n*-3 FAs. In the body, LA and ALA can undergo a series of elongations and desaturations to yield arachidonic acid (AA; C20:4*n*-6), and eicosapentaenoic acid (EPA; C20:5*n*-3) and docosahexaenoic acid (DHA; C22:6*n*-3), respectively (Fig. 27.2). However, the amount of ALA converted to EPA and *especially* DHA is very low [61] and these FAs are obtained primarily from fatty fish in the diet [62,63].

Dietary PUFAs have many physiological functions. EPA and AA are metabolized into a variety of hormone-like compounds called eicosanoids, which include prostaglandins, thromboxanes, leukotrienes, and lipoxins. These compounds play a key role in inflammatory and thrombotic pathways. AA, EPA, and DHA are also the precursors for lipoxins [64,65], resolvins, protectins, and maresins [66,67] that actively assist in the resolution of inflammation. Concerns have been raised that PUFA may be more susceptible to oxidation, and thus may have adverse health effects; however, this is unlikely within the context of a healthy dietary pattern.

Many longer term clinical studies have shown that increased PUFA intakes improve lipids/lipoproteins and lower CVD risk [29,31,35–37,68]. Based on predictive equations [16,28], a 1% increase in energy from PUFA translates to a 0.9 mg/dL decrease in TC. Replacement of CHO with PUFA also increases HDL-C [52], albeit to a lesser extent than MUFA [8]. Early controlled trials verified these hypocholesterolemic effects of high PUFA diets and also found an associated reduction in the incidence of CVD (16–34%) [69–71]. A dose–response relationship between PUFA intake and CVD risk was also reported in the Nurses' Health Study, with the highest quintile of intake (6.4% of calories) conferring an approximately 30% reduction in risk [29]. However, there remains much debate over the relative benefits of *n*-6 versus *n*-3 PUFA, as well as the effects of individual PUFAs (i.e., EPA, DHA, and ALA).

a Eicosapentaenoic Acid and Docosahexaenoic Acid

Interest in EPA and DHA was first generated by the seminal studies of Dyerberg et al. [72], in which the low incidence of CHD among Greenland Eskimos was attributed in part to a high intake of marine oils rich in EPA and DHA. Numerous epidemiological studies and RCTs have since confirmed that these FAs reduce CVD risk and confer cardioprotective effects via multiple mechanisms of

action, and have been reviewed previously in detail [73–75]. Of particular note are the key large-scale intervention studies that first demonstrated the beneficial effects of *n*-3 FA for primary and secondary prevention, including The Diet and Reinfarction Trial (DART), Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico (GISSI)-Prevenzione, GISSI-Heart Failure, and Japan EPA Lipid Intervention Study (JELIS). In DART—the first RCT to investigate the effects of *n*-3 FA on secondary prevention of MI—men advised to consume oily fish 2–3 times per week experienced a 29% reduction in all-cause mortality [76]. Further evidence for the use of EPA and DHA in secondary prevention of CVD was provided by GISSI-P and GISSI-HF. In GISSI-P, *n*-3 supplementation (1 g/day) resulted in a 15% reduction in the combined primary endpoint of death and nonfatal cardiovascular events [77], and in GISSI-HF the intervention (1 g/day) reduced all-cause mortality by 9% [78]. JELIS was the first large-scale, prospective RCT to evaluate *n*-3 supplementation for primary prevention, as well as the combined effect of statin treatment and EPA supplementation. In this study, supplementation with 1.8 g/day EPA and statin treatment reduced major coronary events by 19% compared to the control group (statin only) [79]. This finding was also particularly notable given the much higher background *n*-3 FA intake of Japanese individuals compared to Americans. These studies provide much of the basis for recommendations to increase EPA and DHA to reduce CVD risk.

Unfortunately, many of the more recent clinical studies have failed to replicate the findings from earlier trials [80–82]. For instance, in the ALPHA-OMEGA trial, there was no significant difference in cardiovascular events among those who received 400 mg/day EPA + DHA compared to the control group [80]. Many have attributed these null findings to several key differences in study design [73,83,84]. For instance, in the more recent trials, a large proportion of participants were concurrently using blood pressure and/or lipid-lowering medications that may have overwhelmed any potential effects of *n*-3 FAs [83]. Furthermore, many of the studies were underpowered to detect effects on CHD mortality and/or had lower than expected event rates [85]. Other potential explanations for the absence of effects include: insufficient dosing, failure to assess the *n*-3 status of participants prior to and during treatment, and insufficient treatment duration [73,83,85]. Due to these concerns, it is unlikely that these results from more recent studies will drastically alter dietary recommendations for *n*-3 intake. However, future RCTs of *n*-3 FAs should be designed with these factors in mind, and are needed to clarify these discrepancies.

Intermediate risk factors for CVD can also be improved by greater EPA + DHA intake. Fish oil has a marked hypotriglyceridemic effect in individuals with normal or elevated TG levels (> 150 mg/dL). In 21 studies that examined the effects of fish or fish oil (0.1–5.4 g/day EPA + DHA) on lipids and lipoproteins, EPA + DHA dose-dependently reduced TG, with a net effect of −27 mg/dL [86]. The TG-lowering effects of fish oil are also stronger in individuals with elevated TG [87]. Although there is substantial preclinical evidence of the antiinflammatory potential of EPA and DHA [88], this has not translated to consistent results on inflammatory outcomes in clinical intervention studies [89,90]. EPA and DHA can also lower resting heart rate and BP, and may improve endothelial function [85]; however, the effect of these changes on clinical events (i.e., CHD death) tends to have varying time courses and depend on the dose of EPA + DHA (Fig. 27.3) [75]. For instance, at intakes of <750 mg/day, antiarrhythmic effects predominate and can reduce clinical events within weeks. This has

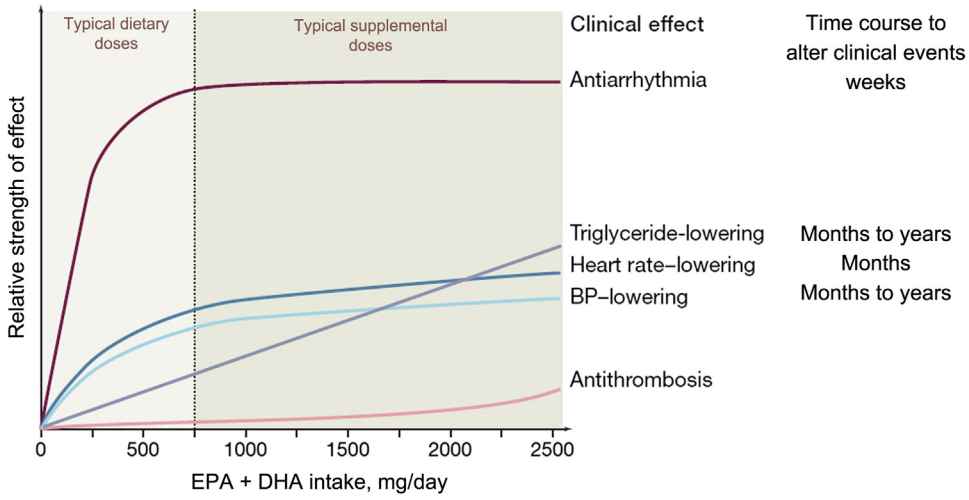

FIGURE 27.3 Schema of potential dose responses and time courses for altering clinical events due to the physiologic effects of EPA + DHA intake. Source: *D. Mozaffarian, E.B. Rimm, Fish intake, contaminants, and human health: evaluating the risks and the benefits, JAMA 296 (15) (2006) 1885–1899.*

important clinical implications as arrhythmias are the primary cause of sudden cardiac death. Conversely, a reduction in TGs is hypothesized to require a longer period of time to reduce clinical events (i.e., months or years) and to have a stronger effect at higher doses of EPA + DHA [75]. Ongoing clinical studies are examining whether TG-lowering doses of *n*-3 reduce CVD mortality (Reduction of Cardiovascular Events with EPA—Intervention Trial [REDUCE-IT], NCT01492361 and STatin Residual Risk Reduction with EpaNova in HiGh Cardiovascular Risk PatienTs With Hypertriglyceridemia [STRENGTH], NCT02104817).

Concerns have been raised regarding potential increases in LDL-C with greater EPA + DHA intake. In an evaluation of 15 RCTs, the Agency for Healthcare Research and Quality found that marine *n*-3 FA consumption (ranging from 45 to 5400 mg/day of EPA and/or DHA) resulted in a net LDL-C increase of 10 mg/dL [91]. This may be due in part to an increase in LDL particle size [92,93] and is thereby less atherogenic, although some have found no change in LDL particle size following *n*-3 supplementation [94]. It has also been proposed that the change in size depends on an individual's baseline LDL particle size. Those who have a greater amount of small dense LDL particles—termed a pattern B phenotype—tend to respond to fish oil supplementation with an increase in LDL particle size, whereas others do not [94]. A prescription dose of EPA and DHA (3.4 g/day EPA + DHA) can be combined with statin therapy to attenuate the increase in LDL-C [95]. Physician oversight is recommended when doses exceed 2 g/day EPA + DHA for TG reduction [96].

Another area of concern when recommending increased fish intake pertains to the issue of environmental contaminants such as methylmercury. Most fish contain trace amounts of methylmercury from natural sources, but this can be exacerbated by environmental contamination from industrial practices. Larger, older, and higher trophic-level species generally have higher methylmercury content because methylmercury is readily absorbed by tissues and tends to bioaccumulate [97]. However, the majority of fatty fish that are regularly consumed have relatively low methylmercury concentrations (Fig. 27.4) [75]. Consumption of certain fish high in methylmercury (e.g., shark, tilefish, king mackerel, and swordfish) should be avoided by at-risk population groups (i.e., women who are pregnant, could become pregnant, or are lactating, and infants and young children) [99]. State and local advisories for safe fish consumption should also be followed. Although increased methylmercury intake may modestly decrease the benefits of fish intake [75,99], the health benefits of oily fish consumption far outweigh the potential risks [75,100,101]. Thus, emphasis should be placed on consuming species that are high in *n*-3 FA and also low in methylmercury.

Fish oil supplements can also be used to increase EPA and DHA intake. Fish oil supplements can be cost-effective, convenient, and typically contain negligible quantities of environmental contaminants [102]. Some individuals may prefer supplements due to personal preferences, such as ethical or environmental concerns, disliking the taste of fish, unfamiliarity with seafood preparation and cooking methods, cost, food allergies, and a perceived risk of pollutants. Others may require a supplement to achieve higher recommended LC *n*-3 PUFA intakes that are not attainable by dietary means alone (i.e., those with established CHD or elevated TGs).

A pooled analysis of prospective studies and randomized clinical trials found that modest consumption of fish and/or fish oil (e.g., 1−2 servings/week providing ~250 mg/day of EPA + DHA) reduced CHD death (~35%), sudden death from arrhythmia (~50%), and ischemic stroke (~30%) when compared to little or no intake [75]. Modest benefits were also reported for nonfatal MI, delayed progression of atherosclerosis, recurrent ventricular tachyarrhythmias, and postangioplasty restenosis. However, a threshold of effect has been proposed because higher intakes (e.g., >900 mg/day) do not elicit a greater decrease in risk [75,103]. Based on this evidence, numerous expert authorities have issued recommendations for amounts of fish and/or LC *n*-3 PUFA intake to promote health and reduce CVD risk, with the general consensus specifying intake of 250−500 mg of EPA + DHA per day or 2−3 servings of oily fish per week. For instance, in addition to their dietary pattern recommendations, the AHA has also issued specific guidelines for EPA and DHA intake (Table 27.4) [96]. The 500 mg/day of EPA + DHA recommended for the primary prevention of CHD can be achieved by consuming two servings (4 oz. each) of fatty fish per week. Frequent consumption of oily fish is also a characteristic feature of Mediterranean-style dietary patterns [105,106].

b Alpha-Linolenic Acid

There remains debate as to whether increased dietary ALA confers the same cardioprotective effects as EPA and DHA [107−110]. In a pooled meta-analysis of 27 prospective and retrospective studies comprising over 250,000 individuals, higher ALA exposure was associated with a moderate reduction in CVD risk (RR: 0.86; 95% CI: 0.77−0.97) [110]. However, when analyses were performed separately based on self-reported dietary intake or biomarker data, only self-reported dietary intake of ALA remained significantly associated with reduced CVD risk. With regard to ALA supplementation in RCTs, the Lyon Diet Heart Study is the largest clinical trial to examine

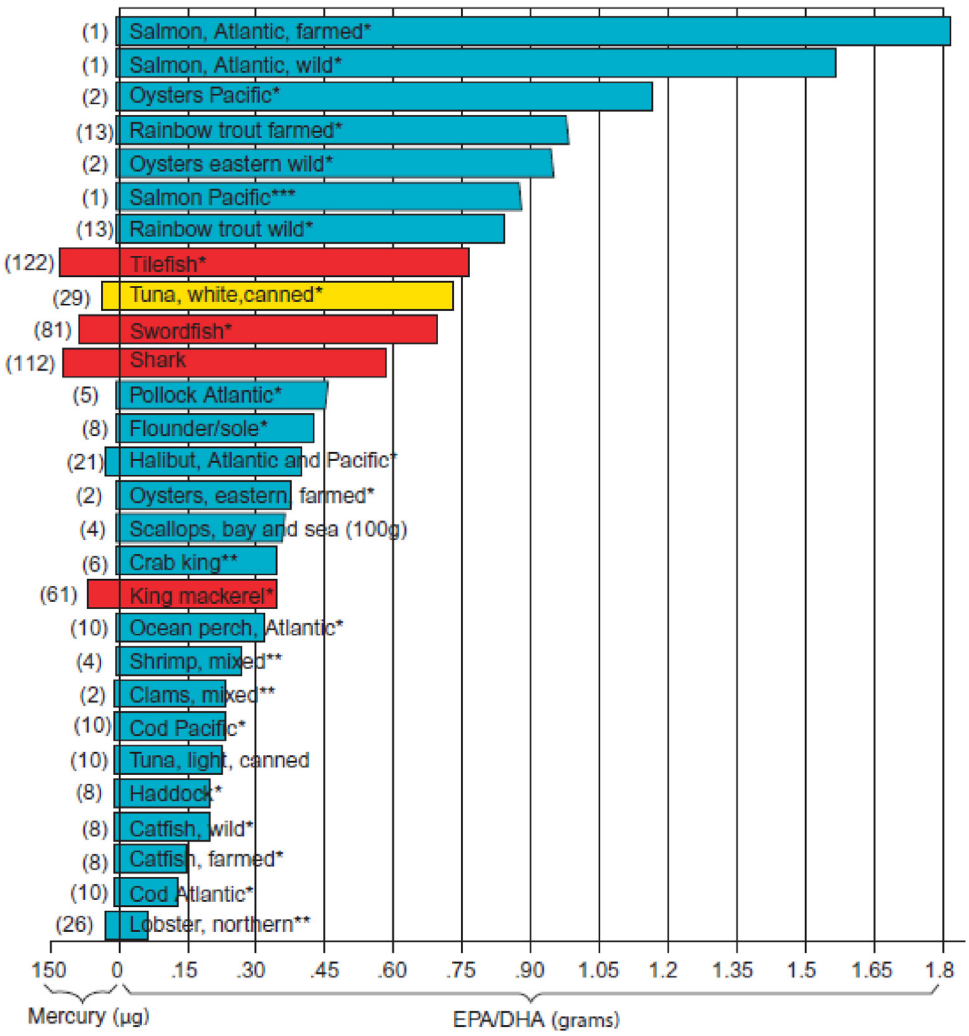

FIGURE 27.4 Estimated EPA + DHA and methylmercury content of different seafood species (per 3 oz. portion). *Cooked, dry heat; **cooked, moist heat; ***the EPA + DHA content in Pacific salmon is a composite from chum, Coho, and sockeye species. Species indicated in black should be avoided by at-risk population groups (i.e., women who are pregnant, could become pregnant, or are lactating, and infants and young children) due to methylmercury concentrations that exceed recommended safe intakes. Gray indicates that consumption should be limited to 6 oz. per week for at-risk population groups. Source: *M. C. Nesheim, A.L. Yaktine, Seafood Choices: Balancing Benefits and Risks, National Academies Press, Washington, DC, 2007.*

TABLE 27.4 Summary of AHA Recommendations for Omega-3 FA Intake

Population	Recommendation
Patients without documented CHD	Eat a variety of (preferably fatty) fish at least twice a week. Include oils and foods rich in ALA (flaxseed, canola, and soybean oils; flaxseed and walnuts).
Patients with documented CHD	Consume ≈1 g of EPA + DHA per day, preferably from fatty fish. EPA + DHA in capsule form could be considered in consultation with the physician.
Patients who need to lower TGs	2–4 g of EPA + DHA per day provided as capsules under a physician's care.

the effects of a high-ALA diet high on CVD. The advice to follow a Mediterranean-style diet high in ALA resulted in a 70% reduction in cardiac death and nonfatal MI and a 50% reduction in all coronary events, despite no improvement in lipids and lipoproteins [111,112]. The authors attributed these benefits largely to the 68% increase in ALA intake (~1.7 g/day) in the experimental group [111]. However, the AHA Science Advisory suggested that other differences in the intervention diet (e.g., increased bread, root vegetables and green vegetables,

and fish; fruit at least once daily; more poultry in place of red meat; and high-ALA margarine in place of butter and cream) likely also played a role [113]. Other systematic reviews have concluded that short-term trials (6–12 weeks) of 1.2–3.6 g/day ALA intake generally show inconsistent effects on lipids/lipoproteins, markers of inflammation and oxidative stress, and glucose metabolism [109]. Thus, many questions remain regarding the cardiovascular benefits of ALA. Additional long-term RCTs are needed to examine the unique effects of ALA on CVD outcomes and thereby inform recommendations for optimal intake.

c Omega-6 (*n*-6) Versus Omega-3 (*n*-3) PUFA

Although *n*-6 FA intake has previously been shown to reduce the risk of CVD [37,114], some have expressed concern that increased *n*-6 FA consumption will inhibit *n*-3 FA metabolism because these FAs share common enzymatic pathways (Fig. 27.2). This inhibition of *n*-3 FA metabolism is hypothesized to occur at two biological steps. First of all, an increase in LA may interfere with the conversion of ALA to EPA because LA utilizes the same desaturase and elongase enzymes to form AA. Secondly, AA, EPA, and DHA are metabolized into eicosanoids and other oxygenated metabolites by the same enzymes; thus, it has been proposed that greater dietary intake of *n*-6 FAs (and thus greater *n*-6 FA concentrations in cell membranes) would result in a greater proportion of proinflammatory lipid mediators derived from AA.

Therefore, rather than increasing *n*-3 FA intake, some have instead advocated for targeting a lower *n*-6 to *n*-3 ratio by reducing the intake of LA [115–119]. This can be achieved by substituting high *n*-6 foods (e.g., vegetable oils, nuts, and seeds) with MUFA and using olive and canola oils for cooking and dressings. However, there is a paucity of research directly comparing increased dietary *n*-6 FA intake to a higher-MUFA diet. Much of the clinical evidence supporting the substitution of MUFA for LA is based on comparisons of Mediterranean-style and Western dietary patterns. In these comparisons, the high *n*-6 vegetable oils that predominate in a Western dietary pattern are often used for frying and the preparation of foods that are relatively low in fiber and other plant-based bioactives (e.g., phytosterols and phytochemicals). In contrast, the high-MUFA olive oil that is characteristic of a Mediterranean-style dietary pattern typically accompanies grains and vegetables, and provides additional antioxidants that are not present in refined vegetable oils. Furthermore, although nuts are high in LA they are also rich in many other bioactive compounds. Thus, these types of comparisons are not directly comparing dietary LA and oleic acid, and cannot account for the complexity of these factors.

It is likely that the ratio of *n*-6 to *n*-3 FA is less important than the total amount of *n*-3 FA intake [120], and its value as a clinically relevant risk factor has been challenged [121,122]. Concerns about the inflammatory effects of *n*-6 FA intake are based primarily on cell-based studies. In humans, LA intake has not been associated with elevated concentrations of inflammatory markers [123]. Moreover, this approach also fails to recognize that LA is an essential FA and that AA also serves as the substrate for proresolving lipoxins [64,65]. Based on evidence to date, dietary advice on PUFAs should encourage increased consumption of ALA, EPA, and DHA, without instruction to limit the intake of plant sources of *n*-6 FAs, such as nuts and seeds.

B Dietary CHO

The characteristics and/or type of dietary CHO consumed are also important considerations. Each of the evidence-based dietary patterns discussed in this chapter recommends decreasing the consumption of foods containing refined CHO (particularly those that are also high in SFA and added sugars) and replacing them with nutrient-dense foods. Fruits, vegetables, legumes, and whole grains are all nutrient-dense high-CHO foods. It is likely that many non-CHO components of these foods contribute to their health benefits (e.g., vitamins, minerals, phytochemicals, etc.), and it is difficult to attribute specific effects to a particular compound. The potential effects of each of these components are beyond the scope of this chapter; thus, the following sections will focus on key areas of research related specifically to CHO and CVD risk.

1 Dietary Fiber

Dietary fiber can be broadly defined as nondigestible CHO polymers of plant origin, but this encompasses a wide range of compounds with differing effects on gastrointestinal and systemic physiological processes. Traditionally, dietary fiber has been categorized as soluble or insoluble based on whether it dissolves in water to become a gelatinous substance. However, there remains much debate regarding the optimal definition for classifying different types of dietary fiber and the Institute of Medicine (IOM) has recommended that “soluble” and “insoluble” be replaced by terms that better account for physiochemical properties, such as viscosity and fermentability. These properties are essential to the mechanism by which these compounds modify CVD risk factors, but both soluble and insoluble fiber are associated with reduced CVD risk [124]. Although an optimal amount of dietary fiber is not specified, evidence-based dietary patterns typically emphasize fiber-rich foods (e.g., whole

grains, vegetables, fruits, legumes, and nuts). Each of these foods are key sources of dietary fiber but it is possible that dietary fiber from particular foods may be more strongly associated with decreased CVD risk [124,125] due to other nonfiber components (e.g., vitamins, minerals, phytochemicals, etc.).

The relationship between dietary fiber intake and CVD risk has been extensively studied and reviewed by others [124,126,127]. In brief, there is substantial epidemiological evidence for an inverse association between dietary fiber intake and CVD risk [124]. Of particular note is a pooled analysis of 10 prospective cohort studies from the United States and Europe, in which each 10 g/day increment of dietary fiber yielded a 27% reduction in the risk of coronary mortality and a 14% reduction in all coronary events [128]. Subsequent systematic reviews of cohort studies have reported similar inverse associations [56,125]. The cholesterol-lowering effects of dietary fiber are also well-documented [127], and are attributed primarily to increased bile acid excretion and reduced cholesterol and fat absorption. There is also strong evidence that regular consumption of dietary fiber may improve blood pressure, body weight regulation, and glucose metabolism [124]. Prolonged satiety and delayed gastric emptying likely plays a role in these effects, but additional research is needed to clarify the biological mechanisms responsible for the cardioprotective effects of dietary fiber.

a Gut Microbiome

The human colon is colonized by a dense population of microorganisms—the majority of which are bacteria that have coevolved in a symbiotic relationship with the body's own cells. There is growing evidence that the composition and/or function of the gut microbiota is strongly linked to the development of multiple diseases [129,130], including CVD [131]. Diet is a major determinant of the composition of the gut microbiota as nondigestible CHO (e.g., resistant starch, nonstarch polysaccharides, and oligosaccharides) serve as the primary substrate for microbial metabolism [132,133]. Diets that are higher in fiber have been associated with a greater abundance of bacterial species that are considered beneficial, such as *Bifidobacterium* [132,133]. Furthermore, the short-chain FAs produced from microbial fermentation of CHO (i.e., acetate, propionate, and butyrate) can directly alter human health [134]. For instance, butyrate contributes to colonic health and has been shown to have anti-inflammatory and anticarcinogenic potential, whereas propionate can inhibit cholesterol synthesis [135]. Increased consumption of resistant starch has been associated with greater abundance of microbial species known to produce short-chain FAs [132,136], whereas diets with less CHO content have been shown to result in diminished production of butyrate and other short-chain FAs [137–139]. Therefore, this is a promising new area of research for reducing CVD risk and provides further support for the whole-food-based approach of the dietary patterns discussed in this chapter.

2 Glycemic Index and Glycemic Load

CHO can also be classified according to their effects on the glycemic response, which can be quantified as the glycemic index (GI) and the glycemic load (GL). Low GI foods (e.g., mature beans and green vegetables) elicit less of a glycemic response than high GI foods (e.g., potatoes and ready-to-eat cereals). Foods that are high in soluble fiber tend to have a low GI, but the GI can be altered by food preparation methods and the consumption of other foods in the context of a mixed meal. The GL incorporates both the type and amount of CHO, and estimates the effect of consuming a particular food based on its GI and the amount of CHO ingested.

However, there remains some debate as to the utility of the GI and the GL for reducing CVD risk. Overall, evidence from epidemiological studies indicates that CVD risk is increased by consuming high GI/GL diets [140] and low-GI diets have been associated with reduced risk of type 2 diabetes [141]. However, recent meta-analyses of cohort studies have suggested that the association between high GI/GL diets and increased CVD risk is stronger in women, and not present in men [142–145]. The association between low GI/GL diets and reduced risk may be due to beneficial effects on CVD risk factors. For instance, a low-GI diet has been recommended for weight loss [146] and as a strategy for diabetes management based on improvements in glycemic control [147]. A meta-analysis of RCTs comparing low-GI diets to high-GI diets over at least 4 weeks also found that lowGI diets significantly reduced TC (−5 mg/dL) and LDL-C (−6.2 mg/dL) without altering HDL-C or TG [148]. Conversely, a meta-analysis of the long-term (≥ 6 months) effects of low GI/GL diets found a significant reduction in C-reactive protein (CRP), fasting insulin, and fat-free mass but no change in blood lipids [149]. Results from controlled feeding studies of low-GI diets have also been inconsistent [150] and a low-GI diet has not been shown to improve insulin sensitivity, lipids/lipoproteins, or systolic BP compared to a healthful Dietary Approaches to Stop Hypertension (DASH)-type diet [151]. Based on these contradictory findings, there is a lack of consensus among the expert authorities regarding whether GI/GL should be emphasized in dietary recommendations [152]. Additional research is needed to clarify which

CVD risk factors are most effectively addressed by reducing the GI/GL of the diet.

3 High- and Low-Carbohydrate Diets

Replacing SFA with CHO is one strategy for reducing LDL-C; however, the resulting high-CHO, low-fat diet also tends to decrease HDL-C and increase TG [8]. This can be particularly problematic for people with insulin resistance and accompanying dyslipidemia characterized by low HDL-C and elevated TG [153]. As previously discussed, the effect of increasing CHO intake is likely dependent on the type of CHO (and the type of fat being replaced). Recommendations to replace fat with CHO should emphasize nutrient-dense vegetables, fruits, legumes, and whole grains in place of refined CHO, SFA, and *trans* fat [7]. The Ornish diet and DASH-type diets (discussed further below) are both consistent with these recommendations and have been shown to improve CVD risk [51,154–160]. However, low-fat diets may be difficult to maintain for many individuals, and other studies have found that reducing fat intake may not translate to a reduction in CVD risk despite modest improvements in intermediate risk factors [14].

CHO restriction has become a popular alternative to low-fat diets, and low-CHO diets have demonstrated some success for weight loss (short term) and other CVD risk factors [161]. For instance, in a recent meta-analysis of 17 RCTs of obese individuals, consuming low-CHO diets for 3–36 months (6–12 month duration of follow-up for majority of studies) significantly increased HDL-C (1.73 mg/dL) and reduced body weight (−7.04 kg), body mass index (BMI) (−2.09 kg/m^2), systolic and diastolic BP (−4.81 and −3.1 mm Hg, respectively), TG (−29.71 mg/dL), fasting glucose (−1.05 mg/dL) and insulin (−2.04 μIU/mL), and CRP (−0.2 mg/L) [161]. Restricting dietary CHO has also been recommended as a primary treatment strategy for type 2 diabetes [162]. However, concerns have been raised that low-CHO diets may result in lower intake of fiber-rich fruits, vegetables, and whole grains (all of which are recommended for CVD risk reduction) and increase the intake of animal protein, SFA, and cholesterol—ultimately increasing CVD risk and mortality [163]. Comparisons of low-CHO diets and low-fat diets [164,165] or isoenergetic balanced diets [166] have also questioned whether low-CHO diets are preferable for CVD risk reduction. For instance, in a meta-analysis of five RCTs of overweight or obese participants, low-CHO diets produced more favorable changes in TG (−22.1 mg/dL) and HDL-C (+ 4.6 mg/dL), while low-fat diets were more effective for TC and LDL-C [164]. The additional weight loss achieved by low-CHO diets in the first 6 months was also no longer present after 1 year [164]. A subsequent 2016 meta-analysis of healthy participants from 11 RCTs found that low-CHO diets produced greater improvements in body weight (−2.17 kg), TG (−23 mg/dL), and HDL-C (+5.4 mg/dL) but also increased LDL-C (+6.2 mg/dL) compared to low-fat diets [165]. However, CHO restriction does not typically occur in isolation and it is likely that the type and/or quality of macronutrient replacement will influence outcomes. Replacing high GI CHO with unrefined plant-based CHO and foods that provide more healthy fats and/or lean protein can be an effective strategy for reducing CVD risk. However, longer term studies with hard endpoints are needed to clarify the effect of consuming a low-CHO diet on CVD risk and mortality.

4 Added Sugars

Added sugars are caloric sweeteners added to foods/beverages during processing or preparation, and do not include naturally occurring sugars such as those in fruit and milk. Added sugars are considered "empty calories" as they provide no essential nutrients and contribute excess calorie intake without improving the overall quality of the diet. Sugar-sweetened beverages (e.g., soft drinks, fruit drinks, sweetened coffee/tea, energy drinks, alcoholic beverages, and flavored waters) are the major source of added sugars in the U.S. diet [7]. Snacks and sweets, including grain-based and dairy-based desserts, are also a primary source. The 2015–2020 DGA recommends that added sugars be limited to less than 10% of daily calories [7]. The 2013 AHA/ACC Guideline also recommends reducing the consumption of sweets and sugar-sweetened beverages, but does not specify added sugars [8].

The recommendation to limit the consumption of added sugars is based largely upon evidence from prospective cohort studies. There is growing evidence that greater intake of added sugars—or sugar-sweetened beverages in particular—increases CVD risk [167], and that individuals who consume higher amounts are more likely to have CVD risk factors, such as obesity, type 2 diabetes, dyslipidemia, and hypertension [168,169]. For instance, numerous prospective studies have demonstrated a significant correlation between the consumption of sugar-sweetened beverages and weight gain [104,170–172]. Conversely, reducing sugar-sweetened beverage intake or replacing sugar-sweetened beverages with water is associated with lower long-term weight gain [104,170]. Fructose in particular—which is a major component of table sugar, high-fructose corn syrup, and other commonly used added sugars—has been shown to dose-dependently increase fasting TGs at intakes >100 g/day [173]. Fructose may also adversely affect visceral adipose deposition and insulin sensitivity [174,175]. Additionally, a recent analysis of National Health and Nutrition

Examination Survey (NHANES) data from 1988 to 2006 found a significant relationship between added sugar consumption and increased risk for CVD mortality [176]. In this study, compared to those who consumed less than 10% of calories from added sugar, individuals who consumed 10−24.9% of calories from added sugar or >25% of calories from added sugar had 30% and 175% greater risk of CVD mortality, respectively [176]. Evidence from RCTs investigating added sugar intake and health outcomes is relatively limited compared to the epidemiological evidence due to cost and feasibility considerations [169]. However, there is evidence from short-term clinical studies to suggest that the mechanistic link between sugar-sweetened beverage consumption and CVD risk may be due to decreased satiety, incomplete compensatory reduction in energy intake at subsequent meals, and/or high GL [168]. Thus, consuming a dietary pattern that includes fewer foods containing added sugars reduces CVD risk and improves multiple CVD risk factors [169].

C Dietary Protein

Increased consumption of dietary protein may benefit cardiovascular health by aiding in weight loss/maintenance, improving the lipid/lipoprotein profile, and reducing blood pressure [177−179]. However, as with other macronutrient substitutions, evidence demonstrating the health benefits of increasing dietary protein must be interpreted with caution. Greater consumption of protein/protein-rich foods typically results in other changes in the diet (i.e., energy, nutrients, and foods) because protein is provided in many different foods. This is likely responsible for the disparate findings regarding the effect of dietary protein intake [180]. For instance, in middle-aged Swedish women [115] and adults in the Greek component of the European Prospective Investigation into Cancer and Nutrition [116] prolonged consumption of a low-CHO high-protein diet has been associated with higher mortality. Conversely, in U.S. women, lower CVD risk was associated with higher protein intake (up to 24% of total calories) [117] or a low-CHO high-protein diet [118]. It is likely that the specific protein food source and the particular macronutrient being replaced in each population influences the effect of increased protein consumption.

With respect to different food sources of protein, there is growing interest in the potential differential effects of plant-based versus animal-based protein on CVD risk [180]. Epidemiological studies have focused primarily on BP. Although numerous epidemiological studies have been conducted, current evidence remains inconsistent. Systematic reviews have found that an inverse association is more commonly found for plant protein but that the current evidence remains limited by inconsistent findings and potential confounders inherent to observational studies [119,181−183]. In studies of industrialized populations, plant protein consumption and blood pressure are more likely to be inversely related, whereas total and animal protein tend to have either no relationship or a direct association with blood pressure [184−186]. Conversely, studies of rural Japanese and Chinese populations have found the opposite relationship, with consumption of animal protein and blood pressure being inversely related [187−189].

The role of plant versus animal protein in cardiovascular outcomes is similarly complex. Analyses of particular food sources of protein (e.g., red meat, poultry, fish, dairy, eggs, legumes, nuts, beans, etc.) have demonstrated that each is associated with a different degree of both CHD risk [190] and CVD mortality [191]. Substituting one standard serving of red meat (~3 oz.) with different plant protein sources was found to reduce CHD risk by 13−30% in the Nurses' Health Study [190] and by 7−19% in combined analyses of the Nurses' Health Study and Health Professionals Follow-up cohorts [191]. It is also necessary to differentiate between various types of red meat to accurately evaluate risk. In a 2010 meta-analysis, Micha et al. concluded that only processed red meat intake, not total red meat intake, was associated with 42% greater risk of CHD [192]. Although dietary guidelines typically recommend reducing high fat red meats due to SFA and cholesterol content, red meat is not among the top contributors to SFA intake in the United States [193] and the primary difference between unprocessed and processed meat is sodium and nonsalt preservatives. However, in other studies, elevated CVD risk has been found with higher intakes of "red meat in addition to processed meat" or total red meat, suggesting that the greater risk associated with red meat is not entirely explained by the salt/preservative content of processed meat [190,194,195]. Therefore, specificity in characterizing each type of plant and/or animal protein is needed to accurately assess associations with CVD risk factors, morbidity, and mortality. The 2015−2020 DGA recommends a variety of nutrient-dense animal and plant sources of protein, with protein providing 10−35% of total calorie intake.

D Other Dietary Components

1 Dietary Cholesterol

Cholesterol is an integral component of cell membranes and is required for steroid hormone and bile acid biosynthesis. However, there is no biological requirement for dietary cholesterol because all tissues synthesize sufficient amounts of cholesterol to meet metabolic and structural needs. Previous dietary guidelines have recommended that cholesterol intake be limited to ≤300 mg/day

because of the dose−response relationship between dietary cholesterol and total and LDL-C [17,196]. However, the epidemiological evidence for a relationship between cholesterol-rich foods such as eggs and CVD risk is inconsistent [197−199]. Furthermore, the hypercholesterolemic effects of dietary cholesterol are relatively small compared to those of saturated fat [17,200], and also extend to HDL-C [201]. Based on this evidence, some have challenged the recommendation to limit dietary cholesterol [201]. However, others continue to assert that dietary cholesterol should be limited, particularly in high-risk individuals, due to harmful effects on postprandial lipemia and LDL-C oxidation [202,203]. The 2015−2020 DGA no longer includes a specific quantitative limit for dietary cholesterol but maintains that dietary cholesterol intake should be kept as low as possible [7]. Because cholesterol and SFA are highly correlated and often found in combination in the same foods [204], following a healthy dietary pattern that is low in SFA is likely to ensure that dietary cholesterol intake is also limited.

2 Plant-Based Bioactives

Although there is substantial epidemiological evidence that fruit and vegetable intake is associated with reduced risk of CVD [159,160,205,206], the mechanisms underlying these health benefits are not fully understood. In addition to fiber and numerous vitamins and minerals, fruits and vegetables also provide phytosterols—the plant analog of cholesterol—and other phytochemicals (i.e., bioactive nonnutritive compounds found in fruits, vegetables, whole grains, and other plant foods). It is likely that each component of this whole food matrix contributes protective effects, and the health benefits of fruits and vegetables cannot be attributed to a single dietary compound. For instance, phytosterols are known for their cholesterol-lowering effects [207−209]. Phytochemicals—which can be classified as carotenoids, phenolics, alkaloids, nitrogen-containing compounds, and organosulfur compounds [210]—have potent antioxidant activity [211,212]. As oxidative stress is a key driver in the development of many chronic diseases, it is likely that phytochemicals contribute to the health benefits associated with fruit and vegetable intake [213−218]. More than 5000 individual phytochemicals have been identified, but it is thought that a large percentage remain uncharacterized. Supplementation with an isolated micronutrient (i.e., vitamin E, vitamin C, and/or beta-carotene) has been largely unsuccessful in intervention trials [219−225] and it is likely that the beneficial effects of fruits and vegetables do not rely on these well-known antioxidants, but rather on lesser characterized and/or unidentified bioactives, or a concerted action of multiple compounds. The combination of phytochemicals in a particular fruit or vegetable is critical [213], and the consumption of fruits in combination may further enhance antioxidant activity [210]. Outside of the whole food matrix, a purified phytochemical may lose its bioactivity or behave in a different manner. Thus, a whole-food approach that emphasizes the consumption of a variety of fruits and vegetables within a healthy dietary pattern will provide numerous bioactive compounds that may have additive and/or synergistic effects and result in greater CVD risk reduction.

III EVIDENCE-BASED DIETARY PATTERNS FOR REDUCING CVD RISK

The recommendations issued in the 2015−2020 DGA and 2013 AHA/ACC Guideline focus on dietary patterns that are designed to reduce the risk of CVD and other chronic diseases. A whole food, dietary pattern approach guarantees the provision of a wide array of nutrients—many of which have yet to be characterized. Although dietary pattern recommendations typically focus on LDL-C and BP targets, they also address a wide array of other CVD risk factors—ultimately providing greater health benefits than focusing solely on individual nutrients. For example, the recommendation to increase fruit and vegetable intake relates to both hypocholesterolemic and blood pressure-lowering effects of fiber, as well as the potential for phytochemicals to ameliorate oxidative stress and inflammation. Modifications to the type and amount of macronutrients remain a primary goal within this approach to dietary guidelines, but it is important to keep the overall dietary pattern in mind as the effects of any macronutrient change depend in large part on the type of fat, carbohydrate, or protein that is used as a replacement.

There is a strong evidence base for the beneficial effects of the DASH diet, Mediterranean-style diets, and certain vegetarian diets (e.g., Portfolio diet and Ornish diet) [7]. Each of these dietary patterns have unique features, but all emphasize greater intake of nutrient-dense foods (e.g., vegetables, fruits, whole grains, nuts, legumes, unsaturated oils, low-fat dairy, and lean protein) in place of foods high in SFA, TFA, added sugars, and refined CHO. Fig. 27.5 summarizes the key recommendations of the DASH diet, Mediterranean-style diets, and the USDA food patterns recommended by the 2015−2020 DGA.

A DASH Diet

The DASH diet recommends increased consumption of fruits, vegetables, low-fat dairy, whole grains, poultry, fish, and nuts while limiting intake of red meat and added sugars [157]. It is relatively low in total fat (27−28% of total calories), saturated fat (∼6% of total calories), and sodium (2300 mg/day). There is substantial evidence that

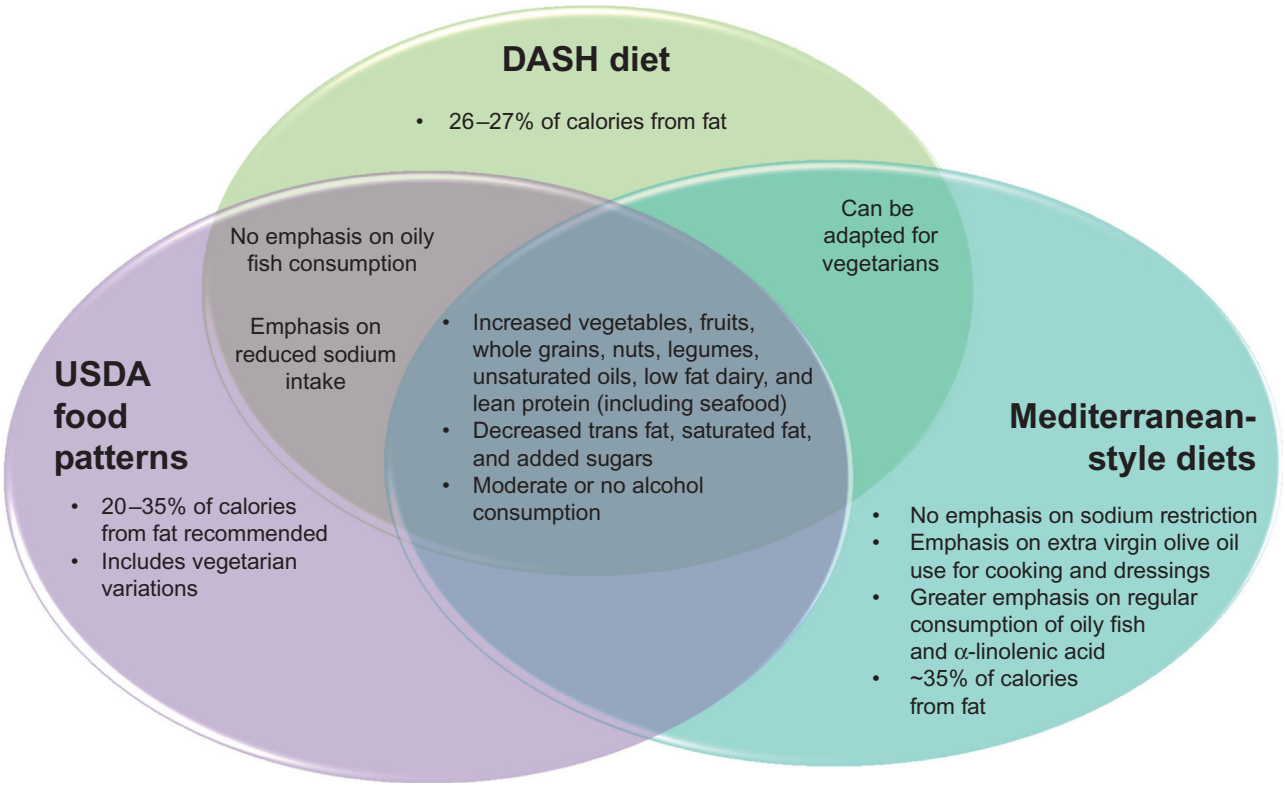

FIGURE 27.5 Commonalities and unique features of the DASH diet, Mediterranean-style diets, and the USDA food pattern recommended by the Dietary Guidelines for Americans 2015. Source: *C.K. Richter, A.C. Skulas-Ray, P.M. Kris-Etherton, Recent findings of studies on the Mediterranean diet: what are the implications for current dietary recommendations? Endocrinol. Metab. Clin. North Am. 43 (4) (2014) 963–980.*

the DASH diet consistently reduces BP, TC, and LDL-C; however, it also reduces HDL-C and does not affect TG [8]. In the original DASH trial [157, 158], participants who consumed the DASH diet had significantly greater reductions in TC (−13.7 mg/dL), LDL-C (−10.7 mg/dL), HDL-C (−3.7 mg/dL), and BP (−5.5/−3.0 mm Hg) compared to individuals consuming the typical American diet control. It was estimated that this translated to an 18% reduction in 10-year CHD risk according to the Framingham risk equations [227].

Additional sodium restriction in the context of a DASH diet can also provide further cardiovascular benefit. In the DASH-Sodium Trial, adults with elevated BP ($n = 412$) were randomized to either a typical American diet or the standard DASH diet. Within their assigned diet group, participants consumed foods to achieve a high, moderate, or low sodium intake for 30-day periods in a randomized crossover design (approximately 3450, 2300, and 1150 mg/day per 2100 kcal, respectively) [228]. The high and intermediate sodium levels were designed to reflect the typical intake in the United States and the upper limit of national recommendations, respectively. Sodium reduction dose-dependently lowered systolic and diastolic BP across all subgroups (i.e., sex, ethnicity, and hypertensive status) with both the control diet and the DASH diet; however, effects were greater in participants who were older [229] and who had hypertension [228]. Compared to the control diet, the DASH diet produced significantly lower systolic BP at each sodium level [228], and the combination of the two interventions—sodium restriction and the DASH diet—provided the greatest benefit. Sodium intake did not affect blood lipid concentrations [230]. Thus, reducing sodium intake—either to current recommendations or to a still lower level of intake—lowers BP and is an important dietary intervention for CVD risk reduction, even in the context of a typical American diet.

Improvements in CVD risk factors can also be achieved using a DASH diet with a modified macronutrient profile. The Optimal Macronutrient Intake Trial to Prevent Heart Disease (OmniHeart) was designed to test the effect of replacing 10% of the CHO in a higher CHO DASH diet (58% CHO, 15% protein, and 27% fat) with either protein or unsaturated fat. All three dietary interventions had favorable effects on BP, lipids, and 10-year CHD risk [231]. However, compared to the high-CHO DASH diet, both the high-protein and unsaturated fat DASH diet variations resulted in significantly greater reductions in systolic and diastolic BP, and lowered TG

[231]. Furthermore, the high-protein DASH diet also reduced LDL-C significantly more than the high-CHO DASH and the unsaturated fat DASH diet increased HDL-C [231]. Therefore, modifying the macronutrient profile of the standard DASH diet can result in greater CVD risk reduction, and these DASH diet variations provide additional options for implementing a healthy dietary pattern.

Systematic reviews of subsequent RCTs using a DASH-style dietary intervention have found similarly beneficial effects on BP, lipids/lipoproteins, and other CVD risk factors. For instance, in a 2015 meta-analysis of 20 RCTs comprising 1917 participants, a DASH diet produced significant reductions in systolic BP (−5.2 mm Hg), diastolic BP (−2.6 mm Hg), and LDL (−3.9 mg/dL) [232]. However, BP reductions were greater in participants with elevated baseline BP or BMI. Together, these changes in BP and cholesterol translated to a 13% reduction in the estimated 10-year Framingham risk score for CVD. Systematic reviews focused specifically on the BP effects of DASH diet interventions have reported similar findings [233,234]. A DASH-style diet may also be beneficial for body weight. Among 10 studies assessing the effect of a DASH diet on body weight, the average weight reduction was 1.42 kg for interventions lasting 8−24 weeks [235]. The reduction in body weight was greater when the DASH diet was implemented as part of an energy-restricted diet (−2.27 kg), for less than 12 weeks (−1.64 kg), and in overweight/obese participants (−1.63 kg) [235]. Therefore, there is strong evidence for the cardiovascular benefits of DASH-diet interventions.

The long-term effectiveness of adherence to a DASH diet is less well defined and relatively few studies have investigated effects on disease incidence. However, a systematic review of six studies concluded that a DASH-style diet significantly reduced the risk of CVD, CHD, stroke, and heart failure incidence by 20%, 21%, 19%, and 29%, respectively [236]. Many studies have reported an inverse relationship between DASH-diet compliance and blood pressure or incident hypertension [237−240], but not all results have been consistent [241,242]. For instance, in a cross-sectional analysis of 2047 adults, self-reported adherence was inversely related to systolic BP, with a difference of 4.4 mm Hg for participants with the highest DASH diet compliance score compared to participants with the lowest [237]. Conversely, in the Framingham Offspring cohort and the Iowa Women's Health Study, DASH diet adherence was not inversely associated with BP or hypertension risk [241,242]. However, it should be noted that participants' adherence to the DASH diet was relatively low in both of these studies, and few participants met the recommendations for specific food groups. The long-term benefits of the DASH diet for CVD risk reduction likely depend on the level of adherence to dietary targets.

There is a large body of evidence demonstrating that a DASH-style diet improves multiple CVD risk factors and reduces the risk of developing CVD. However, compliance to DASH-diet recommendations may be harder to achieve in "real world" settings compared to trials in which foods are provided to participants, and additional approaches may be needed to help individuals implement and sustain a DASH-style dietary pattern. For instance, the ability to modify the standard DASH diet and maintain or enhance its beneficial effects can provide greater flexibility in accommodating personal preferences. The DASH diet is the primary dietary pattern recommended by the 2013 AHA/ACC Guideline for the reduction of LDL-C and BP. Table 27.5 provides a summary of the BP and lipid effects of the diet recommendations in the 2013 AHA/ACC Guideline (i.e., standard DASH diet, DASH-diet variations, and sodium restriction).

B Mediterranean-Style Diets

A Mediterranean-style dietary pattern represents the food habits of the countries in the broad geographical area surrounding the Mediterranean Sea. Although there are country-specific variations in the foods consumed, a Mediterranean-style diet generally emphasizes fresh fruits, root and green vegetables, grains (mostly whole), legumes, oily fish rich in omega-3 FAs, nuts, seeds, and olive oil in place of butter or other animal-based fats. Low-fat or fat-free dairy is consumed daily; fish, poultry, and eggs are consumed in low to moderate amounts; and red meat and sweets are limited. Wine is also consumed in low to moderate amounts in non-Islamic countries. Overall, a Mediterranean-style diet tends to be moderate in total fat (32−35% of total calories), relatively low in saturated fat (9−10% of total calories), high in fiber (27−37 g/day), and high in MUFAs and PUFAs.

The benefits of a Mediterranean-style dietary pattern for CVD risk are based on both epidemiologic evidence and clinical intervention studies. Interest in the Mediterranean-style diet was first generated by reports from the Seven Countries Study in the 1980s, which found that the 15-year mortality rate from CVD in the Mediterranean region of southern Europe was 2−3 times lower than in northern Europe and the United States [243]. It was hypothesized that this was due to the dietary habits of these populations as regions with the highest CVD mortality also had greater SFA intake and higher serum cholesterol. Subsequently, the Lyon Diet Heart Study [111,112] was designed to test the effects of a Mediterranean-style diet on secondary prevention of MI. Participants were randomized to consume either the prudent Western-style control diet or a Mediterranean-style diet lower in SFA and higher in ALA for 104 weeks. Participants who consumed the Mediterranean-style diet

TABLE 27.5 Summary of Diet Recommendations Issued in the 2013 AHA/ACC Guideline on Lifestyle Management to Reduce Cardiovascular Risk and Effects on Blood Pressure and Lipids

Modification	Recommendation	Systolic and Diastolic Blood Pressure Reduction[a] (*Strength of Evidence*)	Lipid Effects[a] (*Strength of Evidence*)
DASH diet[b]	Consume a diet high in vegetables, fruits, low-fat dairy products, whole grains, poultry, fish, and nuts; low in sweets, sugar-sweetened beverages, and red meats	5−6/3 mm Hg (*High*)	↓ LDL-C by 11 mg/dL ↓ HDL-C by 4 mg/dL ↔ TG (*High*)
DASH variations[c]	DASH dietary pattern with 10% of total daily energy from CHO replaced with protein	1 mm Hg (systolic) (*Moderate*)	↓ LDL-C by 3 mg/dL ↓ HDL-C by 1 mg/dL ↓ TG by 16 mg/dL (*Moderate*)
	DASH dietary pattern with 10% of total daily energy from CHO replaced with unsaturated fat (8% MUFA, 2% PUFA)		Similar LDL-C reduction as DASH ↑ HDL-C by 1 mg/dL ↓ TG by 10 mg/dL (*Moderate*)
Dietary sodium restriction	Reduce sodium intake by at least 1000 mg/day; consume no more than 2400 mg/day; further reduction to 1500 mg/day is desirable	2/1 mm Hg with 2400 mg sodium 7/3 mm Hg with 1500 mg sodium (*Moderate*)	–

[a]*Strength of the evidence-base for each recommendation as graded by AHA/ACC Work Group given in parentheses.*

had similar BMI and BP compared to the control group and experienced no change in blood lipids, but had markedly lower prevalence of cardiac death and nonfatal MI, fewer major secondary events, and decreased hospitalizations [112]. Overall, subjects consuming the Mediterranean-style diet had a 50−70% lower risk of recurrent cardiac events, and the study was stopped early because of the evidence of significant CVD benefit [112]. It has been suggested that the abundance of bioactive compounds in the Mediterranean-style diet may in part account for these CVD outcomes, potentially via favorable effects on vascular function, arrhythmia, and oxidative stress.

Observational studies have also demonstrated the beneficial effects of a Mediterranean-style diet on CVD. Meta-analyses have consistently reported that greater adherence to a Mediterranean-style diet is associated with significant reduction in CVD risk, morbidity, and/or mortality [56,244−249]. For instance, in an analysis of 81,722 women in the Nurses' Health Study, women in the highest quintile for the Mediterranean diet score (high intake of vegetables, fruits, nuts, whole grains, legumes, and fish; high ratio of MUFAs to SFAs; moderate intake of alcohol; and low intake of red and processed meat) experienced a 40% reduction in sudden cardiac death relative to women consuming a diet that was least reflective of this pattern [247]. A 2015 systematic review of 24 observational studies reported that individuals in the highest quintile of adherence had lower CVD incidence (RR: 0.73; 95% CI: 0.66−0.80) and mortality (RR: 0.75; 95% CI: 0.68−0.83) compared to those who were least adherent [249]. Significant risk reduction was also found for the incidence of CHD (RR: 0.72; 95% CI: 0.60−0.86), MI (RR: 0.67; 95% CI: 0.54−0.83), and stroke (RR: 0.76; 95% CI: 0.60−0.96) [249]. A Mediterranean-style diet may also reduce the risk of type 2 diabetes and metabolic syndrome [250,251]—both of which increase CVD risk. With regard to diabetes, a meta-analysis of seven cohort studies found a 27% reduction in relative risk for highest versus lowest adherence to the Mediterranean diet score [251]. Thus, there is strong epidemiological evidence for the cardiovascular benefits of consuming a Mediterranean-style dietary pattern.

Multiple short-term intervention trials have also evaluated the effects of a Mediterranean-style diet on CVD risk factors [226]. Overall, meta-analyses of these

RCTs have found significant improvements in lipids/lipoproteins, BP, endothelial function, insulin resistance, and inflammation with Mediterranean-style dietary interventions [252−255]. The lack of significant CVD benefit found in some studies [112,256−259] may reflect differences in study design, duration, and the type of control/comparator diet. However, it should be noted that many of these studies used a parallel arm design and the type of Mediterranean-style diet intervention (and the control or comparator diet) varied greatly among many of these studies.

There are relatively limited data regarding the effect of a Mediterranean-style dietary pattern on CVD morbidity and mortality. Prior to the mid-2000s, the Lyon Diet Heart Study was the only clinical trial that evaluated the effect of a Mediterranean-style diet on cardiovascular morbidity and mortality. In 2003, the Prevención con Dieta Mediterránea (PREDIMED) study—a multicenter clinical trial evaluating the efficacy of a Mediterranean-style diet for primary prevention of CVD—was started. Participants were 55−80 years of age with type 2 diabetes or ≥3 major CVD risk factors (hypertension, hypercholesterolemia, family history of heart disease, tobacco use, or overweight/obesity) and were randomized to: (1) a low (er)-fat diet, (2) a Mediterranean diet with extra-virgin olive oil (1 L/week/family; 50 g/day per participant), or (3) a Mediterranean diet with tree nuts (30 g/day: 15 g walnuts, 7.5 g hazelnuts, 7.5 g almonds) [260,261]. After 3 months, subjects in both Mediterranean diet groups had lower TC/HDL-C ratios compared to the low(er)-fat group (−0.38 and −0.26, respectively) [260]. Additionally, the Mediterranean diet with nuts reduced fasting glucose (−5.4 mg/dL), systolic BP (−7.1 mm Hg), diastolic BP (−2.6 mm Hg), and TG concentrations (−13 mg/dL) relative to the low(er)-fat diet [260]. The Mediterranean diet with olive oil also reduced fasting glucose (−7.0 mg/dL), SBP (−5.9 mmHg), and DBP (−1.6 mmHg), but did not reduce TG concentrations compared to the low(er)-fat diet [260]. The trial was stopped early because of the significant clinical benefits observed for the combined endpoint of stroke, MI, or death from cardiovascular outcomes [261]. Participants in both the higher nut and higher extra-virgin olive oil diets experienced an approximate 30% reduction in the primary endpoint relative to the low(er) fat diet group [261]. When the individual components of the combined CVD outcome were analyzed separately, only the reduction in stroke risk reached significance (HR for Mediterranean diet plus olive oil: 0.67 [95% CI: 0.46−0.98], and 0.54 [95% CI: 0.35−0.84] for Mediterranean diet plus nuts). The Mediterranean diet with olive oil also reduced the incidence of new-onset type 2 diabetes compared to the control diet [262]. It is important to note that the macronutrient composition of the three diet treatments was quite similar, with only a 4 percentage-point difference in total fat intake between the low(er) fat and Mediterranean diet groups. The Lyon Diet Heart Study and PREDIMED remain the only long-term intervention studies of a Mediterranean-style dietary pattern, and demonstrate that this dietary pattern can significantly improve multiple CVD risk factors and reduce cardiovascular mortality.

A Mediterranean-style dietary pattern is recommended by both the 2015−2020 DGA and the AHA/ACC Guideline for lowering CVD risk. According to the AHA/ACC grading methodology, the strength of evidence for the LDL-C and BP-lowering effects of a Mediterranean dietary pattern is "low." However, this is due to the fact that the scope of the AHA/ACC Guideline was limited to modifiable CVD risk factors (e.g., lipids/lipoproteins and blood pressure) rather than cardiovascular events [8]. As such, the 2013 AHA/ACC Guideline did not review the evidence for morbidity and mortality in regards to dietary patterns and does not include the most recent results from PREDIMED [263].

C Vegetarian Diets

Vegetarian diets emphasize fruits, vegetables, whole grains, legumes, nuts, seeds, and soy foods and include little to no animal products. Compared to nonvegetarians, vegetarians typically consume fewer calories, SFA, cholesterol, and sodium but more fiber and total CHO [264,265]. As a whole, these factors can impart favorable effects on CVD risk factors. However, individuals choosing to omit all animal products from their diets must be well informed to ensure adequate intake of some nutrients. A vegetarian diet that is poorly planned with respect to nutrient recommendations will not decrease CVD risk and may increase the potential for nutrient deficiencies. The 2015−2020 DGA includes a healthy vegetarian-style eating pattern but different types of vegetarian diets may vary in the specific food groups that are restricted (e.g., eggs and dairy). The two vegetarian diets with the largest evidence base are described in detail below.

The Portfolio Diet is a vegetarian diet designed to achieve maximal LDL-C reduction. The diet is very low in SFA and cholesterol, and is characterized by its combination of plant sterols, viscous fibers (primarily from oat, barley, and psyllium), soy protein (21 g/1000 kcal), and almonds (14 g/1000 kcal)—the four functional foods recommended by the AHA and National Cholesterol Education Panel (NCEP) Adult Treatment Panel (ATP) III for their cholesterol-lowering capacity [209,266]. In short-term intervention studies, LDL-C reductions of 28−35% have been achieved [209,266−268]. For instance, under controlled feeding conditions, following a Portfolio diet (20% of calories as vegetable protein,

50.6% CHO, 23.2% fat [4.9% SFA, 9.5% MUFA, and 7.9% PUFA], 48 mg cholesterol per 1000 kcal, and 37.2 g fiber per 1000 kcal) for 4 weeks reduced TC and LDL-C (26.6% and 35.0%, respectively) in hyperlipidemic subjects, with no significant effect on HDL-C or TG [266]. These reductions were significantly greater than those produced by the low-SFA diet control. In a crossover study comparing the effects of the Portfolio Diet to a low-SFA control and a low-SFA diet plus statin treatment, the Portfolio Diet reduced LDL-C by 20.6% after 1 month [268]. Although this was significantly different than the effect of the statin treatment (−33.3% LDL-C), the Portfolio Diet and statin treatment were similarly effective in reducing LDL-C to below the 130 mg/dL target [268].

Under free-living conditions, the Portfolio Diet has also been shown to improve LDL-C and other CVD risk factors, although these changes tend to be more modest. In a 1 year free-living study of hypercholesterolemic adults ($n = 66$), maximum LDL-C reduction occurred at 12 weeks (−14%), and these benefits were sustained to the 1 year follow-up (−12.8%) [269]. Approximately one-third of these participants experienced LDL-C reductions of ≥20%, which is similar to the effect of first generation statin treatment. Self-reported dietary compliance—in terms of plant sterol, viscous fiber, soy protein, and nut intake—over the 1 year study period was significantly correlated with the change in LDL-C ($r = -0.42$; $p < 0.001$). However, improvements in LDL-C were also achieved without complete adherence to other portions of the dietary recommendations. For instance, after 1 year, only 2 of 55 participants were following a vegan diet, and five were following a lacto-ovo-vegetarian diet. The remaining participants returned to an omnivorous diet [269]. Similar LDL-C reductions (−13%) were achieved in a subsequent free-living study in which participants received counseling to follow the Portfolio Diet for 6 months [270]. This was significantly more than the reduction achieved by low-SFA dietary advice control (−3%) [270]. Effects of the Portfolio Diet on other CVD risk factors are less well established, but there is some evidence for BP reduction [271,272]. The Portfolio Diet has also been shown to lower the inflammatory marker CRP to a similar extent as statin therapy—an effect that has not been achieved by conventional cholesterol-lowering diets [267,273].

Modified Portfolio Diets have also been developed to target additional CVD risk factors. For instance, substituting 13% of the total calories from CHO with MUFA has been tested under controlled feeding conditions. After 1 month, hyperlipidemic patients randomized to either a low-MUFA (13% of total kcal) or high-MUFA (26% of total kcal) Portfolio Diet experienced similar reductions in LDL-C (−35%), but the high-MUFA Portfolio Diet also increased HDL-C and lowered CRP compared to the low-MUFA control [274]. Increasing the MUFA content of the Portfolio Diet also increased the apoA1 pool size and tended to increase LDL clearance rate ($p = 0.09$) relative to the low-MUFA comparator [275]. Adding strawberries to the standard Portfolio Diet has also been shown to provide greater protection against LDL oxidation while maintaining reductions in LDL-C (−13.4%) and the TC:HDL-C ratio (−15.2%) [276].

The Ornish diet is another plant-based diet that has been shown to produce striking reductions in CVD risk factors and events. The Ornish diet advocates "intensive lifestyle changes" and incorporates aerobic exercise, meditation, and smoking cessation in addition to dietary modifications. The diet is characterized by the exclusion of animal products (except for minimal amounts of nonfat yogurt), salt, alcohol, sugar, and caffeine; being very low fat (<10% of total calories); and emphasizing fresh fruits and vegetables, whole grains, legumes, tubers, and soybean products. All sources of fat are restricted, including vegetarian sources such as avocados, seeds, and oils, and questions have been raised about the lack of distinction between different types of fats. An unfavorable FA profile is unlikely when following a low-fat, whole-food vegetarian diet but omega-3 FAs may need to be obtained from supplements and/or enriched food products. In the Lifestyle Heart Trial, 48 patients with moderate to severe CVD were randomized to the Ornish diet or a usual care control group. Under short-term inpatient conditions, the Ornish diet improved left ventricular response to exercise and reduced TC (−20.5%) and anginal episodes (−91%) [156]. The reductions in LDL-C and angina episodes were maintained by patients in the Ornish group after 1 year of free-living conditions [154]. After 5 years, 35 participants remained in the study with similar compliance between groups (71% of intervention patients and 75% of control patients). Patients following the Ornish diet experienced more regression in coronary artery stenosis and fewer cardiac events compared to the standard-care control group [155]. The LDL-C reductions of 37% at 1 year [154] and 20% after 5 years [155] are comparable to the effects of statin therapy.

Since the Lifestyle Heart Trial, subsequent studies have provided further support for Ornish lifestyle interventions. For instance, in CVD patients, the Ornish program significantly reduced anginal frequency, body weight, BMI, systolic BP, TC, LDL-C, and glucose compared to traditional cardiac rehabilitation and a control group that received no formal cardiac risk reduction [277]. Similar benefits for CVD risk factors were reported for patients with coronary artery disease [278−280], although the Ornish program had no significant effect on carotid intima-media thickness compared to traditional cardiac rehabilitation [280]. An ongoing Multisite Cardiac Lifestyle Intervention Program for primary and secondary

prevention of CHD has reported significant reduction in overall coronary risk after 3 months [281] by addressing multiple CVD risk factors, including endothelial function and inflammatory markers [282], as well as BMI, systolic and diastolic BP, and LDL-C [283]. However, it should be noted that most of these changes are relative to baseline values rather than a control group [278,279,282,283]. In other studies, the Ornish diet has also demonstrated significant reductions in LDL-C during both weight loss [284] and weight maintenance [285]. However, the Ornish program also typically reduces HDL-C [284,285].

Despite these promising findings for the beneficial cardiovascular effects of the Portfolio and Ornish diets, additional strategies may be needed to reinforce adherence and achieve maximal CVD risk reduction. For instance, under free-living conditions, overall adherence to the Portfolio Diet was only 46.4% after 6 months despite multiple dietary counseling sessions [270]. Discontinuation rates after 1 year were similarly high (50%) for the Ornish diet in a free-living study [284]. Nonetheless, significant improvements in multiple CVD risk factors were achieved in both cases [270, 284]. The Ornish plan is also covered by Medicare as an alternative intensive cardiac rehabilitation program, and other studies have reported higher retention rates [286]. Adding strawberries to the Portfolio Diet has previously been shown to increase palatability, and the addition of strawberries or other fruits may improve the overall utility of the Portfolio Diet for CVD risk reduction [276]. Additional research is needed to identify practical techniques to increase dietary adherence. For instance, individuals can be matched to a diet that is well-suited to their personal food preferences and lifestyle. Cost and time considerations should also be taken into account to ensure that healthy dietary patterns are achievable for all individuals regardless of financial limitations.

IV CONCLUSIONS

A health-promoting dietary pattern can be achieved in a variety of ways, but consistently emphasizes the consumption of nutrient-dense foods (e.g., fruits, vegetables, whole grains, legumes, oily fish, nuts and seeds, lean meat, low-fat/skim dairy products, and liquid vegetable oils) in place of foods that are high in SFA, TFA, refined CHO, and added sugars. The specific evidence-based dietary patterns discussed in this chapter (i.e., the DASH Diet, Mediterranean-style diet, and vegetarian diets) each have characteristic features, but can be modified with respect to macronutrient distributions to suit an individual's specific needs and preferences. It is likely that the ability to personalize healthy dietary patterns will improve long-term adherence and maximize CVD risk reduction. These dietary patterns are recommended in the 2015–2020 DGA and 2013 AHA/ACC Guideline on Lifestyle Management, and can modify both traditional and emerging CVD risk factors. A healthy diet is essential for the prevention and treatment of CVD, and implementation of these evidence-based dietary patterns can have a substantial impact on public health.

Chapter 28

Nutrition, Lifestyle, and Hypertension

Pao-Hwa Lin, Crystal C. Tyson, Bryan C. Batch and Laura P. Svetkey
Duke University Medical Center, Durham, NC, United States

I INTRODUCTION

Hypertension is a major risk factor for coronary heart disease (CHD), stroke, and premature death and a leading risk factor for global disease burden [1−5]. Prevalence for those 18 years and older in the United States has remained around 29% since 1999 with little improvement [6]. Further approximately one-third of American adults have prehypertension [7], which is also associated with a graded, increased risk of cardiovascular disease (CVD) and progression to hypertension [4,5,8]. Studies have shown that for every 20-mmHg increase in systolic blood pressure (SBP) or 10-mmHg increase in diastolic blood pressure (DBP) there is a doubling of mortality from ischemic heart disease (IHD) and stroke (Table 28.1) [4]. In industrialized societies such as the United States, blood pressure (BP) increases with age: the prevalence of hypertension is 7.3% among adults aged 18−39 years, and the figure increases to 32.3% among those aged 40−59 years and to 64.9% among those 60 years and above [6]. Hypertension is more common in non-Hispanic black (41.2%) than non-Hispanic white (28.0%), non-Hispanic Asian (24.9%), or Hispanic (25.9%) adults. Although the cause of hypertension is largely unknown, 1−5% of hypertension cases are due to a secondary underlying correctable condition.

In contrast to the prevalence in the United States and many developed or developing countries, many non-Westernized, remote populations have a low prevalence of hypertension and do not experience an increase in BP with age [9,10]. Their protection from hypertension is often attributed to very low salt intake [11−13], high potassium intake [12,14], being physically active [9], low alcohol consumption [12,15], and generally high plant food and fish consumption. Migration studies of indigenous populations also report increasing prevalence of hypertension with urbanization, providing additional evidence for a role of environmental (including nutritional) factors [16,17]. With urbanization, access to processed food increases which in turn reduces diet quality in general, increases intakes of the BP raising nutrients like sodium and saturated fat and decreases intakes of BP-lowering nutrients like potassium, magnesium, and fiber. Further fresh foods that were previously readily available become less affordable. These changes potentially contribute to the prevalence of hypertension. In addition to other lifestyle changes, increases in body weight, sodium intake, dietary fat, and the ratio of urinary sodium-to-potassium have been observed during the process of acculturation [15−21]. Taken all together these observations support an important role of diet and lifestyle in BP regulation and inspired much of the later research in this area.

The relationship between dietary intake and BP suggests the possibility of nutritional intervention to prevent the development of hypertension, an urgent need given its high prevalence and associated risk. In addition, effective strategies are urgently needed to improve the poor rates of hypertension control. BP control among adults with hypertension has increased from 31.5% in 1999−2000 to 53.3% in 2013−14, however, there remain nearly half of adults with hypertension with uncontrolled hypertension [6].

In this chapter we provide an overview of epidemiologic and clinical evidence for established and potential dietary factors for hypertension prevention and control. Because a comprehensive review of all individual trials in this area is beyond the scope of this chapter, when applicable, we review meta-analyses. Although meta-analyses are useful for evaluating consistency in the literature, they tend to weigh large studies more heavily [22,23], may be limited by the predetermined inclusion criteria, and it is

rarely feasible to conduct subanalyses on potentially important modifying factors or to account for variable dietary adherence among studies. Nonetheless, whenever available, multiple meta-analyses combined provide comprehensive overview of the existing evidence.

In addition to the scientific foundation found in epidemiologic and clinical data, it is important to consider application of these findings. Accordingly, the last two sections of this chapter are devoted to the review of several large-scale intervention trials. These trials include the whole diet-based controlled feeding trials such as the Dietary Approaches to Stop Hypertension (DASH) trial [24], DASH-Sodium [25], and OmniHeart [26] trials. Additionally large-scale multilifestyle intervention trials including Trials of Hypertension Prevention (TOHP) I [27], TOHPII [28], and PREMIER [29] are also reviewed. Issues related to implementation of the current national guidelines are discussed. We conclude with a summary of qualitative and quantitative dietary and lifestyle recommendations for the prevention and treatment of hypertension.

II MICRONUTRIENTS

In observational studies, micronutrients directly associated with lower BP include potassium, magnesium, calcium, and fiber; an inverse association is seen with dietary sodium. Epidemiologic and clinical data that demonstrate these relationships are reviewed further. However, it is important to recognize that determining the independent effect of each micronutrient on BP is often limited because several of these micronutrients derive from similar food sources [30] and are highly correlated with each other. For example, foods high in magnesium (e.g., nuts) are also high in fiber and potassium, making it virtually impossible to attribute associations with BP to the effects of a single micronutrient. To isolate and test the effect of individual nutrients, intervention studies typically use dietary supplements. The use of supplements allows for any changes in BP seen as a result of the intervention to be attributed solely to the nutrient being examined. Although using supplements provides an opportunity for the relationship between an individual micronutrient and BP to be precisely examined, it also has its limitations. Micronutrient supplements may not be absorbed as well or have the same physiologic effects when they are consumed in food. Varying levels of other dietary components may also modify the effectiveness of the supplemented micronutrient. These challenges have led to less focus on individual micronutrients and increased focus on dietary patterns, as discussed later in this chapter.

A Potassium

The evidence for a role of potassium in lowering BP is relatively consistent across study types and is biologically plausible [31].

1 Observational Studies

An extensive body of epidemiologic data demonstrates an association between dietary potassium and BP [32]. Both potassium alone (inversely) and the sodium-to-potassium ratio (directly) have been associated with BP [33,34]. A lower urinary excretion of potassium (a good marker of dietary intake) is associated with higher BP [32] and risk for hypertension [35]. The linear association of BP with

potassium intake is actually tighter than with sodium intake, with the mean potassium intake in hypertensives about 15% lower than in nonhypertensives [36].

2 Interventional Studies

Several meta-analyses have examined the effect of potassium supplementation on BP. In 1997 Whelton et al. [37] reviewed 33 randomized controlled trials (RCT) of potassium and BP. These studies included mostly individuals with hypertension, some of whom were receiving antihypertensive medication. In all studies potassium was provided as a supplement (median 75 mmol (2925 mg)/day), either superimposed on a controlled research diet or added to participants' usual diets. After excluding one outlier study, a high potassium intake was associated with net 3.11/1.97-mmHg reduction in SBP/DBP. Interestingly, greater BP reductions occurred in those with progressively higher urinary sodium excretion during follow-up (measured at the end of the study). This suggests that potassium is more effective at higher levels of sodium intake. Other research evidence also points to the interaction of potassium and sodium in BP [31]. In addition, results were significantly stronger in studies that included a high proportion of African Americans. This meta-analysis reached qualitatively similar conclusions to those of a 1995 analysis by Cappuccio et al. [38] with roughly a 50% overlap in studies included.

In a large intervention trial of US female nurses (Nurses Health Study II), Sacks and colleagues [39] administered either supplemental potassium (40 mmol, 1560 mg), calcium (30 mmol, 1200 mg), magnesium (14 mmol, 336 mg), or all three minerals combined, or placebo to women who reported habitually low intakes of these nutrients, for a 6-month period. Potassium, administered alone, was the only intervention that reduced BP. The mild yet significant reduction occurred even though the women were nonhypertensive (mean BP: 116/73 mmHg).

Furthermore two meta-analyses provide supporting evidence for an effect of a potassium supplement on BP. Geleijnse et al. [40] examined 27 randomized trials with at least 2 weeks of follow-up among both hypertensives and nonhypertensives. They found that a median potassium supplementation of 44 mmol/day (1716 mg/day) was associated with a reduction of SBP/DBP by 2.42/1.57 mmHg. This reduction was even greater among those who were hypertensive (3.51/2.51 mmHg), but it was only borderline significant ($p=0.08$). Dickinson et al. [41] reviewed 4 of the 27 trials in the Geleijnse study plus 2 other trials, all of which included at least 8 weeks follow-up and only hypertensives. They found a large reduction in BP by potassium supplementation (11.2/5.0 mmHg), but the reduction was not statistically significant, perhaps partially because of the heterogeneity of the trials. The authors stated that the heterogeneity of the trials was not explained by the varying dosage of potassium supplementation, study quality, or the baseline BP.

Perhaps the strongest support for the effect of dietary potassium on BP comes from the DASH trial. DASH was a controlled feeding study in which adults with prehypertension or untreated stage I hypertension were randomly assigned to one of three diets: a typical American diet, a diet that eventually became known as "the DASH dietary pattern" (see below), and a fruits and vegetables diet that was identical to the typical American diet except for the addition of more fruits and vegetables. All three treatment groups were fed isocaloric diets without sodium restriction. The nutrient content of the fruits and vegetables diet, relative to the control diet, was increased in potassium, magnesium, and fiber. Participants eating 2000 kcal/day in this study consumed 4700 mg/day of potassium; potassium intake was increased or decreased proportionally for higher or lower energy intakes. The fruits and vegetables diet significantly reduced SBP/DBP, relative to the control diet, by 2.8/1.1 mmHg [24]. Although the increase in potassium was not the only difference from the control diet, the strength of epidemiologic, metaanalytic and biologic evidence suggests that potassium was the BP-active nutrient.

Further, the BP reduction was greater in those with hypertension (11.6/5.3 mmHg) compared to prehypertension (3.5/2.2 mmHg) and among African Americans (6.9/3.7 mmHg) compared to non-African Americans (3.3/2.4 mmHg) [42]. The greater effect in African Americans is particularly intriguing since this population has both higher rates and severity of hypertension [43] and lower dietary intake of potassium [44], suggesting both a mechanism and an intervention for racial disparities in hypertension.

3 Mechanism

Potassium may lower BP through a direct vasodilatory role, alterations in the renin–angiotensin system [45], nitric oxide production [46], renal sodium handling, and/or natriuretic effects [47,48] (Fig. 28.1).

4 Summary

There is compelling evidence that increasing potassium intake lowers BP. Thus research strongly supports the recommendation of increasing potassium intake to 4700 mg/day for the prevention and control of high BP. This recommendation has been endorsed by the American Heart Association (AHA) [49] and Dietary Guidelines for Americans [50]. However, average intake in the United

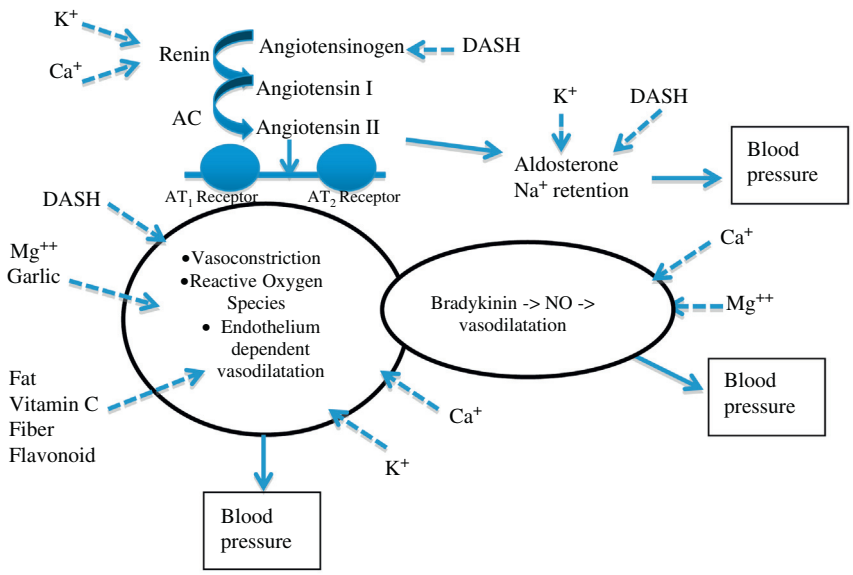

FIGURE 28.1 The potential effect of various dietary factors and DASH dietary pattern on BP regulation.

States continues to fall below this recommendation, with less than 3% of adults consuming 4700 mg/day [51]. Even though potassium is rich in foods of various food groups, choices may need to be intentionally planned in order to reach this recommendation.

B Sodium

Many studies have supported the relationship between sodium intake with BP, CVD risk, and all-cause mortality [52,53]. This relationship has been difficult to study because dietary sodium intake is not easily measured by standard dietary assessment methods. Salt added at the table and during cooking is difficult to quantify, and processed foods vary widely in sodium content. Most often, 24-hour urine collections are used to assess daily sodium intake. Under stable conditions (e.g., adequate health, hydration, no excessive sweating), 90–95% of dietary sodium is excreted in the urine [54]. Nonetheless, wide variations in day-to-day sodium excretion within individuals will weaken the correlation of single 24-hour urinary sodium levels with BP. This weakness may be minimized by collecting multiple samples in individuals or by increasing sample size in group analyses. Neither solution may be feasible; however, it is possible to employ statistical methods to correct for this source of error by using data from repeated collections in a subset of the study population [55,56]. Improperly collected urine samples and varying geographic conditions (e.g., climate) among populations [9] can introduce additional error. Despite these methodologic limitations, a relationship between dietary sodium intake and BP is well established and supported by many studies.

1 Observational Studies

A direct relationship between sodium intake and BP is repeatedly observed across populations [57–61]. For example, the INTERSALT study measured the relationship between 24-hour urinary sodium excretion and BP in 10,079 men and women from 52 centers around the world [33].

After appropriate adjustments, including correction for measurement error due to use of single 24-hour urine collections, a 100 mmol/day (2300 mg sodium) increase in urinary sodium was associated with an increase in SBP of 3–6 mmHg and DBP of 0–3 mmHg [62]. The INTERSALT investigators also reported a significant relationship between sodium intake and the slope of BP increase with age across populations [33], suggesting a role for sodium in age-related BP increase.

2 Interventional Studies

The early observation of a large BP reduction in patients with severe hypertension consuming the Kempner rice diet [63] is often attributed to its low sodium content (7 mmol or 150 mg/day), though the diet was also rich in fruit, low in fat and protein, and supplemented with vitamins. The many trials of sodium reduction conducted since then have demonstrated a BP-lowering effect of reducing sodium intake, but have differed with regard to the magnitude of effect. Metaanalyses of numerous clinical trials of sodium reduction demonstrate that reduction to currently recommended levels (2300 mg/day) lowers BP by approximately 3–6/1–3 mmHg in hypertensives and 1–2/1 mmHg in nonhypertensives [64–66].

Given the difficulties in measuring sodium intake, as noted previously, perhaps the most compelling trial data

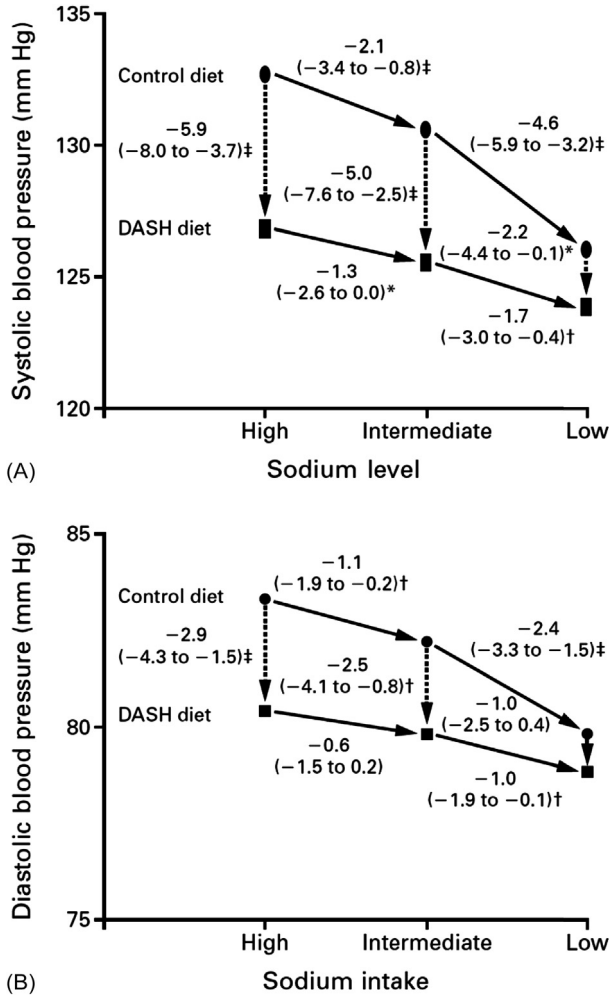

FIGURE 28.2 The effect on Systolic Blood Pressure (SBP) (Panel A) and Diastolic Blood Pressure (DBP) (Panel B) of Reduced Sodium Intake and the DASH Diet. *Source: F.M. Sacks, L.P. Svetkey, W.M. Vollmer, et al., Effects on blood pressure of reduced dietary sodium and the Dietary Approaches to Stop Hypertension (DASH) diet. DASH-Sodium Collaborative Research Group. New Eng. J. Med. 344(1) (2001) 3–10 [25]. *$p < 0.05$, †$p < 0.01$, ‡$p < 0.001$.*

come from the DASH-sodium trial, a controlled feeding study in which nutrient content was precisely determined in a metabolic kitchen and all foods and beverages were provided to study participants. DASH-sodium trial demonstrated that the effect of sodium intake on BP is markedly influenced by dietary pattern: in the context of a typical American diet, reducing sodium intake from an average of 3500 (High) to 2400 mg/day (Intermediate) led to an average reduction in BP of 2.1/0.6 mmHg, and reduction from 3500 to 1500 mg (Low) reduced BP by an average of 6.1/3.5 mmHg (Fig. 28.2) [25]. But when participants were eating the DASH dietary pattern (see below), reducing sodium intake had about half that effect. As with the fruits and vegetables diet in the DASH study, effects of reducing sodium were more pronounced in those with hypertension compared to prehypertension and in blacks compared to whites [25].

Although reducing sodium lowered BP more while eating a relatively unhealthy diet, the combination of DASH and reduced sodium had a larger BP-lowering effect than either dietary change alone, leading to current recommendations to implement both changes [67].

3 Mechanism

A high sodium intake may affect BP via sodium retention and/or via effects on endothelial health [68,69]. It is clear that there are genetic influences on the BP response to sodium intake [70], and other dietary components may interact with sodium's effect on BP [71,72].

4 Summary

The preponderance of evidence supports the 2015–2020 Dietary Guidelines for Americans recommendation that individuals 14 years and older consume sodium less than 2300 mg/day. The guidelines also state that those younger than 14 years follow the age and gender-appropriate upper limits (UL) [50].

In addition, the AHA [73] recommends that those with hypertension or prehypertension attempt to further reduce sodium intake to 1500 mg/day to receive even greater benefit on BP. This recommendation is consistent with the recommendations of the World Health Organization (WHO) [74] and the Institute of Medicine (IOM) [75]. However, some have expressed concern that trying to achieve intake of 1500 mg/day or less is not feasible for most people with the current food supply as it would require marked change in dietary habits and purchasing expensive no-salt products (e.g., bread, cheese).

In any case, food labels and modest public and patient education can facilitate achieving the goal of sodium intake of 2300 mg/day or less, with expected beneficial effects on BP.

C Calcium

Although a modest BP-lowering effect of calcium is noted in some observational studies, results from intervention trials have been inconsistent. Studies showing the greatest effect have tended to use dietary sources of calcium (e.g., dairy products), in which several potentially confounding dietary factors also change [24]. In addition, the BP-lowering effect of calcium may be greater among those with a low habitual intake of calcium.

1 Observational Studies

The higher calcium and magnesium content of "hard" water, and its inverse relation to cardiovascular mortality [76] initially sparked epidemiologic investigation into the relation of both minerals to BP. Cutler and Brittain [77] reviewed 25 observational studies and showed only modest associations between calcium and BP. Because most studies used 24-hour recall methods to assess diet, random day-to-day variation may have obscured any relation with BP [77]. It is also worth noting that some low-BP populations have minimal calcium intakes, [14] more counterevidence to the link between calcium and BP. Cappuccio and others [78] later conducted a meta-analysis of 23 observational studies, and found negligible associations for calcium with both SBP and DBP, though a reanalysis of this data resulted in a somewhat stronger inverse association [22]. A cross-sectional analysis of the NHANES III data showed that increasing calcium intake is significantly associated with a lower rate of age-related increase in SBP and pulse pressure [79]. Other cross-sectional or longitudinal studies also have shown a significant and inverse association between calcium intake [34,80–82] or dairy intake [83–86] and BP.

2 Interventional Studies

In 1924 Addison and Clark [87] recorded the BP response to repeated administration and discontinuation of oral calcium supplements in a convenience sample of hospital outpatients and inpatients. They noted that BP decreased after 2 weeks of calcium supplementation and immediately rose with calcium discontinuation. It was not until much later in the century that the calcium hypothesis was tested in a more methodologically rigid fashion in a number of intervention studies.

Several meta-analyses of calcium-intervention trials have been published since 1989 [88–93], all showing only a slight or negligible BP reduction, primarily of SBP, with calcium supplementation of about 1000 mg. Intervention studies using calcium from food sources have sometimes [94], but not always [95], been more effective, though these studies also involve changes in several other nutrients.

A randomized controlled trial (RCT) in 732 postmenopausal women showed that calcium supplementation of 1 g/day significantly reduced SBP by 1–2 mmHg at 6 months; however, this effect disappeared at 30 months despite continual calcium supplementation [96]. Two other small randomized trials did not find any significant effect of calcium supplementation on BP [97,98]. However, supplementing 1000 mg calcium plus 50000IU Vitamin D3/day for 12 weeks significantly improved BP among 60 pregnant women [99]. A daily supplement of three servings of dairy products significantly reduced SBP among men with high normal or hypertension but not in women [100]. An interaction between calcium and other minerals in their effect on BP has been observed [101] such that calcium supplementation may prevent a salt-induced rise in BP in susceptible individuals. Inability to either control for sodium intake or stratify by level of sodium intake in most meta-analyses may obscure a relationship.

Despite weak evidence for a role of calcium in BP, the potential impact of calcium on cardiovascular health has been examined with inconsistent findings [102,103]. A meta-analysis of 11 prospective studies involving 757,304 participants concluded that there is a nonlinear association between dietary calcium intake and risk of CVD mortality [104]. Intakes that were lower and higher than about 800 mg/day were gradually associated with a higher risk of CVD mortality. Further, the risk of all-cause mortality did not decrease at intakes above 900 mg/day. Thus the role of calcium in BP and CVD health remains to be examined and clarified.

3 Mechanism

Potential mechanisms by which calcium may affect BP include effects on plasma renin activity, endothelial function, or the production of nitric oxide (Fig. 28.1).

4 Summary

Overall it is advisable for the public to consume adequate dietary calcium, preferably from food sources, for the benefit of bone health. The Dietary Reference Intakes (DRI) for calcium suggests an intake of 1000 mg/day for all adults and 1200 mg/day for women 51 years and older and men 71 years and older. This level of intake is similar to that tested in the DASH dietary pattern and may also promote BP health.

D Magnesium

In animal models magnesium deficiency has been shown repeatedly to be associated with hypertension [105–107]. In humans, magnesium deficiency, although recognized rarely, is seen in severe malnutrition, in chronic alcoholism, and in association with malabsorption [108].

1 Observational Studies

As with calcium one of the early suggestions for a role of magnesium in hypertension came from reports that water hardness (increased calcium and magnesium) was associated with lower cardiovascular mortality [76]. This finding was corroborated by Yang and Chin [109]. A more recent examination of dietary and plasma magnesium and risk of CHD was conducted among 86,323 women in the Nurses' Health Study [110]. The examination found a

significant inverse association between magnesium intake and risk of fatal CHD and this association appeared to be mediated partially by hypertension. Several cross-sectional [111,112] and prospective observational analyses [113,114] have found higher magnesium diets to be associated with lower BP. However, interpretation of these results is limited by the fact that a high magnesium diet tends to be high in other beneficial dietary factors as well. In a prospective study magnesium intake was found to be inversely associated with risk for hypertension after adjustment for known risk factors among 28,349 participants of the Women's Health Study [115]. Low serum magnesium (hypomagnesium) was significantly associated with the prevalence of prehypertension among 4,272 Mexican adults [116]. In addition, among 5,511 participants in the PREVEND trial, urinary magnesium excretion was inversely associated with risk of hypertension [117]. Dietary intake of magnesium was also found to be inversely associated with SBP in this study and with both SBP and DBP in another cross-sectional study [112].

2 Interventional Studies

Many intervention trials of magnesium supplementation have been conducted [27,39,118–128] and some have shown a beneficial effect on BP [118,119,124,125,127]. Patients were magnesium depleted (due to diuretic treatment) in two of the studies [118,119], and in one study an effect was only seen in those with a low baseline intake of dietary magnesium [128]. Kawano et al. [126] found the greatest BP reduction with magnesium supplementation in older men on antihypertensive medications. More than half of these studies, however, found no BP-lowering effect with magnesium supplementation. In a meta-analysis of 12 randomized trials, magnesium supplementation significantly reduced DBP only (by 2.2 mmHg) but had no significant effect on SBP [128].

Epsom salt is magnesium sulfate that has been suggested to benefit BP in some media. There has been very little research conducted to examine its impact on BP. The potential benefit of Epsom salt on BP may be related to its magnesium content. Individuals are advised to consume adequate magnesium from natural food sources instead of taking Epsom salt.

Overall, the quality of the included trials was poor, results varied, and thus the evidence was weak. In another meta-analysis of nine randomized trials in participants with diabetes, a median level of 360 mg/day magnesium supplementation did not have any significant effect on BP [129].

3 Mechanism

Adequate magnesium is required for the Na/K-ATPase pump, which regulates intracellular calcium—one of the critical determinants of vascular smooth muscle contraction [108] (Fig. 28.1).

4 Summary

Despite the potential role for magnesium in BP control, evidence from intervention trials to date has not been supportive. However, individuals are encouraged to consume adequate amount of magnesium from natural food sources as recommended by adopting the DASH eating pattern (see Section V-A).

E Vitamin C

Many studies have examined the association between vitamin C intake and BP regulation and findings are inconsistent [130].

1 Observational Studies

Earlier observational studies have shown an association between either vitamin C intake [36] or plasma ascorbic acid [131] and BP. A recent prospective cohort study of 2,884 adults showed that dietary intake of vitamin C and several food groups high in vitamin C were inversely related to hypertension whereas supplemental vitamin C was not [132]. In addition, this study showed that plasma ascorbic acid independently predicts hypertension.

2 Interventional Studies

Most interventional studies employed vitamin C supplements and the findings have not been as consistent as that from observational studies. In a meta-analysis of 29 clinical trials with 10–120 participants, the median dose of vitamin C supplement was 500 mg/day and the median duration was 8 weeks [133]. The pooled changes in SBP and DBP were −3.84 mmHg (95% CI: −5.29, −2.38 mmHg; $p < .01$) and −1.48 mmHg (95%CI: −2.86, −0.10 mmHg; $p = .04$), respectively. Corresponding reductions were greater among those with hypertension (−4.85/−1.67 mmHg, $p < .01$/$p = .17$). In a study of 32 untreated hypertensive patients and 20 normotensive subjects, acute infusion of vitamin C (3 g intravenously in 5 minutes) significantly reduced BP in hypertensive patients but not in normotensive subjects [134]. Intravenous vitamin C alone (>30–100 g) reduced the mean BP up to 8–9 mmHg in prehypertensive patients [135]. Thus, short-term or acute effect of vitamin C supplementation was consistently observed, however, BP was not changed after 5 years supplementation of either 50 or 500 mg/day among 439 Japanese participants with atrophic gastritis [136].

3 Mechanism

Potential mechanism for the role of vitamin C on BP regulation mainly relates to its antioxidant function. Supplementation of vitamin C may improve arterial stiffness and endothelial function, which subsequently may reduce BP [137]. Vitamin C supplementation (2 g orally) may also impact BP through its effect on endothelium-dependent vasodilatation as observed in the radial circulation of patients with coronary artery disease [138].

4 Summary

Overall evidence supports the role of vitamin C on BP regulation; however, long-term effect is less clear. Individuals are advised to consume a dietary pattern rich in fruits and vegetables (8−10 combined servings of fruits and vegetables per day) to ensure adequate and sufficient intake of vitamin C.

III MACRONUTRIENTS

Studies of macronutrients and BP are subject to the same design limitations as studies of micronutrients described earlier. For example, a study designed to examine the effect of the amount of fat intake on BP under isocaloric conditions inevitably will alter the amount of protein and/or carbohydrate, as well as other nutrients consumed. As a result it may be difficult to attribute changes in BP to change in fat intake alone. In addition, BP may be influenced by not only the quantity of macronutrient consumed, but also the type of macronutrient and the food source that it is derived. Both aspects can affect BP independently, but they are not always distinguishable in research designs.

A Protein

1 Observational Studies

Observational studies continue to show an inverse relationship between dietary protein intake and BP [139−142], particularly with plant protein. Cross-sectional studies conducted in rural Japanese and Chinese populations found only an inverse relationship between animal protein and BP [143,144]. In contrast, cohort studies conducted in the United States have shown an inverse association between SBP and baseline intakes of plant protein but not animal protein [145,146]. Thus, there may be differential effects of animal and plant protein on BP, but the exact relationship is not clear.

2 Interventional Studies

It should be noted that many intervention trials employ different types or amounts of protein, and the delivery mechanism may differ as well, all of which contribute to variation in results. Using data from the PREMIER clinical trial [29], we found that dietary plant protein intake was inversely associated with both SBP ($p = .0009$) and DBP ($p = .0126$) in cross-sectional analyses at 6-month follow-up [147]. An increase in plant protein intake was marginally associated with a reduction of both SBP ($p = .052$) and DBP ($p = .082$) from baseline to month 6, independent of change in body weight. Furthermore, among those with prehypertension, increased intake of plant protein was significantly associated with a lower risk of developing hypertension at 6 months. Animal protein was not associated with BP or change in BP in PREMIER. In contrast, Hodgson et al. [148] demonstrated in a small trial that replacing carbohydrate with lean red meat while keeping total calorie and fat intake constant reduced SBP but not DBP. Although the reduction in SBP was statistically significant, the magnitude within the active intervention participants was quite small (−1.9 mmHg using clinic BP and −0.6 mmHg using ambulatory 24-hour BP).

A meta-analysis of 15 RCTs showed no significant difference between high and low intakes of protein on BP [149]. However, other intervention studies have shown a positive impact on BP of increasing protein intake or protein supplement, particularly from plant sources [150−152]. In a 6-week randomized three-phase crossover trial in subjects diagnosed with hypertension, substitution of protein for carbohydrate led to a decrease in SBP of 3.5 mmHg [26].

Most trials use protein supplements that include soy, vegetable, or animal protein and do not control for other nutrients.

The results of numerous RCTs that supplemented soy protein have been mixed. In two randomized double-blind controlled trials, He et al. demonstrated a significant decrease in SBP and/or DBP with soybean protein supplements or with milk protein supplement [153,154]. Further Rivas et al. [155] demonstrated that soy milk supplements significantly reduced SBP by 18.4 mmHg in a 3-month randomized trial. In contrast three RCTs [156−158] showed no difference in SBP or DBP between the soy protein-supplemented group and the placebo group. A meta-analysis of 27 RCTs showed that soy protein supplement was associated with BP reduction and the association was greater among hypertensives [159].

It should be noted that some studies used milk supplements, which provide not only protein but also other nutrients that may affect BP. Other studies that used soy products (e.g., soy nuts) contain other nutrients such as isoflavones that may also impact on BP. Thus, the reported positive impact on BP cannot be attributed to protein alone.

3 Mechanism

Although the exact mechanism(s) linking amount or type of protein to BP is still unclear, several mechanisms have been suggested. First, an increase in protein intake may induce increases in renal plasma flow, renal size, glomerular filtration rate, and sodium excretion [160,161]. Second, the amino acid arginine, a precursor for the vasodilator nitric oxide, may act as a vasodilator and contribute to BP lowering [162]. One possibility that soy protein was hypothesized to reduce BP may be related to its rich content in arginine. Other amino acids including glutamic acid, leucine, and tyrosine may also impact arterial stiffness and benefit BP control [163]. On the contrary, diets high in amino acids rich in animal sources such as glycine may adversely affect BP [164].

4 Summary

Despite controversial evidence that protein restriction may preserve kidney function, especially in those with existing kidney disease [165], the overall effect of protein on BP appears to be salutary. Considering the evidence available, it is advisable to ensure an adequate protein intake on the basis of a healthy eating pattern, such as the DASH eating pattern that may likely benefit BP. Further selecting protein from mainly plant sources may benefit BP control and overall cardiovascular health.

B Dietary Fat

Numerous studies have investigated the relationship between dietary fat and BP. However, because of differences in study design, lack of adequate sample size, and other design limitations, the issue remains controversial. Both the absolute total intake of dietary fat and the relative fatty acid composition may independently relate to BP control.

1 Observational Studies

Most observational studies have not found an association between total fat intake and BP [30,166–168]. However, type of fat intake has been found to be associated with BP in two large studies [166–168] but not others [30,169] that showed a positive relationship between saturated fatty acids and BP. In addition, Hajjar and Kotchen [170] examined the NHANES III data and reported that the southern region of the United States, which consumed the highest amounts of monounsaturated (MUFA) and polyunsaturated fats (PUFA), also had the highest SBP and DBP compared to other regions. Conversely the INTERMAP study found that MUFA intake was significantly and inversely associated with DBP among 4,680 participants from four countries [171]. A significant and inverse association was also found between oleic acid (a MUFA) intake and BP. In a cross-sectional study of 2,447 Chinese adults, serum fatty acids characterized by high proportion of saturated fats was associated with higher SBP while high proportion of PUFA was associated with lower DBP [172]. Similarly a meta-analysis of 8 prospective cohort studies with 56,204 adults found that circulating, but not dietary, long chain m-3 PUFA, especially docosahexaenoic acid (DHA), was significantly and inversely associated with incidence of elevated BP [173]. Thus these observational findings support a beneficial role of PUFA and MUFA and an adverse role of saturated fats on BP.

2 Interventional Studies

Many studies have examined the impact of the amount and/or type of fat on BP. However, as discussed previously in this chapter, the effect of any change in total fat intake on BP is often confounded by changes in other dietary factors or use of fat supplements. Thus the BP responses may not be attributed solely to the change in fat intake. In a crossover randomized study, consumption of a single high-fat meal (42 g) was found to increase both SBP and DBP significantly more than a low-fat meal did (1 g) [174]. Ferrara et al. [175] investigated the effect of MUFA versus PUFA on BP in a 6-month double-blind randomized crossover study. The MUFA diet reduced SBP and DBP significantly more than the PUFA diet. Later, Appel et al. [26] reported that substituting MUFA for saturated fats significantly reduced SBP by 2.9 mmHg in a group of 191 subjects with prehypertension or stage I hypertension. This study finding suggests that a high-fat intake (37% energy) mainly provided as MUFA, in combination with other beneficial dietary factors, can effectively lower BP.

Many short-term intervention trials have been undertaken to determine whether supplementation of either fish or fish oil lowers BP. Because of variations in research design, participant criteria, dosage and type of supplements, and length of intervention, the results have been inconsistent. A meta-analysis of RCTs (36 of which included fish oil) explored the impact of fish oil intake on hypertension prevalence in five populations (Finland, Italy, the Netherlands, the United Kingdom, and the United States) [176]. Pooled metaregression of data from these trials showed that a 4.1 g supplement of fish oil was associated with a 2.1/1.6-mmHg decrease in SBP/DBP. Further a RCT testing 5 oil supplements varying in amounts of *n*-3, *n*-6, and *n*-9 fatty acids among 130 adults found that a high oleic acid, canola oil, with DHA significantly reduced SBP after 4 weeks [177]. Other oil blends did not reach significant BP impact. An olive oil supplement also was found to reduce SBP after 3 months among 41 older adults [178]. When fish intake was examined with its potential impact on BP, one study found a

beneficial association with BP while the other found no effect [179,180].

3 Mechanism

Research has suggested that increased intake of total fat and saturated fats may impair endothelial function, which may subsequently affect BP (Fig. 28.1). Conversely diets rich in omega-3 fatty acids may improve endothelial function and therefore lower BP, the exact mechanism is unclear. How fat intake and various fatty acids affect BP and whether an interaction exists among these factors awaits future research.

4 Summary

Despite the promising benefit of MUFA, PUFA, or fish oil on BP, long-term studies are required to confirm the benefit. Until such information is available, it is more advisable to encourage greater fish consumption as part of a healthy diet than taking fish oil supplementation. Further the current dietary guidelines for Americans in minimizing saturated fats and replacing with MUFA and PUFA should be encouraged [50].

C Carbohydrates

Very few observational and interventional studies have been designed specifically to investigate the impact of the quantity or type of carbohydrate intake on BP. Nevertheless studies of the relationship between fat intake and BP often alter intakes of both fat and carbohydrate while keeping protein intake constant. Thus interpretation of the effect of dietary fat on BP is potentially confounded by the effects from dietary carbohydrate. Nonetheless these studies provide some observation on the potential impact of carbohydrate intake on BP.

1 Observational Studies

As mentioned earlier examination of carbohydrate intake is often confounded by other nutrients or dietary factors. Using the NHANES III data quintile of carbohydrate intake was not associated with the risk for increased SBP ($\geq$140 mmHg) after adjustment for potential confounders and total sugar intake [181]. In fact, three cross-sectional studies, using NHANES 1999–2004 and 2003–2006 data, showed that sugary drinks or fructose consumption was positively associated with a higher BP [182–184]. Yet a cross-sectional study of 814 youth did not find a significant association between fructose intake and BP [185]. In a secondary analysis of the PREMIER clinical trial data, reduction of sugary drink was also found to be associated with a decreased SBP/DBP [186]. Similar finding were observed in one study of 320 children [187] but not another study of 2286 youth with type 1 diabetes [188]. Together these findings suggest a negative impact of simple carbohydrate intake on BP. Further a high intake of whole grains has been shown to be associated with a reduction of hypertension risk in the Women's Health Study [189] and the Health Professionals Follow-up study [190].

2 Interventional Studies

Manipulation of the amount of carbohydrate in interventional studies is often associated with changing intake of other nutrients if total energy is to be kept constant. In the context of whole dietary pattern change, various levels of carbohydrate intakes in combination with other dietary changes have been associated with various findings in BP lowering [24,26,181,191–193].

Some human studies have examined the impact of the type of carbohydrate on BP, but the studies have been limited in number and yielded inconsistent results. In one study [194] SBP rose significantly 1 hour after ingestion of a sucrose or glucose solution, but not after ingestion of fructose. In contrast, a fructose drink, but not glucose, was found to significantly increase SBP/DBP within 2 hours in another study [195]. However, in an earlier study of patients with coronary artery disease, both SBP and DBP decreased after 4-days of a sucrose and fructose load at 4 g/kg/day but not glucose load [196]. In another study that was designed to examine the metabolic effect of sucrose in a group of overweight women, BP was not changed over 6 weeks after consuming a hypocaloric diet with sucrose as the main source of carbohydrate [197]. A more recent RCT also showed that consuming sugar-reduced foods for 8 weeks had no impact on BP as compared to consuming regular sugar foods [198]. Similarly consuming a milk drink sweetened with either sucrose, high fructose corn syrup, fructose, or glucose daily for 10 weeks did not change BP or uric acid level among 267 adults [199].

In a meta-analysis comparing high-carbohydrate to high-monounsaturated fat diets, the high-carbohydrate diet resulted in slightly higher SBP/DBP (2.6/1.8 mmHg) while energy intake and weight were kept constant [200]. Thus the impact of the amount or type of carbohydrate on BP is still inconclusive.

3 Mechanism

Although not well understood, carbohydrate may contribute to the development of essential hypertension through its glycemic effect. Kopp [201] suggests that consumption of a high-glycemic-index diet may create a chronic state of postprandial hyperinsulinemia, sympathetic nervous system overactivity, and vascular remodeling of renal vessels leading to chronic activation of the renin–angiotensin–aldosterone system and

development of essential hypertension. Although logical, the relationship of a high-carbohydrate diet to high BP has not been consistent in all studies.

4 Summary

It is unclear if the amount of carbohydrate alone or the type of carbohydrate affect BP. Future research designed specifically to examine these questions is needed to help clarify the roles of carbohydrate in BP control. Nevertheless, evidence is strong that consuming whole grains may benefit BP and overall cardiovascular health and should be encouraged as the main type of carbohydrate source. Limiting simple carbohydrate such as sugar or sugar-sweetened foods may benefit BP control either directly or indirectly via weight control.

D Fiber

The impact of both the amount and type of fiber on BP has been examined by many studies.

1 Observational Studies

Both cross-sectional [146,202–204] and prospective analyses [205–207] have consistently demonstrated inverse associations between fiber intake and BP but have also noted a high correlation of fiber with other nutrients that can affect BP in a salutary manner. Intake of either total fiber or insoluble fiber have been associated with lower BP. Further dietary fiber intake has also been associated with a lower risk for stroke in a prospective study with 69,677 adults [207] and with a healthier profile of metabolic syndrome markers [204,208].

2 Interventional Studies

Many interventional studies have examined the effect of fiber on BP with varying modes of increasing fiber. Earlier studies suggest that an average supplementation of 14 g fiber reduces SBP/DBP by about 1.6/2.0 mmHg, respectively [209]. Similarly a meta-analysis of 25 RCTs between 1966 and 2003 demonstrates that fiber supplementation (average 11.5 g/day) leads to a reduction in SBP/DBP of 1.13/1.26 mmHg [210]. More recently another meta-analysis analyzed 18 RCTs lasting at least 6 weeks each from 1990 to 2013 and the intervention used either fiber isolate or fiber-rich foods. This analysis showed that all fiber types combined was significantly associated with lower DBP but not with SBP with each 1 g increase in total fiber associated with a 0.11 mmHg reduction in DBP [211]. However, a higher intake of a particular fiber type, β-glucan, was significantly associated with reduction in both SBP and DBP.

3 Mechanism

Potential mechanisms through which fiber may benefit BP include impact on postprandial glucose and insulin response, reduction of insulin levels [209], LDL-cholesterol lowering action and/or endothelial function [212]. This is supported by the observation that hyperinsulinemia is often associated with obesity, impaired glucose tolerance, and hypertension.

4 Summary

Thus, the previous evidence suggests a consistent and small beneficial effect of fiber on BP. Individuals should be encouraged to increase fiber intake to the current recommended level not only for BP control but possibly for other benefits to cardiovascular health. Such recommendations should be achieved by increasing fruits, vegetables, and whole grains based on the foundation of a healthy eating pattern rather than using a supplement.

IV OTHER FOODS AND DIETARY FACTORS

Many food items and dietary factors have been suggested to affect BP regulation with varying levels of evidence.

A Alcohol

1 Observational Studies

Alcohol consumption is directly associated with BP and with prevalence of hypertension in observational studies [213]. Earlier studies showed that men who consume three or more drinks per day [214], and women who consume two or more drinks per day [215] may be at higher risk, but levels below this are not associated with increased risk. In a cohort study of 8334 participants from the Atherosclerosis Risk in Communities (ARIC) study [216], participants were free of hypertension at baseline and were followed for 6 years. Risk of incident hypertension was increased by 20% in those who consumed greater than or equal to 210 g alcohol (78 oz. wine, 191 oz. beer, or 21 oz. liquor) per week as compared to those who did not consume alcohol.

Similarly in a prospective study of 28,848 women from the Women's Health Study and 13,455 men from the Physician' Health study free of hypertension at baseline, alcohol intake was positively and significantly associated with the risk of hypertension in men [217]. Whereas the association between alcohol intake and hypertension was J-shaped in women. The threshold above which alcohol became deleterious for hypertension risk occurred at ≥ 4 drinks/day in women versus ≥ 1 drink/day in men. In a meta-analysis of 16 prospective studies (33,904 men and 193,752 women), increased risk

of hypertension was associated with heavy alcohol consumption of 31−40 g/day (RR, 1.77; 95% CI: 1.39−2.26; $p < .001$) and >50 g/day (RR, 1.61; 95% CI, 1.38−1.87; $p < .001$) [218]. However, significantly increased risk was observed in women when alcohol consumption was 31−40 g/day (RR, 1.19; 95% CI: 1.07−1.32; $p < .002$) and a protective effect was observed at <10 g/day (RR, 0.87; 95% CI: 0.82−0.92; $p < .001$). Thus a J-shaped association between alcohol consumption and hypertension was also observed among the women participants of this study.

Alcohol intake was also shown to have a significant positive relationship with DBP in a linear regression analysis among 1968 adults of the French Nutrition and Health Survey but the association with SBP did not reach statistical significance [219]. Conversely red wine drinkers who consumed ≥1 drink/day had a lower risk of high BP in the cross-sectional PREDIMED study of 3897 adults [220].

Most observational studies seem to support an impact of alcohol on BP, but the relationship between type of alcohol consumed and BP is not consistent. Furthermore chronic habitual intake may be more related to BP than distant moderate to heavy drinking. In one study men who quit drinking alcohol during an 18-year follow-up period experienced less age-related increase in BP than those who did not [221]. A dietary pattern characterized by high drinking was also shown to associate with a higher risk for prehypertension and hypertension [222].

2 Interventional Studies

The relatively few intervention studies of alcohol and BP have tended to be small and of short duration. Cushman et al. [223] reviewed 12 RCTs of alcohol reduction on BP and concluded that a daily reduction of one drink lowers SBP and DBP by approximately 1 mmHg. The Prevention and Treatment of Hypertension Study (PATHS) [224] was designed to evaluate the long-term BP-lowering effect of reducing alcohol consumption in nondependent moderate drinkers (those who consumed more than 3 drinks/day). The goal of intervention was either two or fewer drinks daily or a 50% reduction in intake (whichever was less). After 6 months the intervention group experienced a 1.2/0.7 mmHg greater reduction in BP than the control group (NS), and among hypertensives, this reduction was more modest. In this study the intervention group reduced their intake by 2 alcoholic drinks/day, but the control group also lowered their alcohol intake during intervention, so that the difference in intake between the groups was only 1.3 drinks/day. This small difference between the two groups limits the interpretation of the true BP effect of the intervention group. In addition, perhaps a greater reduction in alcohol consumption is necessary to see a significant effect on BP. However, this level of reduction appears realistic in moderate alcohol drinkers and is similar to the absolute reduction achieved in an earlier study [225].

In another study [226] of mainly heavier drinkers (>5 drinks/day), replacing alcohol with low-alcoholic substitutes resulted in a reduction of approximately 5 drinks/week and a greater reduction in BP (−4.8/3.3 mmHg). Importantly this intervention also reduced body weight of the participants by an average of 2.1 kg, which may explain the larger BP reduction than that observed in the PATHS trial. However, in a meta-analysis [227] of 15 RCTs including a total of 2,234 participants who drank an average of 3−6 drinks/day at baseline, the effect of alcohol reduction on BP was explored. Reduced alcohol consumption, varying from 29% to 100% reduction from baseline, was associated with a significant reduction in mean SBP of −3.31 mmHg (95% CI: −2.52 to −4.10 mmHg) and DBP of −2.04 mmHg (95% CI: −1.49 to −2.58 mmHg), whereas the body weight was minimally changed (mean change: −0.56 kg). There was a dose-response relationship between the mean percentage of alcohol reduction and mean percentage of BP reduction. Effects of intervention were enhanced among those with higher baseline BP.

3 Mechanism

The exact mechanism for an alcohol−BP association is not clear, but possibilities include stimulation of the sympathetic nervous system, inhibition of vascular relaxing substances, calcium or magnesium depletion, and increased intracellular calcium in vascular smooth muscle [213,228,229]. Further the impact of alcohol on BP may also be influenced by a genetic polymorphism in the aldehyde dehydrogenase-2 [230].

4 Summary

Limiting alcohol consumption to the current recommendation of two or fewer drinks per day for men and one or fewer for women is supported by most research evidence and will likely improve BP. There is no need to recommend total abstinence; indeed, light to moderate alcohol consumption has been associated with a reduced risk of multiple cardiovascular outcomes [231] and may be protective against ischemic stroke [232].

B Garlic

Garlic has been shown by many studies to affect BP and most are interventional in nature.

1 Observational Studies

None identified.

2 Interventional Studies

In a meta-analysis of 20 RCTs with 970 participants, garlic reduced SBP/DBP by $5.1 \pm 2.2/2.5 \pm 1.6$ mmHg among all participants and by $8.7 \pm 2.2/6.1 \pm 1.3$ mmHg among those with hypertension [233]. Another umbrella review of eight meta-analyses synthesizing data from both observational and RCTs reported consistent findings of an effect of garlic on BP. Seven of the eight analyses showed a significant reduction in SBP while six of the eight analyses showed a significant reduction in DBP from garlic supplementation [234].

3 Mechanism

Garlic contains many bioactive compounds that may have antioxidative function and allicin may be the most effective compound in lowering reactive oxygen species and stimulating the production of antioxidative substances such as glutathione [235]. Garlic may also affect BP by improving endothelial function [236].

4 Summary

The evidence is consistent that garlic may benefit BP regulation. Various amounts of garlic extract or powder have been used in the interventional studies, ranging from 600 to 2400 mg/day (3.6−13.6 mg allicin) or approximately 2 g raw garlic per day (5−9 mg allicin). Since rare adverse effect has been reported from garlic supplements, this may be an effective and safe strategy to improve BP.

C Flavonoid

Flavonoid includes a group of phytochemicals that may benefit health conditions including CVD and hypertension [237]. Studies examining the impact of flavonoids have employed either supplements or flavonoid-rich foods such as fruits, and vegetables, and thus the association may be attributed to other beneficial factors in addition to flavonoid.

1 Observational Studies

Observational study [238] has shown a lower increase in BP over time when dietary intake of fruits and vegetables was high. Intake of a flavonoid subclass-anthocyanin was found to be inversely related to clinic SBP [239] or risk of hypertension [240]. In a more recent prospective cohort of 40,574 disease-free French women at baseline, intakes of total flavonoid, flavonol, anthocyanins, and proanthocyanidin polymers were found to be significantly and inversely associated with rate of hypertension [240]. Women in the highest quintile had a 9−10% lower rate of hypertension as compared to those in the lowest quintile. Thus these studies support an inverse association between flavonoids and BP.

2 Interventional Studies

Many studies have examined the impact of either flavonoid products or flavonoid-rich foods such as chocolate, tea, fruits, and vegetables on BP. Supplementing 1.4 g/day cocoa extract for 4 weeks reduced postprandial SBP significantly in 24 obese participants [241]. Similarly consuming a cocoa flavonol (450 mg) drink twice daily for a month reduced SBP/DBP significantly (−4.4/3.9 mmHg) [242]. Supplementing 520 mg or 993 mg of cocoa flavanol daily for 8 weeks also reduced BP significantly in 90 elderly individuals [243]. Quercetin appears to be a subclass of flavonoid that has shown more consistent impact on BP [237,244]. However, other studies have not supported an impact of flavonoids or flavonoid-rich foods on BP [245,246]. A meta-analysis of RCTs testing flavonoids or flavonoid-rich foods on endothelial function and BP showed significant effect on BP (−1.46/ − 1.25 mmHg) [247]. In another meta-analysis of 20 RCTs, 30−1080 mg of flavanols (3.6−105 g cocoa products per day) for 2−18 weeks was found to significantly reduce BP by 2.8/2.2 mmHg (both $p < .01$).

Tea is rich in flavonoid and has been suggested to benefit cardiovascular health including BP. Three meta-analyses examined 20, 25, and 13 RCTs separately but included many of the same RCTs in the analyses [248−250]. These analyses concluded that tea consumption reduced BP significantly, ranging from −1.94 to −2.6 mmHg in SBP and from −1.17 to −2.2 mmHg in DBP.

Other flavonoid-rich foods that have been suggested to benefit BP control include beetroot [251,252], dark chocolate [253,254], and grape or grape seed extracts [255,256], however, the evidence is relatively weak due to small sample size. Thus the potential impact of flavonoids or flavonoid-rich foods on BP regulation remains to be clarified and confirmed in properly powered trials.

3 Mechanism

Potential mechanisms of flavonoids' impact on BP regulation are related to its antiinflammatory and antioxidant nature [257]. Flavonoids may benefit BP by improving endothelial function and/or increasing the bioavailability of the vasodilator nitric oxide.

4 Summary

The evidence supports a potential impact of flavonoids or flavonoid-rich foods on BP regulation, however, the impact may be moderate and long-term effect is unclear. Incorporating flavonoid-rich foods like fruits and vegetables is consistent with current recommendation to

prevent or manage hypertension. Other flavonoid-rich foods like tea and cocoa-containing products may also be incorporated into a healthy BP-friendly pattern.

D Vitamin D

Many studies have examined the potential impact of vitamin D on BP or risk for hypertension.

1 Observational Studies

In cross-sectional analyses of data from NHANES III, serum vitamin D was inversely associated with BP [258] and optimal vitamin D status was significantly associated with a decreased age-related increase in SBP by 20% [259]. Data from two large cohort studies also showed that plasma 25(OH)D level was significantly and inversely associated with risk of incident hypertension [260]. Dietary intake of vitamin D, but not vitamin D supplementation, was associated with a lower risk for hypertension [261]. But not all observational studies showed a significant association between either dietary vitamin D intake or serum vitamin D with BP [84,262].

2 Interventional Studies

Many studies have examined the effect of vitamin D supplementation on BP. In a large meta-analysis of 46 RCTs, vitamin D supplement of ≥ 4 weeks did not show an effect on BP [263]. Similarly studies conducted after this meta-analysis did not support an impact of vitamin D supplementation on BP either [264–266].

3 Mechanism

Vitamin D was suggested to be a potent endocrine suppressor of renin biosynthesis and vitamin D deficiency stimulates renin expression [267].

4 Summary

Despite the potential impact of vitamin D on BP, the overall evidence is weak and the strength of impact may be small. Nevertheless vitamin D intake tends to be inadequate in many individuals, thus it is important to encourage regular consumption of vitamin D rich foods such as dairy and certain fish like tuna and salmon.

V DIETARY PATTERNS

The previous sections on micro- and macronutrients highlight extensive confounding due to simultaneous changes in multiple nutrients. It is difficult to study (and change) one component of the diet without affecting others. Thus it may be more appropriate to focus on dietary pattern rather than on individual micro- and macronutrients, and indeed there is extensive evidence that dietary pattern affects BP. For example, vegetarian groups in the United States and abroad have been observed to have lower BP than their nonvegetarian counterparts in many [268,269] but not all studies [270]. The term *vegetarian* comprises several heterogeneous groups [271], but in general, the diet tends to be high in whole grains, beans, vegetables, and sometimes fish, dairy products, eggs, and fruit [272]. Aspects of the vegetarian diet suggested to benefit BP include ample amount of plant foods, a low intake of animal products [269], and a high potassium, magnesium, fiber, (sometimes) calcium [271,272], a high ratio of polyunsaturated to saturated fat, and often a low sodium intake. However, as outlined in previous sections of this chapter, studies on individual nutrients have shown inconsistent results. Explanations for such inconsistencies may include the following: (1) The effect of individual nutrients may be too small to be detected, particularly when trials contain insufficient sample size and thus statistical power; (2) most intervention studies employed supplements of nutrients, which may function differently from nutrients in foods; (3) other dietary factors naturally occurring in foods that are not hypothesized to affect BP may also have an impact on BP; and (4) nutrients occurring in foods simultaneously may exert synergistic effects on BP. Clearly, differences in physical activity, stress, alcohol consumption, and other unmeasured factors may also contribute to a lower BP among vegetarians. But when research participants were counseled to follow the vegetarian diet pattern in intervention studies, significant reductions in BP in both nonhypertensive [273] and mildly hypertensive [272] participants were reported.

Despite the clear BP effect of a vegetarian diet, it is not realistic to expect a wide-scale adoption of this dietary pattern. In addition, a vegetarian diet does not include all dietary factors associated with lower BP. Thus the DASH multicenter trials were designed to test the impact of whole dietary patterns on BP simultaneously while controlling for multiple nutrients, weight, and dietary factors [24,25].

A The Dietary Approaches to Stop Hypertension Dietary Pattern

The original DASH trial [24] was an 11-week randomized controlled feeding trial of 459 individuals with prehypertension or stage I hypertension. Three dietary patterns varying in amounts of fruits, vegetables, dairy products, meats, sweets, nuts, and seeds and thus fats, cholesterol, fiber, calcium, potassium, and magnesium were tested (Table 28.2). In brief, the dietary patterns were (1) the control diet, which mimicked what most

TABLE 28.2 Nutrient Targets for the Three Dietary Patterns Tested in the DASH Trial

Item	Control Diet	Fruits and Vegetables Diet	DASH Diet
Nutrients (2100 kcal/day)			
Fat (% kcal)	37	37	27
Saturated (% kcal)	16	16	6
Monounsaturated (% kcal)	13	13	13
Polyunsaturated (% kcal)	8	8	8
Carbohydrates (% kcal)	48	48	55
Protein (% kcal)	15	15	18
Cholesterol (mg/day)	300	300	150
Fiber (g/day)	9	31	31
Potassium (mg/day)	1700	4700	4700
Magnesium (mg/day)	165	500	500
Calcium (mg/day)	450	450	1240
Sodium (mg/day)	3000	3000	3000
Food groups (servings/day)			
Fruits and juices	1.6	5.2	5.2
Vegetables	2.0	3.3	4.4
Grains	8.2	6.9	7.5
Low-fat dairy	0.1	0.0	2.0
Regular-fat dairy	0.4	0.3	0.7
Nuts, seeds, and legumes	0.0	0.6	0.7
Beef, pork, and ham	1.5	1.8	0.5
Poultry	0.8	0.4	0.6
Fish	0.2	0.3	0.5
Fat, oils, and salad dressing	5.8	5.3	2.5
Snacks and sweets	4.1	1.4	0.7

Americans were consuming at the time the trial was conducted; (2) a fruits and vegetables diet, which contained a macronutrient profile similar to that of the control diet except with a higher amount of fruits and vegetables; and (3) the DASH dietary pattern, which was higher in fruits, vegetables, and low-fat dairy products; lower in total and saturated fats and cholesterol; and rich in fiber, potassium, magnesium, and calcium. Sodium intake, body weight, and alcohol consumption were kept constant throughout the intervention.

The DASH dietary pattern reduced BP by 5.5/3.0 mmHg more than the control group (both SBP and DBP $p < .001$). The fruits and vegetables diet reduced BP by 2.8/1.1 mmHg more than the control diet ($p < .001$ for SBP and $p = .07$ for DBP). The reductions in BP were significant after participants consumed the diets for 2 weeks and were sustained for the following 6 weeks (Fig. 28.3). In addition, BP lowering was similarly effective in men and women and in younger and older persons, and it was particularly effective among African Americans and those who had high BP. These reductions occurred while body weight, sodium intake, alcohol consumption, and exercise patterns remained stable. Of note, sodium intake was not reduced and was identical in all treatment groups (3000 mg/2100 kcal/day). Among the 133 participants with hypertension (SBP $\geq$ 140 mmHg and/or DBP $\geq$ 90 mmHg), the DASH dietary pattern lowered SBP and DBP by 11.4 and 5.5 mmHg, respectively. These effects in hypertensives are similar to reductions seen with single-drug therapy [274] and more effective

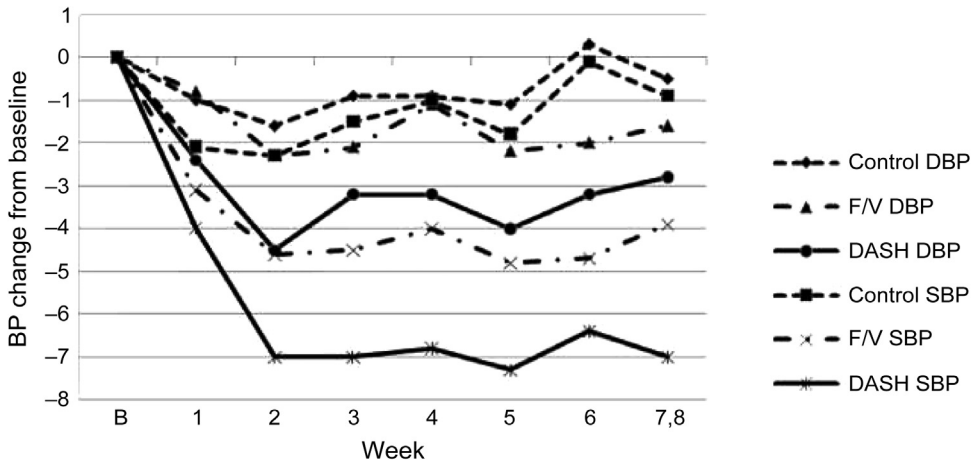

FIGURE 28.3 Mean changes in systolic and diastolic blood pressures from baseline during each intervention week, according to diet, for participants in DASH study.

than most of the other lifestyle modifications for BP reduction (Table 28.3).

Even though the DASH trial was not designed to identify specific nutrient(s) responsible for the BP-lowering effect, data from the fruits and vegetables group support the hypothesis that increasing potassium, magnesium, and dietary fiber intake reduces BP. In addition, by further lowering total and saturated fat and cholesterol, and increasing low-fat dairy products in the DASH dietary pattern, BP reduction was nearly doubled compared to the fruits and vegetables diet. Because whole food items rather than single nutrients were manipulated in this trial, other nutrients that were not controlled for in the study or other beneficial factors as yet unrecognized may also have contributed to the BP responses. Further research is needed to analyze the specific nutrients or factors responsible for the BP effect. Further details on DASH can be found on the following web site: http://www.nhlbi.nih.gov/health/resources/heart/hbp-dash-index.

B Variations of the DASH Dietary Pattern

Even though the DASH trial provided strong evidence of the efficacy of the DASH dietary pattern in reducing BP, this trial alone was not able to test all hypotheses related to dietary pattern and BP. As discussed in the previous sections, research suggests that a high unsaturated fat intake and high-protein intake may benefit BP. Thus the OmniHeart study [26] was designed to further understand the impact on BP of macronutrient variations of the DASH dietary pattern. The dietary patterns tested were (1) the DASH dietary pattern with a slight reduction in total protein (called the carbohydrate diet, with 15% kcal protein instead of 18% tested in the original DASH trial); (2) the DASH dietary pattern with 10% of the carbohydrate energy replaced with unsaturated fats (called the unsaturated fat diet with mainly monounsaturated fats); and (3) the DASH dietary pattern with 10% of the carbohydrate energy replaced with protein (called the protein diet). A total of 164 adults with prehypertension or stage I hypertension were randomized into the three diets in a crossover fashion for 6 weeks each. All three diets lowered BP significantly but the protein and unsaturated fat diets significantly reduced SBP by 1.4 and 1.3 mmHg more than the carbohydrate diet. The further reductions in BP were even greater among those who were hypertensive at baseline.

Thus, these studies have vigorously and consistently proven that whole dietary patterns such as the DASH dietary pattern or the two modified DASH patterns in the OmniHeart study are effective strategies for BP control. As noted earlier DASH in combination with reduced sodium intake lowers BP more than either intervention alone [25]. In addition, both the DASH and OmniHeart studies demonstrate that benefits of adopting a whole dietary approach extend beyond BP to other health indicators such as lipids [26,275]. Many recent observational studies also have consistently shown that consuming healthy dietary patterns such as DASH, the Mediterranean pattern or that recommended by the Dietary Guidelines for Americans is associated with either a lower SBP, DBP, both or risk of hypertension [276–284]. Conversely, dietary patterns associated with more fried food, higher energy density, saturated fat intake and lower fiber intakes have been associated with a higher BP [285,286]. Further, the DASH dietary pattern was shown to enhance the BP response to BP-lowering medication (Losartan) in hypertensive patients [287].

Intervention studies that counseled participants on following the DASH dietary pattern or other healthy patterns also have shown consistent benefit on BP. A meta-analysis of 17 RCTs showed that following the DASH dietary pattern significantly reduced SPB/DBP by 6.74/3.54 mmHg [288]. RCTs testing intervention with

TABLE 28.3 Summary of Evidence Relating Dietary and Lifestyle Factors with BP

Dietary Factors	Strength of Relationship with BP	Direction of Association	Strength of Impact (mmHg)	Potential Mechanism	Recommendation	Those Most Likely to Benefit
Potassium	1A	Inverse	2−11	Vasodilatory; natriuretic	Increase potassium-rich foods to 4700 mg/day	Those consuming high salt diet
Sodium	1A	Direct	2−8	Changes in blood volume and BP regulating hormones	<2300 mg/day (<65−100 mmol/day)	Hypertensives, salt-sensitive individuals, African Americans, elderly, and those consuming typical Western diet
Calcium	2A	Inverse	1−2	Regulation of parathyroid hormone (PTH) and intracellular calcium; natriuretic	2−3 reduced fat dairy products per day	Possibly salt-sensitive individuals
Magnesium	2B	Inverse	1−2	Modification of Na-K/ATPase activity	Maintain adequate magnesium intake	Those depleted in magnesium, e.g., from diuretics
Vitamin C	1B	Inverse	1−3	Endothelial function, arterial stiffness, and vasodilation	Diet rich in fruits and vegetables	
Protein	2A	Inverse	1−2	BP-related amino acid may act as vasodilator	Consume adequate protein, particularly plant sources; limit high fat animal protein	
Fat	1C	Direct for saturated fat, inverse for monounsaturated fats	2−3	Vasodilatory action of prostaglandins (PGE)	Moderate total fat, include more monounsaturated fat, reduce saturated fat	
Carbohydrates	2B	−	2−3		Consume more whole grains and less sugar or sugar-sweetened products	
Fiber	1A	Inverse	1−2	Possible reduction of insulin, lipids, and action on endothelial functions	Increase fiber-rich foods for overall health	Those who have insulin resistance or impaired glucose tolerance
Alcohol	1B	Direct	2−4	Possible action on sympathetic nervous system, inhibition of vascular relaxing substances, calcium, and magnesium depletion	Moderate consumption: ≥2 drinks/men, ≥1 drink/women	Those consuming >2−3 drinks/day
Body weight	1A	Direct	5−20	Lowering blood volume, cardiac output, and insulin resistance, and raising salt sensitivity	Maintain healthy weight; lose weight if overweight or obese	Overweight and obese individuals
Dietary patterns	1A	Depends on factors	5−14	Multiple mechanisms, as above	Follow DASH, Omni-Heart or Mediterranean dietary pattern	All individuals, those at risk for or with hypertension

1A, clear, consistent, and strong randomized controlled trial (RCT); IB, clear RCT but inconsistent results; 1C+, clear, no RCT but strong observational studies; 1C, clear, observational studies; 2A, unclear, consistent RCT—intermediate strength; 2B, unclear, RCT with inconsistent results; 2C, unclear, observational studies.

Mediterranean dietary pattern supplemented with olive oil or nuts, or the Nordic diet also significantly reduced BP [289–291].

Thus a nutritional approach to BP control that involves changes in overall dietary pattern appears to be superior to approaches that manipulate only a small number of nutritional factors. Consuming a healthy dietary pattern such as DASH is effective in lowering BP and may reduce risk for hypertension, CHD, stroke [292], CVD, and heart failure [293]. Further a meta-analysis of 15 cohort studies concluded that following the DASH dietary pattern is associated with a significant reduction in risk of all-cause mortality, CVD, cancer, and type 2 diabetes mellitus [294]. Thus the recommendation to follow DASH may benefit health beyond BP.

VI WEIGHT REDUCTION AND MULTILIFESTYLE MODIFICATION

BP is closely related to body weight and weight loss alone is an effective strategy for BP reduction. Potential mechanisms for the effect of weight loss on BP include suppression of sympathetic nervous system activity, lowered insulin resistance, normalization of BP regulating hormones [295], decreased body sodium stores, decreased blood volume and cardiac output, and reduction of salt sensitivity [296–298].

A Observational Studies

Several observational studies have reported a positive relationship between several indices of body weight or body fatness with BP [299–303]. Fall et al. analyzed data from 30 studies using a Mendelian randomization approach concluded that adiposity has a significant causal effect on BP [304].

B Intervention Studies

Several large-scale clinical trials have been conducted to evaluate different lifestyle modification programs on BP, several of which provide evidence for a BP-lowering effect of weight loss. For example, in the TOHP Phase I [305], weight loss was found to be the most successful intervention in lowering BP compared to sodium reduction, stress management, or nutritional supplements (calcium, magnesium, or potassium). At the 6-month follow-up, men and women in the intervention group lost 6.5 and 3.7 kg, respectively. This level of weight loss was achieved with a fairly rigorous counseling approach aimed at simultaneously reducing energy intake and increasing exercise [306]. At study termination BP fell an average of 2.9/2.3 mmHg overall (after subtracting the BP change in the control group). In this study, some recidivism occurred, and at 18 months, men had maintained a 4.7-kg weight reduction and women, 1.6 kg. After 7 years' follow-up in a subset of study participants, the odds of developing hypertension were reduced by 77% in the weight loss group [307], even though their long-term weight loss was nearly identical to that of the control group (4.9 kg and 4.5 kg, respectively).

As a follow-up to TOHP Phase I, TOHP Phase II [28] was conducted to examine the effects of weight loss and dietary sodium reduction alone, and in combination, on BP in overweight adults. The intervention lasted 3 years and included individual and group counseling meetings focusing on diet, exercise, and social support. The weight loss intervention group ($n = 595$) achieved a mean reduction in weight from baseline to 6 months of 4.4 kg, 2.0 kg at 18 months, and 0.2 kg at 36 months. BP was significantly lower at all time points mentioned and the greater the weight loss, the greater the BP reduction. At 36 months every kilogram of weight loss was associated with a reduction of 0.35/0.45 mmHg in SBP/DBP. Further this weight loss intervention was associated with a 42% reduction in incident hypertension.

This rigorous study not only provides the evidence of BP-lowering effect of weight loss but also supports the possibility of sustaining BP effect after weight recidivism.

In a meta-analysis of 25 RCTs, weight loss of 1 kg was associated with approximately 1 mmHg reduction in both SBP and DBP in individuals with prehypertension [308]. Thus the evidence of an effect of weight loss on BP is strong and consistent. Since weight loss often involves change in dietary pattern, energy restriction, and increased physical activity, implementing multiple simultaneous lifestyle changes to lose weight and improve dietary quality may be an effective strategy for lowering BP.

In the PREMIER clinical trial [29], the effects on BP of two multicomponent lifestyle interventions compared to an advice-only control group were tested for 18 months. The two behavioral interventions were designed to stimulate adoption of what were at the time the well-established lifestyle guidelines for BP control (EST) or the well-established guidelines plus the DASH dietary pattern (EST+DASH). The well-established guidelines included weight loss if overweight (95% of participants), reducing sodium intake to less than 2300 mg/day, increasing physical activity to 180 minutes of moderate activity per week, and alcohol consumption not exceeding 2 drinks/day for men and 1 drink/day for women. A total of 810 individuals were randomized and completed the study. Participants in both intervention groups significantly reduced weight, improved fitness, and lowered sodium intake, and the EST+DASH group also increased fruit, vegetable, and dairy intake. Mean reduction in SBP, net of the control group, was 3.7 mmHg ($p < .001$) in EST group and 4.3 mmHg ($p < .001$) in EST+DASH

group [29]. Each individual lifestyle modification was independently and significantly associated with SBP reduction at 6 and 18 months [309].

Since PREMIER tested the effects of DASH within a combined lifestyle intervention program which included weight loss, sodium reduction, and increased physical activity, the effect of DASH dietary pattern alone among free-living individuals is not clear. The ENCORE study was thus designed to compare the DASH diet alone or combined with a weight management program with usual diet controls among 144 participants with prehypertension or stage I hypertension in a RCT [310]. Clinic BP reduced by 11.2/7.5 mmHg in the DASH alone group and by 16.1/9.9 mmHg in the DASH plus weight management group. Similar patterns were observed for ambulatory BP, pulse wave velocity, baroreflex sensitivity, and left ventricular mass (all $p < .05$). Thus this study confirms the BP-lowering effect of the DASH dietary pattern in a free-living situation and the improvement in vascular, autonomic function, and reduction in left ventricular mass.

Overall these studies demonstrate that individuals can make multiple dietary and lifestyle changes to reduce BP. Although recidivism is often observed, the beneficial effect of lifestyle changes on BP may last beyond the intervention period. Thus it is important to disseminate proven effective intervention strategies and to develop and test new strategies to help individuals maintain these changes long term.

VII CURRENT RECOMMENDATIONS AND IMPLEMENTATION

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High BP was appointed by the National Heart Lung and Blood Institute to provide evidenced-based clinical guidelines for the prevention and management of hypertension [311]. Current lifestyle guidelines include salt reduction, moderate alcohol consumption, weight loss if overweight, increased potassium intake, regular moderate or vigorous exercise, and following a healthy eating pattern like DASH (Table 28.4). These lifestyle modifications are all recommended as part of the first-line therapy for low-risk individuals, defined as those without diabetes or CVD and with SBP less than 160 mmHg and DBP less than 100 mmHg. They are also recommended in combination with pharmacotherapy for high-risk individuals. These recommendations also apply to individuals with prehypertension in order to prevent the development of high BP.

Although much evidence indicates that diet and lifestyle modification can prevent and treat hypertension, recent reports suggest that about half of hypertensives are not well controlled (SBP/DBP < 140/90 mmHg) [6]. The full potential of diet and lifestyle modification for treatment remains underutilized and poorly realized, both because dietary causes of hypertension have not been completely identified, and because of poor adherence of both the clinicians and the public alike to the established medical and dietary guidelines. Despite data linking overweight and obesity to numerous adverse health outcomes including hypertension, clear guidelines for weight control, and a plethora of weight loss programs, the obesity epidemic continues to grow. Similarly despite clear and long-standing recommendations to reduce sodium intake to 2300 mg/day or less, the average intake in the United States remains around 3400 mg/day. Furthermore according to the 1999–2000 NHANES survey [312,313], Americans are consuming far less than the nationally recommended amounts of fruits, vegetables, fibers, calcium, magnesium, and potassium—all of which are key components of the DASH dietary pattern [314]. During 2007–2010, half of the total US population consumed <1 cup of fruit and <1.5 cups of vegetables daily; 76% and 87% did not meet fruit and vegetable intake recommendations, respectively [315].

Clearly implementing dietary and lifestyle modifications is challenging. Lessons learned from past research indicate that behavioral intervention programs that result in successful behavior change are rooted in social cognitive theory [316] and techniques of behavioral self-management [317]. They are ideally constructed using the transtheoretical or stages-of-change model [318,319] and use motivational enhancement approaches [320,321]. These approaches emphasize the importance of the individual's ability to regulate behavior by setting goals, developing specific behavior change plans, monitoring progress toward the goals, and attaining skills necessary to reach the goals. Self-efficacy (one's confidence in performing a given behavior) and outcome expectancies (one's expectations concerning the outcome of that behavior) are critical mediators of behavior change [321,322]. The transtheoretical model recognizes that behavioral change is a dynamic process of moving through different motivational stages of readiness for change. Different behavioral strategies may need to be emphasized at different times, depending on the individual's stage of change.

In addition, behavioral interventions conducted with small groups can take advantage of the economy of scale and the social support provided by a group of peers. In the PREMIER trial of lifestyle intervention for lowering BP, the behavioral strategies discussed earlier were incorporated into an intervention consisting of frequent group sessions conducted by a trained interventionist. It is also important that any intervention program make efforts to create a culturally appropriate behavioral intervention. Such effort may include but is not limited to (1) having

TABLE 28.4 The DASH Eating Plan

Food Group	Daily Servings	Serving Sizes	Examples and Notes	Significance of Each Food Group to the DASH Eating Plan
Grains[a]	6–8	1 Slice bread 1 oz. dry cereal 1/2 cup cooked rice, pasta, or cereal[b]	Whole wheat bread and rolls, whole wheat pasta, English muffin, pita bread, bagel, cereals, grits, oatmeal, brown rice, unsalted pretzels, and popcorn	Major sources of energy and fiber
Vegetables	4–5	1 cup raw leafy vegetable 1/2 cup cut-up raw or cooked vegetable 1 cup vegetable juice	Broccoli, carrots, collards, green beans, green peas, kale, lima beans, potatoes, spinach, squash, sweet potatoes, tomatoes	Rich source of potassium, magnesium, and fiber
Fruits	4–5	1 medium fruit 1/4 cup dried fruit 1/2 cup fresh, frozen, or canned fruit 1/2 cup fruit juice	Apples, apricots, bananas, dates, grapes, oranges, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Fat-free or low-fat milk and milk products	2–3	1 cup fat-free milk or yogurt 1½ oz. cheese	Fat-free (skim) or low-fat (1%) milk, fat-free low-fat, or reduced-fat cheese, fat-free or low-fat regular or frozen yogurt	Major sources of calcium and protein
Lean meats, poultry, and fish	< 6	1 oz. cooked meats, poultry, or fish 1 egg[c]	Select only lean; trim away visible fats; broil roast, or poach; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	4–5 per week	1/3 cup or 1 1/2 oz. nuts 2 tbsp peanut butter 2 tbsp or ½ oz. seeds 1/2 cup cooked dry beans or peas	Almonds, filberts, mixed nuts, peanuts walnuts, sunflower seeds, kidney beans, lentils, split peas	Rich sources of energy, fiber, magnesium potassium, and protein
Fats and oils[d]	2–3	1 tsp soft margarine 1 tsp vegetable oil 1 tbsp mayonnaise 2 tbsp salad dressing	Soft margarine, vegetable oil (e.g., olive, corn, canola, or safflower), low-fat mayonnaise, light salad dressing	The DASH study had 27% of calories as fat, including fat in or added to foods
Sweets and added sugars	< 5 per week	1 tbsp sugar 1 tbsp jelly or jam 1/2 cup sorbet, gelatin 1 cup lemonade	Fruit-flavored gelatin, fruit punch, hard candy, jelly, maple syrup, sorbet and ices, sugar	Sweets should be low in fat

[a] *Whole grains are recommended for most grain servings.*
[b] *Serving sizes vary from 1/2 to 1 1/4 cups, depending on cereal type. Check the product's Nutrition Facts label.*
[c] *Because eggs are high in cholesterol, limit egg yolk intake to no more than 4/week; 1 egg white has the same protein content as 1 oz. of meat.*
[d] *Fat content changes serving counts for fats and oils. For example, 1 tbsp of regular salad dressing equals 1 serving; 1 tbsp of a low-fat dressing equals 1/2 serving; 1 tbsp of a fat-free dressing equals 0 servings.*

intervention encounters take place at a location in the community; (2) employing staff from the same cultural background as participants; (3) selecting foods, music, or examples from within the culture; and (4) involving staff of the same cultural background in program design and in consultation with the potential participants. Despite considerable understanding of the theory and practice of behavior change, additional research is needed to develop effective strategies for sustaining dietary and lifestyle change long term.

VIII SUMMARY

The overall evidence that diet modification can prevent and treat hypertension is strong. The strength of evidence for various factors and respective recommendations are

summarized in Table 28.3. In some cases, the effective intervention strategy and mechanisms involved are still being clarified. Because of various design limitations, inadequate statistical power, and measurement issues, studies of single nutrients, with the exception of sodium, potassium, and fiber, have generally provided inconsistent results. However, when multiple nutrients or dietary factors are combined in a whole dietary strategy, as seen in the DASH and OmniHeart studies, BP is significantly and effectively reduced. Nutrients may have additive or interactive effects when provided together in whole foods. Thus, the current national guideline of lifestyle modification for BP control includes the DASH pattern, sodium reduction, weight loss, increased physical activity, and moderate consumption of alcohol. Concurrent adherence to several recommendations is likely to hold the greatest promise for preventing and treating hypertension and has been shown to be feasible. In addition to addressing unresolved nutritional hypotheses, future research should focus on strategies to motivate and maintain lifestyle changes long term for BP control. At both the population and individual levels, success in dietary and lifestyle intervention relies on multiple levels of support ranging from clinicians to government agencies to private institutes and industries. In particular, partnering with industry to improve the nutritional quality of the food supply, such as reducing sodium, sugar, and saturated and trans fat content of processed foods, and promoting foods and nutrients consistent with the DASH dietary pattern will play a critical role in implementing dietary and lifestyle modifications. Consistent efforts to educate and promote adherence to dietary and lifestyle guidelines by dietetic and other health care professionals are also instrumental to the prevention and management of hypertension.

To learn more about high BP, visit the NHLBI web site at <http://www.nhlbi.nih.gov/health/health-topics/topics/hbp>. DASH is also online at <http://www.nhlbi.nih.gov/health/health-topics/topics/dash>.

Chapter 29

Genetics and Diabetes

Yoriko Heianza[1] **and Lu Qi**[1,2]

[1]*Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, United States,* [2]*Harvard T.H. Chan School of Public Health, Boston, MA, United States*

I INTRODUCTION

Type 2 diabetes is a common chronic metabolic disease and its prevalence has been dramatically increasing around the world [1]. In patients with type 2 diabetes, both insulin secretion and insulin sensitivity are impaired, and chronic hyperglycemia is a major symptom [2]. Both genetic and nongenetic factors are involved in the development of type 2 diabetes. Discovery of rare mutations determining monogenic forms of diabetes provides direct evidence for the genetic basis of the disease. To map genetic variations affecting type 2 diabetes, initial methods mainly include family-based linkage analysis and candidate gene association analysis. Since the first genome-wide association study (GWAS) in 2007, more than 90 genome-wide significant susceptibility loci have been identified. Genetic variants affecting metabolic traits related to type 2 diabetes, especially glucose homeostasis (such as fasting glucose, insulin, insulin resistance, HbA1c, etc.), have also been identified, while these loci are not completely overlapping with type 2 diabetes loci. Most of the GWAS-identified genes are not previously considered to play roles in the pathophysiology of type 2 diabetes. Recent studies investigate causal variants and biological mechanisms responsible for the disease, and also explore potential interactions with environmental factors such as diet and lifestyle. In this chapter, we summarize recent advances in these research areas.

II DIAGNOSIS OF DIABETES AND NONGENETIC RISK FACTORS

According to the Seventh Diabetes Atlas from the International Diabetes Federation, it is estimated that approximately 415 million adults had diabetes worldwide in 2015, which is equivalent to 1 in every 11 adults with diabetes [1]. Without concerted action, the number of patients with diabetes could grow by 50% in the next 25 years, meaning that 642 million people would be affected [1]. Diabetes can be classified into the following four general groups: type 1 diabetes, type 2 diabetes, gestational diabetes mellitus (GDM), and specific types of diabetes due to other causes [3]. Type 1 diabetes accounts for 5−10% of diabetes cases, and is due to cellular-mediated autoimmune destruction of the pancreatic β-cells. GDM is diagnosed in pregnant women in their second or third trimester and is not clearly overt diabetes. Specific types of diabetes due to other causes include monogenic diabetes syndromes (such as neonatal diabetes and maturity-onset diabetes of the young, MODY), diseases of the exocrine pancreas, and drug- or chemical-induced diabetes. MODY accounts for a small number of patients with diabetes (<5%).

Type 2 diabetes accounts for ∼90−95% of diabetes cases, and is characterized by insulin resistance and impaired insulin secretion. Dysglycemia and insulin resistance can be observed even 10 years before the development of the disease [4,5]. Certain racial/ethnic subgroups (e.g., African-American, Latino, Native American, Asian American, Pacific Islander) are considered to be at high risk of developing diabetes [3]. Overweight or obesity is the most important risk factor for type 2 diabetes [6,7]. Weight gain from early adulthood has been also consistently related to diabetes risk [8,9]. Low birth weight, a marker of prenatal growth retardation, has been also consistently associated with an increased risk of type 2 diabetes [10,11]. Other environmental risk factors, including current smoking habit [12], dietary factors such as high intake of sugar sweetened beverages [13,14] or foods with high glycemic index (GI) and high glycemic load (GL) (GL: calculated by GI × carbohydrate ÷ 100) [15], and less

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00029-1

intake of coffee [16,17], whole grains [18], dietary fiber [19,20], or magnesium [21], have also been related to increased risk of type 2 diabetes. In epidemiological studies, high levels of physical activity such as brisk walking [22] and habitual muscle training [23,24] have consistently shown associations with reduced risk of diabetes. Recently, short sleeping duration and shift work were found to be related to an increased diabetes risk [25–27].

III HERITABILITY AND MONOGENIC FORMS OF DIABETES

There is extensive evidence for the heritability of type 2 diabetes. Type 2 diabetes is a well-known familial disease, and studies have estimated that risk for type 2 diabetes increased approximately two- to fourfold when one or both parents were affected [28–30]. In population studies, family history of diabetes has a significant, independent, and graded association with the prevalence of diabetes. In twin studies, very high concordance (55–100%) for type 2 diabetes has been reported among monozygotic (MZ) twins. Kaprio et al. examined a nationwide cohort of 13,888 Finnish twin pairs, in which the probandwise and pairwise concordance rates for type 2 diabetes were 34% and 20% among MZ twins and 16% and 9% in dizygotic (DZ) twins, respectively [31]. Poulsen et al. found probandwise concordance was 50% in MZ twins and 37% in DZ twins [32]. In general, twin and familial studies estimate that the heritability of type 2 diabetes ranges from 20% to 70% [32–35].

Identification of rare forms of diabetes, namely monogenic diabetes which results from mutations in a single gene, provides direct evidence to support the role of genetics in development of the disease (Table 29.1).

TABLE 29.1 Genes Involved in Monogenic Diabetes

Disease Region/Gene	Chromosome	Protein/Gene Function
Insulin Secretion Defect		
MODY		
HNF4A	20q13.12	β-Cell transcription factor

PPARG	3p25	Cellular signaling/fat differentiation
AKT2	19q13.1-q13.2	Cellular signaling
Type A Insulin Resistance		
Rabson–Mendenhall syndrome, Donohue syndrome		
INSR	19p13.3-p13.2	Insulin signaling

Neonatal diabetes mellitus (NDM) and MODY are the two main forms of monogenic diabetes. NDM, which first occurs in newborns and is diagnosed in the first 6 months of life, can either be transient (TNDM) or be permanent (PNDM). Fine-mapping and sequencing technologies have contributed to identifying the mutational spectrum of causal genes and an increased number of novel MODY genes in recent years. Currently, more than 30 different causal genes for NDM or MODY have been identified [36,37] (Fig. 29.1). NDM is most commonly due to a mutation in the *ABCC8* and *KCNJ11* encoding the Kir6.2 subunit of the β-cell K-ATP channel. Since such patients can be successfully managed with sulfonylureas as first-line therapy [38,39], testing for mutations in these genes is meaningful to make the diagnosis and provide effective treatment. MODY usually first occurs in children or adolescents and is characterized by autosomal dominant family history, continued production of endogenous insulin, absence of β-cell autoimmunity, and absence of signs of insulin resistance [40,41]. MODY is most commonly caused by mutations in the *HNF1A* or *GCK* (glucokinase) gene. Mutations in *ABCC8*, *GCK*, *HNF1B*, *INS*, *KCNJ11*, *NEUROD1*, and *PDX1* may lead to both NDM and MODY (Fig. 29.1) [37,42]. In addition, mutations in genes such as *WFS1*, *EIF2AK3*, *CISD2*, *WRN*, *FXN*, *HFE*, and *SLE19A2* also cause monogenic diabetes (Table 29.1) [37]. While most mutations in monogenic diabetes reduce the body's ability to produce insulin, some mutations in genes such as *AGPAT2*, *BSCL2*, *CAV1*, and *LMNA* mainly affect insulin resistance.

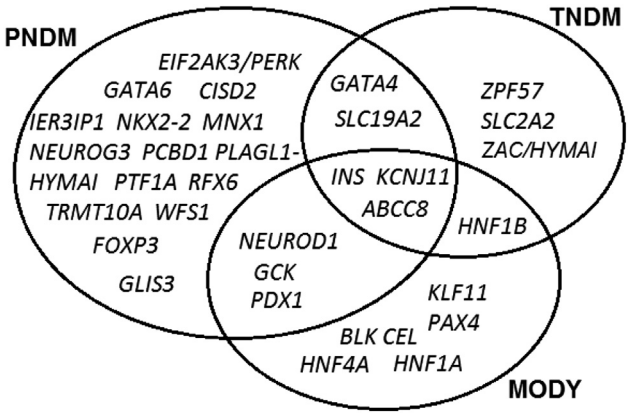

FIGURE 29.1 Monogenic diabetes genes associated with neonatal diabetes mellitus (transient [TNDM] or permanent [PNDM]) and/or MODY.

IV LINKAGE ANALYSIS AND CANDIDATE-GENE-BASED ASSOCIATION STUDIES

The traditional approach for mapping disease genes relies on linkage analysis in affected families followed by progressive fine-mapping of candidate linkage peaks [43]. Linkage is the tendency for genes and other genetic markers to be inherited together because of their position near one another on the same chromosome. Family-based linkage studies are successful in identifying rare variants with a large effect and highly penetrant mutations that underlie Mendelian disorders [44], but these studies are rarely successful in identifying genes that are involved in complex polygenic diseases, such as type 2 diabetes. As a successful example, Hanis conducted the genome-wide linkage scan in Mexican Americans and found a major susceptibility locus on chromosome 2 [45]. Subsequent positional cloning in this region led to the identification of two different haplotypes (121/112) within the *CAPN10* gene conferring higher risk for type 2 diabetes [46]. In 2006, Grant et al. found variants in the *TCF7L2* gene conferring 1.5-fold increased risk of type 2 diabetes in an Icelandic population through fine-mapping a region (chromosome 10q) identified by a previous linkage analysis [47]. The strong association of genetic variants in *TCF7L2* and type 2 diabetes has been consistently replicated in multiple studies, conferring an odds ratio (OR) of 1.4−1.5 per risk allele for type 2 diabetes, which stands out as having by far the biggest effect on diabetes risk [48,49]. Subsequent studies have shown that the originally identified intronic rs7903146 variant is considered to be causative [50,51]. However, the vast majority of linkage studies have not led to the discovery of genes harboring the causal variants for type 2 diabetes.

Since the late 1990s, growing acknowledgment that association studies have considerably greater power than linkage analysis to detect genetic variants with moderate phenotypic effects has instigated the rise of association study as the mainstream approach in the field [52]. In the function-based, candidate-gene association studies, genetic variants in the selected candidate genes are examined based on a hypothesis of pathophysiological mechanisms behind type 2 diabetes. Candidate-gene association studies have discovered several genes such as *PPARG* (peroxisome proliferator-activated receptor gamma) and *KCNJ11* (potassium inwardly-rectifying channel, subfamily J, member 11) as susceptibility loci [53,54], and these findings have been consistently replicated. PPARG is a transcription factor that has a pivotal role in adipocyte differentiation and expression of adipocyte-specific genes. *KCNJ11* gene encodes the Kir6.2 ATP-sensitive potassium channel that regulates insulin secretion by β-cells. Mutations in the *KCNJ11* gene also cause NDM, as discussed above. Both *PPARG* and *KCNJ11* genes encode molecular targets of antidiabetic medications to treat patients with diabetes (thiazolidenediones and sulfonylureas, respectively), and functional relevance makes them compelling candidate genes. Common genetic variants in other genes such as *WFS1* and *TCF2* (MODY5) are also identified using candidate gene association approach [55,56], and these findings have also been replicated in later studies. However, most of the findings from candidate gene association studies are difficult to replicate. Many reasons have been proposed to account for the low reproducibility in the association studies, including the bias introduced by population stratification, lack of power due to small sample size, confounding caused by environmental factors, and heterogeneity in genetic effects [57].

V GWAS OF TYPE 2 DIABETES

The efforts to discover diabetes genes are considerably fueled by GWAS. The new genotyping method comprehensively covers genetic variations on the whole-genome scale, and GWAS is typically designed to study genetic architecture of type 2 diabetes and diabetes-related traits in a hypothesis-free way. Differing from the candidate gene approach, GWAS has unprecedented advantage in uncovering novel genetic contributors and thus lead to insights into the etiology of the disease. GWAS is powerful in identifying common genetic variants (minor allele frequency [MAF] > 0.05) associated with risk of type 2 diabetes, and thus far more than 90 loci have been identified (Table 29.2).

In 2007, the first GWAS on type 2 diabetes identified two novel diabetes loci *SLC30A8* (solute carrier family 30 member 8) and *HHEX* (hematopoietically expressed homeobox) along with confirming the association of *TCF7L2* and *KCNJ11* with type 2 diabetes [58]. The association of *SLC30A8* variant rs13266634 and type 2 diabetes risk was confirmed in subsequent studies across different ethnic groups [59,60]. Other GWAS in 2007 confirmed the associations of *TCF7L2*, *KCNJ11*, *PPARG*, *SLC30A8*, and *HHEX* with type 2 diabetes, and newly discovered *CDKAL1* and *CDKN2A/2B* [61−63]. A strong association of *FTO* gene with type 2 diabetes was replicated in different studies, but this was weakened after an adjustment of BMI, indicating that the association with T2D was mediated by BMI [64−66]. On the other hand, recent studies have pointed out that a variant in *FTO* was associated with risk of type 2 diabetes independently of its observed effect on BMI [67,68]. Large-scale type 2 diabetes case−control studies in which cases and controls are matched at the individual level for BMI, as well as body fat content or body adiposity index, may help to investigate whether the *FTO* variant would cause type 2 diabetes [69]. Also, stratification of type 2 diabetes cases by BMI would be helpful

in identifying additional risk variants, especially in lean cases that may have a stronger genetic predisposition to type 2 diabetes [70].

The first wave of type 2 diabetes GWAS was followed by a second wave combining existing or new GWAS into larger number of participants. In 2008, the DIAGRAM (Diabetes and Genetics Replication and Meta-Analysis) consortium performed meta-analysis of three previously published GWAS to augment power to detect additional loci of similar or smaller effect additional loci [71]. This study identified new loci including *JAZF1*, *CDC123-CAMK1D*, *TSPAN8-LGR5*, *THADA*, *ADAMTS9*, and *NOTCH2* [71]. Also, the first two GWAS of type 2 diabetes among East Asians were conducted in 2008, which identified Asian specific association with *KCNQ1* (potassium voltage-gated channel, KQT-like subfamily, member 1) [72,73]. Association of *KCNQ1* variant with type 2 diabetes was not previously detected in studies of European populations due to much lower risk allele frequency in Europeans than East Asians (5% vs 40%). The subsequent round of meta-analysis by the DIAGRAM consortium identified an independent signal in *KCNQ1* among Europeans [74].

In 2009, two additional diabetes loci, *IRS1* (insulin receptor substrate 1), which is related to insulin resistance and hyperinsulinemia [75], and *MTNR1B* (melatonin receptor 1B), which is related to impaired early insulin secretion [76,77] were identified. Qi et al. identified *RBMS1* (RNA binding motif single-stranded interacting protein 1) gene in a nested case–control study of two prospective cohorts in a discovery stage, and 11 studies in a replication stage [78]. The DIAGRAM consortium further identified 12 additional diabetes susceptibility loci such as *HNF1A* (HNF1 homeobox A) and *HMGA2* (high-mobility group AT-hook 2) by combining GWAS data from 8130 individuals with type 2 diabetes and 38,987 controls of European descent and following up previously unidentified meta-analysis signals in a further 34,412

cases and 59,925 controls [74]. Subsequently, MAGIC (the Meta-Analyses of Glucose and Insulin-related traits Consortium) investigators combined data from multiple GWAS of traits of glucose and insulin metabolism, and found five new loci, *ADCY5* (adenylate cyclase 5), *PROX1* (prospero homeobox 1), *GCK*, *GCKR* (glucokinase (hexokinase 4) regulator), and *DGKB* (diacylglycerol kinase β)-*TMEM195* (transmembrane protein 195), as well as replicated known signals at *TCF7L2* and *SLC30A8* [79]. Since the identified single-nucleotide polymorphisms (SNPs) for type 2 diabetes are considered to be markers for the functional variant responsible for the observed effect, additional fine-mapping of the loci in even larger sample sets is necessary. To do this cost-efficiently, Metabochip, a custom genotyping array, was developed to examine variants nominally associated with type 2 diabetes and other metabolic traits and to perform fine-mapping of established loci [80]. This cost-effective Metabochip contributed to genotyping many additional samples and increasing the power of meta-analysis. A meta-analysis of Metabochip data by the DIAGRAM consortium identified 10 novel type 2 diabetes susceptibility loci in the European population [81]. In addition, large-scale meta-analyses in multiethnic population-based studies from European, African-American, Hispanic-Latino, and Asian studies using a gene-based CardioChip array identified type 2 diabetes-associated variants in *BCL2* [82]. Further GWASs across different ethnicities have identified additional type 2 diabetes loci [83–89]; some population-specific genetic variants, such as variant in the *SLC16A11* among Hispanic/Latino population, were also identified [90].

To better understand the genetic basis of type 2 diabetes susceptibility, genome-wide trans-ancestry meta-analysis was conducted in a large number of participants among 26,488 cases and 83,964 controls of multiple ethnicities (European, East Asian, south Asian, and Mexican and Mexican American). The trans-ethnic meta-analysis increases the power to detect new candidate loci and enhances the fine-mapping resolution of causal variants because of differences in the structure of linkage disequilibrium (LD) between diverse populations through combining GWAS across different ancestry groups. By following up the strongest signals of association from the trans-ethnic meta-analysis among additional 21,491 cases and 55,647 controls of European ancestry, seven new susceptibility loci of type 2 diabetes were recently identified [91].

VI GWAS OF TYPE 2 DIABETES-RELATED QUANTITATIVE TRAITS

GWASs of type 2 diabetes-related quantitative traits have also discovered more than 70 loci associated with glucose homeostasis [79,92–100] (Fig. 29.2). The MAGIC investigators performed a large meta-analysis of 21 discovery GWAS cohorts followed by targeted replication of 25 loci in 33 additional cohorts [79]. They identified associations of SNPs in or near *ADCY5* (adenylate cyclase 5), *MADD* (MAP kinase activating death domain), *ADRA2A* (adrenoceptor alpha 2A), *CRY2* (cryptochrome 2 [photolyase-like]), *FADS1* (fatty acid desaturase 1), *GLIS3* (GLIS family zinc finger 3),

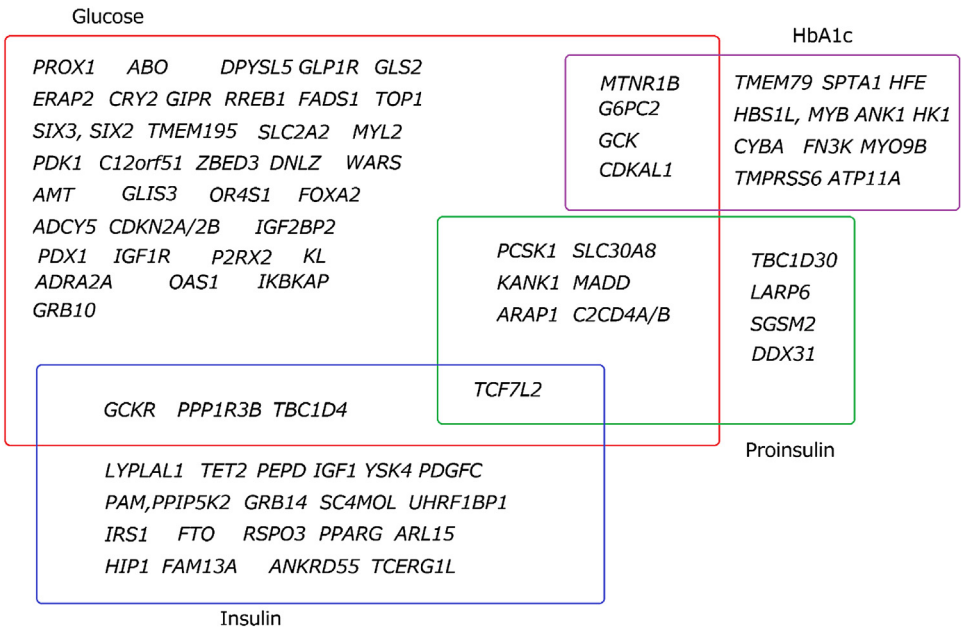

FIGURE 29.2 Loci associated at genome-wide significance with glucose homeostasis.

SLC2A2 (solute carrier family 2 member 2), *PROX1* (prospero homeobox 1), and *C2CD4B* (C2 calcium-dependent domain containing 4B) with fasting glucose and one locus near *IGF1* (insulin-like growth factor 1) associated with fasting insulin and HOMA-IR [79]. They also replicated associations of variants in *GCK*, *GCKR*, *G6PC2* (glucose-6-phosphatase catalytic subunit 2), and *MTNR1B* with fasting glucose. Most of the identified type 2 diabetes loci are related to insulin secretion and β-cell function, while fewer loci are implicated in insulin resistance [79]. For example, *GCKR* is reported to be associated with fasting insulin and insulin resistance, as well as fasting glucose and type 2 diabetes [101,102]. In more recent studies, including larger sample sizes and also considering effect of BMI, more genetic variants associated with insulin sensitivity were identified [99,100]. Some loci associated with glucose homeostasis also showed associations with type 2 diabetes, though the loci affecting these two outcomes do not completely overlap. In a study of 53 glycemic loci, 33 were also associated with an increased risk of type 2 diabetes [99]. Fig. 29.3 shows per-allele β-coefficients for glucose and insulin concentrations versus ORs for type 2 diabetes resulting from meta-analysis investigating associations

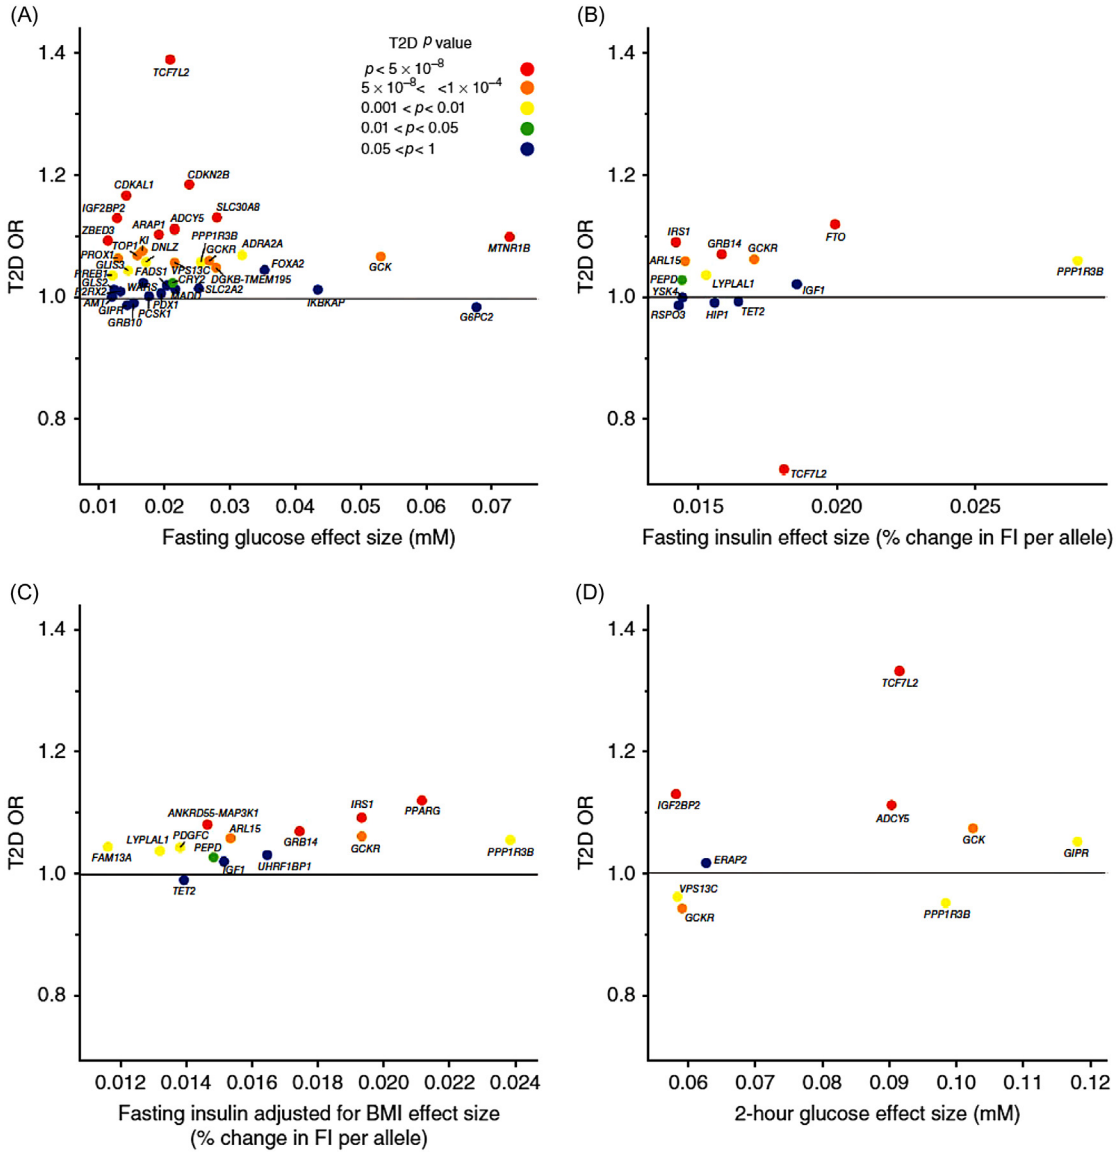

FIGURE 29.3 Per-allele β-coefficients for glucose and insulin concentrations versus ORs for type 2 diabetes (T2D). Panel (A): fasting glucose concentration versus T2D; panel (B): fasting insulin (FI) concentration versus T2D; panel (C): fasting insulin concentration adjusted for BMI versus T2D; and panel (D): 2-hour glucose versus T2D. *From R.A. Scott, V. Lagou, R.P. Welch, et al., Large-scale association analyses identify new loci influencing glycemic traits and provide insight into the underlying biological pathways. Nat. Genet. 44 (2012) 991–1005.*

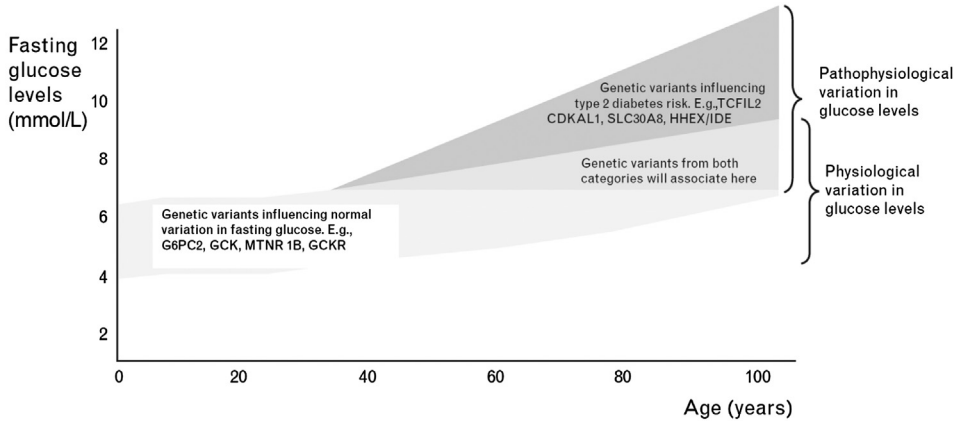

FIGURE 29.4 A schematic representation of how genetic variants influence fasting glucose concentrations in the normoglycemic population and genetic variants that influence the risk of type 2 diabetes may be observed in different glycemic states. Genes determining the normal variation in fasting glucose levels within the normoglycemic population differ from the genes that influence fasting glucose to rise above the normal level leading to type 2 diabetes. There is a gray zone in between these two extremes where people with glucose concentrations approaching the diabetes range (>7 mmol/L) may be either at the top end of the normal range of physiological glucose that shifts slightly upward with age, or at the bottom end of the pathophysiological range and on their way to diabetes. *From N.M. De Silva, T.M. Frayling, Novel biological insights emerging from genetic studies of type 2 diabetes and related metabolic traits, Curr. Opin. Lipidol. 21 (2010) 44–50.*

with glycemic traits [99]. The glucose-raising allele was associated with increased risk of type 2 diabetes, although effect sizes for fasting glucose and type 2 diabetes were weakly correlated (Fig. 29.3A) [99]. Also, a total of 13 among 19 loci associated with fasting insulin concentration showed associations with type 2 diabetes, with the insulin-raising allele associated with higher risk of type 2 diabetes, except at *TCF7L2* (Fig. 29.3B and C), where the allele associated with lower fasting insulin was associated with higher fasting glucose levels [99]. In this study, some SNPs associated with 2-hour glucose were also associated with type 2 diabetes, although the 2-hour glucose-raising alleles at *PPP1R3B*, *GCKR*, and *VPS13C-C2CD4A-C2CD4B* showed associations of decreasing risk of type 2 diabetes (Fig. 29.3D) [99]. The results indicate that not all effects of genetic variants on concentrations of glucose variations in healthy individuals would translate to the risk of type 2 diabetes (Fig. 29.4).

Among studies included in the MAGIC meta-analysis, investigators performed a cluster analysis of effects of 36 type 2 diabetes loci [103] and showed that there were five clusters of loci that appear to have primary effects on: (1) insulin sensitivity (*PPARG*, *KLF14*, *IRS1*, *GCKR*); (2) reduced insulin secretion and fasting hyperglycemia (*MTNR1B*, *GCK*); (3) insulin processing (*ARAP1*); (4) insulin processing and secretion without a detectable change in fasting glucose levels (*TCF7L2*, *SLC30A8*, *HHEX/IDE*, *CDKAL1*, *CDKN2A/2B*); and (5) a final group which contained 20 risk loci with no clear-cut associations to continuous glycemic traits. More studies are warranted to understand the functional alterations underlying genetic associations.

VII FINE-MAPPING OF IDENTIFIED TYPE 2 DIABETES LOCI

Type 2 diabetes loci are mainly identified in European ancestry, partly taking advantage of long-range LD among Europeans. However, the discovered loci usually contain more than one variant affecting diabetes risk, and one could be causal. To distinguish a causal variant from many nearby variants associated with type 2 diabetes, trans-ethnic fine-mapping in multiple ethnic groups has been performed by leveraging the differences in the structure of LD between different populations [91,104]. A large-scale trans-ethnic study was conducted by the DIAGRAM Consortium investigators and they showed improvement in the resolution of fine-mapping of common variant association signals through trans-ethnic meta-analysis [91]. In a recent study of East Asian, European, South Asian, African-American, and Mexican American descent, comprehensive trans-ancestral fine-mapping of four established type 2 diabetes susceptibility loci (*CDKAL1*, *CDKN2A-B*, *IGF2BP2*, and *KCNQ1*) was conducted [104]. These studies provide further evidence to understand the biology of specific susceptibility loci [91,104].

The DIAGRAM Consortium investigators also performed fine-mapping of 39 established type 2 diabetes loci in 27,206 cases and 57,574 controls of European ancestry, and their data suggested potential mechanisms underlying the association between variations in *MTNR1B* gene and type 2 diabetes risk [105]. Melatonin plays a key role in adjusting the biological clock, and MTNR1B has been associated with fasting glucose and risk of type 2 diabetes [76,77,106]. An epidemiological study also

showed significant association between lower melatonin secretion and a higher risk of developing type 2 diabetes [107]. In human islets and liver, the risk allele of rs10830963 at the *MTNR1B* gene creates a binding site for NEUROD1, increasing FOXA2 enhancer activity; this increased MTNR1B expression might contribute to development of type 2 diabetes [105,108].

VIII SEQUENCING AND RARE VARIANTS

Many of the GWAS-identified common variants confer only modest to small effects on risk of type 2 diabetes, and it has been considered that low-frequency ($0.005 < \text{MAF} \leq 0.05$) and rare ($\text{MAF} \leq 0.005$) variants may explain the majority of heritability of type 2 diabetes [109] since these variants are not tagged by conventional genome-wide genotyping arrays [44]. Rare variant association studies have become possible methods because the price of sequencing has dramatically fallen, along with advances of next-generation sequencing technologies. Nonetheless, deep whole-genome sequencing (WGS) remains expensive to perform for large numbers of individuals, and alternative approaches to discover these variants include targeted sequencing, exome sequencing, low-depth WGS (when combined with imputation), and extreme-phenotype sampling. For example, array-based genotyping and exome sequencing in Greenlandic population revealed a nonsense p.Arg684Ter variant (allele frequency of 17%) in *TBC1D4* associated with higher concentrations of 2-hour glucose and insulin [110].

In a recent study of a large numbers of individuals with and without type 2 diabetes, whole-genome and exome sequencing, together with genotyping and imputation, was performed to increase statistical power, and the authors tested whether lower-frequency variants explained much of the reaming heritability of type 2 diabetes [111]. In their results, variants associated with type 2 diabetes after sequencing were overwhelmingly common and most fell within regions previously identified by GWAS [111]. These data suggest that combination of genome and exome sequencing in large number of participants may provide limited evidence to document the role of lower-frequency variants in predisposition to common form of type 2 diabetes [111].

IX GENETIC RISK SCORE AND PREDICTION MODEL FOR TYPE 2 DIABETES

Use of genetic risk score (GRS) and genetic prediction models, which are calculated on basis of GWAS-identified multiple SNPs, has become a common approach to represent genetic predisposition in many studies [112]. A GRS combining multiple SNPs may be useful for screening individuals with a genetically high risk for type 2 diabetes [113,114]. Also, it has been found that a GRS for type 2 diabetes might be predictive of cardiovascular complications among patients with type 2 diabetes [115].

In a Danish population-based Inter99 study, a GRS combining 46 variants was predictive of 5-year changes in plasma glucose and β-cell function, as well as the development of type 2 diabetes [116]. The effect of the GRS on 5-year changes in fasting plasma glucose was stronger among individuals who increased their BMI in the study [116]. A longitudinal study of Chinese adults with a 9-year follow-up also suggested that a GRS combing 40 SNPs was predictive of glucose deterioration through its effect on deteriorating β-cell function [117].

Nonetheless, clinical utility of the GRS of type 2 diabetes has been an issue, especially when compared with classical risk factors (such as clinical measurements and demographic variables including family history of diabetes). The discriminatory ability of a GRS for diabetes, which is usually assessed by area under the curve of ROC, is limited [118,119]. On the other hand, the GRS in combination with classical risk factors, such as obesity and family history of diabetes, showed competence in identifying subgroups with a particularly high risk for type 2 diabetes in the Health Professionals Follow-up Study (HPFS) and Nurses' Health Study [113]. Individuals with a positive family history of diabetes and a GRS in the highest quintile had a nine times higher risk of type 2 diabetes compared with those without a family history of diabetes and with a GRS in the lowest quintile (Fig. 29.5) [113]. In another study, GRS derived using 65 SNPs into a classical risk model (Framingham Offspring Study type 2 diabetes risk model) slightly improved discrimination and reclassification for type 2 diabetes [119]. Clinical utility of genetic variants can be further investigated when more diabetes-related genetic variants are identified.

X GENE–ENVIRONMENT INTERACTIONS IN TYPE 2 DIABETES AND DIABETES-RELATED TRAITS

Most of the variants identified so far explain only a small proportion of heritability of type 2 diabetes, which is so-called "missing" heritability [109]. The missing heritability of type 2 diabetes could be partly explained by interactions between the genetic variations and lifestyle factors [120–122]. Increasing studies have shown gene–environment interactions on type 2 diabetes and diabetes-related traits. In the HPFS, there were significant interactions between the diabetes GRS and the Western

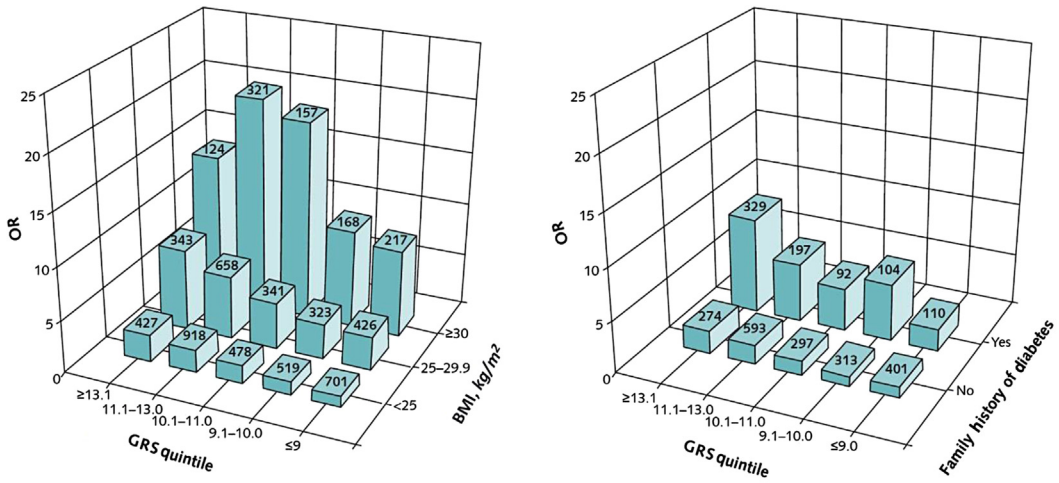

FIGURE 29.5 Joint effects of conventional risk factors and GRS on risk for type 2 diabetes. Values on bars indicate sample size. Left: Joint effects of body mass index and GRS (adjusted for age and sex) from pooled data for men and women. Right: Joint effects of family history of diabetes and GRS (adjusted for age, sex, and body mass index) from pooled data for men and women. *From M.C. Cornelis, L. Qi, C. Zhang, et al., Joint effects of common genetic variants on the risk for type 2 diabetes in U.S. men and women of European ancestry, Ann. Intern. Med. 150 (2009) 541–550.*

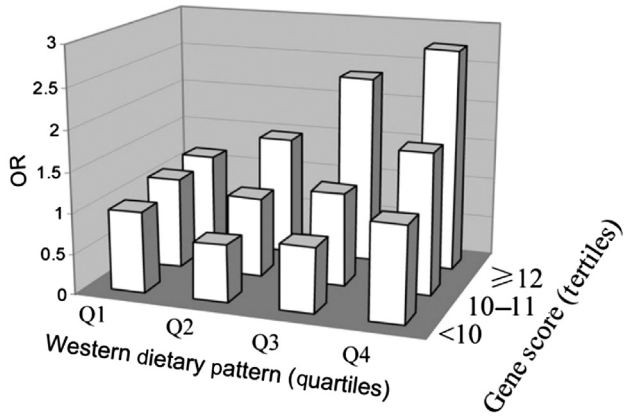

FIGURE 29.6 ORs of diabetes risk according to joint association of Western dietary pattern scores (in quartiles; Q) and GRSs. The ORs were adjusted for age, BMI, smoking, alcohol consumption, physical activity, family history of diabetes, and total energy intakes. *From L. Qi, M.C. Cornelis, C, Zhang, et al., Genetic predisposition, Western dietary pattern, and the risk of type 2 diabetes in men, Am. J. Clin. Nutr. 89 (2009) 1453–1458.*

dietary pattern, which were characterized by high intakes of red meat, processed meat, and refined foods [123]. The Western dietary pattern showed a significant association for increased risk of diabetes among men with a higher GRS, but not among those with a low GRS [123] (Fig. 29.6). In the Malmö Diet and Cancer Study, dietary fiber intake modified an association of *TCF7L2* genotype (rs7903146) and incidence of type 2 diabetes; higher fiber intake was associated with a low risk of type 2 diabetes among persons without the risk allele (p interaction = 0.049) [124]. Results of the National Health and Nutrition Examination Surveys suggest that carbohydrate intake may modify the associations of *CDKAL1* rs4712523 and *FTO* rs8050136 with type 2 diabetes among non-Hispanic whites [125]. A meta-analysis of 14 cohort studies of Europeans from the CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology) Consortium showed significant interactions of *GCKR* rs780094 genotype and whole-grain intake on fasting insulin concentrations ($p = 0.006$), where higher whole-grain intake was associated with less reduction in fasting insulin concentrations among individuals with insulin-raising allele [126]. Zinc is an essential micronutrient found in most foods and it is important for β-cell function and glucose homeostasis. A meta-analysis of cohort studies showed that higher total zinc intake may attenuate the glucose-raising effect of *SLC30A8* variant rs11558471 [127]. In results of the Preventing Overweight Using Novel Dietary Strategies (POUNDS Lost) trial, which is a 2-year randomized diet intervention trial among overweight and obese individuals, *PCSK7* genotype modified an association of dietary carbohydrate intake on changes in insulin sensitivity [128].

The Diabetes Prevention Program (DPP) is a multicenter randomized clinical trial to investigate whether lifestyle intervention or metformin therapy would prevent or delay the onset of diabetes among individuals at high risk for the disease [129]. Results of the DPP suggest that the lifestyle intervention was effective in individuals with higher genetic risk of diabetes [130]. Individuals with diabetes-risk-increasing TT genotype of *TCF7L2* variant rs7903146 were 1.55 times more likely to develop diabetes than those without the T allele [131]. Such association

was stronger in the placebo group than in the lifestyle intervention group, suggesting that lifestyle modification might attenuate the genetic effect, although test of interaction was not statistically significant [131]. On the other hand, for improvement of insulin sensitivity, metformin treatment and lifestyle modification improve insulin sensitivity independent of insulin-resistance GRS [132]. While an increasing number of studies has investigated the gene−environment interaction in type 2 diabetes and its related traits, characterizing details of interactions using currently available statistical approaches is still challenging because of requisite for a sufficient sample size with prospective design to assess the incidence of type 2 diabetes, a multiple testing issue to test a large number of hypotheses, and measurement errors, especially for the assessment of dietary intake. Also, a few studies are accompanied by adequate replication data or compelling mechanistic explanations [133]. Some patients with diabetes may change their dietary habits before the clinical diagnosis of diabetes, and thus well-designed large prospective cohort studies collecting genetic and detailed lifestyle factors would be warranted to study the gene−environment interactions in type 2 diabetes.

XI CHALLENGE AND FUTURE DIRECTION

Much progress has been made to reveal genetic architecture for type 2 diabetes, and nearly 100 loci for type 2 diabetes have been identified. Nonetheless, their roles in genetic prediction, actual causal variants, and biological functions remain to be explored. With continued efforts on fine-mapping studies, it is likely that a full picture of variants of type 2 diabetes can be evaluated and introduced for disease prediction in clinical settings. Future efforts to characterize the role of gene−environment interactions as well as other epigenetic modifications are also needed. Epigenetic and structural variation studies, as well as integrating data on various omics [134], would help identify new variants that may be important in type 2 diabetes risk prediction.

XII SUMMARY

Both genetic and nongenetic factors contribute to the risk of developing type 2 diabetes—genetic background determines susceptibility to insulin resistance and β-cell dysfunction, and nongenetic factors such as overweight or obesity, unhealthy dietary habits, and physical inactivity exacerbate the inherited abnormalities [135]. Traditional genetic research, GWAS, and sequencing studies have provided consistent evidence on the genetic basis of type 2 diabetes and glycemic traits, and have identified a group of variants through application of meta-analysis across diverse populations and genotype imputation approaches. Advances in sequencing have led to the discovery of potentially functional variants. Future continuing efforts will contribute to identifying additional loci, investigate the pathogenic roles of the variants and genes involved, and explore their interactions with environmental factors in determining the risk of type 2 diabetes.

Chapter 30

Obesity and the Risk for Type 2 Diabetes

George A. Bray

Pennington Biomedical Research Center/LSU, Baton Rouge, LA, United States

I INTRODUCTION

A Obesity

Obesity is a worldwide problem affecting more than 100 million Americans [1,2]. The prevalence of overweight and obesity has been on the rise since 1980 and now affects 68.5% of the adult population [3,4]. The presence of obesity or overweight is associated with a number of diseases, of which diabetes mellitus is one of the most important, but it also predicts future hypertension, heart disease, obstructive sleep apnea, and many other comorbidities. Preventing the twin time bombs of obesity and diabetes has major importance for the future of health care worldwide [5]. Whether the associated disorders are present or not, the patient with obesity should be encouraged to lose weight by appropriate methods because this will reduce the risk of developing future diabetes, and weight loss, if sufficient, may reverse diabetes that already exists [6].

The first steps in management of body weight are self-directed approaches (diet, physical activity, support groups, and commercial programs with an evidence base to support efficacy). Many patients succeed with these strategies alone. For patients who struggle, and who have medical issues that will improve with more weight loss, there are hospital and community-based lifestyle intervention programs and medically supervised weight management programs that employ adjunctive medications, surgical devices, and surgical procedures.

B Diabetes

The prevalence of diabetes mellitus, like the prevalence of obesity, continues to rise worldwide since obesity is in large measure driving the increase in diabetes. In the United States, approximately 86 million people have prediabetes, and one in three people have the metabolic syndrome [7]. Individuals with prediabetes are at high risk for conversion to type 2 diabetes and 3−11% will convert to type 2 diabetes annually [8]. As the rise in prevalence of obesity has slowed over the past 5 years, there has also been a gradual but sustained decrease in the rate of diabetes occurring from 2008 to 2014 [9].

II DIAGNOSTIC CRITERIA FOR OBESITY AND DIABETES

A Obesity

People who are overweight or obese are most commonly classified using the body mass index or BMI which is the weight in kilograms divided by the square of the height in meters. It is a valuable tool for estimating overweight and obesity in populations, since it correlates with total fat mass [10], but it has significant limitations when applied to individual patients [11]. A classification based on BMI is shown in Table 30.1. When evaluating a patient with obesity, the health care provider should also measure the waist circumference, particularly in patients with a BMI between 25 and 35 kg/m^2 [13]. In addition, evaluation of components of the metabolic syndrome should be considered [12]. A BMI of greater than 25 kg/m^2 is defined as overweight, and a BMI of 30 kg/m^2 or more is defined as obesity (Table 30.1). Padwal et al. [14] evaluated nearly 50,000 women and 5000 men who had body fat estimated by dual energy x-ray absorptiometry (DXA) and BMI and found that both a low BMI and a high percentage of body fat increased mortality in both men and women.

B Central Adiposity and Visceral Fat

An increase in visceral fat increases risk for diabetes, heart disease, and cancer. Either the waist circumference or waist circumference divided by hip circumference (WHR) can be

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00030-8

TABLE 30.1 A Classification of Obesity Based on BMI

Category	Class	BMI Range
Normal range		18.5–24.9 kg/m^2
Overweight		25–29.9 kg/m^2
Obese		>30 kg/m^2
	1	30–34.9 kg/m^2
	2	35–39.9 kg/m^2
	3 (Extreme)	>40 kg/m^2

Within these BMI categories, additional personal risk assessment is needed because degree of risk can vary.

Donato, et al., Harmonizing the metabolic syndrome: a joint interim statement of the International Diabetes Federation Task Force on Epidemiology and Prevention; National Heart, Lung, and Blood Institute; American Heart Association; World Heart Federation; International Atherosclerosis Society; and International Association for the Study of Obesity. International Diabetes Federation Task Force on Epidemiology and Prevention; National Heart, Lung, and Blood Institute; American Heart Association; World Heart Federation; International Atherosclerosis Society; International Association for the Study of Obesity, Circulation 120 (16) (2009) 1640–1645 [15] and Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. Executive summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III), JAMA 285 (2001) 2486–2497 [16].

used as surrogates to assess the amount of central adiposity. A waist circumference greater than 102 cm (40 in.) in men or greater than 88 cm (35 in.) in women is the current American threshold for increased metabolic risk, but for other populations a waist circumference >80 cm for women and >94 cm for men may be more appropriate. Measurement of waist circumference is used in the definition of the "metabolic syndrome," which is a predictor of risk for developing diabetes and heart disease. The criteria for the Metabolic Syndrome are shown in Table 30.2. An individual with this syndrome is at higher risk of developing diabetes and cardiovascular disease (CVD). However, central adiposity can also be measured more precisely using magnetic resonance imaging or computed tomography. When this is done, visceral adipose tissue is shown to be a stronger predictor of diabetes and CVD than subcutaneous adipose tissue [17]. In a study of 15,184 adults aged 18–90 years from NHANES III database, persons with normal weight and central obesity, defined by high WHR, had the worst long-term survival. For example, a man with a normal BMI (22 kg/m^2) and central obesity had an 87% greater risk of mortality than an individual with a similar BMI but no central obesity, and this man had twice the mortality risk of participants who were overweight or obese according to BMI only. Women with normal-weight central obesity also had a 48% higher mortality risk than women with a similar BMI but no central obesity and those who were obese according to BMI only. Expected survival estimates were consistently lower for those with central obesity when age and BMI were controlled for [18].

C Diabetes Mellitus

Diabetes mellitus is a metabolic disorder with elevated concentrations of blood glucose secondary to insulin resistance and defective insulin secretion from the beta-cells of the pancreas [19,20]. Asymptomatic diabetes, particularly type 2 diabetes mellitus, may be diagnosed by abnormally high blood glucose levels during routine health examinations (Table 30.3). Chronic hyperglycemia and abnormal lipid levels are associated with pathologic and functional changes in several organ systems including the eyes, the blood vessels, the heart, and the kidneys [21]. Diabetes can be subdivided into several types, including type 1 or juvenile-onset diabetes, type 2 often called adult-onset diabetes, and gestational diabetes mellitus. Type 1 diabetes is an autoimmune disease with destruction of the β cells of the pancreas, which leads to a deficiency of insulin. Type 2 diabetes is most often seen in adults and is due to a combination of insulin resistance and a deficiency in insulin secretion (Fig. 30.1). Deficiencies in insulin secretion often manifest themselves during pregnancy and lead to a diagnosis of "gestational diabetes" which may resolve. However, these women are at high risk for future type 2 diabetes mellitus.

III EPIDEMIOLOGICAL EVIDENCE FOR A RELATIONSHIP OF OBESITY AND DIABETES

There is overwhelming evidence from epidemiological studies in cohorts of individuals from many countries using both cross-sectional and longitudinal methods that

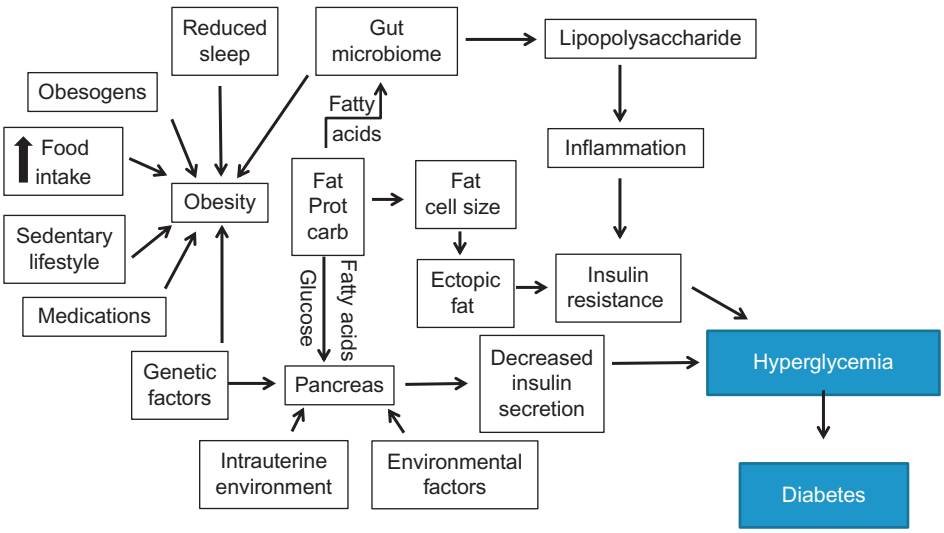

FIGURE 30.1 A model of relation of obesity to development of diabetes.

BMI or central adiposity, and the increase in body weight over time predict future diabetes. One of the most provocative depictions of the relationship of obesity and diabetes is the maps from the Center for Disease Control and Prevention, which show the rising prevalence of obesity preceding rising prevalence of diabetes from 1985 to 2015 [22].

A meta-analysis of prospective studies provided evidence that as upper body adiposity increases, the presence of the metabolic syndrome and the risk of developing diabetes both increase [23]. The duration of obesity in younger compared with older individuals is associated with a greater risk for diabetes [24]. Weight gain in adult life increases the risk of developing diabetes, particularly in the age range 25–40 years [25].

The duration of an increased body weight also increases the risk of diabetes. In the National Longitudinal Survey, a total of 8157 adolescents and young adults aged 14–21 years in 1979 with self-reported measures of height, weight, and diabetes status (type unspecified) were followed from 1981 through 2006. For a given level of excess BMI-years, younger individuals compared with older ones and Hispanic and black compared with white individuals had higher risk of developing diabetes [26].

Foods can increase or decrease the risk of diabetes [27,28]. Coffee, either caffeinated or decaffeinated, reduces the risk of developing type 2 diabetes [29,30] and this risk is associated with an inverse relationship between sex-hormone-binding globulin and the risk of diabetes [31], and it may be that these two are related. The risk of diabetes is also reduced among those with higher consumption of nuts and seeds [32], whole grains [33,34] and in those who consume yogurt [35]. The risk for diabetes is increased by consumption of either processed or unprocessed red meat [36] by consumption of more than 1 egg per day [37] and consumption of sugar-sweetened beverages [38]. Some of these relations of foods with risk of

diabetes may be reflected in the increase in body weight, with sugar-sweetened beverages being the most obvious example [39]. Among these foods consumption of red meats is associated with a 4-year weight gain. In contrast yogurt is associated with weight loss over the 4-year follow-up [40].

A How Does Obesity Increase the Risk of Developing Diabetes?

Not everyone who becomes obese develops diabetes, suggesting that there must be additional genetic and/or environmental factors that are involved. To organize this brief discussion, Fig. 30.1 depicts a "model" of the factors that are involved in producing obesity and how these and other factors lead some individuals with obesity to develop diabetes.

Many individuals with obesity have no "associated" findings such as prediabetes, dyslipidemia, hypertension, or other findings and have been referred to as "Healthy Obese" [41]. However, it is now clear from long-term follow-up studies that half or more of these individuals will develop obesity-related disease during their lifetime [42]. Thus, prevention and treatment remain important.

We can identify a number of factors that produce obesity. The major ones are food intake that is higher than needed for the level of energy expenditure that persists over months to years [11]. An additional important dietary factor is the intake of sugar-sweetened beverages [43]. Some genes have major effects on the risk of obesity [44,45], but a much larger number of genes, possibly more than 100, have minor effects [46,47]. Reduced sleep time is associated with higher risk of obesity [48]. A number of drugs can cause weight gain [49]. The microbiome may play a role, but its relative importance is still unsettled [50,51]. The human microbiota consists of up to 100 trillion microbes that exist in a largely symbiotic relationship with their human hosts, and carry at least 150 times more genes (the microbiome) than are present in the entire human genome. Effects of the microbiota on adiposity are noted following inoculation of germ-free mice with the microbiota from normal mice. In human beings, inoculation of mice with the microbiota from monozygotic (MZ) and dizygotic (DZ) human twin pairs discordant for obesity shows a progressively greater increase in both fat mass and fat-free mass in animals receiving microbes from the obese twins, despite no significant differences between groups in daily chow consumption [52].

The vaginally delivered neonate is initially colonized with the vaginal and distal gut bacteria of the mother, while babies delivered by cesarean section (C-section) are initially colonized predominantly with the skin bacteria from the mother [53,54]. Thus, vaginally delivered neonates have relatively and absolutely larger populations of Bacteroides and Bifidobacteria species than those born by C-section [55]. These differences may persist for months to years [56]. The observations that increased Bacteroidetes populations are present in both obesity and in children born by C-section (seven from Rosenbaum) suggest that the infant microbiome may contribute to the 40% increased risk of obesity in children [57] and young adults [58,59] delivered by C-section.

In most [60,61], but not all [62], studies, both the diversity of the microbiota and the fractional proportion of Bacteroidetes species relative to Firmicutes are decreased in obese versus lean individuals. These proportions are extremely sensitive to caloric balance in subjects studied before, during, and after weight loss while ingesting the same liquid formula diet of identical macronutrient composition [63].

In humans, Kocelak et al. [64] examined resting energy expenditure (REE), body composition, and the gut microbial population in 50 obese and 30 lean healthy weight-stable subjects. They reported that the obese subjects had a significantly greater total microbial count without significant differences in the ratio of Bacteroidetes/Firmicutes, both of which had been reported to be lower in obese individuals in other studies [60,61]. Over the entire group of subjects, the size of the population of Firmicutes was positively correlated with fat mass and negatively correlated with REE and the maximal oxygen consumption (VO_{2max}). Total bacterial count was significantly positively correlated with VO_2 and negatively correlated with VCO_2. In multiple regression analysis including fat mass, none of these correlations between the microbiota and energy expenditure remained significant [64].

Obesity is one of the strongest predictors of the risk for diabetes. Type 2 diabetes, like obesity, has a strong heritable component. It has long been recognized that family history plays an important role in determining if one will develop diabetes. Most prospective studies of individuals with prediabetes demonstrate that they are hyperinsulinemic [65] or have impaired insulin secretion. The diabetes-related gene list, however, is different from the list of genes that are related to obesity. All genes can only account for about 85% of the variance in diabetes [8]. If the mother has diabetes, the risk is higher than if the father has it, and the risk rises substantially if two other siblings have diabetes. The single nucleotide polymorphism for TCF7L2 has the strongest association with type 2 diabetes [66,67]. Genome-wide association studies have identified more than 100 common variants, mostly on "introns," and the function is understood for only a few of these "genes." Those with some mechanism include GCKR which encodes the

glucokinase regulatory protein [68,69], KCNJ11 which encodes an ATP-dependent potassium channel, and SLC30A8 which encodes a zinc transporter that is required to store insulin [70].

B Intrauterine Environment—the Barker Hypothesis and Fetal Origins of Type 2 Diabetes and Obesity

Among the environmental/physiological mechanisms that predispose some people with obesity to develop diabetes are events occurring during intrauterine and early postnatal life. Individuals who were malnourished while in utero may be more prone to insulin resistance and diabetes and weight gain than those who are well nourished. This hypothesis often called the "Developmental Origin of Disease" is also called the "Barker Hypothesis" from the name of the man who first described it [71]. Maternal undernutrition forces the fetus to adapt during its intrauterine development and drives a reprogramming of its endocrine−metabolic state to produce permanent changes in the structure and the physiology of key organ systems [71,72]. These changes in low-birth-weight infants (normal range, 3000−4000 g) contribute factors to chronic diseases such as type 2 diabetes, coronary heart disease, stroke, and hypertension in adult life [73].

Infants born to mothers with diabetes tend to have higher birth weight (macrosomia) but are also at higher risk for developing the metabolic syndrome and type 2 diabetes as adults [74−77]. The inverse association between birth weights and diabetes remains significant even after adjustment for adult adiposity. The increased relative risk was seen among lean, overweight, and obese women, indicating that in utero growth has independent effects from adult body weight on the risk for developing type 2 diabetes. However, the greatest risk remains for women of low birth weight who develop obesity as adults [72].

C Maternal Obesity and Gestational Weight Gain

Maternal obesity alters metabolic adjustments and fetal growth during the neonatal period [78,79]. Women with obesity tend to have larger placentas and bigger babies, which are significant predictors of type 2 diabetes in the offspring. One-third of pregnant women in the United States are obese, with increased metabolic complications, preeclampsia, fetal anomalies, and poor pregnancy outcomes. Risk of gestational diabetes is increased by up to eightfold in severe obesity and increases in women who had gained weight within 5 years prior to pregnancy [80]. Both large and small for gestational age infants are seen more often in the obese compared with normal-weight mothers [81]. Several factors are implicated in maternal obesity including: (1) maternal hypertension and its effect on placental size; (2) a subclinical inflammatory state with elevated cytokine [82] and leptin levels; and (3) an enhanced insulin resistance that exaggerates the pregnancy-associated increase in circulating plasma glucose, lipids, and amino acids, exposing the fetus to an excess of all fuel sources.

Guidelines for maternal weight gain were provided in the 1990 Institute of Medicine's (IOM) gestational weight gain which was revised in 2009 (Table 30.4). Reduced gains of 5−9 kg were recommended for mothers who have obesity [83]. But, less than one-third of pregnant women meet those recommendations [84] and excessive weight gains of >19 kg have become common and account for a growing proportion of cesarean deliveries [85] and postpartum retention of body weight [86]. The risk of having an overweight child at age 3 years among 1044 mother−child pairs increased fourfold in mothers whose gestational weight gain was adequate or excessive compared with mothers whose weight gain was inadequate using the 1990 IOM guidelines. The increased risk was independent of parental BMI, maternal glucose tolerance, breast-feeding duration, fetal and infant growth, and

TABLE 30.4 Institute of Medicine Recommendations for Weight Gain During Pregnancy

Prepregnancy BMI	Total Weight Gain		Rates of Weight Gain	
	Range in Kg	Range in Lbs	Mean Range in Kg per Week	Mean Range in Lbs per Week
Underweight (<18.5 kg/m^2)	12.5−18.2	28−40	0.51 (0.44−0.58)	1 (1−1.3)
Normal weight (18.5−24.9 kg/m^2)	11.5−16	25−35	0.42 (0.35−0.50)	1 (0.8−1)
Overweight (25.0−29.9 kg/m^2)	7−11.5	15−25	0.28 (0.23−0.33)	0.6 (0.5−0.7)
Obese (≥30.0 kg/m^2)	5−9	11−20	0.22 (0.17−0.27)	0.5 (0.4−0.6)

child behaviors including frequency of watching TV or consuming fast-foods. Efforts at weight control should avoid strict energy and carbohydrate restrictions to avoid ketosis and associated metabolic complications, which can have negative effects on fetal cognitive development [78]. Treatment of maternal obesity aims to improve insulin sensitivity in the mother without reducing fetal glucose levels and compromising fetal growth.

D Smoking During Pregnancy

Women who smoke during pregnancy increase the risk of their offspring developing obesity out to 25 years. This effect is present even if smoking is terminated during the first trimester. The simplest explanation is that nicotine from smoking enters the brain and alters the function of neurons related to future development of obesity [11].

Diabetes develops when the secretion of insulin from the pancreas is no longer sufficient to overcome the barriers to the action of insulin which are lumped together in the term "insulin resistance" [8,87]. Development of type 2 diabetes thus depends on changes in one or both of these two principal variables—insulin sensitivity and insulin secretion. As insulin resistance develops, that is, responsiveness to insulin decreases, an individual's risk of diabetes increases unless they can also increase insulin secretion. Thus, obesity must modify one of these two variables.

E Beta-Cell Function

Insulin resistance is one of the first defects to be identified in individuals who will develop diabetes. The progression to diabetes is associated with failure of the beta-cells in the pancreas to keep up with the demand. Multiple factors contribute to the failure of the beta-cells including resistance to incretin hormones (GIP and GLP-1), lipotoxicity, glucotoxicity, aging, genetic abnormalities, increased secretion of islet amyloid polypeptide, reactive oxygen stress, and inflammation [8]. About 60% of the islet mass consists of beta-cells that secrete insulin in response to glucose, arginine, free fatty acids, and neural stimulation. In diabetes, the mass of beta-cells is reduced, probably by apoptosis. In addition, chronic exposure to high levels of glucose may blunt the responsiveness of these cells to incretins [88] and thus their ability to keep up with the demand for insulin to facilitate glucose uptake peripherally. The improvement of beta-cell function following bariatric surgery implies that these cells have been inhibited and can be resuscitated by reducing the flow of nutrients through the individual that need to be metabolized.

F Insulin Resistance and Inflammation

Insulin resistance can be identified earlier than failure of insulin secretion and is not always associated with the development of diabetes when islet cell secretion can keep up with the demand. Insulin resistance is characterized by reduced clearance of glucose as well as reduced response at the cellular membrane (Fig. 30.1). A prospective study that followed second- and third-generation Japanese Americans for up to 10 years confirmed that the amount of intra-abdominal fat plays an important role in the development of diabetes [89]. In this study, visceral adiposity, measured by computed tomography, was predictive of diabetes incidence, regardless of age, sex, family history of diabetes, fasting insulin, insulin secretion, glycemia, and total and regional adiposity. By increasing the demand for insulin, insulin resistance becomes a risk factor for diabetes, causing glucose intolerance in subjects who have impaired insulin secretory capacity and a reduction in the glucose potentiation of insulin secretion. Incremental insulin response to an oral glucose challenge, an assessment of insulin secretion, suggests that a failure in β-cell function preceded the onset of diabetes. Insulin resistance was also associated with a blunted suppression of glucagon secretion by glucose in impaired glucose tolerance, suggesting that β-cell dysfunction and locally reduced insulin concentrations may exaggerate glucagon secretion because the α-cell becomes less sensitive to glucose.

Insulin resistance occurs not only in muscle and liver, but also in most other tissues including the fat cell, kidney, brain, pancreas, and GI track. The defect in muscle has been extensively studied, but the details are beyond the scope of this chapter. In the muscle, there are defects in insulin signaling at the membrane, in glucose transport, in glucose phosphorylation, and in glycogen synthesis, as well as in the pyruvate dehydrogenase complex and in the oxidative machinery in the mitochondrion [8]. Gluconeogenesis in the liver is a major factor in the fasting hyperglycemia of diabetes, but there is also increased renal gluconeogenesis. Gluconeogenesis is the result of multiple endocrine disturbances including insulin resistance and deficiency, increased glucagon levels, and enhanced delivery of substrates (fatty acids, lactate, glycerol, and amino acids) to the liver.

Another factor that may explain why insulin resistance worsens in some obese individuals and not in others as their fat mass increases is the overproduction by specific adipocytes of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6). In a meta-analysis, including 10 prospective studies, with a total of 19,709 participants and 4480 cases, there was a significant dose−response association between IL-6 levels and type 2 diabetes risk. For c-reactive protein (CRP), the

meta-analysis included 22 cohorts, with a total of 40,735 participants and 5753 cases. Elevated CRP levels, like IL-6 levels, were significantly associated with increased risk of type 2 diabetes [90]. This inflammatory process may be set in motion in part by the ingestion of a high-fat diet [91]. In obese individuals, macrophages, referred to as classically activated (M1) macrophages, accumulate in adipose tissue. This may be precipitated by the effect of the high-fat diet on entry of lipopolysaccharide from the intestine into the circulation. These macrophages release cytokines such as IL-1β, IL-6, and TNF-α creating a proinflammatory environment that blocks adipocyte insulin action, contributing to the development of IR and type 2 diabetes mellitus. The Nod-like receptor family, pyrin domain containing 3 (Nlrp3) inflammasome, may play a particularly important role in risk for developing diabetes, since knocking down this gene reduces the inflammatory response to a high-fat diet.

There is evidence (reviewed in DeFronzo et al. [8]) that postabsorptive skeletal muscle fat oxidation in insulin-resistant states is decreased [92]. This decrease is explained by the presence in muscle of carbohydrate-derived malonyl-CoA, which inhibits carnitine palmitoyl transferase, blocking the entry of free fatty acids into the mitochondria. Carnitine palmitoyl transferase activity has been shown to be reduced in the vastus lateralis muscle of insulin-resistant obese individuals. The excess free fatty acids may increase long-chain acyl-CoA concentrations and diacylglycerol, leading to the accumulation of lipids in muscle—an effect conducive to alterations of insulin signaling and insulin action.

IV PREVENTION OF DIABETES BY PREVENTING OBESITY

As noted by DeFronzo et al. [8], a healthy diet, maintaining a BMI $<25\ kg/m^2$, and regular exercise for at least 30 minutes per day could prevent up to 90% of the cases of type 2 diabetes. In the discussion to follow we will focus on prevention and treatment of obesity is a major strategy in this "war" on the prevention of diabetes. One obvious corollary of the fact that obesity is a major risk factor for the development of diabetes is that encouraging individuals at risk for diabetes to lose weight might delay or prevent the development of diabetes. Thus, weight loss might mitigate the effects of diabetes [93].

Five well-designed clinical trials summarized in Table 30.5 have evaluated the effect of lifestyle modification on the risk for developing diabetes. They include (1) the Da Qing Study [94], (2) the Finnish Diabetes Prevention Study [95–97], (3) the Diabetes Prevention Program (DPP, 2002) [110], (4) the Indian Diabetes Prevention Program [99], and (5) and a Japanese Diabetes Prevention study [100].

A Lifestyle Programs

In the Finnish Diabetes Prevention study, subjects were randomized to a control group which was given general information on diet and exercise, or to an intervention group which received detailed counseling by dietitians to help them reduce weight, decrease the intake of fat and saturated fat, and to increase fiber and physical activity. After 3.2 years of follow-up, the lifestyle intervention was associated with a significant reduction in weight (−4.2 vs −0.8 kg) and waist circumference (−4.4 vs −1.3 cm) compared to the control group [95]. There was also a significant reduction in 2-hour plasma glucose and serum insulin, serum triglycerides, and blood pressure. The risk of developing diabetes was reduced by 58% in the intervention group compared to the control group. At 7-year follow-up, participants in the intervention group still had a 43% lower diabetes risk (Lindstrom et al., 2013). In spite of these positive findings, 10-year total mortality and cardiovascular mortality rates did not differ between the control and intervention groups [111]. The number of deaths, however, was only 16 (3%) and the rate was low compared with 11% in another Finnish cohort that had received no intervention.

The DPP was conducted in 27 centers around the United States. Participants were randomly assigned to one of four groups: (1) an intensive lifestyle group with a 7% weight loss goal and a goal of 150 minutes/week of physical activity, (2) metformin (850 mg/day for 1 month, increasing to 850 mg bid if tolerated), (3) a group receiving troglitazone which was terminated prematurely due to side effects from the drug, and (4) a placebo group receiving a pill that "looked" like the metformin pill [98,112]. After 2.8 yearrs of follow-up, average weight loss was 5.6, 2.1, and 0.1 kg in the lifestyle, metformin, and placebo groups, respectively. This produced a 58% reduction in the incidence of type 2 diabetes in the lifestyle group. Interestingly, this is the same figure observed in the Finnish Diabetes Prevention study (Tuomilheto et al., 2001). The lifestyle intervention also resulted in improvements in hypertension, triglycerides, and HDL cholesterol, and the differential between these three main treatment groups persisted for 10 years [110].

B Medication

Medication can also reduce the incidence of diabetes among individuals with impaired glucose tolerance. There are eight randomized controlled trials that have examined the effects of pharmacological agents on the prevention of type 2 diabetes. In the DPP, metformin at a dose of

TABLE 30.5 Interventions to Delay or Prevent the Conversion from Prediabetes to Diabetes

Study	Total Randomized	Population	Duration (Year)	Intervention	Risk Reduction
Lifestyle Interventions					
Chinese Da Qing Study	577	IGT	6	Group diet/exercise	38%
Finnish Diabetes Prevention Study	522	IGT, BMI ≥25 kg/m^2	3.2	Individual diet/exercise	58%
Diabetes Prevention Program	2161	IGT, BMI ≥24, FPG >95 mg/dL (5.3 mmol/L)	2.8	Individual diet/exercise	58%
Indian Diabetes Prevention Program	531	IGT	2.5	Individual diet/exercise	29%
Japanese trial	458	IGT (men), BMI = 24	4	Individual diet/exercise	67%
Pharmacotherapy					
DPP (Diabetes Prevention Program) Metformin Arm	2155	IGT, BMI ≥24, FPG >95 mg/dL (5.3 mmol/L)	2.8	Metformin 850 mg/day	31%
STOP NIDDM: Study to Prevent Noninsulin-Dependent Diabetes	1429	IGT, FPG >100 mg/dL (5.6 mmol/L)	3.2	Acarbose (300 mg)	25%
Voglibose Trial (α-glucosidase inhibitor)	1780	IGT	3	Voglibose 0.2 mg thrice a day	41%
XENDOS: Xenical in the Prevention of Diabetes in Obese Subjects	3305	BMI >30	4	Orlistat (360 mg)	37%
TRIPOD: Troglitazone in Prevention of Diabetes	266	Previous GDM	2.5	Troglitazone (400 mg)	55%
DREAM: Rosiglitazone	5269	IGT or IFG	3	Rosiglitqazone (8 mg)	60%
DPP (Diabetes Prevention Program) Troglitazone Arm	1167	IGT or IFG	0.9	Troglitazone	75%
ACT NOW ACTOS (Pioglitazone) in the Prevention of Diabetes	502	IGT or IFG	2.4	Pioglitazone (45 mg)	72%
SEQUEL (Topiramate/ Phentermine ER or Qsymia)	475	IGT and/or metabolic syndrome	2	Topiramate/ phentermine ER 7.5/46 and 15/92 mg	70% 79%
Bariatric Surgical Intervention					
SOS (Swedish Obese Subjects)	3239*	Obese volunteers for bariatric surgery	Up to 15	Surgery compared to usual care	82%

Nonrandomized group: Bariatric patients ($N = 1658$) volunteered and were matched as closely as possible to a control group ($N = 1771$). *SOS was a "matched" control group not a "randomized" study. The total number included the operated and matched control group. Papers in this table—*Lifestyle*: Pan et al. [94]; Tuomilehto et al. [95]; Knowler et al. [98]; Ramachandra et al. [99]; Kosaka et al. [100]; *Medication*: Metformin: Knowler et al. [98]; DPP [101]; Chiasson et al. [102]; Kawamori et al. [103]; Torgerson et al. [104]; Buchanan et al. [105]; Gerstein et al. [106]; Knowler [107]; DeFronzo et al. [108]; Garvey et al. [13]; *Bariatric Surgery*: Sjostrom et al. [109].

850 mg/day reduced the incidence of diabetes by 31% [98]. Metformin also produced weight loss which was related to the degree of adherence to the drug regimen [101]. Orlistat, an inhibitor of intestinal lipase, reduced the conversion rate from impaired glucose tolerance to diabetes by 37% [104]. Acarbose, a blocker of starch digestion, reduced the incidence by 25% [102]. Another starch blocker voglibose was also shown to have the same effect [103]. Three different thiazolidinediones have been shown to produce a very significant reduction in the risk

of developing diabetes. In the DPP, troglitazone reduced the incidence of new cases of diabetes by 55% [107]. Pioglitazone in the ACT NOW trial reduced the incidence of diabetes by 72% [108]. Rosiglitazone in the DREAM trial reduced the incidence of diabetes by 60% [106]. Most recent data from the combined use of topiramate and phentermine have been shown to have a significant reduction in risk of conversion to diabetes that is related to the degree of weight loss [113]. Table 30.5 summarizes therapies proven to be effective in pharmacotherapy trials.

The final strategy is the use of bariatric surgery that can prevent the development of diabetes in individuals with prediabetes and reverse diabetes that is already present. It was Pories et al. [114] who suggested that the weight loss with bariatric surgery might reverse diabetes and reduce the risk of its development. This was most convincingly established in the Swedish Obese Subjects (SOS) study. The SOS study evaluated the conversion from prediabetes to diabetes [109]. They found that the conversion was reduced by 82%, one of the largest that has been reported. Surgery can also produce a remission from diabetes. Among randomized controlled trials, the percentage of remission from diabetes to nondiabetes after surgery was 92% with a range of 85–97% [115].

In summary, this chapter has examined the relationship between obesity and the risk of developing diabetes. The epidemiological data are very strong and there are clear-cut mechanisms involving insulin resistance and beta-cell failure that can account for the changes. The proof of the pudding in this relationship is that weight loss by any one of several means, or reduction in insulin resistance (thiazolidinediones), can significantly reduce the risk of converting to diabetes.

Chapter 31

The Role of Diet in the Prevention and Treatment of Diabetes

Judith Wylie-Rosett[1] **and Linda M. Delahanty**[2]

[1]Albert Einstein College of Medicine, Bronx, NY, United States, [2]Massachusetts General Hospital Diabetes Center, Boston, MA, United States

I INTRODUCTION

The number of people in the United States with diabetes is estimated to be 29.1 million or 9.3% of the population based on the 2010 U.S. Census population estimates and diabetes prevalence data from the 2009−12 National Health and Nutrition Examination Survey, the 2009−12 National Health Interview Survey, the 2012 Indian Health Service data, and 2012 U.S. population estimates [1,2]. However, only 21.1 million of those with diabetes have diagnosed diabetes, and the other 8.1 million are unaware they have diabetes. The risk of having diabetes increases with age, and 25.9% of the U.S. population aged 65 years or older have diabetes. In addition, 37% (86 million) of U.S. adults (≥20 years of age) are at high risk for developing diabetes and can be classified as having prediabetes [1,2].

Data from 219 countries and territories were used to estimate the global prevalence of diabetes for 2013 and projections for 2035 [3]. The number of adults (age 20−79 years) with diabetes was estimated to be 382 million (8.3% of the world population) in 2013, with an increase to 592 million (8.8% of the world population) by 2035. The increase between 2013 and 2035 is expected to be 55% globally. The largest proportional increase is expected in low-income countries (108%); middle-income countries are expected to be intermediate (51%), and the high-income countries are expected to have the smallest increase (28%). Countries with a large population and rapid economic development are likely to carry the greatest diabetes burden. For example, China and India rank first and second, respectively, for number of diabetes cases, with the U.S. ranking third. The projected number of adults with diabetes in 2035 is 143 million in China, 109 million in India, and 30 million in the United States [3].

The increased global diabetes burden appears to be the result of population aging and urbanization, with the associated changes in diet and physical activity. However, there is growing evidence that in India and China, the prevalence in rural areas is approaching that in urban areas, perhaps related to mechanization [4]. The estimated direct medical cost for prevention and treatment of diabetes worldwide was approximately $376 billion in 2010 and will exceed $490 billion by 2030 [5]. Total costs are substantially higher due to loss of productive years of life, particularly in developing countries. The effort to reduce the growing public health burden of diabetes in the United States and throughout the world includes goals for prevention as well as treatment.

This chapter provides an overview of criteria for diagnosing and classifying diabetes. Prevention of diabetes is addressed focusing on weight management and increased physical activity. The review of treatment focuses on medical nutrition therapy (MNT). Diabetes MNT for preventing complications focuses on the goal of achieving as close to normal metabolism as possible. Metabolic goals target controlling blood pressure and lipid levels as well as glycemic control. The role of MNT in treating diabetes complications is also addressed. The chapter concludes with an overview of programs and resources for preventing and treating diabetes.

II DIAGNOSTIC CRITERIA AND DIABETES CATEGORIES

Diagnostic tests and criteria used to identify individuals who are at risk for developing diabetes (prediabetes) or who have diabetes [6] are listed in Table 31.1. The

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00031-X

TABLE 31.1 Assessment Methods and Criteria for Diabetes Diagnoses

Assessment Method	At Increased Risk for Diabetes (Prediabetes)	Diagnostic for Diabetes	GDM (At Least Two of the Following)
Hemoglobin A1c[a]	A1c 5.7–6.4%	≥ 6.5%	Not applicable
Fasting plasma glucose (FPG)	Impaired fasting glucose of 100–125 mg/dL (5.6–6.9 mmol/L)	FPG ≥ 126 mg/dL (7.0 mmol/L) (on two occasions)	FPG ≥ 95 mg/dL (5.3 mmol/L)
Oral glucose tolerance test, 75 g glucose load	Impaired glucose tolerance 2-hour glucose of 140–199 mg/dL (7.8–11.0 mmol/L)	2-Hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L)	1-Hour plasma glucose ≥ 180 mg/dL (10.0 mmol/L) 2-Hour plasma glucose ≥ 155 mg/dL (8.6 mmol/L) 3-Hour plasma glucose ≥ 140 mg/dL (7.8 mmol/L)
Symptomatic	Not applicable	Symptoms of hyperglycemia or hyperglycemic crisis with random plasma glucose ≥ 200 mg/dL (11.1 mmol/L)	Not applicable

[a]*National Glycohemoglobin Standardization Program certified and standardized to the DCCT assay.*

classifications of diabetes include type 1, type 2, gestational, and diabetes due to other causes [6].

Type 1 diabetes, formerly known as insulin-dependent or juvenile diabetes, represents approximately 5–10% of known cases of diabetes [6]. Type 1 diabetes is characterized by severe insulin deficiency requiring exogenous insulin to prevent ketoacidosis, coma, and death. Population-based research in the United States from the SEARCH for Diabetes in Youth Study multicenter observational study of youth has assessed the incidence of clinically diagnosed diabetes [7]. Data from 2002 and 2003 suggest that approximately 15,000 youth are newly diagnosed with type 1 diabetes annually in the United States [7]. The incidence of type 1 diabetes is higher in whites than in other ethnic/racial groups, with the greatest discrepancy at younger ages [7].

Type 2 diabetes, formerly known as noninsulin-dependent or adult-onset diabetes, accounts for the vast majority (90–95%) of diabetes cases [8]. Development of type 2 diabetes is associated with insulin resistance and inadequate pancreatic cell compensatory insulin production [6]. Symptoms and signs associated with developing type 2 diabetes, which are usually more subtle than for type 1 diabetes, may be related to the presence of complications and include poor wound healing, blurred vision, recurrent gum or bladder infections, and changes in hand or foot sensation. Type 2 diabetes may remain undiagnosed for several years before a clinical diagnosis is made. Many individuals are asymptomatic, and their glucose elevation may be detected as the result of a routine blood test. Type 2 diabetes is rare in children younger than the age of 10 years, but it accounts for an increasing proportion of cases as age increases [7].

Gestational diabetes (GDM) is defined as hyperglycemia identified during pregnancy [8], but for many women undiagnosed type 2 diabetes may be identified during pregnancy. The diagnosis and management of GDM is addressed in a separate chapter.

Specific types of diabetes due to other causes include monogenic diabetes syndromes (such as neonatal diabetes and maturity-onset diabetes of the young), diseases of the exocrine pancreas (such as cystic fibrosis), and drug- or chemical-induced diabetes (such as with glucocorticoid use, in the treatment of HIV/AIDS, or after organ transplantation) [6]. Any disorder or compound that affects the function of the cell in the pancreas can cause diabetes. Endocrinopathies increase counterregulatory hormone production (e.g., acromegaly [excess growth hormone] and Cushing's syndrome [excess cortisol] can cause diabetes if there is insufficient compensatory insulin production). Steroids and second-generation antipsychotic medications, which increase insulin resistance and visceral fat, may increase insulin requirements beyond endogenous capacity. Cystic fibrosis-related diabetes is the most common comorbidity in people with cystic fibrosis. The addition of diabetes to cystic fibrosis is associated with poorer nutrition outcomes in addition to more severe inflammatory lung disease. However, the increase in mortality-associated diabetes in cystic fibrosis patients has decreased with advances in treatment [6].

III MNT FOR DIABETES PREVENTION AND TREATMENT

The American Diabetes Association (ADA) has stated that "medical nutrition therapy (MNT) is an integral component of diabetes prevention, management,

and self-management education" [8] and that "individuals who have diabetes should receive individualized MNT as needed to achieve treatment goals, preferably provided by registered dietitian (RD) familiar with the components of diabetes MNT" [9]. These recommendations are based on evidence that individualized MNT is effective in decreasing hemoglobin A1c (A1c) levels in patients diagnosed with prediabetes [10]. Research data from type 1 and type 2 diabetes have demonstrated a decrease in A1c of −0.3 to −1% in patients with type 1 diabetes and −0.5 to −2% in patients with type 2 diabetes [8,9]. The evidence review for the recommendations noted that randomized controlled trials have demonstrated the effectiveness of nutrition therapy in improving various markers of cardiovascular and hypertension risk. MNT provided by an RD for patients with abnormal lipid profiles has been shown to "reduce daily fat (5−8%), saturated fat (2−4%) and energy intake (232−710 kcal/day) and lower triglycerides (11−31%), LDL cholesterol (7−22%) and total cholesterol (7−21%) levels" [9]. Medicare and other third-party payers require that MNT be administered by a licensed/certified RD or nutrition professional. The steps and strategies for MNT in the prevention and treatment of diabetes are listed in Table 31.2.

The ADA endorses eating a healthful dietary pattern high in fruits, vegetables, whole grains, and nuts; low sodium intake (<2300 mg/day with further reduction in sodium intake individualized for patients with hypertension); and, for most individuals, a modest amount of weight loss [8]. However, the ADA evidence review also noted that a variety of dietary patterns are "modestly effective in managing diabetes including Mediterranean-style, Dietary Approaches to Stop Hypertension (DASH) style, plant-based (vegan or vegetarian), lower-fat, and lower carbohydrate patterns" [9]. Larger scale trials are needed to refine MNT recommendations regarding dietary patterns.

A Prevention of Diabetes

Prevention is an important strategy for reducing health care costs as well as the morbidity and mortality resulting from diabetes. Although there are no established approaches for prevention of type 1 diabetes, research is needed to provide a better understanding of environmental triggers as well as the potential role of immunosuppressive therapy and other possible approaches.

Strategies for the prevention of type 2 diabetes target intervention goals of weight loss and increased physical activity to reduce insulin resistance [11,12]. The evidence that a lifestyle intervention can prevent or delay type 2 diabetes is from randomized clinical trials conducted in people at high risk of developing the disease. These trials demonstrate the critical role of lifestyle intervention addressing excess body weight and physical inactivity [11−16].

The Da Qing Diabetes Prevention Study was a 6-year lifestyle intervention (diet, exercise, or diet plus exercise) in 577 adults with impaired glucose tolerance in China. The results of this study provided preliminary evidence that diet and exercise interventions can lower the conversion to overt diabetes [13]. The 20-year follow-up results showed that individuals in the combined intervention group had a 43% lower incidence of diabetes during the 20-year period and spent an average of 3.6 fewer years with diabetes compared to control group participants [17]. After 23 years of follow-up, this lifestyle intervention was the first to show a reduction in the long-term cardiovascular consequences of diabetes, reducing all-cause and cardiovascular disease (CVD) mortality, mainly among women. The reduction in mortality associated with the lifestyle intervention was mediated by its effect in delaying the onset of diabetes [18].

The Finnish Diabetes Prevention Study (FDPS) was a randomized, controlled clinical trial in 522 individuals with impaired glucose tolerance randomized to either a control or an intervention group [11]. The lifestyle intervention involved a low-fat (<30% of calories from fat and <10% of calories from saturated fat), high-fiber (at least 15 g/1000 kcal) diet in conjunction with moderate-intensity exercise for at least 30 minutes/day [11]. After an average follow-up of 3.2 years, results of the FDPS showed a 58% reduction in the incidence of type 2 diabetes with lifestyle intervention [19]. There were small but significant reductions in total cholesterol, triglyceride, systolic blood pressure, and measurements of inflammation as well as an increase in high-density lipoprotein (HDL) cholesterol in the lifestyle intervention group but not in the control group [19]. Studies from the FDPS of candidate genes affecting energy metabolism showed the importance of genetic polymorphisms in defining responses to lifestyle interventions [20].

The Diabetes Prevention Program (DPP), which was a randomized, controlled, clinical trial conducted in 3234 ethnically diverse individuals with impaired glucose tolerance, randomized participants to one of three treatments: (1) standard lifestyle recommendations plus metformin, (2) standard lifestyle recommendations plus placebo, or (3) intensive lifestyle intervention [12]. The intensive lifestyle intervention was designed to achieve a 7% weight loss (based on initial body weight) and at least 150 minutes of moderate-intensity physical activity per week. The intervention goals included reducing energy intake (500−1000 fewer calories than the amount needed to maintain baseline weight) with a low-fat (25% of calories from fat) diet. The intensive lifestyle intervention program consisted of a 16-session core curriculum in which participants received individualized advice on how

TABLE 31.2 MNT Steps and Strategies by Class of Diabetes

MNT Steps
1. Nutrition referral (physician): Include medical diagnoses and history, laboratory tests, medications, relative body weight, and other pertinent information. 2. Nutrition assessment (RD): Evaluate referring information, the patient's concerns/questions, and review patient's relevant knowledge, skills, and behavior. 3. Nutrition diagnosis (RD): Develop coded problem list for MNT intervention; for example, "Inconsistent carbohydrate intake and inadequate meal planning with meals and snacks varying from 0 to 150 g of carbohydrates on a regular basis." 4. Nutrition intervention (RD): Teach skills for planning meals and carbohydrate intake, develop goals collaboratively with patient related to inconsistent intake, ask patient about barriers to achieving goals, and develop problem-solving strategies with patient to address barriers. 5. Nutrition monitoring and evaluation (RD): Conduct ongoing review of biochemical factors such as A1c and serum lipid levels, as well as lifestyle factors such as dietary intake.
MNT Strategies
Prediabetes
• If overweight, reduce calorie intake to achieve 5–10% weight loss. • Increase moderate-intensity physical activity to at least 150 min per week. • Reduce and/or modify type of fat to achieve weight and lipid goals.
Type 1 diabetes
• Assess usual lifestyle, focusing on eating and physical activity habits, noting time schedule. • Plan insulin therapy to match insulin action to lifestyle schedule—for example, starting with one unit of insulin for 15 g of carbohydrate. • Monitor blood glucose levels while keeping lifestyle consistent to better assess how to match insulin to carbohydrate intake and physical activity. • Adjust insulin and lifestyle to achieve blood glucose levels in the target range. • Create algorithms for adjusting insulin for lifestyle flexibility (e.g., insulin to carbohydrate ratios) and to correct blood glucose levels that are not in the target range.
Type 2 diabetes
• If overweight, reduce calorie intake to achieve 5–10% weight loss. • Increase physical activity. • Monitor blood glucose to assess pattern of glycemic control. • If postprandial glucose level is high, spread food intake throughout the day (using five or six small meals/snacks rather than having fewer larger ones). • Reduce and/or modify type of fat to achieve weight and lipid goals.
GDM
• Plan calorie intake to achieve desired weight gain based on desirable body weight. • Balance carbohydrate intake throughout the day (usually 40–50% of calories). • Monitor glucose approximately seven times per day; adjust intake to achieve glucose levels in target range. • Add exogenous insulin if target glucose levels are not achieved by diet alone.
Secondary diabetes
• Assess interrelationship between primary disease(s) and its treatment in relation to the secondary diabetes to establish treatment priorities. • Institute diabetes treatment as needed to avoid short- and long-term complications.

to reach their goals with follow-up booster sessions to support maintenance of lifestyle changes [21].

After an average follow-up period of 2.8 years, the DPP results showed that the incidence of diabetes was reduced by 58% in the intensive lifestyle intervention group compared to 31% in the metformin group [12]. Further analysis revealed that weight loss was the dominant predictor of the observed reduced diabetes incidence: when adjusted for changes in diet and physical activity, each kilogram of weight loss resulted in a 16% reduction in diabetes risk [22]. Furthermore, lower percentage of calories from fat and increased physical activity accounted for the weight loss, indicating that it was through these intermediates that the diabetes risk reduction was accomplished [22]. However, participants in the intensive lifestyle intervention who did not achieve

the 7% weight loss goal but did achieve the goal of 150 minutes of physical activity per week had a 44% reduction in the incidence of diabetes [22]. The intensive lifestyle treatment effects did not differ by sex, race, or ethnic group.

Unlike the intensive lifestyle intervention, which was effective across the entire baseline body weight and fasting glucose ranges, metformin was ineffective in those with a body mass index (BMI) less than 30 kg/m^2 and minimally effective in those with a BMI less than 35 kg/m^2 or with a fasting glucose level less than 110 mg/dL (6.1 mmol/L). As in the FDPS [19], insulin sensitivity improved in the intensive lifestyle intervention group, with a smaller increase in the metformin group and no change in the placebo group. Insulin secretion decreased in all groups, but it was associated with improved cell function only in the intensive lifestyle intervention group [23]. The lifestyle intervention resulted in a lower prevalence and need for medical treatment of hypertension and dyslipidemia [24]. The lifestyle intervention also lowered inflammatory biomarkers associated with increased cardiovascular risk [25].

Ten-year follow-up of the DPP found that the cumulative incidence of diabetes remained the lowest in the intensive lifestyle intervention group [16]. After 15 years of follow-up, diabetes incidence was reduced by 27% in the lifestyle intervention group and by 18% in the metformin group, compared with the placebo group. There were no overall differences in microvascular outcomes between treatment groups; however, in women, the lifestyle intervention was associated with a 21% ($p = 0.03$) and 22% ($p = 0.02$) lower prevalence of microvascular complications compared with the placebo and metformin groups, respectively. In addition, participants who did not develop diabetes had a 28% lower prevalence of microvascular complications, again supporting the importance of diabetes prevention [26].

Both the DPP and the FDPS asked participants to self-monitor their food intake [19,21,27]. In the FDPS, participants were asked to complete 3-day food records four times per year [19,27]; in the DPP, participants were asked to self-monitor their activity, food intake, calories, and fat grams daily during the first 24 weeks and then at least 1 week per month thereafter. In the DPP, the frequency of dietary self-monitoring was related to success at achieving both the physical activity goal and the weight loss goal. Moreover, DPP participants, who were 65 years old or older, were more likely to complete self-monitoring records, report a lower percentage of calories from fat, and meet the activity and weight loss goals than were those who were younger than 45 years [28]. Thus, it is not surprising that older participants had a greater (71%) risk reduction in the development of diabetes with lifestyle intervention [12]. Lifestyle coaches in the DPP taught the participants to use a problem-solving approach to manage high-risk situations (stress, vacations, and eating out) and used a toolbox approach to deal with barriers to lifestyle change [21,29]. The DPP lifestyle intervention materials have been made available to all health care practitioners at https://dppos.bsc.gwu.edu/web/dppos/lifestyle. Diabetes prevention intervention materials for community programs are available at http://www.cdc.gov/diabetes/prevention/index.html. When translating the DPP lifestyle intervention into practice, it is important to provide clients with both the knowledge and the skills needed to make lifestyle changes. The skills of goal setting, self-monitoring, problem-solving, relapse prevention, and managing high-risk situations were critical in facilitating the lifestyle change process [29,30].

Dietary patterns that are higher in intake of fruits, vegetables, legumes and nuts, whole grains rather than refined grain, and lower intake of red/processed meats and sugar-sweetened beverages are associated with reduced risk of developing diabetes [31]. Such dietary patterns focus on intake of naturally occurring nutrient-rich food groups with increasing emphasis on the quality of dietary fats and carbohydrates consumed. Meta-analyses of prospective studies have indicated that greater adherence to Mediterranean patterns (higher diet score) resulted in a respective 23% and 19% reduction in risk of developing diabetes [32,33]. Both of the meta-analysis papers noted methodological limitations of the observational studies, and both included the PREDIMED-Reus study [34,35] as the only randomized controlled clinical trial. The PREDIMED-Reus compared the effects of a low-fat dietary pattern (control) to a Mediterranean dietary pattern supplemented with virgin olive oil or mixed nuts on the incidence of diabetes over a 4-year period in a community dwelling with older adults who had three cardiovascular risk factors but did have over diabetes. The PREDIMED intervention did not include any intervention goals related to physical activity or weight loss [34,35]. Relative to the low-fat pattern, the combined Mediterranean patterns resulted in a 30% reduction in the incidence of diabetes after adjusting for confounders that may affect the risk of developing diabetes [34,35].

The HEALTHY study was a randomized, controlled, multicenter study of middle-school-aged children in the United States designed to reduce risk factors associated with developing type 2 diabetes [36]. The combined prevalence (intervention and control schools) of overweight and obesity in schools was decreased (primary outcome), but there were no differences in prevalence of overweight and obesity between intervention and control schools. However, the intervention schools had significantly greater decreases in BMI z-scores, percentage of students with a waist circumference at or above the 90th percentile, fasting insulin levels, and obesity prevalence [37].

The efficacy of the intervention in prevention of type 2 diabetes in youth will require additional participant follow-up and further testing.

B Diabetes Treatment

The overall goal of therapy for diabetes is to normalize metabolism (with emphasis on blood glucose and lipids, particularly low-density lipoprotein [LDL] cholesterol and blood pressure) in order to prevent diabetes-related complications [8]. Acute complications include hyperglycemia resulting in ketoacidosis in type 1 and hyperglycemic coma in type 2 diabetes and hypoglycemia in patients treated with insulin or medications that raise blood insulin levels [8]. Longer term complications include microvascular, macrovascular, and neuropathic complications [8]. Results from clinical trials in individuals with both type 1 and type 2 diabetes provide evidence that improving metabolic control (glycemia, blood pressure, and lipids) greatly reduces the development and progression rates for microvascular, macrovascular, and neuropathic complications [21,27,38–41]. The goals are sometimes referred to as the ABCs, with targets of A1c $\leq$ 7%, blood pressure (systolic $<$ 140 mm Hg and diastolic $<$ 90 mm Hg), and LDL cholesterol $<$ 100 mg/dL [42,43]. These clinical goals are typically achieved with a combination of nutrition and lifestyle interventions and medications.

A range of oral medications, injectables, and insulin are available to manage glycemia in addition to nutrition and lifestyle recommendations (Table 31.3) [42,44]. Type 1 diabetes is primarily managed with intensive insulin therapy. Due to the increasingly large number of antihyperglycemic drugs for type 2 diabetes, the growing uncertainty regarding their proper selection and sequence, and the paucity of comparative effectiveness research on long-term treatment outcomes with many of these medications, the ADA and the European Association for the Study of Diabetes (EASD) position statement focuses individualizing both treatment targets and treatment strategies using a patient-centered approach and shared decision making [44,45].

The target for glycemic control is influenced by a variety of fixed and modifiable patient and disease factors including age, disease duration, life expectancy, important comorbidities, established vascular complications, the risks and consequences to the patient from an adverse drug event, patient attitude, and expected treatment efforts and access to resources and support system. Initial therapy with lifestyle intervention and metformin as monotherapy is recommended for patients with type 2 diabetes due to its low cost, proven safety record, weight neutrality, and possible benefits on cardiovascular outcomes. Assessment of motivation to focus on weight loss and increased activity along with results of self-monitoring of blood glucose is important in determining the need for adjustment or advancement of the medication regimen. If glycemic targets are not achieved within 2 or 3 months or are not sustained, the addition of other medications and transition to new regimens including insulin is recommended with consideration given to the additional complexity and costs of multiple combinations of glucose-lowering medications. MNT and diabetes self-management education are integral to the therapeutic program and ensure that patients have access to information on methods to reduce where possible the amount of medications needed and safely monitor and control blood glucose levels [8].

Diabetes standards of care include routine blood glucose monitoring for all patients with type 1 diabetes and meaningful monitoring for patients with type 2 diabetes based on risk of hypoglycemia [42,46]. Continuous blood glucose monitoring can be useful for patients with type 1 or type 2 diabetes who have unappreciated hyperglycemia, a history of severe hypoglycemia, hypoglycemia unawareness, or an inability to achieve A1c targets. Blood glucose monitoring data can be used as an education tool to help both patients and providers assess the quality of glycemic control, evaluate glucose variability, and interpret blood glucose patterns related to insulin, diet, and activity. Patients who use an insulin pump have a rich data set of additional information to supplement glucose monitoring data that include recorded carbohydrate intake, and time and amount of insulin delivered whether for a meal or correction dose. Nonpump users need to track this information separately [46].

1 Type 1 Diabetes

The Diabetes Control and Complications Trial (DCCT) was conducted in individuals with type 1 diabetes to compare the effects of intensive versus standard glycemic control [47]. Intensive treatment reduced the mean A1c from 9% to 7.2%, and greater attention to dietary strategies accounted for almost one-fourth of the glycemic improvement [47,48]. The risk of the development and progression of retinopathy, albuminuria, and neuropathy was reduced by between 50% and 75% over 8 years [47]. Reduction in the risk of complications was linearly related to the reduction in A1c, indicating that risk reduction can be achieved by improving glycemic control, even if a perfect or normal metabolic state is not achieved [49–51]. These accomplishments, as well as efforts to attenuate the two- or threefold increase in severe hypoglycemia and weight gain, were largely due to educational and nutritional strategies [48,52].

Longer term follow-up of the DCCT cohort in the Epidemiology of Diabetes Interventions and Complications study has documented a continued differential in the risk of microvascular (nephropathy and

TABLE 31.3 Properties of Glucose-Lowering Medications for Treating Diabetes

Class	Compound(s)	Cellular Mechanism(s)	Primary Physiological Action(s)	Advantages	Disadvantages	Cost
Biguanides	• Metformin	Activates AMP-kinase (? other)	• ↓ Hepatic glucose production	• Extensive experience • No hypoglycemia • ↓ CVD events (UKPDS)	• Gastrointestinal side effects (diarrhea, abdominal cramping) • Lactic acidosis risk (rare) • Vitamin B12 deficiency • Multiple contraindications: CKD, acidosis, hypoxia, dehydration, etc.	Low
Sulfonylureas	2nd Generation • Glyburide/ glibenclamide • Glipizide • Gliclazide[a] • Glimepiride	Closes KATP channels on β-cell plasma membranes	• ↑ Insulin secretion	• Extensive experience • ↓ Microvascular risk (UKPDS)	• Hypoglycemia • ↑ Weight • ? Blunts myocardial ischemic preconditioning • Low durability	Low
Meglitinides (glinides)	• Repaglinide • Nateglinide	Closes KATP channels on β-cell plasma membranes	• ↑ Insulin secretion	• ↓Postprandial glucose excursions • Dosing flexibility	• Hypoglycemia • ↑ Weight • ? Blunts myocardial ischemic preconditioning • Frequent dosing schedule	Moderate
Thiazolidinones	• Pioglitazone[a] • Rosiglitazone[b]	Activates the nuclear transcription factor PPAR-γ	• ↑ Insulin sensitivity	• No hypoglycemia • Durability • ↑ HDL-C • ↓ Triglycerides (pioglitazone) • ? ↓ CVD events (PROactive, pioglitazone)	• ↑ Weight • Edema/heart failure • Bone fractures • ↑ LDL-C (rosiglitazone) • ? ↑ MI (meta-analyses, rosiglitazone)	Low
α-Glucosidase inhibitors	• Acarbose • Miglitol	Inhibits intestinal α-glucosidase	• Slows intestinal carbohydrate digestion/ absorption	• No hypoglycemia • ↓Postprandial glucose excursions • ? ↓ CVD events (STOP-NIDDM) • Nonsystemic	• Generally modest HbA1c efficacy • Gastrointestinal side effects (flatulence, diarrhea) • Frequent dosing schedule	Moderate
DPP-4 inhibitors	• Sitagliptin • Vildagliptin[a] • Saxagliptin • Linagliptin • Alogliptin	Inhibits DPP-4 activity, increasing postprandial active incretin (GLP-1, GIP) concentrations	• ↑ Insulin secretion (glucose-dependent) • ↓ Glucagon secretion (glucose-dependent)	• No hypoglycemia • Well tolerated	• Angioedema/urticaria and other immune-mediated dermatological effects • ? Acute pancreatitis • ? ↑ Heart failure hospitalizations	High
Bile acid sequestrants	• Colesevelam	Binds bile acids in intestinal tract, increasing hepatic bile acid production	• ? ↓ Hepatic glucose production • ? ↑ Incretin levels	• No hypoglycemia • ↓ LDL-C	• Generally modest HbA1c efficacy • Constipation • ↑ Triglycerides • May ↓ absorption of other medications	High

(*Continued*)

TABLE 31.3 (Continued)

Class	Compound(s)	Cellular Mechanism(s)	Primary Physiological Action(s)	Advantages	Disadvantages	Cost
Dopamine-2 agonists	• Bromocriptine (quick release)[b]	Activates dopaminergic receptors	• Modulates hypothalamic regulation of metabolism • ↑ Insulin sensitivity	• No hypoglycemia • ? ↓ CVD events	• Generally modest HbA1c efficacy • Dizziness/syncope • Nausea • Fatigue • Rhinitis	High
SGLT2 inhibitors	• Canagliflozin • Dapagliflozin[a] • Empagliflozin	Inhibits SGLT2 in the proximal nephron	• Blocks glucose reabsorption by the kidney, increasing glycosuria	• No hypoglycemia • ↓ Weight • ↓ Blood pressure • Effective at all stages of T2DM	• Genitourinary infections • Polyuria • Volume depletion/hypotension/ dizziness • ↑ LDL-C • ↑ Creatinine (transient)	High
GLP-1 receptor agonists	• Exenatide • Exenatide extended release • Liraglutide • Albiglutide • Lixisenatide[a] • Dulaglutide	Activates GLP-1 receptors	• ↑ Insulin secretion (glucose-dependent) • ↓ Glucagon secretion (glucose-dependent) • Slows gastric emptying • ↑ Satiety	• No hypoglycemia • ↓ Weight • ↓ Postprandial glucose excursions • ↓ Some cardiovascular risk factors	• Gastrointestinal side effects (nausea/ vomiting/diarrhea) • ↑ Heart rate • ? Acute pancreatitis • C-cell hyperplasia/medullary thyroid tumors in animals • Injectable	High
Amylin mimetics	• Pramlintide[b]	Activates amylin receptors	• ↓ Glucagon secretion • ↑ Satiety • Slows gastric emptying	• ↓ Postprandial glucose excursions • ↓ Weight	• Generally modest HbA1c efficacy • Gastrointestinal side effects (nausea/ vomiting) • Hypoglycemia unless insulin dose is simultaneously reduced • Injectable • Frequent dosing schedule • Training requirements	High
Insulins	• Rapid-acting analogs – Lispro – Aspart – Glulisine • Short-acting – Human Regular • Intermediate-acting – Human NPH • Basal insulin analogs – Glargine – Detemir – Degludec[a] • Premixed (several types)	Activates insulin receptors	• ↑ Glucose disposal • ↓ Hepatic glucose production • Other	• Nearly universal response • ↓ Microvascular risk (UKPDS) • Theoretically unlimited efficacy	• Hypoglycemia • Weight gain • ? Mitogenic effects • Injectable • Training requirements • Patient reluctance	Variable

retinopathy) and macrovascular (CVD) complications, even though A1c levels in the two groups have been similar for approximately 8 years [53,54]. After 30 years of follow-up, intensive therapy reduced the incidence of CVD by 30% and the incidence of major cardiovascular events (nonfatal heart attacks, stroke, or cardiovascular death) by 32% [55]. The lower HbA1c levels during the 30-year trial statistically explain all of the observed treatment effect.

Several types of insulin are available (Table 31.3), and they are often used in various combinations in order to match insulin action to the patient's lifestyle—for example, time and type and amount of food eaten. A typical approach in terms of insulin use is a "basal-bolus" regimen, either via subcutaneous insulin infusion (or pump therapy) or via multiple daily injections (MDIs), in which insulin is delivered as a bolus before meals in amounts matched to total carbohydrate intake, with basal insulin on board consistently over time. There are other approaches to MDI that utilize different types of insulin. Patients can either vary their insulin dose to match the amount of food consumed, with additional considerations for physical activity, or meals and physical activity can be held constant in order to match a constant dosing of insulin from day to day. Reduction of insulin dosage is the preferred method of preventing hypoglycemia during and/or after exercise, but this requires planning physical activity ahead of time. For unplanned exercise, increased carbohydrate intake may be needed.

In the DCCT, dietary behaviors associated with better glycemic control in the intensively treated group included adherence to an overall meal plan (timing and amount of carbohydrate), appropriate treatment of hypoglycemia (avoiding excess consumption of carbohydrate to treat symptoms), prompt intervention for hyperglycemia (more insulin and/or less food), and consistent consumption of planned evening snacks [48]. The mean level of weight gain in the intensively treated group was reduced by 50% after the intervention staff focused on strategies to control weight gain. Strategies to minimize potential for weight gain included discussing risk for weight gain prior to initiation of intensive therapy, proactively reducing calorie intake goals by 250−300 calories, adjusting insulin doses preferentially for anticipated increases in activity (rather than adding extra snacks), and avoiding excessive food consumption to prevent and treat hypoglycemia [52].

A strategy to avoid overtreating hypoglycemic symptoms involves (1) documenting that the symptoms are truly indicative of hypoglycemia (blood glucose below the normal fasting range of 70−120 mg/dL), (2) treating the hypoglycemia with 15 g of carbohydrate, and (3) waiting for 15 minutes before eating more. This strategy is sometimes referred to as the 15/15 rule for hypoglycemia. Strategies to minimize the frequency of hypoglycemia focused on the importance of carbohydrate consistency and prioritizing reduction of fat intake when reducing calories to prevent weight gain and teaching tailored adjustment of insulin dose for activities of various intensities and durations based on blood glucose monitoring results [48].

The Academy of Nutrition and Dietetics has established evidenced-based diabetes MNT for patients with type 1 diabetes [56]. In the randomized field test, specific guidelines for nutrition counseling were used by dietitians with 24 patients, and results were compared with those of 30 patients receiving "usual counseling" as the control treatment condition. The mean A1c in the guidelines-treated patient group was significantly reduced compared with the control group (1.0% vs 0.3%) [57].

The Dose Adjustment for Normal Eating study demonstrated improvements in A1c, quality of life, psychological well-being, and satisfaction with treatment in individuals with type 1 diabetes, who learned to use glucose testing to better match insulin to carbohydrate intake despite an increase in the number of daily glucose tests and insulin injections [58]. The quality-of-life improvements were maintained at the 4-year follow-up, although the glycemic control improvements were maintained to a lesser extent [59].

2 Type 2 Diabetes

The United Kingdom Prospective Diabetes Study (UKPDS) examined the benefit of metabolic control (glucose and blood pressure) in patients newly diagnosed with type 2 diabetes [41,60−64]. Fundamentally, the UKPDS confirmed that the findings of the DCCT also apply to type 2 diabetes. There was a reduction in macrovascular and microvascular complications, and the best results were obtained in those individuals who achieved both glucose and blood pressure control. Similarly, there was a clear dose−response relationship between metabolic and blood pressure control and the risk of diabetes complications.

The Lifestyle Over and Above Drugs in Diabetes randomized, controlled trial in New Zealand examined the impact of intensive nutritional counseling over a period of 6 months in patients with type 2 diabetes ($n = 93$). Significant reductions in the intervention group were observed in A1c, weight, BMI, and waist circumference compared to the control group [65]. MNT for treatment of type 2 diabetes focused on weight loss and physical activity to improve insulin sensitivity and metabolic control of glucose, lipids, and blood pressure.

The ADA and the EASD position statement recommends metformin as the optimal drug for monotherapy of diabetes and then outlines the properties of available glucose-lowering agents in the United States and Europe (Table 31.3) that may guide individualized treatment options to achieve glycemic targets [44,45]. Many

patients with type 2 diabetes take five or more medications to achieve blood glucose, blood pressure, and cholesterol goals, as well as low-dose aspirin. The impact of weight loss is most dramatically demonstrated by bariatric surgery, although the effects of bariatric surgery on diabetes appear to be largely independent of weight loss and may be due to changes in hormonal metabolism [66].

The Look-AHEAD (Action for Health in Diabetes) study, a multicenter, randomized, controlled trial of an intensive lifestyle intervention in 5145 patients with type 2 diabetes, found that a weight loss of 8.6% was associated with improved diabetes control, as indicated by reductions in diabetes medication use and A1c levels [67]. Four-year results of the Look-AHEAD study indicate that significant improvements in weight loss, fitness, and A1c observed in the intensive lifestyle intervention group compared to the control group were sustained [68]. By study end, the differences in CVD risk factors had diminished, with A1c and blood pressure showing the most sustained improvements. The Look-AHEAD lifestyle intervention was adapted from the DPP intervention to meet the needs of people with diabetes and incorporated the use of meal replacements to provide structure and enhance weight loss results [69]. These lifestyle interventions are currently being translated into clinical practice settings for primary care patients in more cost-efficient ways with comparable effectiveness in terms of weight loss, A1c, and reductions in medications and associated costs [70].

The Treatment Options for type 2 Diabetes in Adolescents and Youth (TODAY) study found that metformin alone achieved durable glycemic control (A1c < 8%) in approximately half of the subjects, suggesting that many youth with type 2 diabetes are likely to require combination treatment within a few years of diagnosis [71–75]. The participants in this clinical trial were reported to consume unhealthful diets and be unfit [72,73]; dyslipidemia, hypertension, microalbuminuria, and chronic inflammation were common and appeared to worsen over time in these youth regardless of diabetes treatment [74,75]. Youth with type 2 diabetes and their families need to prioritize lifestyle modifications such as eating a healthful diet, maintaining a healthy weight, and exercising regularly. Nutrition and lifestyle interventions that are culturally appropriate and sensitive to family resources are needed to improve the diets and lifestyle-related health outcomes of these youth [71].

IV APPROACHES TO TREAT COMORBIDITIES AND REDUCE COMPLICATIONS

The rates of CVD and related complications have improved significantly over the past decade and morbidity and mortality have decreased [43]. Diabetes is also the leading cause of kidney failure, nontraumatic amputations, and new cases of blindness for U.S. adults. The Action to Control Cardiovascular Risk in Diabetes study was a randomized, controlled trial that examined the effects of intensive glycemic control (target A1c < 6%) versus standard glycemic control (target A1C between 7% and 7.9%) in 10,251 patients with extant diabetes on CVD outcomes. The treatment arm receiving intensive control of blood pressure and lipids did not have a significant improvement over controls [76]. Results from two other large, randomized, controlled trials—the ADVANCE study and the Veterans Affairs Diabetes Trial—also found no significant reduction in CVD risk with intensive glycemic control [38,77]. The results of these three trials indicate that intensive treatment may not provide any additional benefit, at least in the time period of treatment and populations observed in these studies [78].

The Look-AHEAD study also examined the effect of achieving and maintaining weight loss on cardiovascular risk reduction. One-year results of the intervention indicated that the clinically significant weight loss (8.6%) was associated with reductions in CVD risk factors as indicated by blood pressure, triglycerides, HDL cholesterol, and urine albumin-to-creatinine ratio [67]. Reductions in C-reactive protein have also been observed [79]. Four-year results of the study indicate that the improvements in systolic blood pressure and HDL cholesterol levels observed in the intensive lifestyle intervention group compared to the control group were sustained [68]. After a median follow-up of 9.6 years, the Look-AHEAD trial was stopped early based on a futility analysis [80]. There were no significant differences found between the lifestyle intervention and the diabetes support and education treatment groups in the hazard rates for the primary composite CVD outcomes (fatal and nonfatal heart attacks and strokes, hospitalized angina). The overall cardiovascular event rate was low in both groups, with the lifestyle intervention group achieving greater weight loss and activity levels and the diabetes support and education group receiving greater amounts of medications for A1c, blood pressure, and lipid management [80]. At study end, the lifestyle intervention group had sustained a weight loss of 6% versus 3.5% weight loss in the diabetes support and education group. Moreover, the lifestyle intervention group achieved many other clinical and psychological benefits compared with the diabetes support and education group. They achieved improved outcomes for A1c, blood pressure, triglycerides, C-reactive protein, self-reported retinopathy, nephropathy, diabetes remission rates, sleep apnea, fatty liver disease, sexual dysfunction, urinary incontinence, physical function, knee pain, quality of life, depression and body image dissatisfaction and

reductions in number of medications, medication costs, and hospitalizations. These results have important implications for clinical practice [81].

V NUTRIENT INTAKE CONSIDERATIONS

The ADA and other diabetes organizations address nutrient intake in their nutritional recommendations [9,82,83]. The guidelines are similar; therefore, this section focuses on ADA [9] and highlights a few additional recommendations developed by the EASD [82,83].

A Protein

The ADA recommends basing protein intake for individuals with all classes of diabetes and normal renal function largely on the review by the Institute of Medicine to establish recommendations for the general public with 15−20% of energy intake from protein [9]. The EASD recommends 10−20% of energy intake from protein without established nephropathy [82]. Individuals who may need more than 20% of energy intake from protein include those in a catabolic state, those with growth needs (children, adolescents, and pregnant women), and individuals on very low energy diets to achieve weight loss.

B Fat

Intake of fat can blunt and extend postprandial glycemic excursions. An evaluation of the intensively treated DCCT patients revealed that a higher intake of fat and saturated fat and lower intake of carbohydrate were associated with worse glycemic control, independent of exercise and BMI [84]. The ADA recommends that all individuals with diabetes limit their saturated fat to less than 7% of total energy, minimize *trans*-fat intake [9]. In addition to these recommendations, the ADA also recommends consumption of two or more servings of fish per week in order to increase intake of *n*-3 fatty acids, which may contribute to improved cardiometabolic risk factor outcomes [9]. Similar to the ADA, the EASD recommends limiting saturated and *trans*-fat intakes and consuming two or three servings of fish per week [9,82].

C Carbohydrates

Dietary carbohydrate is the major determinant of postprandial glucose concentration and is therefore integral to glycemic control. The ADA recognizes total carbohydrate as the major determinant of postprandial glucose concentration, with the type of carbohydrate as an additional determinant [9]. Although fructose is associated with a reduction in postprandial hyperglycemia when it is substituted for sucrose or starch, the long-term consequences of high fructose intake on plasma lipids and other diabetic complications is unknown. Based on a 2009 meta-analysis of 16 trials reporting that the effects of fructose intake on blood lipids in individuals with type 2 diabetes were mixed [9,85], both the ADA and EASD make no specific recommendation regarding the use of fructose [9,82,83]. The ADA's nutrition recommendations indicate that glycemic control is not contingent on restricting sucrose and suggest that the decision about sugar consumption should be based on overall nutrition considerations [9]. Nonetheless, consumption of large quantities of sugars (e.g., high-fructose corn syrup in soft drinks and other beverages) can make a substantial contribution to the intake of excess calories [86].

The concept of glycemic indexing of food was developed to compare the effects of the quality of carbohydrate while keeping the amount of carbohydrate standardized. The estimated glycemic load of foods, meals, and dietary patterns is calculated by multiplying the glycemic index by the amount of carbohydrate in each food and then totaling for all of the foods in a meal or dietary pattern. The role of the glycemic index and/or glycemic load lacks consensus recommendations, although modifying the type as well as the amount of carbohydrate can improve glycemic control [9]. A randomized trial conducted in children with type 1 diabetes achieved better A1c and quality-of-life outcomes with a flexible low-glycemic index diet than with a measured carbohydrate exchange diet [87]. Randomized controlled trials in individuals with type 2 diabetes have achieved mixed results: A 6-month trial found a moderate decrease in A1c [88], whereas a 1-year trial found no improvement in A1c [89]. A third trial found a decrease in A1c in both the low-glycemic diet group and the ADA diet education group at 1 year [90]. Meta-analysis results have also been mixed; a review by Brand-Miller et al. [91] found significant decreases in A1c levels while on low-glycemic diets, whereas Anderson et al. [92] found no significant difference in A1c levels between a low- and high-glycemic diet. Taking this evidence into account, the ADA and the EASD recognize that considering the glycemic index of carbohydrates may provide additional benefit over considering total carbohydrate alone, provided that the overall attributes of the carbohydrate are taken into account [9,82,83]. More recently, research on an 800-person cohort without diabetes revealed that people eating identical meals present high variability in postmeal blood glucose response and that use of an algorithm that integrates blood parameters, dietary habits, anthropometrics, physical activity, and gut microbiome features enabled accurate glucose response prediction [93]. Future research will further elucidate the utility of this approach over longer periods of time. In the meantime, both organizations recommend dietary patterns that include carbohydrates from

whole grain cereals, fruits, vegetables, legumes, and low-fat milk [9,82].

Findings from several randomized, controlled trials [94–96] indicate that fiber supplements (additional 4–19 g/day) do not improve glycemia or CVD risk factors, and therefore the recommended dietary intake for the general public is also recommended for people with diabetes [9]. In essence, given the many factors that can affect glucose metabolism, including those beyond nutrition per se (e.g., medicines and activity), it is often problematic to predict the exact plasma glucose response to specific carbohydrate-containing foods. Certainly, blood glucose self-monitoring and experience can help predict the glycemic effects of food products. Furthermore, a variety of methods can be used to estimate the nutrient content of meals, including carbohydrate counting, the exchange system, and experience. With emerging evidence of the relations between postprandial glycemia and CVD [97], postprandial glucose levels are of increasing importance.

Fructose, mannitol, and sorbitol are often substituted for sucrose in "sugar-free" products. In experimental studies, these products can shift the balance from oxidation of fatty acids to esterification of fatty acids in the liver, which can in turn increase VLDL synthesis [56]. Although the effects on serum lipids are inconsistent, susceptible individuals may have a worsening of dyslipidemia. These sweeteners appear to offer no documented advantage in the management of diabetes over other carbohydrate sources.

Labeling of food products with regard to carbohydrate composition can be confusing. Food products may list the "net" or "impact" carbohydrate on the front of the label, a value considerably lower than the "total" carbohydrate listed on the nutrient facts panel. Fiber or fiber plus the sugar alcohols are usually subtracted to obtain the net or impact carbohydrate value, but there is no standardization [98]. If patients with diabetes use these products, monitoring is needed to determine the effects on blood glucose. Nonnutritive sweeteners, which are considered high-intensity sweeteners, are widely used as a replacement of various types of sugar in food and beverage products. An evidence-based review by the Academy of Nutrition and Dietetics suggests that all approved intense sweeteners, also known as noncaloric and nonnutritive sweeteners (aspartame, saccharin, acesulfame K, sucrolose, and stevia), have no adverse effects on diabetes management [56].

Alcohol can inhibit hepatic glucose production, resulting in hypoglycemia if consumed without food when the diabetes treatment regimen includes insulin or sulfonylureas [56]. Conversely, consuming large amounts of alcohol can increase blood glucose levels during severe insulin deficiency. A systemic review found that alcohol intake, diabetes, hypertension, and hypertriglyceridemia are associated with increased risk of developing gout [99]. Alcohol intake can exacerbate pancreatitis, severe hypertriglyceridemia, severe neuropathy, myocardiopathy, or renal failure, which are comorbidities associated with diabetes.

The Study to Help Improve Early Evaluation and Management of Risk Factors Leading to Diabetes findings [100] have demonstrated that for people with diabetes there is a significant gap between knowledge of nutrition and lifestyle recommendations (what to do) and how to incorporate these recommendations into lifestyle routines. MNT is the process by which these evidence-based nutrition recommendations are translated into a plan that individuals can follow based on a thorough assessment of each person's lifestyle, capabilities, and motivation to change. The tools and techniques to facilitate behavior change are discussed in another chapter.

VI COLLABORATIVE EFFORTS FOR DIABETES PREVENTION AND TREATMENT

In the United States, much effort within the voluntary, professional, academic, and private sectors is directed at addressing the challenges of diabetes. The National Diabetes Education Program (NDEP), a partnership of the National Institutes of Health and the CDC, serves as a "coordinating entity" among public and private organizations (http://www.cdc.gov/diabetes/ndep/index.html). The NDEP developed the Guiding Principles for the Care of People with or at Risk for Diabetes in collaboration with several partner organizations. The Guiding Principles recommend providing patient-centered care and shared decision making, which is achieved by "eliciting patient perspectives and presenting options and information so patients can participate more actively in care." Use of the medical home model is suggested to provide "accessible, continuous, comprehensive, and coordinated care that is delivered by a health care team in the context of family and community" [101]. Guiding Principles for Diabetes educational materials and other resources are available from the NDEP and some of its partners from their websites (Table 31.4).

In addition, the CDC's Division of Diabetes Translation is addressing community infrastructure and environmental issues to reduce the burden of diabetes, including public health surveillance systems for diabetes, applied translational research, state-based diabetes control programs, and public information (see http://www.cdc.gov/diabetes/about/). The National Institutes of Health has also expanded the focus of research to address how environmental factors and community infrastructure are related to obesity and the risk of diabetes and other chronic

VII CONCLUSION

The long-term goal of diabetes prevention and treatment is restoring metabolism as close to normal as possible in order to reduce the morbidity and mortality associated with diabetes. The focus for all classes of diabetes is on reducing cardiovascular risk factors such as hypertension and dyslipidemia. The distribution of macronutrient intake may vary based on a number of factors, including matching insulin to lifestyle in type 1 diabetes and weight loss in type 2 diabetes.

MNT is based on individual assessment and development of a personalized tailored evidence-based treatment plan. An RD who consults with the health care team and assesses the patient's needs is well positioned to develop a tailored treatment plan that considers overall health needs and individual capabilities with the goal of ameliorating the metabolic effects of diabetes and its complications.

Chapter 32

Nutritional Management for Gestational Diabetes

Alyce M. Thomas[1] and Maria Duarte-Gardea[2]

[1]St. Joseph's Regional Medical Center, Paterson, NJ, United States, [2]The University of Texas at El Paso, El Paso, TX, United States

I INTRODUCTION

Gestational diabetes mellitus (GDM) is diabetes diagnosed in the second or third trimester of pregnancy that is not clearly either type 1 diabetes (T1DM) or type 2 diabetes (T2DM) [1]. This is how the American Diabetes Association (ADA) defines GDM in its 2016 Standards of Medical Care and it represents a shift in the previous definition. Prior to 2016, GDM was defined for many years as carbohydrate intolerance of variable degree with onset or first recognition during pregnancy and included all women regardless of whether the condition may have predated the pregnancy. Now, according to the ADA, diabetes diagnosed in the first trimester is considered undiagnosed T2DM and the treatment protocol is the same as for women with T2DM.

However, other organizations have not adopted this definition. The World Health Organization (WHO) defines GDM as hyperglycemia that is first recognized during pregnancy [2]. GDM is defined by the American College of Obstetricians and Gynecologists (ACOG) as a condition in women who have carbohydrate intolerance with onset or recognition during pregnancy [3].

GDM is associated with complications during and after pregnancy. The woman is at risk of developing GDM in subsequent pregnancies and/or T2DM in the future. Exposure to maternal hyperglycemia in utero conveys a risk for obesity and T2DM in the offspring. The key to prevention or decreasing the risk of complications is to achieve and maintain optimal glycemic control during the pregnancy. The management of GDM includes medical nutrition therapy (MNT), physical activity, and, if indicated, pharmacological therapy [4]. An interdisciplinary health care team, which includes endocrinologists, obstetricians, registered dietitians, diabetes educators, nurses, social workers, and other professionals, works in collaboration with the common goal of normoglycemia from diagnosis to postpartum.

The benefits of lifestyle modifications go beyond the immediate postpartum period. It may represent an opportunity for the registered dietitian and other health care providers to impact lifestyle patterns aimed toward establishing future habits that will benefit the woman and her family.

II PREVALENCE

Almost 4 million babies were born in the United States in 2014 [5]. Although the true prevalence of GDM is unknown, it is estimated to affect 1−14% of pregnancies in the United States annually [6]. In a study using the Pregnancy Risk Assessment Monitoring System, the prevalence was 9.2% [6], which could mean the number of pregnancies affected by GDM is greater than 350,000 per year. This variation in the prevalence depends on the population studied and the diagnostic tests used [7]. In populations with a higher prevalence of obesity and T2DM, the prevalence of GDM is also higher [8,9]. This includes Native Americans, Asians, Hispanics, and African American women [10].

A cohort study in Colorado that examined the trends in GDM prevalence among women with diverse ethnic backgrounds reported an increase from 1.7% to 3.1% among non-Hispanic whites; from 2.8% to 5.4% in Hispanics, and from 2.9% to 5.4% in African Americans [11]. A similar trend has been reported for Canadian aboriginal populations. The prevalence in the inland communities was twice as high as in the coastal communities (18.0% vs 9.3%, $p = 0.002$) [12].

TABLE 32.1 Risk Factors for Testing for Diabetes in Pregnant Women at Their Initial Prenatal Visit

BMI ≥ 25 kg/m^2 or ≥23 kg/m^2 in Asian Americans and with additional risk factors:

- Physical inactivity
- First-degree relative with diabetes
- High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
- Previous delivery of infant whose birth weight >9 lb or previously diagnosed with GDM
- Hypertension (≥140/90 mm Hg on therapy for hypertension)
- HDL-cholesterol level <35 mg/dL (0.90 mmol/L) and/or triglyceride level >250 mg/dL (2.82 mmol/L)
- Polycystic ovary syndrome
- A1C ≥ 5.7%
- Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
- History of cardiovascular disease

TABLE 32.2 Maternal and Fetal Complications Associated With GDM

Maternal	Fetal
• Hypertension	• Macrosomia
• Preeclampsia	• Neonatal hypoglycemia
• Premature delivery	• Neonatal hypocalcemia
• Cesarean delivery	• Hyperbilirubinemia
• GDM in subsequent pregnancies[a]	• Polycythemia
• Type 2 diabetes[a]	• Respiratory distress syndrome
• Cardiovascular disease[a]	• Stillbirth
• Metabolic syndrome[a]	• Shoulder dystocia

[a]*Postpregnancy complications.*

III RISK FACTORS

Risk factors associated with GDM also vary among organizations. Women were previously categorized as being at low, average, or high risk for developing GDM. Low-risk women were not universally screened for GDM because it was not considered cost-effective since they represented only 10% of the pregnant population. However, according to the ACOG, if traditional historical factors are used (family or personal history of diabetes, previous adverse pregnancy outcome, glycosuria, and obesity) to identify GDM, approximately 50% of women with GDM will be missed [3]. ADA identifies women at risk for developing GDM in Table 32.1.

IV COMPLICATIONS ASSOCIATED WITH GDM

Although complications associated with GDM are generally not as severe when compared to pregnancies with preexisting diabetes, perinatal morbidity and even mortality may occur with uncontrolled glycemic levels (Table 32.2). Maternal risks associated with gestational diabetes include hypertension, and increased risk of operative and preterm deliveries. In the infant, complications include macrosomia, neonatal hypoglycemia, neonatal hypocalcemia, neonatal hyperbilirubinemia, and polycythemia. Shoulder dystocia, clavicular fracture, brachial palsy, and respiratory distress syndrome are associated with GDM more so than in infants born to women with normoglycemia. Macrosomia, which is defined as a birth weight greater than 4000 g or 4500 g, is the most common complication associated with GDM and occurs in approximately 20% of pregnancies in undiagnosed or untreated GDM [13]. Pedersen hypothesized that maternal hyperglycemia results in fetal hyperinsulinemia, lipogenesis, glycogen, and protein synthesis and subsequent macrosomia [14]. In a prospective study that included 115 untreated women with borderline GDM by the broader criteria of Carpenter and Coustan, the untreated borderline GDM group had increased rates of macrosomia (28.7% vs 13.7%, $p < 0.001$) and cesarean delivery (29.6% vs 20.2%, $p = 0.02$) when compared with normoglycemic controls [15].

The effect of complications that develop during pregnancy may extend beyond delivery. Women with a history of GDM are at increased risk of developing the condition in a subsequent pregnancy or T2DM within 10 years. Her infant is at a higher risk of developing obesity and T2DM later in life.

V SCREENING AND DIAGNOSIS

Currently, there is no gold standard for the screening or diagnosis of GDM. This inconsistency is the result of the lack of data that shows adverse outcomes at various levels of hyperglycemia. O'Sullivan and Mahan established the first diagnostic testing for GDM using a 3-hour oral glucose tolerance test (OGTT) and whole blood [16]. The National Diabetes Data Group (NDDG) proposed using plasma blood glucose and defined GDM as two or more values higher than the thresholds [17]. Carpenter and Coustan proposed using diagnostic criteria which was lower than those of the NDDG [18]. This diagnostic criteria also used a two-step approach, with a 50-g, 1-hour glucose challenge test to screen for

diabetes as the first step. Depending on the results of the screening (usually >135 mg/dL or 7.5 mmol/L), the 100-g, 3-hour OGTT was performed to diagnose GDM. This two-step process of screening and diagnosing GDM is still widely used by many obstetricians.

In 2008, a large multinational study of approximately 23,000 pregnant women, known as HAPO (Hyperglycemia and Adverse Pregnancy Outcomes), demonstrated adverse perinatal outcomes (infant birth weight greater than the 90th percentile, cord-blood serum C-peptide, primary cesarean section, and neonatal hypoglycemia) at levels that were considered normal in pregnancy [19]. Based on the HAPO data, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) proposed new cutoffs for the diagnostic criteria for GDM [20]. These criteria which use the 75-g, 2-hour one-step approach and have been adopted by the ADA are not universally accepted (see Box 32.1). In 2013, the National Institutes of Health's Consensus Panel on Diagnosing GDM recommended the continuation of the two-step approach because of the lack of evidence which showed the 2-hour OGTT improved perinatal outcomes [21]. The two-step approach is supported by the ACOG. (See Table 32.3 for the diagnostic criteria of various organizations).

BOX 32.1 Oral Glucose Tolerance Test

One-Step Approach	Two-Step Approach
	Oral Glucose Challenge Test (GCT) • 50-g glucose solution given at any time of day • If results <135 or 140 mg/dL 1 h later, administer 3-h OGTT 3 days later
Oral Glucose Challenge Test (OGTT) • 3 days before—normal carbohydrate load of at least 150 g • fast at least 8 h before test • 75-g glucose solution given • blood drawn at fasting, and 1 and 2 h • during test—no eating, smoking, drinking (except water), or walking (remain seated) • diagnosis made if one value is abnormal	Oral Glucose Challenge Test (OGTT) • 3 days before—normal carbohydrate load of at least 150 g • fast at least 8 h before test • 100-g glucose solution given • blood drawn at fasting, and 1, 2, and 3 h • during test—no eating, smoking, drinking (except water), or walking (remain seated) • diagnosis made if two values are abnormal

VI WEIGHT GAIN IN PREGNANCY

The current weight gain guidelines from the Institute of Medicine are based on women's prepregnancy BMI. Table 32.4 shows the guidelines for total weight gain for each BMI category and the weekly weight gain for the second and third trimesters [22]. Women should be advised to gain according to their BMI category. Inadequate weight gain is associated with low birth weight and small-for-gestational-age infants. Excessive weight gain may lead to macrosomia in the infant, cesarean delivery, and postpartum weight retention. A prenatal weight gain grid can be used to monitor and evaluate the amount of weight gain. (See Table 32.5 for an example of a prenatal weight gain grid for normal weight women.)

VII MONITORING IN PREGNANCY

Monitoring during GDM provides the woman and her health care team with the necessary tools to assist her with diabetes management. These tools include self–blood glucose monitoring, ketone monitoring, and glycosylated hemoglobin (A1C).

A Blood Glucose Monitoring

The use of self-monitoring blood glucose (SMBG) allows the medical team to objectively evaluate and, if necessary, adjust the meal plan or medication. The ADA and ACOG recommend that women with GDM monitor their blood glucose levels four times daily—fasting and after meals [3,4]. However, the timing of postmeal monitoring has been debated for many years. According to the ACOG Practice Bulletin on GDM, no research has demonstrated the superiority of either 1- or 2-hour postmeal testing [3]. Other studies using continuous glucose monitoring (CGM) to determine the peak glucose elevation in pregnant woman showed that the peak time was 60–90 minutes from the beginning of a meal [23–25]. Whether monitoring is performed 1 or 2 hours after eating, it should be from the beginning, and not the end, of the meal. The frequency of monitoring may be reduced from daily to every third or fourth day once control of blood glucose is established. The target blood glucose levels in pregnancy are found in Table 32.6.

B Urinary Ketone Testing in GDM

While blood glucose monitoring is generally recommended in the management of GDM, ketone testing is not. Pregnancy is considered a ketogenic state and ketones may be found in the urine in the nondiabetic pregnant woman. However, the presence of ketones may suggest starvation ketosis as the result of inadequate energy intake. One early

study had indicated a possible link between ketonemia and decreased intelligence in the offspring [26]. Neither the ADA nor the ACOG include ketone testing for women with GDM in the Standards of Medical Care or Practice Bulletin on GDM, respectively [3,4]. However, women with GDM should avoid controlling their blood glucose levels by consuming insufficient calories.

C Hemoglobin A1C

The target of A1C in pregnant women with preexisting diabetes is 6–6.5% (42–49 mmol/mol) [4]. There is currently no recommendation to monitor the A1C in women with GDM.

VIII NUTRITION MANAGEMENT

MNT for GDM primarily involves a carbohydrate-controlled meal plan that promotes optimal nutrition for maternal and fetal health with adequate energy for appropriate gestational weight gain, achievement and maintenance of normoglycemia, and absence of ketosis. Due to the continuous fetal draw of glucose from the mother, maintaining consistency of times and amounts of food eaten are important to avoid hypoglycemia. During pregnancy, the distribution of energy and carbohydrate intake should be individualized and based on the woman's food preferences and plasma glucose responses. Plasma glucose monitoring and daily food records provide valuable information for insulin and meal plan adjustments [27]. The estimated energy requirements (EERs) during the first trimester are the same as those for a nonpregnant woman with an additional 340 calories during the second and 452 calories during the third trimesters [28]:

1st trimester: adult EER for women (no calorie increase);
2nd trimester: adult EER for women + 160 kcal (8 kcal*/week × 20 week) + 180 kcal**; and
3rd trimester: adult EER for women + 272 kcal (8 kcal*/week × 34 week)+180 kcal**.
*8 kcal/week = estimated change in the total energy expenditure in pregnancy.
**180 = mean energy deposition during pregnancy.

The amount and distribution of carbohydrate should be based on clinical outcome measures including hunger, plasma glucose levels, weight gain, and ketone levels. To ensure provision of glucose to the fetal brain (approximately 33 g/day) a minimum amount of 175 g/day of carbohydrates should be provided [28]. Carbohydrate should be distributed throughout the day in three small- to moderate-sized meals and two to four snacks. An evening snack may be needed to prevent accelerated ketosis overnight. Carbohydrate is generally less well tolerated at breakfast than at other meals [29].

A Carbohydrates

Carbohydrate is the primary nutrient affecting postprandial glucose levels, and postprandial blood glucose concentration is the one that has the most important role in macrosomia [30]. The conventional diet approach to GDM advocates for carbohydrate restriction, resulting in higher fat content, which is also a substrate for fetal fat deposit and associated with maternal insulin resistance. Consequently, there is no consensus about the optimal GDM diet. The traditional approach to diet therapy in GDM has been carbohydrate restriction (30–40% energy from total calories), with the goal of reducing postprandial glucose, in order to mitigate glucose-mediated fetal macrosomia [3,31].

However, in a randomized controlled trial of 152 women with GDM that were assigned to follow a diet low (40%) or high (55%) of total energy from carbohydrates (CHO), no difference was found in insulin use between the groups. In addition, no differences were found in the obstetric and perinatal outcomes between the treatment groups (e.g., ketonuria, hypertension, cesarean sections) [32]. The blood glucose levels of women with GDM were significantly lower after lunch and dinner when they were exposed to a high-carbohydrate diet. In another study that compared two different carbohydrate levels in women with GDM, 30 Caucasian women were randomly assigned to follow either a low- or a high-carbohydrate diet (45% and 65% of energy, respectively). The blood glucose levels of women who followed the low CHO diet were significantly lower after breakfast (102 ± 16 vs 94 ± 11 mg/dL), lunch (105 ± 12 vs 99 ± 9 mg/dL), and dinner (112 ± 16 vs 103 ± 13 mg/dL) ($p < 0.05$). Women following the high carbohydrate diet also experienced a significant decrease in glycemia after lunch (106 ± 15 vs 96 ± 7 mg/dL) and dinner (107 ± 12 vs 97 ± 7 mg/dL) ($p < 0.05$); however, their glucose concentration after breakfast did not change. It was concluded that high and low carbohydrate diets are effective and safe; however, a low-carbohydrate diet should be recommended to women who experience high glucose levels after breakfast [33].

B Dietary Fat

Fat content in the diet of a pregnant woman usually ranges from 30% to 40% of total calories; however, large amounts of fat beyond total caloric needs should be avoided to prevent excessive weight gain, which can result in further insulin resistance. The acceptable macronutrient distribution range of fat is 20–35% of total energy, the same as for nonpregnant women [28]. The impact of increasing polyunsaturated fatty acid intake on blood glucose, lipid metabolism, and pregnancy outcomes of women with GDM was assessed in a randomized controlled study that included 84 pregnant Chinese women. Women were randomly divided into two groups: an intervention group (prescribed a daily oil-rich diet of 45–50 g sunflower oil, 50–54% carbohydrates, 31–35% fat) and a control group (low-oil diet of 20 g sunflower oil, 55–60% carbohydrates, 25–30% fat). In both the intervention and the control groups, fasting blood glucose, 2-hour postprandial plasma glucose, and the insulin resistance index decreased significantly post-intervention ($p < 0.05$); the lipid changes and pregnancy outcomes did not differ significantly between the two groups ($p > 0.05$). It was concluded that an appropriate increase in polyunsaturated fatty acid intake benefits pregnant women with GDM as well as fetuses, as long as the diet therapy follows basic recommendations and total energy intake is strictly controlled [34].

In a randomized controlled study by Lauszus et al., the effects of a high monounsaturated fatty acid (MUFA) diet compared to recommended high-carbohydrate diet were studied in 27 women with GDM. After randomization women received either a high-carbohydrate diet (H-CHO): 50% carbohydrate, 20% protein, 30% fat [11% MUFA]) or a high-MUFA diet (H-MUFA): 46% carbohydrate, 16% protein, 37% fat [22% MUFA]) from the 33rd gestational week of pregnancy. Outcome measures were 24-hour ambulatory blood pressure, blood lipids, glycemic control, and insulin sensitivity estimated by an intravenous glucose tolerance test. Results indicated that the 24-hour diastolic blood pressure increased more in the H-CHO group than in the H-MUFA group ($p < 0.04$). The H-MUFA diet had no advantage to the H-CHO diet in ameliorating the decline of insulin sensitivity in the third term of pregnancy in GDM; however, the favorable effect on blood pressure by the MUFA diet might be used as a possible nonmedication treatment [35].

Furthermore, the effects of omega-3 fatty acid supplementation were studied in a randomized, double-blind, placebo-controlled study among 56 women with GDM. Subjects were randomly assigned to receive either 1000 mg omega-3 fatty acid supplements containing 180 mg eicosapentaenoic acid and 120 mg docosahexanoic acid ($n = 28$) or placebo ($n = 28$) for 6 weeks. Fasting blood samples were taken at baseline and after 6 weeks of intervention. A significant difference in changes in serum insulin levels (from baseline: -1.5 ± 7.5 vs $+3.5 \pm 8.5$ μIU/mL, $p = 0.02$) and homeostasis model assessment estimated insulin resistance (HOMA-IR) (-0.4 ± 2.1 vs $+1.1 \pm 2.4$, $p = 0.02$) was found when comparing the two groups. In addition, a significant reduction in serum high-sensitivity C-reactive protein (hs-CRP) levels was seen after omega-3 fatty acid supplementation when compared with the placebo (-236.3 ± 1541.9 vs 898.6 ± 2292.7 ng/mL, $p = 0.03$). The authors concluded that omega-3 fatty acid supplementation in GDM women had beneficial effects on insulin resistance. Plasma glucose, HOMA for beta-cells, quantitative insulin sensitivity check index, and lipid profiles were not affected [36].

The combination of omega-3 fatty acid supplementation with vitamin E was tested on glucose homeostasis parameters and lipid concentrations among women with GDM not taking oral hypoglycemic agents. In a randomized controlled trial, women were allocated to take either 1000 mg omega-3 fatty acids from flaxseed oil plus 400 IU vitamin E supplements ($n = 30$) or placebo ($n = 30$) for 6 weeks. Fasting blood samples were obtained at the beginning of the study and after 6-week intervention. Changes in fasting plasma glucose (-11.8 ± 11.0 vs $+1.5 \pm 11.9$ mg/dL, $p < 0.001$), serum insulin concentrations, HOMA-IR, HOMA of beta-cell function, and quantitative insulin sensitivity check index in the omega-3 fatty acids plus vitamin E group were significantly different from the changes in these indicators in the placebo group. Overall, it was demonstrated that omega-3 fatty acids and vitamin E cosupplementation in GDM women had beneficial effects not only on glucose homeostasis parameters but also in serum triglycerides, VLDL-cholesterol, and HDL-cholesterol concentrations. Supplementation of omega-3 fatty acids and vitamin E did not have an influence on total cholesterol and LDL-cholesterol levels [37].

C Protein

The diet of well-nourished women in the preconception period and throughout most of pregnancy has a significant effect on birth weight, and protein is the macronutrient with the greatest influence. Cuco et al. [38] demonstrated that in a protein and fat model, a 1-g increase in maternal protein intake during preconception and in the 10th, 26th, and 38th weeks of pregnancy led to a significant increase in birth weight of 7.8−11.4 g. Conversely, high intakes of protein and fat during pregnancy may impair development of the fetal pancreatic beta-cells and lead to insulin deficiency in the offspring [39]. In a case−control study of 2341 women with singleton pregnancies, three different levels of protein in the diet were associated with birth weight. Birth weight was 77 g lower ($p = -0.021$) in the low-protein group and 71 g lower ($p = 0.009$) in the high-protein group compared with the intermediate-protein group. Birth weight increased with protein levels up to 69.5 g/day and declined with higher protein intake. A high average prenatal protein consumption resulted in a significant depression of birth weight; in fact, a protein intake of more than 84 g/day on average is more detrimental than a low protein intake. It appears that moderate protein intake is optimal during pregnancy [40].

The effect of soy intake on metabolic status of women with GDM was studied in a randomized clinical trial among 68 women with GDM. Women were randomly assigned to receive either a control diet containing 0.8 g/kg protein (70% animal and 30% plant proteins) ($n=34$) or a soy diet containing the same amount of protein with 35% animal protein, 35% soy protein, and 30% other plant proteins ($n=34$) for 6 weeks. Compared with soy protein consumption, the control group significantly increased fasting plasma glucose ($+1.4 \pm 11.6$ vs -12.7 ± 13.2 mg/dL, $p < 0.001$), serum insulin levels ($+5.0 \pm 11.6$ vs -0.9 ± 10.0 μIU/mL, $p = 0.02$), and HOMA-IR ($+1.2 \pm 2.7$ vs -0.8 ± 2.2, $p = 0.002$) and decreased quantitative insulin sensitivity check index (-0.007 ± 0.02 vs $+0.01 \pm 0.03$, $p=0.004$). Administration of the control diet resulted in a significant difference in serum triglyceride changes ($+31.3 \pm 38.0$ vs $+8.9 \pm 46.1$ mg/dL, $p = 0.03$) compared with soy protein. There were significant

decreases in total antioxidant capacity (-35.0 ± 136.2 vs $+81.8 \pm 188.8$ mmol/L, $p = 0.005$) and glutathione (-41.3 ± 145.7 vs $+53.3 \pm 117.3$ μmol/L, $p = 0.004$) by the control diet intake compared with soy protein. The control diet group had a higher incidence of newborn hyperbilirubinemia (32.4% vs 8.8%, $p = 0.01$) and newborn hospitalization (20.6% vs 2.9%, $p = 0.02$) compared with soy protein. Soy protein consumption in women with GDM significantly improved the glucose homeostasis parameters, triglycerides, and biomarkers of oxidative stress, as well as reductions in the incidence of newborn hyperbilirubinemia and hospitalizations [41].

D Dietary Patterns

1 Low Glycemic Index Diet

In controlling diabetes, it is generally recommended to limit the intake of high glycemic index (GI) foods (highly processed breakfast cereals, instant potatoes, instant noodles, sugar, honey, molasses, corn syrup, candy, sweetened beverages, and fruit, fruit juice, and milk). A diet consisting of low glycemic index (LGI) foods (e.g., whole wheat bread, old-fashioned oatmeal, bran cereal, nuts, legumes, and lentils) may offer a viable alternative to the traditional lower carbohydrate meal plan [42].

An LGI diet in pregnancy was found to have a beneficial effect on neonatal central adiposity and also on postprandial glucose [43]. Grant et al. studied the effect of an LGI diet on blood glucose in women with GDM. Non-Caucasian women were randomized to an LGI ($n = 23$) or control ($n = 24$) diet and followed from 28 weeks gestation until delivery. Glycemic control improved on both diets; however, more postprandial glucose values were within target on LGI (58.4% of $n = 1891$) compared to control (48.7% of $n = 1834$; $p < 0.001$). SMBG postbreakfast was directly related to the prepregnancy BMI at baseline. The authors concluded that an LGI diet was acceptable in this sample and enabled control of postprandial glucose [44].

In another randomized study, 63 women with GDM were assigned to receive either an LGI diet or a conventional high-fiber (and higher GI) diet. Of the 31 women randomly assigned to an LGI diet, 9 (29%) required insulin. Of the women randomly assigned to a higher GI diet, a significantly higher proportion, 19 of 32 (59%), required insulin treatment ($p = 0.023$). However, 9 of these 19 women were able to avoid insulin use by changing to an LGI diet, thus demonstrating that the use of insulin was reduced in almost half [45]. A similar study examined the effect of low glycemic load (LGL) diet with (additional 15 g of wheat fiber) and without fiber in women with GDM requiring insulin. A total of 31 GDM women were randomly assigned to consume either an LGL diet with fiber or LGL diet without fiber. It was found that 7 (38.9%) of 18 women with GDM in the fiber group and 10 (76.9%) in the without fiber group required insulin treatment, thus demonstrating that an LGL diet with added fiber for women with GDM dramatically reduced the need for insulin treatment [46].

The effect of an LGI versus a conventional high-fiber diet on pregnancy maternal metabolic profile in GDM was examined. A total of 99 women (age 26–42 years; mean ± SD prepregnancy BMI 24 ± 5 kg/m^2) diagnosed with GDM at 20–32 weeks' gestation were randomized to follow either an LGI ($n = 50$; target GI ~50) or a high-fiber moderate-GI diet (HF) ($n = 49$; target GI ~60). LGI group achieved a modestly lower GI than the HF group (mean ± SEM 47 ± 1 vs 53 ± 1; $p < 0.001$). At birth, there were no significant differences in birth weight (LGI 3.3 ± 0.1 kg vs HF 3.3 ± 0.1 kg; $p = 0.619$), birth weight centile (LGI 52.5 ± 4.3 vs HF 52.2 ± 4.0; $p = 0.969$), prevalence of macrosomia (LGI 2.1% vs HF 6.7%; $p = 0.157$), insulin treatment (LGI 53% vs HF 65%; $p = 0.251$), or adverse pregnancy outcomes. In this study, an LGI diet and a conventional HF diet produced similar pregnancy outcomes [47].

A randomized study compared the effects of a conventional diet (40% carbohydrate/45% fat/15% protein) to one consisting of a higher-complex carbohydrate (HCC) and low fat (LF) (60/25/15%) Choosing Healthy Options In Carbohydrate Energy (CHOICE) diet in 16 women with GDM. There were no between-diet differences for fasting or mean nocturnal glucose, but 24-hour area under the curve (AUC) was slightly higher (~6%) on the HCC/LF CHOICE diet ($p = 0.02$). The continuous glucose monitoring system (CGMS) revealed modestly higher 1- and 2-hour postprandial glucose on CHOICE (1 hour, 115 ± 2 vs 107 ± 3 mg/dL, $p \leq 0.01$; 2 hour, 106 ± 3 vs 97 ± 3 mg/dL, $p = 0.001$) but well below current targets. After breakfast, 5-hour glucose and insulin AUCs were slightly higher ($p < 0.05$), triglycerides AUC was no different, but the free fatty acids (FFAs) AUC was significantly lower (~19%; $p \leq 0.01$) on the CHOICE diet. This highly controlled study randomizing isocaloric diets and using a CGMS was the first to demonstrate that liberalizing complex carbohydrates and reducing fat still achieved glycemia below current treatment targets and lower postprandial FFAs. The authors concluded that this diet strategy may have important implications for preventing macrosomia [48]. Additional maternal and infant parameters were measured in 12 of the 16 participating women. After approximately 7 weeks, fasting blood glucose ($p = 0.03$) and FFAs ($p = 0.06$) decreased on the CHOICE diet, whereas fasting glucose increased on the conventional diet ($p = 0.03$). Insulin suppression of adipose tissue lipolysis was improved on CHOICE versus conventional diet (56% vs 31%, $p = 0.005$), consistent

with improved insulin resistance. Adipose tissue expression of multiple proinflammatory genes was lower on the CHOICE diet ($p < 0.01$). Infant adiposity was lower with CHOICE versus conventional diet ($10.1 \pm 1.4\%$ vs $12.6 \pm 2\%$) [49].

Overall, a diet higher in complex carbohydrate and fiber and low in simple sugars and fat may be effective in preventing postprandial hyperglycemia, reduce FFAs, improve insulin resistance, and reduce the need for insulin during GDM. In addition, reduced neonatal central adiposity and overall reduced fetal adiposity were observed when using these diets.

2 DASH Diet

In a randomized trial of 52 women with GDM, the study participants were assigned to consume either a control ($n=26$) or a Dietary Approaches to Stop Hypertension (DASH) diet ($n=26$) for 4 weeks. The control diet contained 45−55% carbohydrates, 15−20% protein, and 25−30% total fat. The DASH diet was rich in fruits, vegetables, whole grains, and low-fat dairy products and contained lower amounts of saturated fats, cholesterol, and refined grains with a total of 2400 mg/day sodium. The need for insulin in the DASH diet group was significantly lower than for women in the control group (23% for DASH vs 73% for control group, $p < 0.0001$). Compared to infants in the control diet, those born to mothers following the DASH diet had significantly lower weight (3222.7 vs 3818.8 g, $p < 0.0001$), head circumference (34.2 vs 35.1 cm, $p=0.01$), and ponderal index (2.50 vs 2.87 kg/m^3, $p < 0.0001$) [50]. In a randomized controlled study of women with GDM, the effects of the DASH diet on insulin resistance, serum hs-CRP, and biomarkers of oxidative stress among pregnant women with GDM were studied. The control diet contained 40−55% of its energy as carbohydrates, 10−20% as proteins, and 25−30% as total fats. Consumption of the DASH diet compared with the control diet resulted in decreased FPG (−7.62 vs 3.68 mg/dL; $p=0.02$), serum insulin levels (−2.62 vs 4.32 μIU/mL, $p=0.03$), and HOMA-IR score (−0.8 vs 1.1; $p=0.03$). Increased concentrations of plasma total antioxidant capacity (45.2 vs −159.2 mmol/L; $p < 0.0001$) and total glutathione levels (108.1 vs −150.9 μmol/L; $p < 0.0001$) also were seen in the DASH group compared to the control group [51]. A similar study that compared adherence to the DASH dietary pattern to a control diet in women with GDM resulted in improved glucose tolerance after the glucose load. Decreased A1C levels were also seen in the DASH group compared with the control group. Mean changes for serum total and LDL-cholesterol, and total HDL-cholesterol ratio were significantly different between the two diets. Additionally, consumption of the DASH diet favorably influenced systolic blood pressure. Mean changes of fasting plasma glucose were not significant when comparing the DASH diet with the control diet [52].

Overall, the benefits of the DASH diet in GDM when followed for a 4-week period resulted in improved infant (lower birth weight, head circumference, and ponderal index) and maternal (reduced insulin, hemoglobin A1C, total cholesterol, LDL-cholesterol, oxidative stress, and systolic blood pressure) outcomes.

E Nutrition Management Summary

MNT remains the cornerstone of treatment for GDM and is best prescribed by a registered dietitian or a qualified individual with experience in the management of GDM. Nutrition recommendations for GDM, including gestational weight gain, calorie intake, and macronutrient composition and distribution, are based on limited scientific evidence [53]. Current nutrition practice guidelines for GDM recommend a carbohydrate-controlled meal plan with adequate nutrient content aimed to support maternal needs and fetal growth [54]. In addition to practice guidelines, research findings associating macronutrients and caloric prescriptions to maternal and birth outcomes are also available [29]. Using the current nutrition practice guidelines in combination with new research findings can help the registered dietitian individualize a meal plan that will contribute to the delivery of a healthy infant.

IX PHYSICAL ACTIVITY

Moderate exercise may be an important adjunctive therapy in the management of diabetes in pregnancy, particularly in GDM. The benefits of regular physical activity are found in Table 32.7. ACOG recommends that unless contraindicated, pregnant women should participate in at least 20−30 minutes of moderate-intensity physical activity on most or all days of the week [55]. Physical activity should include aerobic and strength conditioning exercises individualized by the health care provider. A list of exercises deemed safe and unsafe during pregnancy is found in Table 32.8. Women with GDM and taking insulin

TABLE 32.7 Physical Activity Benefits in GDM

- Decreased physical discomforts associated with pregnancy
- Shorter active phase of labor
- Improved sleep
- Decreased stress and anxiety
- Increased insulin sensitivity
- Improved glycemic control
- May help to avoid excessive weight gain
- ↓ physical discomforts

or an oral hypoglycemic agent may need to have carbohydrate-type snacks close at hand should they experience hypoglycemia. To prevent hypoglycemia, exercise should be avoided in the fasting state and during periods of peak insulin activity. Blood glucose levels should be monitored before and after exercise.

TABLE 32.8 Physical Activities Considered Safe and Unsafe During Pregnancy

Safe Activities
• Swimming
• Water aerobics
• Walking
• Jogging
• Low-impact aerobics
• Prenatal yoga
• Stationary bike
• Modified weight training
Unsafe Activities
• Horseback riding
• Contact sports (e.g., soccer, basketball, volleyball)
• Downhill skiing
• Gymnastics
• Bike riding
• Scuba diving
• Sauna, hot tubs, steam room
• Any activity that involves lying on the back

X PHARMACOLOGICAL THERAPY

Pharmacological therapy is prescribed when MNT, physical activity, and lifestyle intervention in a woman with GDM cannot achieve or maintain target blood glucose levels and/or when the rate of fetal growth is higher than normal [54]. However, there is no conclusive evidence to recommend an optimal time to begin pharmacotherapy. Studies have suggested 1–2 weeks after the initiation of MNT and the glycemic levels remain elevated [54,56].

A Insulin Therapy

For many years, insulin was the only medication approved for use to control blood glucose levels in pregnancy. Although several types of insulin are available today, not all are used in pregnancy. Insulin is either identical to human insulin (regular, neutral protamin Hagedorn [NPH]) or insulin analogs (aspart, lispro, glulisine, determir, glargine, or degludec) and varies in onset, peak times, and duration in the body (see Table 32.9). Until June 2015, all drugs used in pregnancy were categorized by the U.S. Food and Drug Administration using the following lettering system: A, B, C, D, and X. In its place, medications are now based on an individualized risk assessment [57].

The amount of insulin is dependent on the woman's body weight and trimester of pregnancy (Table 32.10). The total amount of insulin is based on the insulin to carbohydrate (ICR) ratio. Rapid-acting analogs are preferred to regular insulin because their action begins 5 to 15 minutes and food is consumed immediately after the injection. The onset and peak times for regular women delays when the

woman is able to eat. NPH is usually given in 2 doses: one at breakfast and the othe before bedtime. If using a long-acting insulin, it is usually injected once daily during the evening meal or at bedtime. Adjustment is made to the insulin dosage based on the glycemic levels.

B Oral Hypoglycemic Agents

Since the landmark trial on the use of glyburide in the management of GDM, the popularity of oral hypoglycemic agents has increased. This randomized trial reported no difference in the incidence of maternal or fetal complications between glyburide and insulin and no glyburide was detected in the cord serum [58]. Glyburide, a sulfonylurea, releases insulin from the pancreas, thereby lowering blood glucose levels. It is considered a viable alternative to insulin because of its ease of use and the cost benefit. However, later studies have shown that glyburide crosses the placenta and is associated with an increased risk of neonatal intensive care admissions, respiratory distress syndrome, neonatal hypoglycemia, birth injury, and large-for-gestational age infants [59,60]. Glyburide is also associated with hypoglycemia in the mother. The maximum dosage of glyburide in pregnancy is 20 mg. Insulin is initiated if maternal glycemic levels remain above target after the maximum dose has been reached.

Metformin is a biguanide, an insulin sensitizer that acts by decreasing the hepatic production and intestinal absorption of glucose. Although metformin was also shown to cross the placenta, it does not cause maternal hypoglycemia and may be a superior alternative to glyburide [61]. Metformin is associated with mild weight loss and may slightly increase the risk of prematurity [4]. The beginning dose of metformin is 500 mg one or two times daily, with a maximum dose in pregnancy of 2500 mg; there are currently no long-term studies on the effect of oral hypoglycemic agents on the offspring.

XI DIABETES SELF-MANAGEMENT EDUCATION AND BEHAVIORAL APPROACH

Diabetes self-management education (DSME) is a critical element of care for all people with diabetes and is necessary in order to improve patient outcomes. The National Standards for DSME are designed to define quality DSME and to assist diabetes educators in a variety of settings to provide evidence-based education. Because of the dynamic nature of health care and diabetes-related research, these standards are reviewed and revised approximately every 5 years by key organizations and federal agencies within the diabetes education community [62]. The overall objectives of DSME are to support informed decision-making, self-care behaviors, problem-solving, and active collaboration with the health care team and to improve clinical outcomes, health status, and quality of life. One of the guiding principles of DSME is behavioral goal setting as an effective strategy to support self-management behaviors [62]. Diabetes self-management support (DSMS) refers to the support that is required for implementing and sustaining coping skills and behaviors needed to self-manage on an ongoing basis. The initial DSME is typically provided by a health professional, whereas ongoing support can be provided by personnel within a practice and a variety of community-based resources. DSME/S programs are designed to address the patient's health beliefs, cultural needs, current knowledge, physical limitations, emotional concerns, family support, financial status, medical history, health literacy, numeracy, and other factors that influence each person's ability to meet the challenges of self-management [63]. Successful diabetes care requires a systematic approach to supporting patients' behavioral change including (a) healthy lifestyle changes (physical activity, healthy eating, nonuse of tobacco, weight management, effective coping), (b) disease self-management (medication taking and management; self-monitoring of blood glucose and blood pressure when clinically appropriate), and (c) prevention of diabetes complications (self-monitoring of foot health; active participation in screening for eye, foot, and renal complications; immunizations). National DSME standards call for an integrated approach that includes clinical content and skills, behavioral strategies (goal setting, problem-solving), and addressing emotional concerns in each needed curriculum content area [64].

A systematic review of controlled trials evaluated behavior modification interventions to prevent the development of GDM. Nine studies were identified involving such techniques as repetition of information, use of verbal and written educational information, goal setting, and planning, in addition to group and individual counseling

TABLE 32.11 Specific, Measurable, Achievable, Relevant, and Time-Limited Goals in the Management of Diabetes

Type of Goals	Example
Specific goal	I will check my blood glucose
Specific, measurable goal	I will check my blood glucose three times every day
Specific, measurable, achievable goal	I will check my blood glucose before breakfast, after lunch, and before bed time
Specific, measurable, achievable, relevant goal	To avoid hypoglycemic episodes, I will check my blood glucose every day before breakfast, after lunch, and before bed time
Specific, measurable, achievable, relevant, time-limited goal	Starting tomorrow and to avoid hypoglycemia episodes, I will check my blood glucose every day before breakfast, after lunch, and before bed time

sessions. The combination of planning and goal setting was used successfully in improving the diets of women. The findings of the review determined that the use of self-monitoring, goal setting, and achievement appears to be effective in the prevention of excessive gestational weight gain (EGWG), especially when combined with a high frequency of intervention contact, individual attention, and professional involvement [65]. The effectiveness of single versus multiple goal setting for diet and physical activity was evaluated in a randomized controlled trial of overweight or obese adults with T2DM and multiple cardiovascular disease risk factors. At baseline, the multiple-goal group self-selected both diet- and physical activity-related goals, the single-goal group set a single goal, and the control group received information about community health resources. From pre- to postintervention, the single-goal group demonstrated significant improvement in systolic blood pressure and intake of servings of fruits, vegetables, and refined grains (all $p < 0.05$). The multiple-goal group reported significant reduction in percent energy from total, saturated, monounsaturated, and *trans*-fat intake and significant increase in leisure time walking (all $p < 0.05$). The authors concluded that a multiple-goal approach over 4 months can improve dietary and physical activity outcomes, while a single-goal approach may facilitate improvement in one behavioral domain [66].

Patients' perception of collaborative goal setting was evaluated using a semistructured focus group guide. Collaborative goal setting was described by patients as occurring within the context of a caring relationship where patients and health care providers: (1) listen and learn from each other; (2) share ideas; (3) agree on a measurable objective; and (4) support goal achievement. Patients also articulated clear responsibilities for themselves and clinicians and described collaborative goal setting as a process that occurs over time [67]. Therefore, goal setting and goal achievement are instrumental in the management of diabetes and behavior modification. In diabetes management a technique that has been proposed to achieve goals is the use of S.M.A.R.T. (Specific, Measurable, Achievable, Relevant, and Time-limited) goals (Table 32.11).

Specific. The goal should be clearly defined. Stating that people want to have a better glucose control is not specific enough. Focusing on one specific element such as blood glucose control would make the goal specific.

Measurable. Setting a measurable goal would make people accountable for an action that could result in diabetes control.

Achievable. A realistic goal that allows accomplishment.

Relevant. Knowing that a better glucose control could result in positive diabetes outcomes such as A1C within target levels.

Time-limited. A tangible and concrete goal would allow people with diabetes to have a sense of accomplishment.

An example of a S.M.A.R.T. goal is: "I will eat a lunch containing 60 grams of carbohydrates every day during the month" [68].

A Team-Based Approach

According to ADA, persons with diabetes should receive medical care from a team that may include physicians, nurse practitioners, physician's assistants, nurses, registered dietitians, pharmacists, and mental health professionals with expertise in diabetes. It is essential in this collaborative and integrated team approach that individuals with diabetes assume an active role in their care. The management plan should be formulated as a collaborative therapeutic alliance among the patient and family, the physician, and other members of the health care team. A variety of strategies and techniques should be used to provide adequate education and development of problem-solving skills in the various aspects of diabetes management. Implementation of the management plan requires the goals and treatment plan to be individualized and to

take patient preferences into account. The management plan should recognize DSME and ongoing diabetes support as an integral component of care. In developing the plan, consideration should be given to the patient's age, school or work schedule and conditions, physical activity, eating patterns, social situation and cultural factors, and the presence of diabetes and other medical complications [69].

The Chronic Care Model (CCM), an organizational approach to caring for people with chronic disease in a primary care setting, has been shown to be an effective framework for improving the quality of diabetes care [70]. Collaborative, multidisciplinary teams are best equipped to provide care for people with chronic conditions such as diabetes. The key objectives of the CCM are to:

1. Optimize provider and team behavior. The care team should prioritize timely and appropriate intensification of lifestyle and/or pharmacological therapy for patients who have not achieved beneficial levels of glucose, blood pressure, or lipid control.
2. Support patient behavior change. High-quality DSME has been shown to improve patient self-management, satisfaction, and glucose control.
3. Change the care system. Optimal diabetes management requires an organized, systematic approach and involves a coordinated team of dedicated health care professionals.

In addition, a patient-centered communication style should be used that incorporates patient preferences, assesses literacy and numeracy, and addresses cultural barriers to care [71].

A high-performing team is now widely recognized as an essential tool for constructing a more patient-centered, coordinated, and effective health care delivery system. Team-based health care is the provision of health services to individuals, families, and/or their communities by at least two health providers who work collaboratively with patients and their caregivers—to the extent preferred by each patient—to accomplish shared goals within and across settings to achieve coordinated, high-quality care. In conjunction with the patient and family members, health professionals from different disciplines and community providers compose the team. The five personal values that characterize the most effective members of high-functioning teams in health care are: honesty, discipline, creativity, humility, and curiosity. The principles that support high-quality team-based care include shared goals, clear roles, mutual trust, effective communication, and measurable processes and outcomes. These principles are not intended to be in isolation but are interwoven and each is dependent on the others. In addition, these teams require sufficient organizational resources to sustain their work [72]. Developing a clear understanding of and respect for specific roles and responsibilities can be maximized to support achievement of the team's shared goals. The organizational factors that enable establishing and maintaining clear roles include:

- Providing time, space, and support for interprofessional education and training, including explicit opportunities to practice the skills and refine the values that support teamwork.
- Facilitating communication among team members regarding their roles and responsibilities.
- Redesigning care processes and reimbursement to reflect individual and team capacities for the safe and effective provision of patient care needs.

A number of strategies and practices provide the framework for an effective team-based approach. An example of a team-based plan of work is shown in Table 32.12.

A study by Baker et al. found evidence that team training improves patient safety. Three competencies critical for effective team work include:

1. Teamwork-related knowledge: understanding the skills and behaviors needed for an effective team and how they are manifested in a team setting.
2. Teamwork-related skills: the learned capacity to interact with other team members.
3. Teamwork-related attitudes: internal states that influence a team member.

TABLE 32.12 Team-Based Plan to Prevent T2DM After GDM

T2DM Prevention After GDM
Team Composition: Patient, family members, physicians, nurse practitioners, physician's assistants, nurses, registered dietitians, pharmacists, and mental health professionals and support personnel with expertise in diabetes.
Clinical Care: The goal of the multidisciplinary team is to support and treat women with a history of GDM to avoid or delay the onset of T2DM. Women will require an OGTT at 8–12 weeks postpartum.
Team Process: Clinicians collaboratively develop and implement a treatment plan. The team agrees on and implements reliable and timely feedback on successes and failures and on the achievements of the team's goals. These are used to track and improve performance. The team agrees on communication strategies and on a continuous improvement quality plan.

Areas that support effective team-based care are interprofessional education and workforce development, health informatics, and care coordination [73].

B Cultural Aspects

Diabetes management requires individualized, patient-centered, and culturally appropriate strategies. Cultural competency is critical to reducing health disparities and improving access to high-quality health care that is respectful of and responsive to the needs of diverse patients [74]. According to the U.S. Census Bureau, ethnic and minority groups accounted for more than one-third of the population in 2012, with projections indicating that the United States will become a majority-minority nation for the first time in 2044. The minority population is projected to rise to 56% of the total in 2060, compared with 38% in 2014 [75]. Ethnic groups at high risk for developing GDM include Hispanic, African-Americans, Native American, South East Asian, Pacific Islander, or Indigenous Australian groups. Women with GDM who are of Hispanic or African-American backgrounds are more likely to develop hypertension postpartum. A literature review highlights the fact that diabetes management must be individualized and the clinician should be mindful of the impact differences in ethnicity may have on the clinical characteristics and pregnancy outcomes in women affected by GDM, particularly those living in Western countries. MNT plays a key role in the management of GDM and the nutrition prescription should be culturally sensitive. Understanding these differences is critical in the delivery of optimal antenatal care for women from diverse ethnic backgrounds [76].

Cultural competency plays an important role in the communication and counseling carried out by food and nutrition practitioners [77]. To understand the connections between cultural food practices and diabetes among ethnic and racial groups, cultural competence must be gained first. Culture influences values, beliefs, and practices related to food and diabetes. Differences between racial and ethnic groups provide a context for examining cultural food practices and their impact on diabetes management. To best serve the health care needs of racial and ethnic groups with diabetes, health care professionals must acknowledge each group's attitudes, beliefs, and values, including specific knowledge about food habits, preferences, and practices (e.g., holidays, celebrations, and fasting practices). Cultural competence constructs include understanding the language, thoughts, communications, actions, customs, beliefs, values, and institutions of ethnic, racial, religious, or social groups. Recognizing these cultural constructs may better prepare health care professionals to understand their clients' feelings and thoughts about diabetes. By applying the cultural competence constructs, health care professionals may be better prepared to interact with a diverse population requiring diabetes care and education [78].

According to the American Association of Diabetes Educators' position statement on cultural sensitivity, diabetes educators are encouraged to develop a basic understanding of key terminology, such as *cultural sensitivity*, *cultural humility*, *cultural competence*, *multicultural*, *cultural tailoring*, *racial identity*, and *ethnic identity* [79].

Summary recommendations for diabetes education on cultural competency in support of persons affected by diabetes include [80]:

- Acknowledges that cultural perceptions of health can be unique for each individual.
- Considers the context of learning experiences already present when developing collaborative efforts with the patient to identify barriers to diabetes care success.
- Conveys accurate information that is understandable to the learner.
- Proactively addresses limitations to self-management plan adherence and designs/brokers culturally appropriate goals.
- Utilizes educational materials and resources appropriate for culture, age, literacy level, and learning readiness.
- Includes resources that address access limitations to diabetes care needs and considers the milieu in which the care plan is to be executed.
- Incorporates sensitivity and respect when educating all people irrespective of ethnicity, race, age, and socioeconomic status.

XII POSTPARTUM

A Breast-feeding

Research continues to support the positive effects of breast-feeding (BF) on maternal and infant health, as human milk contains the proper balance of nutrients and immunologic agents that closely match infant growth requirements. It is the position of the Academy of Nutrition and Dietetics that exclusive BF provides optimal nutrition and health protection for the first 6 months of life, and BF with complementary foods from 6 months until at least 12 months of age is the ideal feeding pattern for infants. The position recommends BF regardless of the presence of GDM [81].

Recent studies have documented the association of GDM and BF on maternal biomarkers for T2DM and on childhood overweight. The Study of Women, Infant Feeding, and Type 2 Diabetes (SWIFT) investigated whether higher lactation intensity is related to more

favorable blood lipids, lipoproteins, and adipokines (adiponectin, leptin) after a GDM pregnancy independent of obesity, sociodemographics, and insulin resistance. A sample of 1007 women of diverse ethnic backgrounds with previous GDM were divided into exclusive and mostly BF or exclusive or mostly formula feeding (FF) groups, with biomarkers being measured after 6–9 weeks postpartum. Compared to FF groups, BF group reported 5–8% higher HDL cholesterol, 20–28% lower fasting triglycerides, 15–21% lower leptin (all trend p-values <0.01), and 6% lower adiponectin, but only after adjustment for insulin resistance (trend p-value $=0.04$). Findings suggest that lactation has favorable short-term influences on biomarkers for T2DM, except for plasma adiponectin [82]. Furthermore, the long-term effects of lactation and the incidence of T2DM after a GDM pregnancy were evaluated in a subsample of 959 women from the SWIFT study wherein 113 (11.8%) developed incident T2DM. It was found that higher lactation intensity and longer duration were independently associated with lower 2-year incidences of T2DM after GDM pregnancy, thus concluding that lactation may prevent T2DM after GDM delivery [83].

The association of GDM and BF on childhood overweight has been evaluated. One study of 15,710 mother–offspring pairs delivered in 2011 assessed the relationship among maternal obesity, EGWG, GDM, and BF with respect to childhood obesity (BMI >85th percentile) at age 2 years. Logistic regression was used to assess associations between maternal exposures and childhood overweight. Analysis adjusted for exposures and covariates revealed an adjusted odds ratio (95% confidence interval [CI]) associated with childhood overweight at age 2 years of 2.34 (2.09–2.62), 1.50 (1.34–1.68), 1.23 (1.12–1.35), 0.95 (0.83–1.10), and 0.76 (0.69–0.83) for maternal obesity, overweight, EGWG, GDM, and BF $\geq$ 6 months versus <6 months, respectively. The study concluded that GDM and BF $\geq$ 6 months were not associated with childhood overweight at age 2 years. However, maternal prepregnancy obesity or overweight and EGWG were independently associated with an increased risk of childhood overweight and BF $\geq$ 6 months with a decreased risk of childhood overweight at age 2 years [84]. Another study examined the association of GDM and BF on obesity prevalence in predominately Hispanic low-income children (2–4 years). Data from 2295 children (84% Hispanic and 48% female) were obtained from caregivers participating in the Special Supplemental Food Program Women, Infant, and Children. Chi-square and binary logistic regression were used to assess GDM and BF duration with the children's ethnicity, birth weight, age in months, and sex as prior covariates. The results showed that GDM offspring who were breastfed $\geq$ 12 months had a 72% decrease in obesity prevalence (adjusted odds ratio = 0.28, CI 0.89–0.03, $p = 0.05$) [85].

B Prevention of Gestational Diabetes

Evidence on the association between dietary patterns and the risk of GDM has been extensively documented. In the Nurses' Health Study II, the Western diet (characterized by a high intake of red meat, processed meat, refined grain products, sweets, French fries, and pizza) was found to increase the risk for developing GDM. Pregravid intake of red and processed meats was significantly and positively associated with GDM risk, independent of known risk factors for T2DM and GDM. After the adjustment for major risk factors for GDM, those who consumed more than six servings of red meat in a week had more than a 1.7-fold increased risk of GDM compared with those women who consumed less than 1.5 servings of red meat/week (relative risk: 1.74; 95% CI: 1.35, 2.26). In addition, compared to women who consumed one serving per month, those who consumed more than five servings per week of sugar-sweetened cola had a 22% greater GDM risk (relative risk: 1.22; 95% CI: 1.01, 1.47) [86]. Similarly, the consumption of fried foods was associated with the risk of GDM. After adjustment for age, parity, dietary, and nondietary factors, the relative risks (95% CIs) of GDM among women who consumed fried foods 1–3, 4–6, and $\geq$7 times/week, compared with those who consumed them less than once/week, were 1.13 (0.97, 1.32), 1.31 (1.08, 1.59), and 2.18 (1.53, 3.09), respectively ($p <0.001$). The association persisted after further adjustment for BMI ($p=0.01$) [87].

Dietary patterns found to reduce the risk for developing GDM include the prudent diet (characterized by a high intake of fruit, green leafy vegetables, poultry, and fish) [86], Mediterranean patterns (high intake of fruit, vegetables, legumes, fish, and whole grains), and the DASH diet [88–90]. Overall, dietary patterns rich in fruit, vegetables, whole grains, and fish and low in red and processed meat, refined grains, and high-fat dairy were found to be beneficial in the prevention of GDM [91,92].

C Prevention of Type 2 Diabetes Mellitus (T2DM)

Women with a history of GDM are at risk for developing T2DM within 5–10 years after delivery [93]. The ADA—2016 Standards of Medical Care in Diabetes recommends screening women with GDM for persistent diabetes at 6–12 weeks postpartum using the OGTT and clinically appropriate nonpregnancy diagnostic criteria (Table 32.13) [1]. However, less than half of women who had GDM return for diabetes testing [94].

Healthy Babies Need Healthy Moms (HBNHM) is an education program that combines the recommended 2-hour postpartum OGTT with diabetes prevention education for women who had GDM. The 2-hour OGTT is performed during the class and in between venipunctures,

TABLE 32.13 Criteria for Diagnosis of Diabetes Mellitus Using a 75 g OGTT

	Normal Values, mg/dL (mmol/L)	Prediabetes	Diabetes Mellitus, mg/dL (mmol/L)
Fasting plasma glucose	<100 mg/dL	≥100– <126 mg/dL	≥126 mg/dL
	(5.6 mmol/L)	(≥5.6–7.8 mmol/L)	(≥7.0 mmol/L)
75 g OGTT	<140 mg/dL	<140 mg/dL	≥200 mg/dL
	(7.8 mmol/L)	(7.8 mmol/L)	(11.8 mmol/L)

Source: From American Diabetes Association, Standards of Medical Care. Classification and diagnosis of diabetes, Diabetes Care 39 (Suppl. 1) (2016) S13–S22.

the women participate in group education focused on evidence-based diabetes prevention strategies that promote lifestyle behavior, the importance of preconception care for subsequent pregnancies, and the need for follow-up care for women who screen positive for abnormal glucose levels. For women who screen positive for overt diabetes or prediabetes, the educational strategies are directed toward encouraging follow-up care. For women with normal screening results, the program is designed to help prevent the future development of T2DM. Topics covered in the curriculum include pathophysiology of T2DM; diabetes prevention and exercise; BMI, weight loss, and nutrition; preconception counseling and tobacco screening. The nutrition goals of the program are to reduce fat intake to <30% of total energy intake, reduce saturated fat intake to <10%, and increase fiber intake to 15 g/1000 kilocalories [95].

Several healthful dietary patterns, including the alternate Mediterranean Diet (aMED), DASH, and alternate Healthy Eating Index (aHEI), have been inversely associated with T2DM risk and other cardiovascular disease in the general population but rarely investigated among women with a history of GDM (Table 32.14). Validated food-frequency questionnaires were used to measure adherence to a healthful diet of 4413 women from the Nurses' Health Study II cohort with histories of GDM. Results of the study showed that the Mediterranean pattern was associated with 40% lower risk of T2DM (hazard ratio, 0.60 [95% CI, 0.44–0.82; $p = 0.002$]); the DASH pattern, with 46% lower risk (0.54 [0.39–0.73; $p = 0.001$]); and the aHEI pattern, with 57% lower risk (0.43 [0.31–0.59; $p = 0.001$]). Adherence to healthful dietary patterns is associated with lower T2DM risk among women with a history of GDM [96]. In a study by Bao et al., the effect of low-carbohydrate dietary pattern in women with prior GDM with respect to T2DM risk found that a low-carbohydrate dietary pattern, particularly with high protein and fat intake primarily from animal-source foods, was associated with a higher T2DM risk, whereas a low-carbohydrate dietary pattern with high protein and fat intake from plant-based foods was not significantly associated with a risk of T2DM [97].

The Diabetes Prevention Program (DPP) was a major multicenter clinical research study aimed at discovering whether modest weight loss through dietary changes and increased physical activity or treatment with the oral diabetes drug metformin could prevent or delay the onset of T2DM in study participants [98]. The DPP lifestyle intervention has been translated to community settings using the DPP goals of reducing body weight by 7% and engaging in moderate physical activity of 150 minutes per week. The CDC's National Diabetes Prevention Program is an evidence-based behavioral change program, designed to support lifestyle balance, healthy eating, physical activity, and motivational support. The program is delivered by a lifestyle coach, who facilitates the CDC-approved curricula and works to encourage and sustain group interaction so that participants support each other during the year-long program. It includes a handy preparation checklist with materials needed and tasks that are performed to do before participants arrive, as they arrive, and after each session. For each session a lifestyle coach briefly outlines the objectives and key messages. Step-by-step instructions make it easy for lifestyle coaches to facilitate discussions and activities. The curriculum also offers tips on tailoring the sessions to meet participants' needs and preferences, including cultural considerations. The CDC-developed curriculum is available in English and Spanish [99].

As part of the DPP, two studies assessed the effects of metformin on T2DM prevention in women with a history of GDM. In the study by Ratner et al., 2190 women were randomized to either standard lifestyle and placebo, metformin therapy or to an intensive lifestyle intervention. The outcome was the time to development of diabetes ascertained by semiannual fasting plasma glucose and annual OGTT. Results of the study indicated that women with a history of GDM randomized to placebo had a crude incidence rate of diabetes 71% higher than that of women without such histories. Among women reporting a history of GDM, both intensive lifestyle and metformin therapy

TABLE 32.14 Dietary Patterns and Risk for Developing GDM and T2DM After GDM

Stage	Risk	Dietary Pattern	Foods	Relative Risk (95% CI)
Risk for GDM Prepregnancy	High	Western diet	Overall diet: high intake of red meat, processed, refined grain products, sweets, French fries, and pizza	RR: 1.63 (1.20, 2.21); $p = 0.001$ [88]
				RR: 1.74 (1.35, 2.26) [86]
				RR:1.22 (1.01, 1.47) [86]
			Red meat	RR: 1.13 (0.97, 1.32) [87]
			Sugar-sweetened cola	RR: 1.31 (1.08, 1.59)
			Fried foods	RR: 2.18 (1.53, 3.09); p trend <0.001
	Low	Mediterranean diet	Plant-based foods (fruits, vegetables, whole grains, legumes, and nuts), fish and seafood, olive and canola oil and reduced intake of red and processed meats	RR: 0.76 (0.60, 0.95); p trend = 0.004 [90]
		Dietary Approaches to Stop Hypertension (DASH) diet	Plant-based foods (fruits, vegetables, whole grains, legumes, whole grains), low-fat dairy, and reduced intake of sweetened beverages and sodium	RR: 0.66 (0.53, 0.82); p trend = 0.0005 [90]
		Healthy Eating Index diet	Plant-based foods (fruits, vegetables, whole grains, legumes, nuts, whole grains, cereal fiber), higher ratio of white:red meat, PUFA:SFA, multivitamin use, and reduced *trans* fats	RR: 0.54 (0.43, 0.68); p trend = 0.0001 [90]
Risk for GDM During pregnancy	Low	Healthful diet and 150 min/week moderate to intense physical activity	Vegetables, fruits and berries, whole-grain products, rich in fiber, low-fat dairy products, vegetable fats high in unsaturated fatty acids, fish, and low-fat meat products, and a lower intake of sugar-rich foods	RR: 0.64 (0.38, 1.09) [92]
Risk for type 2 DM postpartum	High	Low-carbohydrate diet	Overall diet	HR: 1.36 (1.04, 1.78); p trend = 0.003 [97]
			with high protein and fat intake from animal-source food	HR: 1.40 (1.06, 1.84); p trend = 0.004
			with high protein and fat intake from plant-source food	HR: 1.19 (0.91, 1.55); p trend = 0.50
	Low	Mediterranean diet		RR: 0.60 (0.44, 0.82); $p = 0.002$ [90]
		DASH diet		RR: 0.54 (0.39,0.73); $p = 0.001$
		Healthy Eating Index diet		RR: 0.43 (0.31, 0.59); $p = 0.001$

RR, relative risk; HR, hazard ratio.
Source: From C. Zhang, M.B. Schulze, C.G. Solomon, F.B. Hu, A prospective study of dietary patterns, meat intake and the risk of gestational diabetes mellitus, Diabetologia 49 (2006) 2604–2613.

reduced the incidence of diabetes by approximately 50% compared with the placebo group, whereas this reduction was 49% and 14%, respectively, in parous women without GDM. These data suggest that metformin may be more effective in women with GDM histories as compared with those without GDM [100]. In another similar study, 350 women with a history of GDM and 1416 women with previous live births but no history of GDM were assigned to either placebo, intensive lifestyle intervention (ILS), or metformin. In women with a history of GDM, ILS and

metformin reduced the progression to diabetes compared with placebo by 35% and 40%, respectively. Among women without a history of GDM, ILS reduced the progression to diabetes by 30%, and metformin did not reduce the progression to diabetes. It was concluded that both lifestyle and metformin were highly effective in reducing the progression to diabetes during a 10-year follow-up period. Among women without a history of GDM, lifestyle but not metformin reduced progression to diabetes [101].

XIII CONCLUSION

The diagnosis of GDM should initiate a long-term intervention and diagnostic process to minimize the risk of developing diabetes later in life. Pregnancy complicated by diabetes represents a window of opportunity for the implementation of nutrition education and a physical activity program to modify lifestyle patterns toward healthier habits for the woman and her family. Furthermore, the prevention of T2DM and subsequent gestational diabetes could begin with a healthy lifestyle in the interconception period and last into the future.

Chapter 33

Interaction of Genetic Factors With Nutrition in Cancer

Jo L. Freudenheim and Emily Gower

University at Buffalo, The State University of New York, Buffalo, NY, United States

I INTRODUCTION

Each year, there are more than 14.1 million new cases of cancer and approximately 8.2 million deaths from cancer worldwide. In the United States alone, there are approximately 1.6 million new cases annually [1]; there are approximately 15.5 million people alive in the United States with a cancer history. Approximately 67% of those cancer patients survive for 5 years or longer after diagnosis [2]. Therapies to cure cancer continue to improve, but prevention is clearly an essential strategy in ameliorating cancer-related morbidity and mortality.

There are considerable differences in the rate of different kinds of cancers worldwide. Given those differences and changes in rates of cancer when populations migrate from one environment to another, it is generally agreed that most common cancers are caused, in large part, by external factors, including diet, that have the potential to be altered [3,4]. Genetic factors alone do not explain the observed variation in rates. An understanding of how dietary factors and overall nutrition contribute to cancer is one part of understanding cancer prevention and prognosis.

There is accumulating evidence that carcinogenesis is a complicated process involving interactions of an individual's endogenous milieu, including his or her genetic makeup, with other exogenous exposures including diet and nutrition. One simplified model for an interaction of diet and genetics is shown in Fig. 33.1. In this case, there is a different rate of increase in risk with a dietary exposure for those with a particular gene that increases the likelihood of cancer compared to those without the gene. Both factors affect the risk of the disease [5].

In conceptualizing what causes cancer, it is crucial to understand that a cancer may have more than one cause. For example, both occupational exposures and diet could contribute to the etiology of one kind of cancer and even to the cancer of one individual, and either a change in the occupational exposure or a change in diet might prevent that cancer or reduce the risk. Similarly, both dietary and genetic factors may contribute to the same cancer. Sometimes those contributions are additive. That is, the risk for both is the sum of the risks for each. In other cases, the contributions are interactive. That is, the genetic factors interact with the nutritional factors so that the risk is not the same as the sum of each.

It is estimated that nutritional factors contribute to between 30% and 40% of tumors [3]. Genetic factors likely play a role in many, if not all, cancers. Even when an exposure is clearly required for a particular kind of cancer, genetic factors often play a role in determining who, among exposed individuals, develops that cancer. In examining the interactions of nutrition and cancer, it is also important to recognize that cancer is a collection of diseases that differ in their causes; even among cancers at one site such as breast cancer, there are several different kinds of breast cancer with differences in risk factors and underlying etiology.

II BACKGROUND AND DEFINITIONS

Cancer is a disease of uncontrolled growth of cells with spread to other tissues [6]; it is characterized by a number of changes in cells. Tumor cells have their own growth signals, do not respond to signals inhibiting growth, can replicate indefinitely (replicative immortality), can avoid programmed cell death (apoptosis), can alter energy metabolism, can avoid immune surveillance, can invade

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00033-3

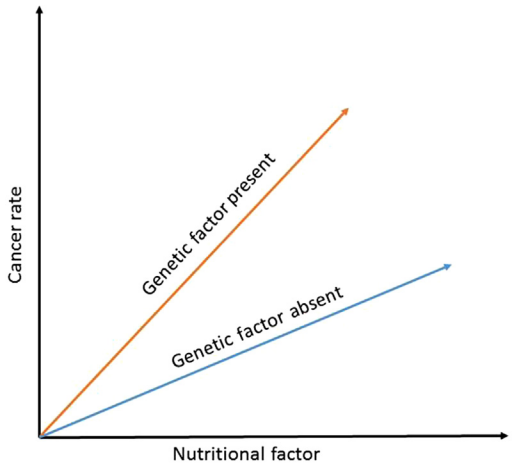

FIGURE 33.1 The effect of a dietary factor or other nutritional exposure on the rate of cancer might vary depending on the presence of a particular genetic factor. *Adapted from V. Andersen, R. Holst, U. Vogel, Systematic review: diet-gene interactions and the risk of colorectal cancer, Aliment. Pharmacol. Ther. 37 (4) (2013) 383–391.*

other tissues (metastasis), and can develop a blood supply for those metastases (angiogenesis). Inflammation and instability in the genome leading to mutations and other alterations are also part to the observed changes [7]. In the process of carcinogenesis, there is an accumulation of genetic and other alterations that lead to these significant changes in the functioning of the cell.

Genes are the basic unit of heredity; each gene has its own location in the DNA on a particular chromosome [8]. A *mutation* is a structural change in the base pair sequence of DNA, the chromosomal material that provides the code for gene expression [8]. In tumor cells, there are usually a number of mutations of the DNA. In addition, there may also be *epigenetic* changes. These are changes other than changes to the DNA base pair sequences. Like mutations, epigenetic changes can also affect gene structure, function, and expression. One such change is *altered DNA methylation*, the addition or loss of methyl groups on the DNA, which can affect gene expression. *Hypermethylation* of the promoter region of tumor suppressor genes can lead to silencing of the gene. This change is common in tumors and may be as important a mechanism as mutation in carcinogenesis. Other epigenetic changes include methylation or acetylation of *histones*, proteins associated with DNA that affect its structure [8]. There may also be alterations in copy number—that is, the number of copies of the same gene—altering the overall expression. In cancer cells, there may also be the loss of one or more sections of the genome as well as translocation of sections of the genome from one location to another.

Genotype refers to an individual's genetic structure, based on his or her DNA [8]; it is the nucleic acid sequence of the DNA. Generally, each individual has two copies of each gene, one inherited from each parent. In some but not all cases, differences in genotype provide information regarding protein activity. For example, genotype for a faster or slower version of a particular enzyme would influence the rate of the reaction catalyzed by that enzyme. Other factors besides genotype can also influence activity of an enzyme or other protein. These include the rate of transcription of the gene, available concentration of substrate(s), and the rates of synthesis and degradation of the protein. *Phenotype* refers to observable characteristics; it represents the expression of the genotype, including the effects of interactions with other genes and with the environment [8]. Examples of phenotype are general characteristics such as height and body weight, as well as other, more specific characteristics such as the activity of an enzyme or receptor, or blood vitamin concentration.

Agreement between genotype and phenotype often is not exact, as described in more detail later. Phenotype may not be dependent on a single gene but, rather, the result of genotype of a number of different genes in a pathway, combined with the impact of external exposures. For example, height is influenced by a number of genes and by external factors including nutrition.

When there is an *interaction*, the effect of a factor differs depending on the presence or absence of another factor. In many instances, there are gene–gene interactions as well as gene–environment interactions. For example, a person may have the genotype for lower activity for a particular enzyme. However, there can be other exposures including dietary factors that induce greater expression of that enzyme. Phenotype, the activity of the enzyme, would depend on the combination of the genotype (faster or slower) and the other exposures (e.g., higher intake of a dietary exposure that increases the amount of the enzyme that is present). The measurement of phenotype is of interest because it gives an indication of the true level of exposure. Thus, for example, measurement of serum vitamin D would be a phenotype of interest, which might be more informative than measurement of genotype for the number of genes related to vitamin D status. In other cases, genotype may be the preferable measure. Genotype may give a better indication of lifetime exposure, whereas phenotype (gene expression) may be influenced by recent exposures. In particular, when study participants have a disease, phenotype may be less informative if the disease process influences it.

Penetrance of a genetic factor refers to the likelihood that those with a specific genotype will exhibit a particular phenotype in given environmental circumstances [8]. A gene with very high penetrance is one for which virtually everyone with the gene has the expressed trait, whereas a gene with low penetrance is one for which there is a lower likelihood of the trait being expressed.

Some individuals are at greater risk for certain types of cancers. This increased risk can be related to differences in exposure to cancer-inducing or -protecting agents, to the individual's genetic makeup, or to a combination of these factors. Genetic factors vary widely with regard to the magnitude of their impact. Some inherited mutations greatly increase the risk of cancer; others cause smaller increases in risk. Some mutations may only increase risk in the presence of a particular exposure.

Examples of inherited mutations with high penetrance are mutations identified in the *BRCA1* and *BRCA2* genes. Particular mutations in these genes have been shown to be strongly related to risk of breast and ovarian cancer. It is estimated that carriers of the *BRCA1* and *BRCA2* genes have a 45−65% risk of breast cancer by age 70 years; that is, many, but not all, women with this mutation will develop breast cancer. Relatively few individuals in the population carry this factor (less than 1%). Therefore, although those with the gene are at high risk, only approximately 5−10% of women with breast cancer have this mutation [9].

There is a considerable range in the impact of genetic differences on phenotype. Other genetic variants that are more common and that have weaker effects on risk are referred to as *genetic polymorphisms*. A gene that is polymorphic has more than one form; its structure varies among individuals in a population. Many polymorphisms are silent, not affecting phenotype. Other polymorphisms can alter the activity of a protein and/or may affect its interaction with other compounds including nutrients. The change in one nucleotide is referred to as a *single nucleotide polymorphism* (SNP). There are frequently one or more polymorphisms found in a gene. The frequency of the occurrence of a genetic polymorphism among individuals within a population may vary greatly depending on the ancestry of the individuals in that population. Generally, polymorphisms have less impact on cancer risk than do highly penetrant mutations such as *BRCA1/2*. However, when they are common, they may still have an overall significant effect on the rate of disease in a population. Common polymorphisms may affect the response to an exposure so that their effect on risk would be evident only when that exposure or exposures are present, referred to as a gene−environment interaction. When there are gene−environment interactions, an understanding of both the genetic factor and the environmental exposure is needed in order to understand disease etiology and prevention.

Studies examining associations with disease risk of a single gene or of several genes in a pathway are called *candidate gene* studies. In these studies, genes are selected based on a hypothesis regarding a likely mechanism. In *genome-wide association studies* (*GWAS*), instead of examining SNP-outcome associations in particular genes, genetic variation across all of the chromosomes is examined. For this "agnostic" approach, hundreds of thousands of SNPs are examined in one study to understand which, if any, are associated with a particular outcome, such as a disease (e.g., cancer) or a biological marker (e.g., concentration of a vitamin in blood or body mass index). To be effective, such studies must include genetic data and outcome data from hundreds of thousands of participants [10]. When a particular SNP is identified from a GWAS, it does not necessarily mean that the identified SNP increases the likelihood of the outcome. SNPs can be in *linkage disequilibrium*, which means that there are SNPs that are often found together; the SNPs are not randomly distributed across the population. If there is linkage disequilibrium, an identified SNP, with a strong association with the outcome, may be an indicator for another SNP that is causally related to the outcome (Fig. 33.2).

- Examination of hundreds of thousands of genetic variants at one time
- Examination also possible of variation in epigenetics (e.g., DNA methylation)
- Compare frequency of each variant for those with and without an outcome of interest
- Outcome can be a disease (e.g., bladder cancer cases vs controls without bladder cancer)
- Outcome can be a nutrition-related variable (e.g., blood vitamin D binding protein high vs low, intake of macronutrients)
- Variants with strongest statistical associations may be investigated further to better understand findings including identifying variant more specifically and understanding mechanisms of action

FIGURE 33.2 Genome-wide association studies.

Similar to the methods for GWAS of genetic variation, genome-wide variation in DNA methylation can be studied. In a genome-wide study of diet in relation to DNA methylation, generally the dietary factor would be considered the exposure and the genome-wide methylation the outcome. For example, there are studies examining the association of obesity or vitamin intake with DNA methylation, examining hundreds of thousands of locations in the genome to identify those that are associated with the nutritional exposure.

Several terms have been developed to describe the interaction of food components with genes. *Nutrigenomics* is the broadest term, describing the interaction of dietary components with genes. Included in this term is *nutrigenetics*, the study of the impact of genetic variation on response to dietary components; *nutritional epigenetics*, the study of interactions of food-derived compounds with epigenetic alterations—for example,

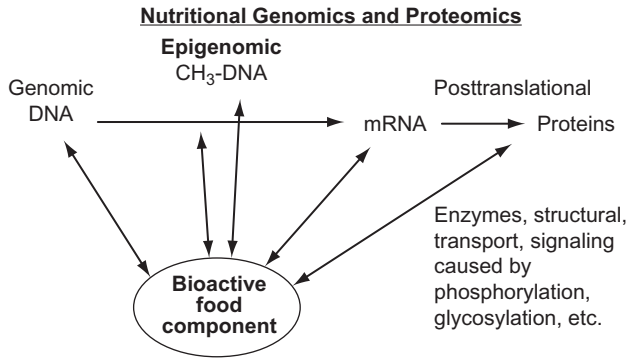

FIGURE 33.3 Bioactive food components may interact with genes and their products in a number of different ways, including interactions with the coding DNA, with other parts of the chromosome structure, with the messenger RNA, and with the protein product after translation. *From J.A. effects of nutrition on DNA methylation and on chromatin structure; and *nutritional transcriptomics*, the study of the impact of dietary components on gene transcription. In addition, dietary components may affect protein structure posttranslation; the study of these interactions is *nutritional proteomics* (Fig. 33.3) [11,12].

III MECHANISMS OF DIET–GENE INTERACTIONS

A Overview of Interactions

In the exploration of the role of dietary factors in carcinogenesis, both essential nutrients and other compounds in foods with biological activity may be important. Interactions of nutritional and food-derived bioactive compounds with genetic factors may operate in two directions. Genes can affect the action of compounds of dietary origin (e.g., increasing or decreasing the amount needed for good nutritional status), and the dietary compounds can affect the action of genes (e.g., leading to increased or decreased expression of a particular gene) (Fig. 33.4).

To understand these processes, several layers of complexity need to be taken into account. Individual bioactive food components may have more than one action, in some cases interacting with other food components and with more than one gene. Food composition can differ significantly, depending on growing conditions, genetic differences of the foodstuff, storage and cooking, and other food processing [13]. After consumption, there can be interactions of a particular bioactive compound with other food constituents, with other environmental exposures (e.g., from air and water), and with genes. Furthermore, genes can interact with each other. The resulting metabolic environment derives from these numerous interactions of factors of both endogenous and exogenous origin. In understanding the role of a particular food component, examination of its interactions with other food components and with one or more metabolic pathways may be necessary, as well as possible consideration of differing actions depending on dose or on tissue site.

This complexity is only partially understood for most of the bioactive compounds that have been studied. Single food components and single foods have been studied in relation to single genes for cancer. A limited number of studies have examined the impact of a group of foods or of dietary patterns on risk or prognosis. There have been a limited number of GWAS, examining thousands of SNPs in relation to nutritionally significant outcomes, for example, with the blood concentration of a particular nutrient. These studies are essential first steps; there is much to be learned as the more complex systems of interactions are examined. Presented here is information about the impact of genetic variation on the availability and utilization of dietary compounds in relation to carcinogenesis and about the impact of diet on genetic factors in relation to carcinogenesis [14].

B Genetic Variation in Relation to Metabolism of Food Components

1 Carcinogen Metabolism

Genes may impact the metabolism of carcinogens including both compounds occurring naturally in foods and others that contaminate foods. If an individual has genetic variants that result in slower metabolism of a carcinogen, that individual will be more affected by a given dose of that carcinogen than would someone who can metabolize and excrete the carcinogen more rapidly. Conversely, if an individual has genetic variants that result in more rapid metabolism of a carcinogen, then he or she may be less affected by the same dose than someone who does not have that variant.

Enzymes related to carcinogen metabolism and excretion are divided into two groups: phase I and phase II.

Phase I enzymes activate the compound, and phase II enzymes attach polar groups to the activated compound so that it will be more water soluble and can be excreted in the urine. Many of the phase I enzymes are in the cytochrome P-450 (CYP) family. Phase II enzymes include glutathione-*S*-transferases (GSTs) and *N*-acetyltransferases (NATs). In some cases, phase I activation leads to the production of compounds with greater carcinogenic potential. Often, foods contain procarcinogens, compounds that are carcinogenic after metabolic activation. The process of metabolic activation may vary depending on genetic factors. For example, heterocyclic amines are a group of compounds found in meat cooked at high temperatures, primarily "well-done" meat and fish. There is some, although not consistent, evidence that consumption of heterocyclic amines may increase the risk of cancer. For example, there is evidence of an association between intake of these compounds from meat with increased risk of colorectal [15] and of prostate cancer [16]. This association may depend on genetic factors. Metabolism and excretion of heterocyclic amines involve CYP1A2, *N*-acetyltransferases 1 and 2 (NAT-1 and -2), and UDP-glucuronosyltransferases [17]. There is evidence that the association of colorectal cancer with intake of heterocyclic amines differs depending on genetic variation in NAT-1 [18]. In another study, there was an interaction of NAT-1 genotype and intake of dietary mutagens in relation to prostate cancer risk [19]. The relationships between these phase I and phase II enzyme systems are shown in Fig. 33.5 [20,21].

Other kinds of genetic variation may also affect association of nutrition and diet with cancer outcomes. Copy number variation—the number of copies an individual has of a particular gene—may also affect metabolism. For example, there is evidence that the number of copies of the amylase gene is correlated with the levels of the amylase protein in saliva [22]. Dietary intake of nutrients important in one-carbon metabolism may impact DNA methylation. One study showed an association of folate and green vegetable intake with promoter methylation in sputum from apparently healthy smokers [23]. In another, there was no association of folate intake with DNA methylation of three particular genes in breast tumors [24]. Genome-wide studies of DNA methylation may provide more insight as to changes associated with diet. For example, in a study of elderly individuals, there was evidence that supplementation with folic acid and vitamin B12 affected methylation of particular genes and regions of chromosomes [25].

2 Metabolism of Nutrients and Other Food Components

There can be significant genetic variation among individuals in the absorption, tolerance, transport, and excretion of nutrients and other bioactive food components as well as their metabolism [13,26]. All of these can alter effects of intake of the same amount of a food component by individuals with different genes. Furthermore, genetic factors may alter food preferences and therefore food consumption [27]. In one study of more than 37,000 individuals, SNPs were identified that were associated with differences in intake of macronutrients providing evidence that macronutrient intake may be affected by genetic factors [28].

The impact of a particular genetic polymorphism may differ for different compounds. It is even possible for a genetic variant to protect against cancer for exposure to one compound and increase risk for another. For example, the GSTs are phase II enzymes that catalyze transformation of carcinogens such as polycyclic aromatic hydrocarbons (PAHs) for excretion. For those with higher exposure to PAHs, including PAHs of dietary origin produced in the cooking of foods, more rapid metabolism would be advantageous. Some of the GSTs also deactivate other phytochemicals that are thought to exert protective effects. Included in the latter group are the isothiocyanates from cruciferous vegetables, which are metabolized by GST, also resulting in their excretion [27]. For those compounds, GST metabolism resulting in slower excretion would be advantageous.

Genetic variation in the metabolic pathway for a nutrient or bioactive food component can affect the physiologic impact of intake of that compound. For example, if a vitamin plays a role in cancer prevention, genetic differences in the receptor for the vitamin could also affect the susceptibility of an individual to cancer. There are commonly occurring genetic differences in the vitamin D receptor that may have functional significance. A number of studies have examined the association of those variants with risk of several cancers. There is some evidence that genetic variation in the receptor is associated with cancer risk [29]. Genetic factors may influence status of a nutrient. A GWAS was done to identify the SNPs most associated with the blood concentration of the vitamin D binding protein. More than 590,000 SNPs were examined for approximately 1300 study participants. Some of the results of that study are shown in the plot in Fig. 33.6. From that plot of the statistical association of the D binding protein with each of the SNPs, it is possible to identify the ones most strongly associated with blood concentration of the binding protein [30]. In another GWAS examining a large number of SNPs in association with vitamin D in blood, several genetic variants were found to be associated with circulating 25-hydroxyvitamin D [31].

There has been considerable exploration of genetic variants in the one-carbon metabolism pathway. Genetic variation in this pathway affects blood folate concentrations and folate transport and utilization. This pathway

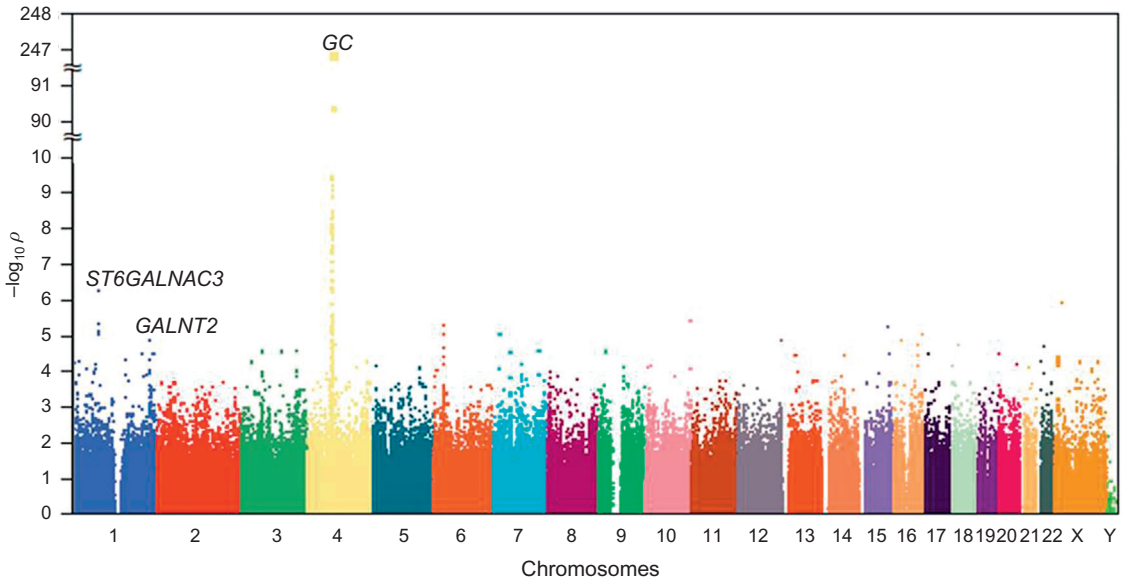

FIGURE 33.6 GWAS of SNP with blood concentrations of the vitamin D binding protein. For each SNP location on the chromosome (*x*-axis) there is a *p*-value for the association (*y*-axis). There were two SNPs, both in the binding protein (chromosome 4) that were strongly associated with the blood concentration of the binding protein. *From K.A. Moy, A.M. Mondul, H. Zhang, S.J. Weinstein, W. Wheeler, C.C. Chung, S. Mannisto, K. Yu, S.J. Chanock, D. ALbanes, Genome-wide association study of circulating vitamin D-binding protein, Am. J. Clin. Nutr. 99 (2014) 1424–1431. Reprinted by permission.*

also includes the synthesis of nucleic acids. Genetic variation may therefore also affect the synthesis of purines and pyrimidines for DNA synthesis as well as potentially impacting gene methylation and the expression of genes. There is some, although not consistent, evidence of an association of variants in genes in this pathway and risk of several cancers [11]. However, in one study examining genetic variation of genes involved in one-carbon

metabolism, there was no association with the prevalence of DNA methylation in breast tumors [32].

Another example of a gene that affects nutrient utilization is the *HFE* gene. This gene contains a variant, common among Europeans, that affects iron storage and contributes to the etiology of hemochromatosis [33]. There is also evidence of genetic variants that are associated with total iron binding capacity and percent iron saturation [34]. Iron overload is associated with increased risk of hepatocellular carcinoma [35].

There is genetic variation in several of the enzymes involved in alcohol metabolism. A variant in the gene for aldehyde dehydrogenase (ALDH2) is carried by approximately 50% of Asians and significantly impacts alcohol metabolism. Among those with the variant, there is greatly reduced clearance of acetaldehyde; those who are either heterozygous or homozygous for the variant experience an adverse reaction, an intense flushing, when they consume alcohol. The variant has been shown to be associated with both lower alcohol consumption and alcoholism [36]. Acetaldehyde is a carcinogen. There is evidence of an interaction between *ALDH* genotype, alcohol intake, and risk of cancer at several sites [37].

Another example of an interaction of diet, genetics, and a health outcome related to cancer is that of sugar-sweetened beverages and obesity. There are number of genetic variants that have been found to be associated with obesity; obesity increases the risk of a number of kinds of cancer. In one prospective study, investigators looked at a signature of those genes associated with obesity. They found that the association of the gene signature with obesity was stronger among those who consumed more sugar-sweetened beverages; there was a statistically significant interaction of the selected genetic variants with the sweet beverages and likelihood of obesity [38]. It appears likely that we are just beginning to understand how genetic variation affects nutrient metabolism and affects the role of nutrients in pathways relevant to carcinogenesis. Better understanding of those interactions may help in providing clearer guidance regarding appropriate prevention strategies. It may also be that there will eventually be personalized prevention programs, identifying individuals with particular genetic signatures that indicate that they have different requirements for nutrients that impact cancer prevention.

C Interactions of Bioactive Food Components With Gene Functions in Relation to Carcinogenesis

1 Mutations and Metastasis

Nutrients and other bioactive food components appear to contribute both in positive and negative ways at every stage of the carcinogenic process, including interactions with DNA mutations and tumor metastasis. Some DNA mutations result from carcinogens that bind to the DNA, forming DNA adducts. Carcinogens in foods, such as the PAHs described previously, are one potential source of these carcinogens. Binding to the DNA, such adducts may interfere with DNA replication and result in mutations or deletions in DNA structure. Dietary factors may also affect the formation of adducts, such as those from smoking. For example, there is evidence that among smokers, adduct formation is more likely among those with lower β-carotene intake. Furthermore, genetic variation may also affect this association. The association between adduct formation and β-carotene intake appears to be limited to individuals who carry homozygous deletions for the gene for glutathione-*S*-transferase (*GSTM1null*) [39].

Oxidative stress may also affect carcinogenesis. There is evidence that reactive oxygen species from both exogenous and endogenous sources can cause DNA mutations. Diet can affect exposure to reactive oxygen species both positively and negatively. With greater energy consumption, there is a tendency for a greater number of oxidized DNA bases [3]. Antioxidant vitamins and certain other enzymes are part of the body's defense against these oxidative processes. As described above, the concentration of those vitamins may be affected by genetic factors. The enzymes too may have more or less reactivity depending on genetic factors. Those who have genetically weaker defense systems against oxidation may benefit more from increased intake of antioxidant vitamins, such as vitamins C and E. For example, superoxide dismutase is important in the control of endogenously produced reactive oxygen species; manganese superoxide dismutase (MnSOD) is found in the mitochondria, a location for production of oxidative species. The gene coding for MnSOD is polymorphic, and a study suggests that one variant of this gene may be associated with increased risk of premenopausal breast cancer but primarily among women with a low intake of antioxidant vitamins from fruits and vegetables [40].

Dietary factors may also influence genes that are related to metastasis. Catechins—found particularly in green tea but also found in black tea, apples, and chocolate—can downregulate enzymes important in the development of metastases [41]. Other vitamins including vitamin A impact gene expression including expression that plays a role in pathways related to carcinogenesis such as cell differentiation and control of cell death [42]. Vitamins with antioxidant properties including vitamins C and E and green tea extract may affect genes significant in carcinogenesis including those not directly related to control of oxidation [43].

Genetic variation may also affect genetic stability and DNA repair. There is evidence that nutrients may be able to promote stability and thereby prevent carcinogenesis.

Although the data regarding this potential mechanism are rather limited, there is evidence of an effect of diet on functions essential to the maintenance of DNA integrity [44].

2 Gene Expression

In addition to effects on gene structure and mutations, nutrients and other dietary factors may also impact cancer by altering gene expression. For example, the *CYP1A2* gene can be induced by indole-3-carbinol found in cruciferous vegetables, by heterocyclic amines in cooked meats, and by PAHs found in grilled meat. *CYP1A2* is also inhibited by the compound naringenin, which is found in grapefruit [45]. Therefore, metabolism of heterocyclic amines by the enzyme encoded by the *CYP1A2* gene may depend not only on the genetic variant of *CYP1A2* that is carried by an individual but also on the individual's intake of these other food components that affect *CYP1A2* expression. Similarly, consumption of a diet that is low in fat and low in glycemic load was shown to be associated with alterations in gene expression in the prostate epithelium in humans [46].

Interactions with gene expression may be part of the normal functioning of the food component and of the gene, leading to either upregulation or downregulation of the gene expression. Vitamins A and D interact with the promoter regions of a number of genes, influencing their expression and thereby affecting a host of cellular functions, including cell proliferation and differentiation and DNA replication and repair [47]. A group of receptors called peroxisome proliferation-activated receptors (PPARs) affect the expression of genes important in fatty acid metabolism and tumorigenesis. One of these, PPARα, is activated by oxidized fats, affecting expression of genes important in fatty acid synthesis [48]. The intracellular energy balance can also affect gene expression [49]. A number of other nutrients and other food components have been shown to affect gene expression in cell culture, including vitamin E, biotin, zinc, flavones, and catechins [49].

3 Epigenetic Alterations

Alterations of DNA structure other than base pair changes can also affect gene expression. Important among these are DNA methylation and alterations in histones. There is evidence of possible contributions to carcinogenesis by an overall decrease in DNA methylation (global hypomethylation). In addition, an increase in the methylation (hypermethylation) of the promoters of certain genes, particularly tumor suppressor genes, may contribute to the development of cancer by silencing them. Dietary factors involved in one-carbon metabolism may affect this methylation. These factors include folate, vitamins B6 and B12, biotin, choline, and methionine as well as alcohol. Alcohol can adversely affect folate status and indirectly affect methyl availability. In one study, there was more methylation of DNA in breast tumors from women who drank more than in the breast tumors from women who drank less [50]. In addition to nutrients related to methyl availability, there is also evidence that genistein, coumestrol, and a high-fiber diet may all affect methylation patterns [51]. Mechanisms for both hypo- and hypermethylation are not well understood and may involve other factors of both exogenous and endogenous origin.

In addition to methylation changes, dietary factors may impact other epigenetic factors including effects on the histones. Inhibitors of histone deacetylators include butyrate (formed by the bacterial fermentation of fiber in the colon), diallyl disulfide (from plants in the allium family, including garlic), and sulforaphane from cruciferous vegetables [11]. Resveratrol, found in grapes and grape products, may affect carbonylation of histones. Diet may also affect gene expression through other epigenetic mechanisms. One such mechanism is the impact of diet on microRNA expression, affecting expression of a number of other genes including tumor suppressor genes and oncogenes [52].

The fields of genetics in general and nutrigenetics in particular are changing rapidly; numerous discoveries are leading to major shifts in our understanding of the role of genetic factors in cancer risk and of the interaction of dietary and other exposures with those genetic factors. There is evidence that a number of pathways involving diet and gene interactions may ultimately impact disease. Other pathways of interaction will likely be identified, and some of those detailed here may be determined to be of lesser importance to humans. Because much of our understanding of gene−environment interactions in relation to cancer is based on relatively new information, it is important to recognize that much of the data will be subject to reinterpretation and that an understanding of the methodological issues involved is key.

IV METHODOLOGICAL ISSUES

Data regarding interactions of diet and genes and cancer come from a number of sources, including studies of normal and tumor cells in culture, animal models, and human epidemiologic studies. Each of these study modalities has advantages and disadvantages. For cell culture studies, the concentration of an agent may be very important, and the studied concentration may or may not relate to physiological conditions in the tissue of interest. Also important to consider are the duration of the dosage and the type of cells used. Some cultured cells may also have characteristics different from what occurs in vivo. In addition, results may vary depending on the cell model used, even for different models of the same cancer site.

Animal models are an important source of understanding of the underlying mechanisms of carcinogenesis. Again, however, in interpretation of findings, considerations of the dose and duration of administration of an agent are important. Also important is an understanding of differences between the physiology of a particular animal used in the experimental systems and humans. In addition, the complex mix of exposures humans experience over an extended period of time may be of importance and may not be replicated in laboratory animal or cell culture studies. Even when the animal model can provide very good information, there may be important caveats that inform the conclusions that can be made from the experiments. For example, there are numerous studies of the administration of high-fat diets to animals leading to mammary tumor development. One limitation of such studies that is often not noted is that the observed increases in mammary tumors were found only when the high-fat diets were administered to virgin animals. In parous animals, the high-fat diets did not increase mammary tumors [53]. Such caveats are important in understanding the results from animal studies and especially in the translation of findings from animals to understanding human disease processes. Epidemiologic studies have the advantage of studying human populations with gene frequencies and exogenous exposure levels (e.g., nutrients) at the pertinent levels. However, there are other concerns with studies of this kind.

In epidemiologic studies, an individual's genotype can be determined from DNA extracted from cells. The DNA is typically obtained from blood cells, from sloughed cells in saliva, or from sloughed cells from the inside of the mouth. For polymorphic genes, laboratory methods are used to identify which of the variants for a particular gene are carried by an individual based on the sequence of the DNA. Because the presence of one mutation may be frequently found with the presence of others, it may not be necessary to measure every variant in a particular gene. Rather, markers or tag SNPs can be measured that identify the group of variants in a gene. These variant groups that tend to travel together are referred to as haplotypes.

An individual's phenotype may also be measured. Phenotype may be the measure of some physical characteristic such as body weight, eye color, or blood concentration of a vitamin. Alternatively, phenotype may be measured as the response to an exposure. An individual ingests a measured amount of a substance (e.g., caffeine), and then blood or urine samples are collected for several hours or days to determine the rate of metabolism of that substance. Measurement of phenotype is advantageous in that it provides an indication of the sum of the processes involved and therefore an indication of the true exposure. As noted previously, phenotype may depend on more than one gene; it may reflect processes involved in absorption and excretion as well as synthesis and metabolism. However, when comparisons are being made of individuals with and without a disease, the phenotype may be affected by the disease state and might not be reflective of the diseased individual's lifetime exposure. In studies that include people with disease, a determination of phenotype may be less useful than determination of a genotype, unless it can be shown that the phenotype does not change for those with the disease.

In epidemiology, the interaction of genes and diet may be assessed in case–control studies, in cohort and nested case–control studies, or in randomized trials. In case–control studies, the cases are the people with recently diagnosed disease and they are compared to healthy controls from the same population. Statistical methods are used to determine whether there are systematic differences between those people who get the disease and those who do not. In a prospective cohort study, a population of exposed and unexposed individuals is identified and their exposure status measured. Those individuals are then followed-up to compare the rate of disease in the exposed and unexposed groups. Because cancer is relatively rare, cohort studies generally need to include thousands or even hundreds of thousands of individuals in order to examine diet in relation to cancer.

When blood has been collected from study participants, it is possible to determine genotype for the participants. In a cohort study, a nested case–control study may be conducted for analysis of gene–environment interactions. Individuals in the cohort with incident cancer (cases) are compared to a group of non-cases selected from the cohort. The non-cases are chosen to be similar to the cases for relevant characteristics such as age, race, and gender. Genotypes are then determined and the gene–environment interactions analyzed for this subset of the whole cohort. Environmental exposures are estimated from interview data (e.g., a food frequency questionnaire) or from other, more direct measures of exposure (e.g., blood vitamin concentration).

In a randomized trial, study participants are randomly allocated to exposure category. For example, participants would be randomly selected into a group to be given a dietary intervention such as selenium. Others would be randomly selected to take a placebo. For randomized trials of supplements, often none of the participants know which group they are in. The trial is "blinded." For trials of change in diet, it is often not possible to blind the participants; they know if they are receiving the intervention diet or the control diet. To examine diet–gene interactions, the effect of the intervention could be compared by genotype. It is possible to determine genotype in advance of randomization in order to group participants based on their genotype, to ensure that the number of participants with a particular genotype is the same in the intervention and control groups.

For both case–control and nested case–control studies, the examination of gene–diet interactions generally involves a few steps: (1) the examination of the association between risk of a particular cancer and the genetic factor(s) alone—genetic factors can be a single polymorphism with known functional significance, haplotypes within a gene, a group of genes in one or more pathways, or thousands of variants across the entire genome; (2) the examination of the association between risk of that cancer and the dietary factor(s) alone—dietary factors can be nutrients, single food components, foods, groups of bioactive agents, or dietary patterns; and (3) the examination of the gene–diet interactions. In some cases, there will be further examination of interaction with other exposures (e.g., exposure to hormone replacement therapy or categories of body weight).

Although this is a relatively new area of research, in some clinical trials, the interaction of genes and environment is studied. The effect of a dietary intervention might be examined within and across groups to determine if one group is more susceptible to the intervention.

For all these study designs, there are some important methodological considerations. Many of these are the same considerations as for any epidemiologic study of diet and cancer [54]. A significant one is that, as in all epidemiology, conclusions about causality need to be derived from a synthesis of epidemiologic findings in a number of populations, as well as finding from animal research and metabolic studies. Generally, no single epidemiologic study can be considered definitive and used to establish causality. In case–control and cohort studies, there is concern that the findings may not be causal but rather the result of confounding. That is, another factor may be correlated both with the exposure under study and with the disease and may be the causative agent. If the investigators are unaware of this confounding factor or they are unable to control for it sufficiently well, it might appear that the exposure under study is associated with disease simply because it is correlated with the second factor. The confounding factor can be an exogenous exposure or another genetic factor. As defined above, sometimes certain genes tend to be inherited together and therefore one can confound an investigation of another of the genes, linkage disequilibrium.

Confounding may occur, for example, in a study of diet and lung cancer. In many populations, individuals who smoke are also more likely to drink alcohol. Unless smoking is measured well and controlled for in the analysis, one might incorrectly assess the relation of alcohol to lung cancer because of the correlation between these two behaviors. That is, it might be difficult to determine if alcohol is associated with lung cancer because of the confounding by smoking; disentangling the separate effects of alcohol from smoking may be very difficult. When studies are done in different populations in different cultures, the likelihood of confounding being the same in all of the populations is diminished; it is less likely that the same correlations exist between behaviors. In addition, other sources of error may differ among studies, making a consistent finding more believable. Only with a very well executed randomized trial can a causal link be identified with certainty because of the randomization to intervention or control group. However, even among randomized trials, differences in study results can occur because of differences in participant populations, so results need to be carefully interpreted. Clearly, it is only possible to stratify participants based on a limited number of genotypes, and linkage disequilibrium can make determination difficult as to which gene or genes are important in the process being studied.

Many hypotheses regarding gene–diet interactions in cancer risk have been examined in only a single study. With further development of the field, it will be possible to begin to identify the most consistent and important associations. At all times, it is important to examine findings critically and to search for consistent findings from well-conducted studies.

A major concern in evaluating diet and genetic interactions in relation to risk of cancer is that studies need to have large numbers of participants in order to have sufficient power to examine risk within strata defined by genotype or by diet. Because of the need to examine interactions, large studies are required to provide a sufficient number of individuals within the group of interest. Even if the results are statistically significant, such findings can be unstable. That is, if the study were redone, findings may not be consistent. In particular, for genes with low frequencies, the number of participants required to obtain a stable result can be very large. Furthermore, to examine the interactions of more than one gene and more than one dietary or other exposure, the number of participants required may be exceedingly large. In the evaluation of any study, it is important to consider the number of participants in each cell to make a determination of the likely stability of the findings.

Cancer is a multifactorial disease, and it is likely that several genetic factors are of importance even within a single causative pathway. Analysis of a single polymorphism or even of several genes in a pathway might not capture the total picture of variation in risk. Similarly, several nutrients are likely to be important even within a single causal pathway. As noted previously, the examination of gene–gene and gene–environment interactions can be seriously hampered by the required sample size.

Diet is also a complex set of exposures. A single food may include different factors with both carcinogenic and anticarcinogenic properties. Intakes of different nutrients are often highly correlated so that an association attributed to intake of one nutrient may in fact be the result of a causal relationship with a different nutrient. These differences are very important if the findings are interpreted to mean that

taking a supplement of a single nutrient will have a protective effect. Finally, when there is evidence that a particular nutrient is related to a decrease in risk, it cannot be assumed that larger quantities of that nutrient would be even more protective. For example, whereas vitamin C has antioxidant properties at the level found in most foods, at higher intake levels, it may have pro-oxidant properties [55].

A final challenge in this field is in the measurement of dietary exposure. Much literature is available on the problems of measurement of diet for epidemiologic purposes [56]. Beyond those concerns, the study of gene–diet interactions in relation to cancer risk has led to an interest in a number of new bioactive compounds found in foods. For many of these compounds, the dietary instruments used in the past may not provide sufficient detail for assessment of intake of that compound. For example, the study of heterocyclic amines led to the development of a questionnaire that specifically addresses the sources of these compounds because the information regarding intake on the existing questionnaires did not include the necessary detail to assess intake of heterocyclic amines [57]. Furthermore, nutrient composition databases may be limited and may need work in order to determine the composition for compounds that may relate to disease risk but that have not been previously analyzed.

V DIET–GENE INTERACTIONS AND CANCER

As described previously, there are a number of properties that distinguish a tumor. These properties contribute to the ability of a tumor to break loose from normal control of cell growth and to invade tissues. Tumor cells have their own growth signals, they do not respond to signals inhibiting growth, they can replicate indefinitely and do not go into programmed cell death (apoptosis), they can invade other tissues (metastasis), and they can develop a blood supply for those metastases (angiogenesis) [7]. All of these pathways may be appropriate targets for cancer prevention. Given the nature of tumor biology, it is unlikely that there will be one food or compound that will prevent all cancers or even all of one kind of tumor; rather, the cumulative effect of a number of compounds may be important in prevention [58]. Many processes are important in carcinogenesis, including carcinogen metabolism, hormone regulation, cell differentiation, DNA repair, apoptosis, cell growth cycle, and inflammatory response. Nutrients and other bioactive food components may play a role in each of these processes (Fig. 33.7) [59]. This area of research is rapidly changing, and our understanding of these relationships is likely to shift with further investigation. This overview is provided to give examples of the developing understanding.

A Carcinogen Metabolism

One example of a possible interaction of genetic factors with diet is the association of alcohol and esophageal cancer. There is consistent epidemiologic evidence that heavy alcohol consumption is associated with increased esophageal cancer risk [60]. There is also emerging evidence of increased risk even among light drinkers, especially in Asian countries [61]. Although there are several possible mechanisms to explain these observations, it may be that the mechanism of this association includes gene–environment interactions in carcinogen metabolism. As described earlier, the rate of metabolism of alcohol to acetaldehyde is impacted by an SNP, which is common among Asians. Acetaldehyde has been identified as a carcinogen [60]. It may be that among light drinkers, the exposure to alcohol combined with slower metabolism in those Asians with the gene for slower metabolism accounts for the increased risk associated with alcohol consumption.

B Regulation of Hormones

There is considerable evidence that estrogen exposure is a strong risk factor for breast cancer [62]. Of interest is whether compounds of plant origins with estrogenic properties, called phytoestrogens, affect breast cancer risk. Among these is indole 3-carbinol, which is found in cruciferous vegetables after they are cooked or crushed. There is evidence from studies of breast cells in culture that this compound can affect the estrogen receptor, ER-α. It can alter the estrogen and the DNA binding regions of the ER, leading to decreased response to estrogen in estrogen-responsive cells [63]. Thus, the interaction of this dietary compound with DNA may affect breast cancer risk because of the dampening of response to estrogen. Another phytoestrogen is lignin, found in flax seed, whole grains, sesame and sunflower seeds as well as smaller amounts in some fruits and vegetables. Increased lignin intake has been found to be associated with lower breast cancer risk [64].

C Cellular Differentiation

Genistein, a polyphenol in soy, has been found to decrease mammary tumors in animal models. There is evidence that when genistein is ingested in the prepubertal rat, it can help to regulate mammary development and differentiation. An increase in differentiation of mammary tissue is observed, as are differences in cellular proliferation, apoptosis, and tumor suppressor expression. The effects of genistein on mammary development appear to be most beneficial with administration of this bioactive compound in young animals and may not have the same impact in older ones [65].

Milner, Nutrigenomics, proteomics, metabolomics and the practice of dietetics, J. Am. Diet. Assoc. 106 (2006) 403–413. Copyright The American Dietetic Association. Reprinted by permission.*

D MicroRNAs

MicroRNAs (miRNAs) are noncoding RNA molecules that regulate genes by controlling the translation and degradation of messenger RNA. A single miRNA can impact more than one gene and a single messenger RNA can be regulated by more than one miRNA. There is emerging evidence that dietary factors affect miRNAs. For example, there is evidence of curcumin from cumin, green tea catechins, and retinoic acid, all affecting particular miRNAs in cells in culture. It is possible that these effects in an organism could alter biological processes significant in carcinogenesis including apoptosis, proliferation, and cell growth [66].

E Apoptosis

Programmed cell death or apoptosis is an important function in the maintenance of the integrity of tissues. Dietary factors may also affect apoptosis and may interact with genes that control it. For example, there is evidence that vitamin D can influence genes controlling apoptosis [67]. Other dietary factors may also play a role. In one study, overweight or obese postmenopausal women were placed on a low-fat, high-fiber diet, and an exercise program. A comparison was made of the growth-promoting properties of serum from the women taken before and after the intervention. The properties were evaluated in three different estrogen receptor-positive breast cancer cell lines. Among other changes, there was an increase in apoptosis for several different cell lines when the postintervention serum was used as the growth medium [68]. Other dietary factors that may also affect the expression of genes important in apoptosis include organosulfur compounds from foods from the allium family, including garlic; polyphenols from green tea, chocolate, and chili peppers; and isothiocyanates from cruciferous vegetables [69].

VI FUTURE DIRECTIONS

Understanding of the role of genes in cancer and particularly the role of the interactions of diet with genes in this

disease process is a rapidly expanding field of inquiry. Most of the available evidence remains somewhat preliminary, based on cell culture and animal studies or on a small number of epidemiologic studies. Our understanding of gene−diet interactions and how to study them is advancing rapidly, with tremendous potential implications for our understanding of the role of dietary factors in cancer etiology. Clearly, as the field progresses, extremely large studies will be needed to allow for the examination of multiple levels of interaction to fully understand the relevant etiological pathways.

In the future, genotype needs to be examined in metabolic studies to determine the short-term effects on intermediate outcome measures in healthy individuals. A great deal remains to be understood about the relation between genotype and phenotype for the genes that appear to be important in cancer risk. Furthermore, we need to understand the exposures—both dietary and from other sources—that affect gene expression in the most important etiological pathways. More work must be performed to identify the relevant genes that make the most difference, possibly those that are control points for metabolic pathways or for other pathways of significance. It will also be important to identify variants that are sufficiently common in the population to have an impact. We are moving toward the examination of the role of diet in cancer etiology, examining effects within groups defined by genetic makeup. Such studies may allow us to identify relationships that are important among particular groups of the population but that are not evident when the whole population is studied together.

There is increasing evidence that exposures in early life may be important in the carcinogenic process for some cancers. For example, there is evidence of associations of decreased risk of adult breast cancer with higher consumption of dietary fiber, vegetable protein, and vegetable fat during adolescence [70]. Some genetic factors may be more important in those early years such that studies examining adult diet do not provide the whole picture of the interaction of a nutrient with a genetic factor in cancer risk. Research needs to be done regarding such interactions.

There is also accumulating evidence that diet may affect prognosis following a cancer diagnosis. There is considerable evidence, for example, that weight gain after breast cancer diagnosis is associated with poorer survival [71]. The factors affecting this association are not well understood. It is not known if there are different kinds of weight gain which affect prognosis differently. In addition, it is not known if genetic factors interact with the added weight and impact mortality. In addition to weight gain, it could be that other nutritional factors affect cancer recurrence or progression and that the effects vary depending on the individual's genetics as well as the genetic mutations in the tumor.

There is little doubt that environmental factors are very important in causing cancer. Genetic factors also contribute to the processes determining who will get a cancer and who will not for most cancers. Important among the likely environmental factors are dietary factors. With increased understanding of the interactions of genetic and nutritional factors, it may eventually become possible to identify individuals with higher or lower requirements for particular nutrients or to identify individuals with greater sensitivity to agents such as alcohol. Furthermore, the elucidation of genetic factors in relation to diet will help us to truly understand the natural history of cancer and how best to prevent it.

I INTRODUCTION

Carcinomas of the breast, endometrium, and ovary are hormone-related cancers that have biologic similarities. Among U.S. women, breast cancer is far more common than endometrial or ovarian cancers. In 2011, roughly 230,480 women were diagnosed with breast cancer, thus comprising approximately 30% of the incident cancers among females [1]. In contrast, cancers of the endometrium (uterine corpus) and ovary comprised approximately 6% and 3% of female cancers, respectively. Because of differences in treatment efficacy and usual stage at diagnosis, the mortality estimates for these cancers vary considerably. Breast cancer will be the cause of death for approximately 39,520 women during 2011 (approximately 15% of cancer-related deaths among U.S. females), whereas endometrial and ovarian cancers account for approximately 3% and 6% of cancer-related mortality among women, respectively [1].

Breast cancer occurs infrequently in men, although the incidence is rising. In 2011, an estimated 2140 men were diagnosed with breast cancer, and 450 men will die of this disease [1], accounting for more than 1% of all malignancies and cancer deaths in men. Men tend to have a less favorable breast cancer outcome compared to women, largely due to advanced stage at diagnosis. More than 40% of male breast cancer patients present with stage III or IV disease [2].

Estrogens likely play an important role in breast, endometrial, and ovarian cancers [3]. Normal cell proliferation and differentiation in these tissues is highly responsive to estrogens and the other gonadal hormones. In addition to the ovarian steroids, other growth factors and mitogens influenced by nutritional factors and dietary patterns also appear to play an important role in the initiation and promotion of breast cancer. Insulin and insulin-like growth factor 1 (IGF-1) are currently under active investigation, as well as the interactions of these factors with adiposity and weight gain [4].

Diet and/or nutritional status is presumed to play a major role in the risk and progression of these hormone-related cancers, either through influence on the hormonal milieu or gene expression or via direct effects. Compared to the amount of research on breast cancer, far fewer studies have examined the relationship between nutritional factors and risk and/or progression of endometrial and ovarian cancers. This chapter reviews and summarizes evidence on the relationships between nutritional factors and breast, endometrial, and ovarian cancers. Recent clinical and epidemiological studies are emphasized, with the goal of identifying clinically useful strategies for prevention and patient management.

II BREAST CANCER

A Nutritional Factors and Primary Breast Cancer Risk

1 Height, Weight, and Body Fat Distribution

During the past four decades, numerous studies have evaluated the association between height and breast cancer risk, including a meta-analysis by the World Cancer Research Fund (WCRF)/American Institute for Cancer Research (AICR) confirming a strong association for both pre- and postmenopausal disease [5]. Furthermore, height

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00034-5

has also been associated with increased mammographic density, which is considered a strong risk factor for breast cancer [6]. It is hypothesized that the observed associations between height and breast cancer are due to factors that promote growth rather than height. Height attainment during puberty and selected periods during childhood has also been investigated in relation to breast cancer risk [7,8]. Other studies have concentrated on birth size as a proxy for in utero exposure. A meta-analysis (17 cohort and 15 case−control) found a statistically significant increased risk of breast cancer among women who weighed 4.0 kg or more at birth (relative risk, RR = 1.12; 95% confidence interval (CI), 1.00−1.25) compared to women with birth weights between 3.0 and 3.5 kg [9]. Birth length and head circumference obtained from birth record data were also found to be positively associated with breast cancer risk [9]. Other skeletal indices, such as increased elbow breadth (a frame size marker), femur and trunk length, and bone density, have also been associated with increased risk [10−12].

A clear discrepancy exists between adiposity and its apparent effect on risk for pre- versus postmenopausal disease. Leanness is an acknowledged risk factor for premenopausal breast cancer, whereas obesity serves as a strong risk factor for postmenopausal disease [5]. A meta-analysis of cohort studies reported a 15% decreased risk of premenopausal breast cancer and an 8% increased risk of postmenopausal breast cancer per 5 kg/m^2 difference in body mass index (BMI) [13]. These risks are modified by (1) relative chronicity within the broad categories of pre- versus postmenopause (i.e., younger obese postmenopausal women may be at greatest risk [14]), (2) hormone-replacement therapy use (which may mask associations between obesity and postmenopausal disease) [14,15], and (3) genetic variation [16,17]. Studies also indicate that obesity is a strong risk factor only for estrogen receptor (ER) and progesterone receptor (PR) positive breast cancer [18,19]. The relationship between obesity and breast cancer risk in men is similar to the relationship observed in postmenopausal breast cancer in women [20,21].

There are several hypothesized mechanisms by which overweight and obesity confer risk for male and postmenopausal female breast cancer [22]. A classic hypothesis involves the increased peripheral aromatization of androgens within the adipose tissue, thus yielding increased levels of circulating estrogens. Studies show that obese women have significantly higher circulating levels of total testosterone, estrone, and estradiol, as well as higher free levels of these hormones [23,24], thus providing support for this premise.

Obesity also results in increased circulating levels of insulin and IGFs, which stimulate intracellular signaling pathways and enhance proliferation of cancer cells [25]. For premenopausal breast cancer, in which increased skeletal structure is associated with risk, the IGF-1 pathway has also been implicated as a potentially viable mechanism [26]. Studies are ongoing to determine the role of leptin, adiponectin, interleukin-6, tumor necrosis factor, and other potential mediating factors that may have an impact on carcinogenesis via inflammation [27].

Diabetes has been associated with risk of many cancers, including postmenopausal breast cancer, although the exact mechanisms are unclear [28]. In a prospective analysis of 12,792 cancer-free participants in the Atherosclerosis Risk in Communities study, nondiabetic women with elevated glycated hemoglobin levels (hazard ratio, HR = 1.24; 95% CI, 1.07−1.44) and diabetic women (HR = 1.30; 95% CI, 1.06−1.60) were at increased risk of breast cancer compared to nondiabetic women with normal glycated hemoglobin levels [29]. Similarly, in the Women's Health Initiative (WHI) Observational Study, fasting insulin levels were found to be positively associated with breast cancer risk (HR = 1.46; 95% CI, 1.00−2.13 for highest vs lowest quartile of insulin level; p-trend = 0.02) [30]. The observation that cancer incidence is lower among individuals with diabetes taking metformin [31], which suppresses hepatic gluconeogenesis and increases insulin sensitivity in peripheral tissues, has led to a number of clinical trials of metformin as a breast cancer chemopreventive agent that are currently underway [25].

Because body weight fluctuates throughout life, it is conceivable that risk may be modified by body weight status at differing ages. Birth weight greater than 4000 g was associated with a small but statistically significant increased risk of breast cancer compared to birth weights between 2500 and 2599 g (odds ratio, OR = 1.24; 95% CI, 1.04−1.48) [32]. Other studies that have explored obesity during childhood suggest that it may be protective [33,34], with one study suggesting that this relationship is particularly significant among females with a positive family history of breast cancer [35]. An analysis from the Nurses' Health Study (NHS) II [36] suggests that an increased BMI at age 18 years may be the strongest protective factor for premenopausal disease. A possible explanation for this unanticipated finding is that obese teenage girls have significantly fewer ovulatory cycles and therefore lower circulating levels of both estrogen and progesterone [37]. Weight gain and increased body weight in adulthood have consistently been found to be associated with increased risk for postmenopausal cancer [38−40], although risk may be altered by use of hormone therapy and ethnicity [41,42]. Data from the European Prospective Investigation into Cancer (EPIC) study indicate an 8% increase in risk for each 5-kg gain among nonhormone therapy users [41], which may be largely explained by the fact that as women age, their circulating levels of estrogen become more influenced by estrogens produced by adipose tissue than those produced by the

ovary [22]. Weight gain during adulthood is also more likely to be deposited in an android versus gynoid pattern and hence may promote insulin resistance and the increased production of insulin and IGFs [43]. A meta-analysis (three cohort and eight case−control studies) found that adult weight gain was associated with statistically significant increased risk of both ER^+/PR^+ and ER^-/PR^- breast cancers, although the risk was higher for ER^+/PR^+ breast cancers (summarized risk estimate, RE = 2.03; 95% CI, 1.62−2.45) than ER^-/PR^- tumors (RE = 1.34; 95% CI, 1.06−1.63) [44].

In contrast, studies that have investigated weight loss have found a protective effect [45]. Parker and Folsom [46] found a risk reduction for postmenopausal breast cancer of approximately 19% among women who intentionally lost 20 pounds or more during adulthood. Among women carrying the BRCA1 mutation, weight loss of 10 pounds or more between the ages of 18 and 30 years was associated with a risk reduction of approximately 50% [47].

Studies consistently show that abdominal obesity (primarily assessed via waist:hip ratio) is associated with increased risk of postmenopausal breast cancer; however, a 2007 meta-analysis by the WCRF/AICR found that these associations disappear when analyses are controlled for BMI [13]. Associations between central obesity and increased risk may still exist for select populations, such as Asians [48].

2 Dietary Composition

In ecologic studies, a fivefold difference in breast cancer mortality rates has been observed across countries, and dietary patterns may be one of the environmental exposures that differ across these countries [49]. Also, risk for breast cancer increases on relocation from low-risk countries to high-risk countries, concurrent with the adoption of the dietary and lifestyle patterns of the new locale [50].

The possible link between dietary fat intake and breast cancer risk has received the most attention. However, fat intake, total energy consumption, and adiposity are inextricably linked; therefore, demonstrating an independent effect of total dietary fat per se is a challenge [51]. A meta-analysis of data from five cohort studies showed no statistically significant association between dietary fat and breast cancer risk (RR = 1.06; 95% CI, 0.99−1.14) [13].

Various feeding studies and small diet intervention trials have examined the effect of dietary fat reduction on serum estrogen levels. Low-fat diets were associated with an average 13% reduction in serum estradiol concentrations in a meta-analysis of several small feeding studies [52]. However, significant weight loss occurred in most studies in which serum estradiol was significantly reduced, and dietary fiber was also concurrently increased in 8 of the 13 studies included in the analysis. Thus, an energy deficit, weight loss, or increased fiber intake are just as likely as fat to promote a reduction in hormone levels.

In the WHI randomized controlled dietary modification trial, the impact of a low-fat diet (<20% of energy intake) was tested in comparison to a usual case−control group as a potential means of reducing risk of breast cancer in 48,835 postmenopausal women during an 8-year follow-up period [53]. Adherence was an issue in both study arms, with those in the intervention arm having higher fat intakes than planned, and those in the control arm reporting reductions in intake such that the difference in fat intake between the two study arms was not as great as anticipated (i.e., a difference of only 10.7% in year 1 and 8.1% in year 2). Results indicate a nonsignificant impact on risk (HR = 0.91; 95% CI, 0.83−1.01). Similarly, the Canadian Diet and Breast Cancer Prevention Trial, a multicenter randomized controlled study that tested whether a low-fat (15% of energy), high-carbohydrate diet intervention could reduce the incidence of breast cancer among women with extensive mammographic density, found that a sustained reduction in dietary fat intake did not reduce breast cancer risk, even though the intervention group was able to decrease dietary fat intake from 30% to 20% of total energy intake and maintained a dietary fat intake that was 9 or 10% lower than that of the comparison group throughout the study [54].

The effect of dietary carbohydrates on breast cancer risk has also been evaluated. A meta-analysis of eight cohort studies found no association between glycemic index (GI) (RR = 1.06; 95% CI, 0.98−1.15 for highest vs lowest subgroup) or glycemic load (GL) (RR = 0.99; 95% CI, 0.94−1.06 for highest vs lowest subgroup) and breast cancer risk [55]. A second systematic review and meta-analysis published the same year also found no statistically significant associations between GI or GL and breast cancer risk among pre- or postmenopausal women [56]. Despite the significant limitations of GI and GL determinations in general [57], these findings suggest that weight management may be more effective in decreasing breast cancer risk than modifying dietary carbohydrate intake.

Dietary fiber has been hypothesized to exert a protective effect against breast cancer by binding estrogen in the enterohepatic circulation and hindering reabsorption [58]. However, studies that have examined the relationship between fiber intake and risk for breast cancer have generally not found a significant protective effect [13].

Several studies have examined the association between vegetable and fruit intake and breast cancer risk. A meta-analysis (21 case−control and 5 cohort studies) found that high (vs low) consumption of vegetables exhibited a significant protective effect (RR = 0.75; 95% CI, 0.66−0.85), whereas fruit consumption was not associated with breast cancer risk [59]. A subsequent pooled analysis

including 7377 incident breast cancer cases from 8 prospective cohort studies found a small and only marginally significant protective effect of total fruit and vegetable intake (RR = 0.93; 95% CI, 0.86−1.00 for highest vs lowest quintiles) [60]. Although the median period of follow-up was only 5.3 years, the relationship between vegetable and fruit intake and breast cancer risk also was not significant in the EPIC study [61].

Studies in which tissue concentrations of carotenoids (a marker of vegetable and fruit intake) have been quantified and analyzed suggest a protective effect of higher concentrations of these compounds. In a report from the New York University Women's Health Study [62], α- and β-carotene, lutein, and β-cryptoxanthin levels were inversely associated with breast cancer risk. Similarly, an analysis from the WHI using repeated measures of serum carotenoids, retinol, and tocopherols at years 1, 3, and 6 of the study also found that breast cancer risk was inversely associated with serum α- and β-carotene levels but positively associated with γ-tocopherol levels [63]. In a pooled analysis of 18 prospective cohort studies, α- and β-carotene and lutein/zeaxanthin intakes were inversely associated with risk of ER^- breast cancers but not ER^+ breast cancers [64].

Cell culture studies indicate that retinoids and carotenoids affect cellular differentiation and also inhibit mammary cell growth [65]. Antioxidants, such as vitamin C, may reduce the risk for breast cancer by protecting against DNA damage and other free radical−induced cellular changes associated with neoplasia. Vegetables of the *Brassica* genus, such as broccoli, may favorably alter estrogen metabolism via the induction of cytochrome P450 enzymes [66].

Countries that consume greater amounts of soy and soy products, mainly Asian countries, have historically exhibited the lowest breast cancer mortality rates, compared with the United States and most European countries [67]. Thus, the role of soy and soy isoflavones in breast cancer prevention has been investigated in numerous laboratory and epidemiological studies, but the findings remain inconclusive [13]. Soy is a rich source of phytoestrogens; however, they can act as both estrogen agonists and antagonists [68]. The inconsistent findings between Asian and non-Hispanic white study populations suggest that lifelong or early life soy intake may be necessary in order to observe the breast cancer protective effects [69].

Alcohol intake has been consistently and positively associated with breast cancer risk in epidemiological studies. Pooled analysis of data from six cohort studies indicates that alcohol exhibits a dose−response relationship with risk for breast cancer, at least up to 60 g/day (RR = 1.41; 95% CI, 1.18−1.69, for 30−60 g/day vs no alcohol) [70]. Another meta-analysis confirmed this finding of an increased risk for breast cancer overall (RR = 1.10; 95% CI, 1.06−1.14, per 10 g alcohol/day), and when stratified by premenopausal (RR = 1.09; 95% CI, 1.01−1.17) and postmenopausal (RR = 1.08; 95% CI, 1.05−1.11) breast cancer [13]. The proposed biologic mechanism is that alcohol intake promotes increased serum estrogen levels, which then increase breast cancer risk. Studies of other beverages, such as coffee and tea, have found no association with breast cancer risk [13,71,72].

Although an association between folate intake per se and breast cancer risk has not been observed consistently in epidemiological studies, results from several cohort studies suggest that dietary folate intake may influence breast cancer risk through an interaction with alcohol [73−75]. Alcohol is known to interfere with folate metabolism [76]. A meta-analysis of two prospective cohort studies and two case−control studies found that high dietary folate intake (compared to low folate intake) was protective against breast cancer among women who had moderate to high alcohol intake (summary estimate = 0.51; 95% CI, 0.41−0.63) but not among women who reported low or no alcohol intake [75].

Vitamin D is known to have antiproliferative activity in a variety of cell types [77] and thus may decrease cancer risk. Prospective cohort studies consistently report decreased risks of breast cancer with increased vitamin D intake despite the relatively low intake of dietary vitamin D of the populations studied [78]. However, results vary across studies depending on the menopausal status of the participants and tumor characteristics. The NHS [79] observed decreasing incidence of breast cancer with increased intake of dietary or supplemental vitamin D, but only among premenopausal women (RR = 0.72; 95% CI, 0.55−0.94). A report based on the Women's Health Study also found reduced risk of breast cancer with total vitamin D at levels beginning above 230 IU among pre- but not postmenopausal women [80]. Results were stronger for premenopausal women with ER^+/PR^+ or more advanced stage tumors. In the Cancer Prevention Study (CPS) II Nutrition Cohort of postmenopausal women [81], a weak inverse association was observed between dietary vitamin D and breast cancer (RR = 0.87; 95% CI, 0.75−1.00, comparing >300 IU to ≤100 IU/day). However, the vitamin D associations were somewhat stronger for women diagnosed with ER^+ tumors. Among postmenopausal women participating in the Iowa Women's Health Study (IWHS) [82], those consuming ≥800 IU of vitamin D from diet and supplements had an 11% reduced risk of breast cancer. Findings were stronger for women with ER^- or in situ tumors.

Because diet is a complex, multidimensional, chronic exposure [83], there has been interest in evaluating dietary patterns and adherence scores for dietary

recommendations as measures of overall diet quality. In an analysis of the NHS data, compliance with the Dietary Approaches to Stop Hypertension (DASH) diet was inversely related to risk of ER^- breast cancers, but no association was observed for risk of ER^+ tumors [84]. Similarly, a dietary pattern high in fruits and salads was associated with a reduced risk of breast cancer, especially ER^- and PR^- breast cancers, among participants in the Melbourne Collaborative Cohort Study [85]. Among Chinese women participating in the Shanghai Breast Cancer Study, a Western diet pattern ("meat–sweet" pattern: shrimp, chicken, beef, pork, candy, and desserts) was associated with an increased risk of breast cancer in postmenopausal women, especially with ER^+ tumors [86].

To date, only one small case–control study has explored the association between intake of selected foods and male breast cancer [87]. No statistically significant associations were reported; however, study design issues (e.g., small sample size, use of death index to identify cases, and use of next-of-kin interviews to assess dietary intake among cases) limit the ability to draw conclusions from this study, and further research is needed.

B Nutritional Factors and Breast Cancer Recurrence, Progression, and Survival

Breast cancer mortality has been declining in recent years—a trend that has been attributed to earlier diagnosis and improvements in treatment [1]. A majority of all breast cancers are now diagnosed at a localized stage, with 98% 5-year relative survival rates [1]. As a result, there are increasing numbers of women in the population who are breast cancer survivors and at risk for breast cancer recurrence. Women who have been diagnosed with breast cancer have higher rates of mortality from other causes, such as cardiovascular disease and diabetes—comorbid factors in which diet and nutritional status play an important role [88].

1 Obesity and Overweight

Weight is the nutritional factor associated most consistently with mortality. Although several studies suggest that overweight and obesity may be linked to increased recurrence or to progressive disease [89–92], findings are somewhat mixed with regard to these outcomes [93–95]. However, because overweight is associated with several other chronic diseases, data are fairly consistent regarding overall survival, for which normal-weight women demonstrate a significant advantage [96]. Findings by Pierce and colleagues [97] suggest that physical activity may be more important than weight in conferring a survival advantage; however, further study is needed. Compared to those who are overweight, normal-weight women experience significantly fewer surgical complications [98,99], less lymphedema [100,101], and fewer thromboembolic events while on hormonal therapy [102]. Studies exploring body fat distribution in relation to survival or comorbid conditions have yielded mixed findings [96,103–105].

Weight gain after the diagnosis of breast cancer is a common occurrence and may be undesirable for several reasons. First, weight gain may negatively affect quality of life [106]. Second, weight gain may predispose women to other chronic conditions, such as hypertension, cardiovascular disease, diabetes, and impaired mobility [107]. Finally, weight gain may adversely affect disease-free survival. Kroenke and colleagues [108] found that breast cancer survivors who increased their BMI by 0.5–2 units had an RR of recurrence of 1.40 (95% CI, 1.02–1.92), and those who gained more than 2.0 BMI units had an RR of 1.53 (95% CI, 1.54–2.34); both groups also experienced significantly higher all-cause mortality. In contrast, Caan and colleagues [93] found no evidence of increased mortality with weight gain in a cohort of 3215 early-stage breast cancer patients. More study is needed in this area, especially to determine the impact of weight-loss interventions on survival and other short- and long-term outcomes.

Reports of mean weight gain during chemotherapy vary considerably but typically range from 1 to 5 kg [109]. Some have reported that as many as 20% of women gain 5 kg or more [110]. Weight gain is most prevalent among premenopausal patients receiving adjuvant chemotherapy and may vary by treatment regimen, with anthracycline agents associated with greater gains [109,111,112]. Several groups have conducted weight-loss interventions among women with breast cancer, with success rates differing by type and duration of intervention. Differential effects were found for individual diet counseling by a dietitian, with one study showing significantly favorable effects on body weight status [113] and the other showing no effect [114]. Djuric and colleagues [115] found that counseling by a dietitian was most effective if combined with a structured group weight-loss program that included exercise. Behavioral interventions that utilize a comprehensive approach to energy balance by including both diet and exercise components may be more effective than interventions relying on either component alone. Goodwin et al. [116] found that exercise was the strongest predictor of weight loss among early-stage breast cancer patients receiving a diet and exercise intervention during the time of treatment and extended throughout the year following diagnosis. Exercise (especially strength training exercise) may be of particular importance for cancer survivors because it is considered the cornerstone of treatment for sarcopenic obesity (gain

of adipose tissue at the expense of lean body mass), a documented side effect of both chemotherapy and hormonal therapy [111].

2 Dietary Composition

Observational studies of the relationship between fat intake and survival after a breast cancer diagnosis have reported inconsistent findings, with some studies reporting inverse associations between survival and dietary fat intake at diagnosis [117–119], whereas others [120–122] have found no association.

Protective effects of vegetables and fruits and the micronutrients provided by these foods (e.g., vitamin C and carotenoids) have been observed in several of these cohort studies, with findings somewhat more consistent than those for dietary fat, although the strength of the association is modest. Several studies reported significant inverse associations between fruit and vegetable intake and risk of death [117,118], two found that risk of dying was nonsignificantly decreased in association with frequent vegetable consumption [123,124], and one found a significant inverse association in women with node-negative disease, who comprised 62% of that cohort (but not in the total group, which included women at all stages of invasive breast cancer) [121]. In the studies that found an inverse relationship with survival and intakes of vegetables, fruit, and related nutrients (β-carotene and vitamin C), the magnitude of the protective effect was a 20–90% reduction in risk for death. In a cohort study involving 1511 women previously diagnosed and treated for breast cancer, women in the highest quartile of plasma total carotenoid concentration had an estimated 43% reduction in risk for a new breast cancer event (recurrence or new primary) compared to women in the lowest quintile [125]. In the same cohort, breast cancer survivors who reported consuming five or more daily servings of vegetables and fruit and exercised at least at a moderate level for 30 minutes nearly every day had a 50% reduction in risk associated with these healthy lifestyles [97]. An overall dietary pattern characterized by higher intakes of vegetables, fruit, whole grains, and low-fat dairy products was not related to all-cause or breast cancer mortality but was related to a significantly lower risk of mortality from other causes during a 20-year follow-up period in another cohort of 2619 women [126].

Although alcohol intake has been identified as a risk factor for primary breast cancer, the effect on breast cancer recurrence or survival is unclear, with studies reporting increased [127–130] or decreased [97,119,131,132] risk of death, as well as no association [121,133,134]. The Collaborative Women's Longevity Study ($N = 4441$) found a statistically significant trend toward lower risk of death with higher alcohol consumption (p-trend = 0.01) but no association with breast cancer–specific survival [119]. In contrast, the Life after Cancer Epidemiology (LACE) study ($N = 1897$) found that consuming three or more alcoholic drinks per week was associated with increased risk of breast cancer recurrence, especially among postmenopausal and overweight/obese women [130]. One study ($N = 472$ with a history of early-stage breast cancer) found that beer intake was directly related to risk for recurrence (but not survival), and wine and hard liquor intake were unrelated to risk for either outcome [127].

Two multicenter randomized controlled intervention trials have tested whether diet modification can influence the risk for recurrence and overall survival following the diagnosis of early-stage breast cancer. In the Women's Intervention Nutrition Study (WINS), which involved 2437 postmenopausal women randomized within 12 months of primary surgery, the primary dietary goal was a reduction in dietary fat intake (<15% energy from fat) [135]. Women in the intervention arm in WINS reported a reduction in fat intake (33.3 g/day vs 51.3 g/day in the control group), which was associated with an average 6-pound weight loss. The HR of relapse events in the intervention group compared with the control group was 0.76 (95% CI, 0.60–0.98) after approximately 5 years of follow-up [136]. Results of secondary analysis suggest a greater protective effect among women with hormone receptor-negative breast cancers compared with women whose cancers were hormone receptor-positive. In the Women's Healthy Eating and Living (WHEL) study, the target population consisted of 3088 pre- and postmenopausal women who had been diagnosed with breast cancer within the preceding 4 years and who had completed initial therapies. The primary emphasis of the WHEL study diet intervention was on increased vegetable and fruit intake, with daily dietary goals of five vegetable servings, 16 ounces of vegetable juice or equivalent, three fruit servings, 15–20% energy intake from fat, and 30 g dietary fiber. Feasibility study reports and trial data from this study indicated excellent adherence [137,138], and increased intake of vegetables and fruit in the intensive intervention group was validated by plasma carotenoid concentrations [139]. Overall findings indicated no significant differences in risks for recurrence or survival in the intensive intervention versus the control group during a mean 7.3-year follow-up [140]. Notably, the study participants reported at baseline an average daily consumption of 7.3 servings of vegetables and fruit, which actually meets or exceeds current recommendations, so the WHEL study results mainly indicate that an extraordinarily high intake of vegetables and fruit does not appear to further reduce risk for recurrence.

The effect of dietary patterns on breast cancer recurrence and survival has been evaluated in several large

cancer survivor cohorts. Higher adherence to a prudent diet pattern (high intakes of fruits, vegetables, whole grains, and poultry) was not associated with recurrence but was associated with significantly improved survival among participants in the LACE study [141]. In the NHS, higher intake of a prudent dietary pattern and lower intake of a Western dietary pattern was associated with lower risk of death unrelated to breast cancer [126]. These findings are not surprising given the known beneficial effects of the prudent diet pattern in the prevention of chronic disease, especially cardiovascular disease, for which breast cancer survivors are at increased risk [88].

III ENDOMETRIAL CANCER

Cancer of the endometrium (uterine corpus) is the most common invasive gynecologic cancer [142]. Similar to breast and ovarian cancers, endometrial cancer is most common after menopause and is more prevalent among non-Hispanic whites, although blacks have higher rates of mortality. Relative 5-year survival rates are 96%, 68%, and 17% for cancers diagnosed at local, regional, and distant stages, respectively [1].

Endometrial cancers are stratified histologically by responsiveness to estrogen, with the estrogen-dependent type I being most common (90% of cases) and the nonestrogen-dependent type II being less common (10% of cases) [143,144]. Type I tumors are typically low grade and have a good prognosis, whereas type II tumors are more aggressive, tend to be diagnosed in later stages, and are associated with poor prognosis [145]. High cumulative exposure to estrogen is the major risk factor for type I endometrial cancer, whereas exposure to progesterone is protective [1]. Hence, early menarche, late menopause, and nulliparity are risk factors for type I endometrial cancer, just as they are for breast and ovarian cancers [1]. However, unlike these cancers, risk factors for type I endometrial cancer also include tamoxifen use and factors associated with unopposed estrogens [146]. Risk factors for type II endometrial cancer are less well understood because most of the epidemiology study cohorts currently have too few cases to evaluate these tumors separately.

A Nutritional Factors and Endometrial Cancer Risk

1 Height, Weight, and Body Fat Distribution

The link between obesity and endometrial cancer risk is well-established. A 2007 meta-analysis of 23 cohort studies conducted by the WCRF/AICR found that endometrial cancer risk increased by 52% per 5 kg/m^2 increase in BMI [13]. Research suggests that biomarkers associated with adiposity, such as higher circulating levels of leptin and IGFs and lower levels of adiponectin, may also be independently linked with increased endometrial cancer risk [142]. Data from two large cohort studies (EPIC and the AARP Diet and Health Study) suggest that waist circumferences greater than 88 cm and increased waist-to-hip ratio are associated with increased endometrial cancer risk, independent of body weight status [147,148]. Both studies also found that compared to women who are weight stable, those who gain at least 20 kg during adulthood have an increased risk that is roughly two or three times higher [147,148]. Given the strong associations between endometrial cancer and obesity and other markers of adiposity, it is somewhat surprising that intentional weight loss of $\geq$20 kg was found to be associated with a nonsignificant risk reduction of only 4% among women participating in the IWHS [46]. Although a BMI $\geq$30 was associated with increased risk of type II endometrial cancer (RR = 2.87; 95% CI, 1.59−5.16) in the CPS-II Nutrition Cohort [149], women with the nonestrogen-dependent type II endometrial cancer are less likely to be obese (OR = 0.45; 95% CI, 0.29−0.70) compared to women with type I endometrial cancer [150].

In the Netherlands Cohort Study (NCS; 226 cases within a cohort of 62,573), an increased risk of endometrial cancer (RR = 2.57; 95% CI, 1.32−4.99) was found for women who were at least 175 cm in height compared to those measuring 160 cm or less [151]. This association is similar and of the same magnitude as found between height and breast cancer, and it points to the potential role of growth factors and early nutritional status in the etiology of this disease.

2 Dietary Composition

Although obesity is clearly a strong risk factor for endometrial cancer, there is significantly less research available related to specific dietary components and risk of endometrial cancer. Several large cohort studies [152−154] found no associations with carbohydrate intake and either an absence or very weak association between GI or GL and endometrial cancer risk. However, these factors may increase risk for obese versus normal-weight women [152,153] or for nondiabetic women versus women with diabetes [154]. Similarly, two cohort studies found no association between dietary fat intake and endometrial cancer risk [155,156]. A meta-analysis conducted by a workgroup of the International Agency for Research on Cancer (World Health Organization) found no association between fruit and vegetable consumption and endometrial cancer risk (OR = 1.03; 95% CI, 0.9−1.17) [157]. Similarly, few associations for individual plant food constituents, such as lycopene or fiber, have been reported; however, a study by Horn-Ross and colleagues [158] suggests that isoflavones may be protective (RR = 0.59; 95% CI, 0.37−0.93 for highest vs lowest quartiles). In this study, obesity was

found to interact with phytoestrogen intake, suggesting a sevenfold increase in risk among obese women with the lowest intakes of phytoestrogens.

Whereas Jain et al. [155] found no association between folic acid intake and endometrial cancer risk in general among the Canadian National Breast Screening Study cohort, a report from the IWHS cohort [159] stratified endometrial cancer cases by histologic stage. No associations were observed for type I endometrial cancer; however, for type II endometrial cancer, dietary or supplemental folate, methionine, and vitamins B_2, B_6, and B_{12} were associated with increased risk [159].

Finally, although reports from case–control studies suggest a protective benefit of various foods, such as coffee [160] and fatty fish [161], or nutrients, such as vitamin C [162], calcium [160,163], and vitamin D [163], further research is necessary to corroborate these findings. Cohort studies have reported no association with endometrial cancer risk for vitamin A [155], serum retinol [164], vitamin C [155], or vitamin E [155].

Alcohol use has been shown to be associated with elevated circulating estrogen levels and reduced progesterone; however, a meta-analysis found no association between alcohol intake and endometrial cancer risk among cohort or case–control studies [13]. Small sample sizes, limited range of alcohol intake, and confounding factors (e.g., possible interaction with exogenous estrogens or factors such as age) may have limited the ability to detect associations [165,166]. In addition, no study to date has evaluated potential differences in risk by the two histologic subtypes. Thus, more research is needed to clarify the role of alcohol in the etiology of this cancer.

B Nutritional Factors and Endometrial Cancer Recurrence, Progression, and Survival

Comparatively little is known regarding nutritional issues after the diagnosis of endometrial cancer, although research on this topic is increasing. Data regarding the effect of obesity on recurrence, disease-free survival, and overall survival are conflicting. For example, obesity was found to be unassociated with recurrence in one study [167] but inversely associated with recurrence in two others [168,169]. Furthermore, in two studies conducted in the United States, obesity was associated with increased overall mortality [167,170], whereas in a smaller study conducted in Poland, it was found to be protective [171]. Thus, the only consensus regarding obesity and survivorship of endometrial cancer relates to comorbid conditions, in which obesity was found to be associated with the increased prevalence of diabetes, hypertension, and pulmonary disease [168,170] and was also found to be consistently associated with poorer quality of life [172–174].

To date, no studies have investigated other nutritional issues beyond weight status in endometrial cancer survivors. However, the Survivors of Uterine Cancer Empowered by Exercise and Health Diet (SUCCEED) intervention study is currently underway and will evaluate the effect of a dietary intervention (2 cups fruit, 2.5 cups vegetables, three servings of low-fat dairy foods, and three servings whole grain foods per day) on quality of life and treatment outcomes [175].

IV OVARIAN CANCER

Ovarian cancer is the most lethal of the gynecologic cancers, being the fifth most common cause of cancer death among U.S. women despite having a relatively low incidence rate [1]. Women diagnosed with ovarian cancer typically present at an advanced stage of the disease because the early stages are asymptomatic. The established risk factors for ovarian cancer are older age (>50 years), low parity, never having used oral contraceptives, and having a family history of breast or ovarian cancer [176,177]. Although the etiology is still a focus of intense investigation, one theory is that increased ovulation or hormonal stimulation of ovarian epithelial cells plays a role in the development of ovarian cancer [178,179]. Prevention strategies for women at high risk include oral contraceptive use, tubal ligation, and prophylactic oophorectomy [180]. Relatively few studies on the relationship between nutritional factors and risk for ovarian cancer have been reported, and there is a dearth of research that examines how these factors may influence progression or survival after the diagnosis of ovarian cancer.

A Nutritional Factors and Ovarian Cancer Risk

1 Height, Weight, and Body Fat Distribution

Anthropometric factors have been studied extensively with regard to ovarian cancer risk but remain inconclusive. A pooled analysis of 12 prospective cohort studies (2036 ovarian cancer cases among 531,583 women) found that adult attained height of ≥170 cm (67 in.) was associated with an increased risk of ovarian cancer (RR = 1.38; 95% CI, 1.16–1.65) [181]. BMI was not associated with ovarian cancer risk in postmenopausal women, but premenopausal women with a BMI ≥30 kg/m^2 were at increased risk of ovarian cancer (RR = 1.72; 95% CI, 1.02–2.89) compared to women with a BMI between 18.5 and 23 kg/m^2 [181]. In contrast, the EPIC study (611 ovarian cancer cases among 226,798 women) found that BMI ≥30 kg/m^2 was associated with increased risk for all women combined

(HR = 1.3; 95% CI, 1.05−1.68); however, when stratified by menopausal status, the observed increase in risk was only statistically significant among postmenopausal women [182]. Attained adult height, weight change during adulthood, and measures of body fat distribution (waist circumference, waist:hip ratio, or hip circumference) were not found to be associated with risk of ovarian cancer [182]. The findings suggest that the relationship between obesity and ovarian cancer risk may differ from the relationships observed between obesity and risk for either postmenopausal breast cancer or endometrial cancer.

2 Dietary Composition

Similar to the evidence for breast cancer, international comparisons of the incidence of ovarian cancer indicate a strong inverse relationship with per capita dietary fat consumption [183], and the hypothesis that dietary fat intake is associated with increased circulating estrogen concentrations (discussed previously) has stimulated several observational studies of the relationship between dietary fat intake and risk for ovarian cancer. However, a pooled analysis of 12 prospective cohort studies (2132 cases of epithelial ovarian cancer among 523,217 women) found no association between total fat, mono- or polyunsaturated fats, *trans*-unsaturated fat, cholesterol, animal or vegetable fat, or egg intake, and ovarian cancer risk [184]. Similarly, data from the NCS (340 ovarian cancer cases among 62,573 postmenopausal women) found no association between total fat, saturated fat, mono- or polyunsaturated fat, or fat source (animal, plant, dairy, meat, or fish), and ovarian cancer risk; however, *trans*-unsaturated fatty acid intake was found to be associated with increased risk of ovarian cancer (RR = 1.51; 95% CI, 1.04−2.20 for highest vs lowest quintile) [185].

Dietary carbohydrate has been less well studied with respect to ovarian cancer risk. A report from the Canadian National Breast Screening Study (264 ovarian cancer cases among 49,613 women) found that GL was positively associated with ovarian cancer risk (HR = 1.72; 95% CI, 1.13−2.62); however, dietary carbohydrate, sugar intake, and GI were not associated with ovarian cancer risk [186]. A study from the Swedish Women's Lifestyle and Health Cohort (163 ovarian cancer cases among 47,140 women) found no association between dietary fiber and ovarian cancer risk [187].

A report from the NHS found that women who consumed at least 2.5 servings of vegetables and fruit as adolescents had a 46% reduction in risk for ovarian cancer [188], although adult vegetable and fruit intake was unrelated to ovarian cancer risk. A subsequent evaluation of specific dietary flavonoids in this same cohort found no association for total flavonoid intake; however, a statistically significant decrease in ovarian cancer risk was observed for the highest versus lowest quintile of kaempferol intake (RR = 0.75; 95% CI, 0.49−0.91) [189]. These findings were consistent with inverse associations with ovarian cancer observed for nonherbal tea and broccoli (the primary contributors of kaempferol intake in the cohort). Among participants in the California Teachers Study (280 ovarian cancer cases among 97,275 women), women consuming >3 mg/day of soy isoflavones had a significantly decreased risk of ovarian cancer (RR = 0.56; 95% CI, 0.33−0.96) compared to those consuming <1 mg total isoflavones/day [190]. Dietary carotenoids were not associated with ovarian cancer risk in two large prospective cohort studies [188,191].

One small prospective cohort study (35 cases and 67 controls) examined associations between serum concentrations of micronutrients and risk for ovarian cancer [192] using sera collected prior to diagnosis. It found no relationship between risk and serum retinol, β-carotene, lycopene, and lipid-adjusted α-tocopherol and γ-tocopherol concentrations, but serum selenium concentration was inversely associated with risk of ovarian cancer among cases diagnosed 4 or more years after blood collections (p-trend = 0.02) [192]. In contrast to these findings linking serum selenium to risk, another prospective study did not find any association between toenail selenium level and ovarian cancer risk [193]. A large pooled analysis of data from seven prospective cohort studies found no association between serum 25-hydroxyvitamin D levels and ovarian cancer risk [194].

A meta-analysis of two cohort and seven case−control studies found no association between tea intake and ovarian cancer risk (RR = 0.84; 95% CI, 0.66−1.07) [195]; however, important limitations, such as lack of detailed assessment of type of tea consumed, frequency of tea consumption, and duration of tea intake, limit the ability to make a firm conclusion [196]. A meta-analysis of five cohort studies found a statistically significant decrease in risk of ovarian cancer with higher versus lower tea consumption (RR = 0.71; 95% CI, 0.55−0.93), and it also found a marginally increased risk for higher versus lower coffee consumption (RR = 1.32; 95% CI, 0.99−1.77) among four cohort studies [197]. A subsequent report from the IWHS (266 ovarian cancer cases among 29,060 postmenopausal women) supported those findings by observing that women who consumed five or more cups per day of caffeinated coffee were at increased risk of ovarian cancer compared to nonusers (HR = 1.81; 95% CI, 1.10−2.95) [198].

B Nutritional Factors and Ovarian Cancer Recurrence, Progression, and Survival

Only a small number of studies have examined nutritional factors related to survival after an ovarian cancer

diagnosis. A meta-analysis found no association between obesity at the time of diagnosis and subsequent prognosis [199]. Similarly, a retrospective review of 792 advanced ovarian cancer patients participating in a randomized clinical trial of cisplatin/paclitaxel versus carboplatin/paclitaxel found no association between prechemotherapy BMI and survival; however, weight gain during treatment was associated with a statistically significant improvement in overall survival (68.2 vs 48.0 months for >5% increase vs >5% decrease, $p = 0.01$) [200]. A study of 198 advanced ovarian cancer patients undergoing primary surgery and adjuvant chemotherapy found that weight change in 6 months after completion of treatment had no effect on progression-free or overall survival [201].

In a prospective cohort study of 609 women with invasive epithelial ovarian cancer, a statistically significant survival advantage was observed for women who reported higher vegetable intake in general (HR = 0.75; 95% CI, 0.57−0.99) and cruciferous vegetables in particular (HR = 0.75; 95% CI, 0.57−0.98) [202]. A longitudinal study of 341 women with ovarian cancer found that women who consumed diets higher in total fruits at baseline had a significantly decreased likelihood of death during the follow-up period (HR = 0.61; 95% CI, 0.38−0.98), whereas women who consumed diets high in meats (HR = 2.28; 95% CI, 1.34−3.89) or milk (HR = 2.15; 95% CI, 1.2−3.84) were at increased likelihood of death [203].

V SUMMARY AND CONCLUSION

Although a considerable amount of research has been devoted to understanding the effects of nutritional factors on the risk for breast cancer, much remains to be learned. More research on the relationships between these factors and risk for endometrial and ovarian cancers is sorely needed, and to date, few studies have examined how these factors may influence overall survival in women who have been diagnosed with hormone-related cancers. At this time, guidelines from the American Cancer Society [204,205] and the WCRF/AICR [13] form the basis of current dietary recommendations, with both groups emphasizing the importance of achieving and maintaining a healthy weight; eating a diet rich in vegetables, fruits, and whole grains; and limiting meat and alcohol consumption.

The risk for morbidity and mortality from causes other than breast, endometrial, and ovarian cancer should also be considered in dietary recommendations for women and men at risk for cancer and for cancer survivors, especially those diagnosed with early-stage cancers [107]. For example, although evidence to support a link between fat intake and breast cancer risk and prognosis is inconsistent, limiting saturated fat intake is an established strategy to reduce risk for cardiovascular disease. Similarly, eating a diet with adequate dietary fiber has been associated with decreased risk of coronary heart disease and may contribute to overall health [206], irrespective of a specific link between fiber and hormone-related cancers. Diets that emphasize vegetables, fruit, whole grains, low-fat dairy foods, and lean meats and poultry have been associated with decreased risk of all-cause mortality [207].

Chapter 35

Nutrition and Prostate Cancer

Song-Yi Park and Laurence N. Kolonel
University of Hawaii, Honolulu, HI, United States

I INTRODUCTION

In this chapter, we discuss the epidemiologic evidence for associations of dietary factors with prostate cancer risk and the potential for diet to play a role in prostate cancer prevention. We begin with some general background on the disease and its diagnosis, followed by a description of incidence patterns and risk factors for prostate cancer other than diet. The relationship of nutrition to prostate cancer includes foods and dietary constituents that have been associated with increased risk of the disease, as well as those that have been associated with decreased risk. Some findings from animal and in vitro studies, as well as possible mechanisms for the carcinogenic effects, are presented in support of the epidemiologic findings. We conclude with a few comments on genetic studies of prostate cancer.

A Normal Prostate Anatomy and Function

The normal adult prostate gland is a walnut-sized organ that surrounds the urethra and the neck of the bladder. The gland is composed of three distinct zones: peripheral, central, and transition. The peripheral zone is composed of left and right lobes that can be palpated during digital rectal examination. The transition zone is the region that enlarges in benign prostatic hyperplasia (BPH), which is common in older men [1]. The prostate gland is a male secondary sex organ that secretes one fluid component of semen. Prostatic fluid is essential for male fertility.

Normal growth and activity of the prostate gland is under the control of androgenic hormones. Circulating testosterone, primarily produced in the testes, diffuses into the prostate, where it is irreversibly converted by the enzyme steroid 5α-reductase type II to dihydrotestosterone (DHT), a metabolically more active form of the hormone. DHT binds to the androgen receptor, and this complex then translocates to the cell nucleus, where it activates selected genes [2].

B Pathology and Diagnosis of Prostate Cancer

Almost all prostate tumors are classified as adenocarcinomas (i.e., they arise from the glandular epithelial cells) and occur most commonly in the peripheral zone of the gland. Accordingly, they can often be felt by the physician during digital rectal examination. A unique feature of human prostate cancer is the high frequency of small, latent tumors in older men. A clear relationship between these occult tumors and those that become clinically apparent has not been established, although it is commonly assumed that the latter evolve from the former as a consequence of additional genetic mutations.

Generally, prostate cancer in its early stages is asymptomatic. Enlargement of the prostate gland (BPH) commonly begins after the age of 45 years, ultimately leading to urinary tract symptoms (difficult and frequent urination). Many cases of prostate cancer are diagnosed as a result of digital rectal examination performed when a man visits his physician for relief of these symptoms. (Suspicious lesions on examination may be confirmed by transrectal ultrasound, followed by a biopsy of the gland.) Since its approval by the U.S. Food and Drug Administration in 1986, the prostate-specific antigen (PSA) test has come into widespread use. This test is not specific for prostate cancer, however, and gives an abnormal result if there is any increased tissue growth in the gland, such as occurs in BPH. Because of its sensitivity, the PSA test can lead to the diagnosis of very early, microscopic tumors. Although such lesions might never progress to clinical disease, surgical removal carries a risk of major complications (notably incontinence and/or

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00035-7

impotence), leading to controversy regarding the proper use of PSA as a screening test for early prostate cancer [3,4]. Indeed, in its review in 2011, the U.S. Preventive Services Task Force (USPSTF) concluded that use of PSA as a screening modality has not resulted in any decrease in prostate cancer mortality and that, to the contrary, its use has led to more harm than good [5]. Thus, in 2012, the USPSTF published a statement recommending against PSA-based screening for prostate cancer [6]. Based on national surveys in the United States, the proportion of men aged 50 years and older reporting PSA screening in the past year was 36.9% in 2005, 40.6% in 2008, and 37.8% in 2010, but after the 2012 USPSTF recommendation, declined to 30.8% in 2013 [7].

II DESCRIPTIVE EPIDEMIOLOGY OF PROSTATE CANCER

A Incidence and Mortality Trends

Prostate cancer is a common cancer among men in many Western countries, and it is the leading male incident cancer in the United States, where 180,890 new cases are projected for the year 2016 [8–10]. Incidence trends in the United States show a rather slow increase over most of the past 50 years, with a striking increase between 1989 and 1992, attributable in large measure to the widespread adoption of the PSA screening test, which first became available in the early 1980s [11,12]. After 1992, the incidence declined until approximately 1995, remained stable until 2000, and then declined again after 2000 [13]. Specifically, from 2003 to 2012, rates decreased by 4% per year [10]. Moreover, mortality from prostate cancer is low relative to its incidence. This is because prostate cancer is generally well controlled by treatment (surgery, radiation, and androgen ablation) and occurs at relatively late ages so that even men who are not cured of the disease often die from other causes. Interestingly, a parallel increase in prostate cancer mortality did not occur during the period 1989–92, presumably because most of the additional cases diagnosed would not otherwise have led to fatal outcomes. Prostate cancer mortality rates decreased by 3.5% per year from 2003 to 2012, attributed to improvements in early detection and treatment [10].

B Risk Factors for Prostate Cancer

Few risk factors for prostate cancer have been established. Proposed factors are listed in Table 35.1. Age is the strongest risk factor. Prostate cancer incidence increases more sharply with age than does any other cancer; about 60% of cases in the United States are diagnosed in men 65 years of age or older [9,14].

Race/ethnicity is a second risk factor for prostate cancer. In the United States, the lowest incidence rates (cases/100,000) are seen among Cambodian (29.1) and Laotian (32.3) men, followed by Vietnamese (45.3) and Korean (48.3) men, relatively recent immigrant groups from Asia; the rates are higher among Chinese (66.4), Japanese (99.9), Filipino (101.8), American Indian/Alaska Native (90.5), and Native Hawaiian (101.8) men [10,15]. Caucasian men have very high rates, but by far the highest incidence of this cancer is among African American men [10].

The incidence of prostate cancer varies widely in populations throughout the world (Fig. 35.1). Indeed, of all common malignancies, this cancer shows the widest variation between low- and high-risk countries or populations. High rates are seen in developed, especially Western, countries, including the United States, Canada, areas of Europe, and Australasia. Low rates tend to occur in Asia [9]. The highest reported rates in the world are among African Americans, whereas the lowest reported rates are among men in China and India. Interestingly, Chinese men in more developed areas of Asia (Singapore and Hong Kong) and Chinese men in the United States have much higher incidence rates than men in mainland China (see cross-hatched populations in Fig. 35.1). Furthermore, immigrants from Japan to Brazil and the United States have higher rates than do men in Japan [16]. The incidence of prostate cancer in Japan increased approximately tenfold between 1975 and 2011 [17],

TABLE 35.1 Proposed Risk Factors for Prostate Cancer

Category	Characteristic or Exposure
Demographic	Age, ethnicity, geography
Genetic	Family history (father, brothers), rare high-penetrance genes, more common susceptibility genes
Occupational	Cadmium products, rubber industry, agricultural chemicals
Hormonal	Androgens (testosterone, DHT)
Lifestyle	Sexually transmitted agents, smoking, alcohol, vasectomy, physical activity, diet

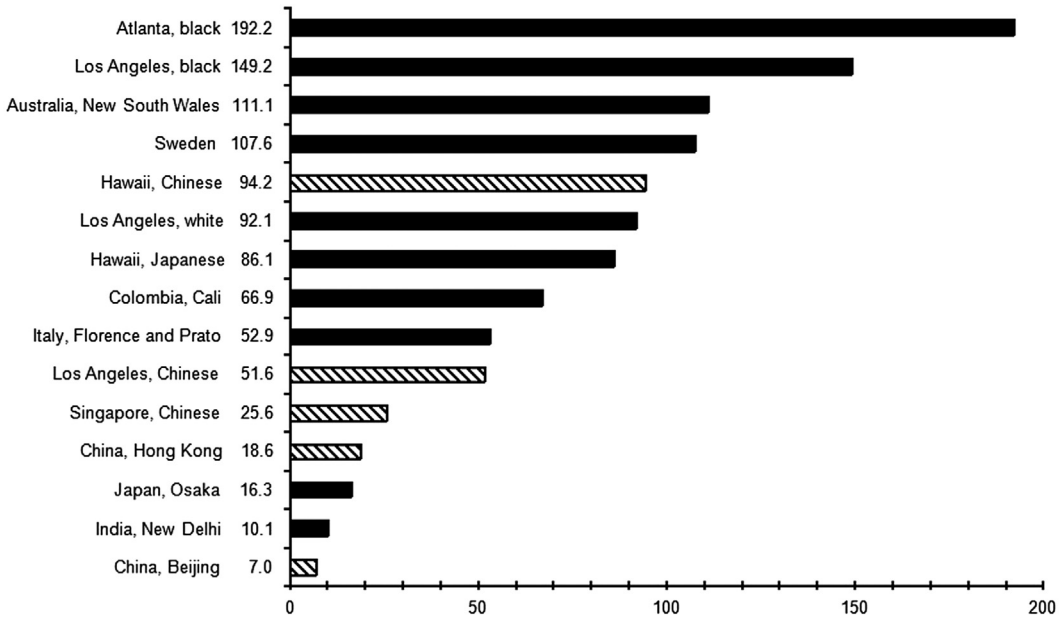

FIGURE 35.1 Prostate cancer incidence per 100,000 in selected populations, 2003–07 (rates age-adjusted to the World Standard Population).

although the actual incidence in Japan is still low compared with that of Japanese men in the United States.

Men with a first-degree male relative who has had prostate cancer are at a two- or threefold increased risk; whether this reflects an inherited predisposition for the disease or a shared environmental exposure has not been confirmed [18,19]. The search for high-penetrance, rare genes for prostate cancer has identified some candidates, although none has yet been confirmed; of even greater interest is the potential role in this disease of low-penetrance, highly prevalent susceptibility genes (discussed later).

Apart from these few established risk factors, the etiology of prostate cancer is unknown. Among the several potential causal agents, apart from diet, that have been proposed are: (1) occupational exposures (rubber industry; manufacture of products containing cadmium, such as paints and batteries; and use of agriculture chemicals), (2) sexually transmitted agents (e.g., gonorrhea, syphilis, and human papillomavirus), (3) smoking, (4) alcohol use, (5) vasectomy, and (6) physical activity [20–30]. However, the evidence is not convincing for any of these exposures.

Although it is suspected that most exogenous factors affecting prostate cancer risk exert their influence by altering endogenous androgen levels [31,32], epidemiologic studies have not clearly established the role of androgens in prostate cancer [33]. Some studies have supported a positive relationship of circulating androgen levels to prostate cancer risk [34–38], but others have not [39–45]. In a pooled analysis of 18 prospective studies, prediagnostic circulating levels of individual androgens were not associated with prostate cancer, whereas the sex hormone-binding globulin level was modestly inversely associated with prostate cancer [46]. Further studies are warranted to understand the role of androgens in tissue, androgen action in the prostate, and the relationship between tissue and blood levels of androgen in the causation of prostate cancer [47].

The most promising area of research, apart from genetics, on the etiology of prostate cancer pertains to diet.

III STUDIES OF DIET IN RELATION TO PROSTATE CANCER

A Origin of the Diet–Prostate Cancer Hypothesis

The descriptive patterns of prostate cancer, especially data showing very different rates of the disease in the same ethnic/racial group living in different geographic settings, as well as changing rates in migrants and their offspring [16], prompted investigators to seek environmental risk factors for this cancer. Diet became an important focus of this research because (1) geographic variations in food and nutrient intakes are known to be large [48] and (2) components of the diet can influence the levels of circulating androgens [49], which, as noted previously, are thought to play a role in prostate cancer risk. Many different dietary factors, including both foods and particular constituents of foods, have been proposed and studied. Some of these appear to increase risk,

TABLE 35.2 Proposed Dietary Risk Factors for Prostate Cancer

Increasing Risk	Decreasing Risk
Foods and Beverages	
Processed and red meat	Vegetables
Milk and dairy products	Fruits
Alcohol	Legumes
	Tea and coffee
Food Components	
Total energy	Vitamin D
Fat	Vitamin E
Calcium	Carotenoids
Zinc	Selenium
Cadmium	Isoflavonoids
Diet-Associated Factors	
Obesity, weight, and height	Physical activity

whereas others are possibly protective. These factors are listed in Table 35.2, and the supporting evidence is discussed in the following sections.

B Dietary Factors that Increase Risk

In 2007, the World Cancer Research Fund (WCRF) and the American Institute for Cancer Research (AICR) produced an authoritative report, titled *Food, Nutrition, Physical Activity, and the Prevention of Cancer: A Global Perspective*, containing recommendations to reduce the risk of cancer [48]. These recommendations were based on comprehensive systematic literature reviews (SLRs) that were evaluated by an international panel of experts, including one of the present authors (LNK) [50]. Following the 2007 report, the WCRF International established the Continuous Update Project (CUP) to update the SLRs on an ongoing basis and to reconsider the recommendations as needed. The CUP published its latest report on the updated evidence for prostate cancer in 2014, covering all major databases up to April 2013, and available online at http://www.wcrf.org/int/research-we-fund/continuous-update-project-findings-reports/prostate-cancer [51]. The 2014 SLR considered randomized controlled trials and cohort studies, but not case−control studies (which had been included in prior reviews) due to their methodological limitations, especially the potential for recall bias which is a major concern for epidemiologic studies of diet and nutrition [52]. Thus, in the following sections, we use the conclusions of the 2014 CUP report as a starting point, and then review the findings from more recent studies, if any, to make an overall assessment of the literature. In its judgments, the CUP expert panel graded the evidence in five categories, as in the 2007 report: convincing, probable, limited—suggestive, limited—no conclusion, and substantial effect on risk unlikely. Recommendations were based only on the highest two categories.

1 Dietary Patterns

Foods are generally consumed in many combinations, and together they may have a greater impact on cancer risk than as individual components [53]. Thus, a dietary pattern approach that reflects the complexity of dietary intake may provide a more comprehensive assessment of the role of diet in cancer causation. Although many different health outcomes have been associated with dietary patterns [54,55], only a few such studies have examined prostate cancer specifically [56−61]. Some patterns, such as those high in consumption of meat, dairy fat, and refined grains (like the so-called Western Diet), were hypothesized to increase prostate cancer risk; while others, such as those high in consumption of fruits, vegetables, and whole grains (like the so-called Mediterranean Diet), were hypothesized to lower prostate cancer risk. The CUP SLR found three studies that examined presumptive high-risk dietary patterns in relation to prostate cancer risk [52]. Two of these examined dietary patterns that had been developed from their respective study datasets (i.e., a posteriori dietary patterns). One of these, a cohort study of U.S. health professionals [56], identified a Western dietary pattern, and the other, an Australian cohort study [57], identified a meat and potatoes pattern but neither pattern was associated with prostate cancer risk. The third study, based on a cohort in Japan [59], found no association of a dietary preference for fatty foods with prostate cancer mortality. Though the evidence at present is limited, the data do not suggest that presumptive high-risk dietary patterns are associated with prostate cancer incidence or mortality.

2 Foods and Beverages

a Processed and Red Meat

The CUP report reached no conclusions regarding processed meat and prostate cancer due to inconsistent evidence [51]. The SLR found 11 cohort studies that met the criteria for a dose-response meta-analysis, as defined in the SLR [52]. The meta-analysis showed no significant association; the summary relative risk estimate per 50 g/day was 1.03 (95% confidence interval, CI: 0.98, 1.08).

A great many epidemiologic studies have investigated associations between red meat consumption and prostate cancer risk. However, the findings are not consistent. The CUP dose−response meta-analysis of eight cohort studies produced nonsignificant summary risk estimates and led to no conclusion by the expert panel. More recent meta-analyses also did not support an association with processed or red meat intake [62,63].

Explaining a possible association with meat intake is not straightforward. Early reports of positive findings were thought to reflect a high exposure to dietary fat, especially saturated fat, because meat and dairy products are the major contributors to fat intake in the Western diet. However, because the findings on dietary fat per se and prostate cancer are equivocal (discussed later), other explanations for an association with meat needed to be considered. There are several possibilities. First, in the American diet, meat is a major source of zinc, which is essential for testosterone synthesis and may have other effects in the prostate (discussed later). Second, diets high in meat and other animal products may be relatively deficient in certain anticarcinogenic constituents found primarily in plant foods. Third, red meat contains high levels of heme iron, which is a source for free radical formation and oxidative damage to tissues [64]. Fourth, nitrates added as preservatives to processed meat may contribute to *N*-nitroso compound production and exposures. These compounds are suspected mutagens and carcinogens [65]. Heme also promotes the formation of *N*-nitroso compounds. Finally, and most intriguing, many meats are cooked at high temperatures, such as by pan frying, grilling, or barbecuing. Cooking meats at high temperatures can result in the formation of heterocyclic amines (HAs), which are potent carcinogens in animals, including the rat prostate [66,67]. Furthermore, when meats are cooked on charcoal grills, rendered fat is pyrolized by the coals, leading to the deposition of polycyclic aromatic hydrocarbons (PAHs), which are also carcinogenic in animals, on the outer surface of the meat [68]. Although an accurate assessment of dietary intake of HAs and PAHs is difficult, two studies reported a positive association of prostate cancer with estimated intakes of very well-done meat and of a particular HA (PhIP) [69,70], especially for advanced tumors [70]. However, other studies that examined intake of well-done meat [71] or estimated HA and PAH intakes from cooked meat [72–76] in relation to risk of prostate cancer as well as a meta-analysis of five prospective studies [63] did not provide clear support for the hypothesis.

b Milk and Dairy Products

The CUP report concluded that there was limited evidence suggesting that dairy products are a cause of prostate cancer. In the SLR, 21 cohort studies were identified and 13 reported a positive association when comparing the highest versus the lowest categories of intake. The dose–response meta-analyses of 15 studies showed a 7% increased risk per 400 g of dairy products per day (the summary relative risk estimate = 1.07, 95% CI: 1.02, 1.12) (Fig. 35.2) [77]. With regard to milk specifically,

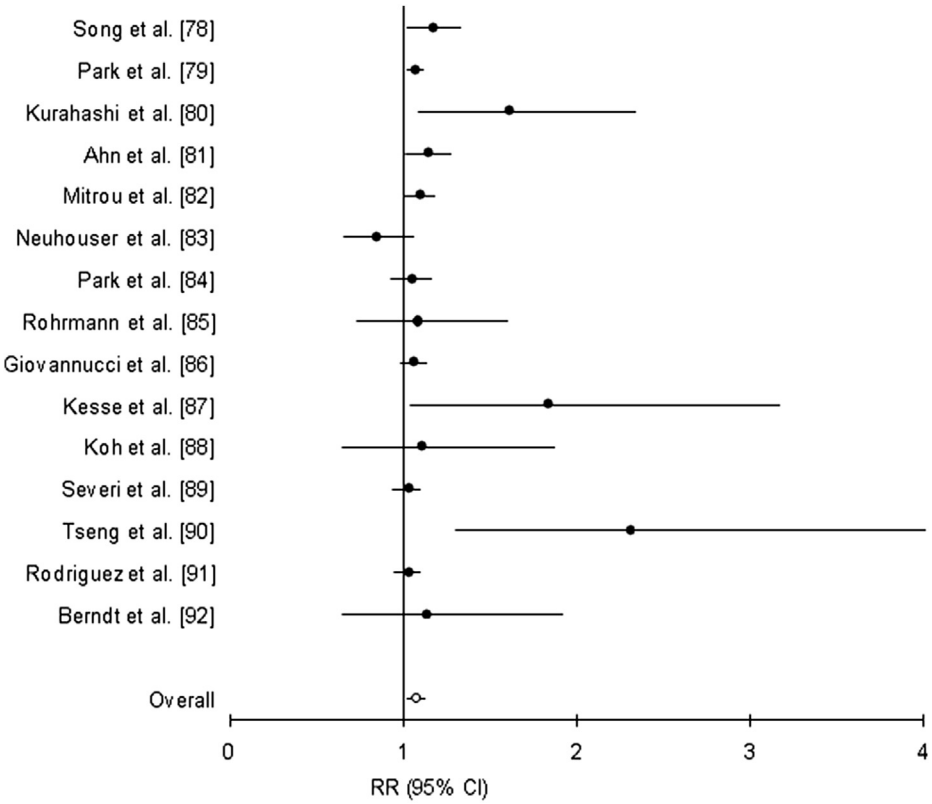

FIGURE 35.2 Dairy product intake and prostate cancer in cohort studies. *RR*, relative risk, per 400 g/day; error bars indicate 95% CIs. *Adopted, with permission of the American Society for Nutrition, from D. Aune, D.A. Navarro Rosenblatt, D.S. Chan, A.R. Vieira, R. Vieira, D.C. Greenwood, L.J. Vatten, T. Norat, Dairy products, calcium, and prostate cancer risk: a systematic review and meta-analysis of cohort studies, Am. J. Clin. Nutr. 101 (1) (2015) 87–117.*

the summary relative risk estimate per 200 g of milk intake per day was 1.03 (95% CI: 1.00, 1.06) for total prostate cancer based on 14 studies and 1.06 (95% CI: 1.00, 1.13) for nonadvanced prostate cancer based on four studies, suggesting a borderline significant association [77].

A possible explanation for the positive associations is an adverse effect on the prostate of the high fat, especially saturated fat, content of dairy products. Another prominent constituent of these foods is calcium, which has also been proposed as a risk factor for prostate cancer (discussed later). Finally, milk consumption may increase blood levels of insulin-like growth factor-I (IGF-I), which has been associated with increased prostate cancer risk in some studies [93].

c Alcoholic Beverages

The CUP meta-analyzed 25 cohort studies, which yielded a summary relative risk estimate of 1.01 (95% CI: 0.99, 1.02) for an increase of one alcoholic drink per day. The expert panel determined that the evidence was too limited for a firm conclusion as to whether alcohol consumption was associated with prostate cancer risk. Since the SLR, two cohort studies found no association between alcohol intake and prostate cancer risk [94,95].

Some general mechanisms by which alcohol might enhance carcinogenesis have been proposed, including the activation of environmental nitrosamines, production of carcinogenic metabolites (acetaldehyde), immune suppression, and secondary nutritional deficiencies [96–98].

3 Nutrients and Other Food Constituents

a Energy

The findings from studies that have examined total energy intake in relation to prostate cancer are very inconsistent. No conclusion was made about energy intake in the CUP report. The meta-analysis in the SLR of eight cohort studies showed no significant dose–response association. No study has reported the relationship between energy intake and prostate cancer since the SLR.

An experimental study in rodents (rats and mice) found that energy restriction reduced prostate tumor growth, possibly by inhibiting tumor angiogenesis [99].

b Fat

Dietary fat has been the most studied nutrient with regard to effects on prostate cancer risk. Detailed reviews on this topic have been published [100–103]. The SLR in the CUP report yielded no significant association for total or saturated fat consumption, either as grams or as percentage energy, in a meta-analysis of nine cohort studies. However, because the evidence was limited, the expert panel reached no conclusion about total and subtypes of dietary fat in relation to prostate cancer. A recent meta-analysis also did not support a dose–response association between total or saturated fat intake and prostate cancer risk [103].

Some epidemiologic studies examined dietary intakes of monounsaturated and polyunsaturated fat as well. The CUP SLR included seven cohort studies in the meta-analysis for monounsaturated fatty acids, with a summary relative risk estimate of 1.00 (95% CI: 0.99, 1.01) per 10 g/day. The meta-analyses for dietary polyunsaturated fatty acids were based on seven cohort studies and did not show any association.

Several studies have also examined specific fatty acids (including several omega-3 and omega-6 polyunsaturated fatty acids), based either on dietary intake data or on biochemical measurements in blood or adipose tissue [100,104]. A few studies suggested that long-chain omega-3 fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), were inversely associated with prostate cancer [105–108], although other studies did not reproduce this finding [109–113]. On the contrary, two nested case–control studies within cohorts reported an increased risk of prostate cancer with high blood concentration of long-chain omega-3 fatty acids [114,115]. Additional support for these inverse findings was provided by studies of fatty fish intake (a good source of long-chain polyunsaturated fatty acids) that also showed inverse associations with prostate cancer risk [116–119]. However, the CUP meta-analysis found no significant association for EPA and DHA, nor for fish consumption overall. The effect of α-linolenic acid (ALA) intake was examined in several studies, with some showing a positive association [106,109,120] and some no association [110–112,121]. A meta-analysis involving eight prospective studies that measured either ALA intake or blood/tissue concentrations supported the positive association with prostate cancer [122]. However, the CUP meta-analysis showed no significant association with ALA based on dietary intake from five cohort studies and biomarker from six cohort studies. Finally, two studies reported that prediagnostic blood concentrations of *trans*-fatty acids were associated with increased risk of prostate cancer [123,124], while another two studies found no association [125,126]. Overall, these reports are not very consistent, and no firm conclusion regarding the role of specific fatty acids on the risk of prostate cancer can be reached on the basis of current data.

Some animal experiments have tested the fat–prostate cancer hypothesis. For example, a high-fat diet increased prostate cancer incidence and shortened the latency period in Lobund–Wistar rats treated with exogenous testosterone to induce the tumors [127]. Conversely, prostate tumor growth rate was reduced by a fat-free diet in Dunning rats [128] or by lowering dietary fat intake in

athymic nude mice injected with LNCaP cells (a human prostate cancer cell line) [129,130]. With regard to specific types of fat, fish oils containing high levels of long-chain omega-3 fatty acids, such as EPA and DHA, generally suppressed prostate tumor growth in rodents, whereas omega-6 polyunsaturated fatty acids, such as linoleic and linolenic acids, promoted tumor growth [119,131,132]. However, because most animal studies have been conducted in rodents, whose prostate glands differ anatomically from that of the human, extrapolation of these findings to humans is particularly tenuous.

A number of plausible mechanisms by which dietary fat could increase cancer risk have been proposed. These include the formation of lipid radicals and hydroperoxides that can produce DNA damage, increased circulating androgen levels, decreased gap-junctional communication between cells, altered activity of signal transduction molecules, effects on eicosanoid metabolism, and decreased immune responsiveness [100].

c Calcium

As noted previously, a number of studies that have examined the relationship of dairy product consumption to prostate cancer risk found a positive association. Dairy products could be a marker of exposure to calcium, although this food group is also a major source of saturated or animal fat in the Western diet. The CUP report concluded that for diets high in calcium, the evidence is "limited-suggestive" for an increased risk of prostate cancer. In the SLR, a total of 16 studies were identified and 13 reported a positive association when comparing the highest versus the lowest categories of dietary calcium intake. A dose–response meta-analysis of 15 cohort studies yielded a summary relative risk estimate of 1.05 (95% CI: 1.02, 1.09) per 400 mg per day for total prostate cancer, 1.07 (95% CI: 1.03, 1.12) for nonadvanced, and 1.02 (95% CI: 0.93, 1.12) for advanced tumors [77]. Since that SLR, one cohort study reported a positive association between dietary calcium and prostate cancer risk, but only with long latency periods [133].

A mechanism for an adverse effect of calcium on prostate carcinogenesis has been proposed based on the observation that a high intake of calcium decreases the circulating levels of $1,25(OH)_2$ vitamin D, which may inhibit cell proliferation and promote differentiation in prostatic tissue [134,135]. The role of vitamin D in prostatic carcinogenesis is discussed later.

d Zinc and Cadmium

The trace elements zinc and cadmium are considered together because they act as antagonists in biological systems. Due to limited evidence, the CUP report categorized zinc in the diet or supplements as "limited-no conclusion."

The frequent association of prostate cancer risk with high intake of red meat (discussed previously) could also be explained by a higher intake of zinc, rather than animal fat, because meat, especially red meat, is an important source of zinc in the American diet (other sources are shellfish, whole grain cereals, nuts, and legumes) [136]. Reports based on zinc levels in blood or prostatic tissue of patients with cancer and controls have not been consistent [137–139], but such studies are unreliable because the levels of zinc measured after diagnosis in the cases may reflect physiologic changes in the prostate as a result of the cancer ("reverse causation"). One study measured prediagnostic toenail zinc in prostate cancer patients and in controls; no association was found [140].

As a major constituent of prostatic fluid [139,141,142], zinc is essential for normal prostate function. Zinc is also essential for normal testicular function, and high levels of zinc have been proposed to increase the production of testosterone, leading to enhanced tissue growth in the prostate. Blood levels of zinc have been positively correlated with testosterone and DHT levels in men [143,144]. Furthermore, in the rat prostate, zinc has been shown to increase 5α-reductase activity [145] and to potentiate androgen receptor binding [146]. Thus, one might speculate that higher intake of zinc could partially offset the normal decline in testosterone levels with age [147–149], thereby contributing to prostate cancer risk. However, an epidemiologic study that analyzed prediagnostic zinc levels in serum in relation to prostate cancer risk reported no clear association [150]. Thus, evidence to support a role of zinc in prostate cancer is still limited, and no firm conclusion can be reached.

Epidemiologic evidence for cadmium as a risk factor for prostate cancer is also limited [151]. The CUP SLR found only three cohort studies that assessed cadmium exposure in relation to prostate cancer risk, and no meta-analysis was conducted. A meta-analysis of one case–control and two cohort studies reported an increased risk with dietary cadmium intake [152]. Since that SLR and the meta-analysis, a Danish cohort study found no association between dietary cadmium and prostate cancer risk [153]. With so few studies and a lack of data from cohorts in particular, no firm conclusion can be reached regarding the association of cadmium exposure with prostate cancer risk.

Cadmium is a competitive inhibitor of zinc in enzyme systems and accumulates in the body throughout life because no mechanism exists for excreting it. Thus, the hypothesis that cadmium may be carcinogenic for the prostate has biologic plausibility. This hypothesis is further supported by studies showing that cadmium is carcinogenic in animals, and that the effect can be blocked by simultaneous injection of zinc [154,155].

4 Diet-Associated Risk Factors

a Obesity, Weight, and Height

Prostate cancer is sometimes considered a male counterpart to breast cancer in women, for which there is clear evidence of a positive association with obesity, especially in postmenopausal cases. However, evidence for a similar association of adult obesity with prostate cancer is much less clear. The CUP concluded that greater body fatness (marked by body mass index, waist circumference, and waist-to-hip ratio) is a "probable cause" of advanced prostate cancer [51]. Of 24 studies reporting on body mass index and advanced prostate cancer risk, 13 reported positive association when compared the highest versus the lowest categories. The dose−response meta-analyses in the SLR yielded a statistically significant risk for advanced, but not for total prostate cancer; summary estimates per 5 kg/m^2 were 1.08 (95% CI: 1.04, 1.12) for advanced prostate cancer based on 23 studies and 1.00 (95% CI: 0.97, 1.03) for total prostate cancer based on 39 studies. Since the CUP, a Danish cohort study reported an increased risk of advanced prostate cancer risk with body mass index [156], while a Swedish cohort study found no association [157]. In a report from a cohort consortium in Asia, body mass index was not associated with prostate cancer mortality [158], while a study in men with prostate cancer found that high body mass index at time of diagnosis was associated with increased overall and prostate cancer-specific mortality [159]. A meta-analysis of 17 cohort studies found that obesity measured by body mass index was a significant risk factor for aggressive prostate cancer and prostate cancer-specific mortality [160]. Some studies examined obesity in early adulthood (age 18−21) or at birth, but the meta-analyses of these studies in the CUP SLR showed no significant overall association. Since then, a cohort study reported an increased risk of prostate cancer with childhood body mass index and height [161,162]. In the CUP SLR, a meta-analysis of 14 cohort studies did not show a significant association of weight with total or advanced prostate cancer risk. However, waist circumference and waist-to-hip ratio were related to an increased risk of advanced cancer; the summary relative risk estimate was 1.12 (95% CI: 1.04, 1.21) per 10 cm and 1.15 (95% CI: 1.03, 1.28) per 0.1 units, respectively.

The CUP concluded that developmental factors leading to greater linear growth (marked by adult attained height) are a "probable cause" of prostate cancer. Of 42 studies identified in the CUP, 25 studies reported on total prostate cancer incidence and 22 reported a positive association, when comparing the highest versus lowest categories of adult attained height. In the SLR, the dose−response meta-analysis yielded a significant association between height and prostate cancer risk; summary risk estimates were 1.04 (95% CI: 1.03, 1.05) per 5 cm based on 34 cohort studies. When stratified by prostate cancer outcome, the meta-analysis showed statistically significant associations; the summary relative risk estimate per 5 cm was 1.03 (95% CI: 1.01, 1.05) for nonadvanced, 1.04 (95% CI: 1.02, 1.06) for advanced, and 1.04 (95% CI: 1.01, 1.06) for fatal prostate cancer. Recent cohort studies confirmed that tallness was associated with an elevated risk of total [156,163,164] and advanced prostate cancer [156], particularly fatal disease [165], although another cohort found no association [95].

The basis for an association between obesity and prostate cancer could involve endocrine factors because adult obesity in men has been associated with decreased circulating levels of testosterone and increased levels of estrogen [166,167]. However, this mechanism would suggest an inverse rather than a direct association between obesity and this cancer. Other possible mechanisms entail pathways that involve insulin, leptin, adipokines, IGF-I, and chronic inflammation [168]. For example, leptin is a hormone produced by adipocytes. Obese men have more and larger adipocytes, and they have been shown to have higher serum levels of leptin [169]. In in vitro studies, leptin promoted proliferation of androgen-independent prostate cancer [170].

5 Dietary Factors that Decrease Risk

a Dietary Patterns

Four cohort studies that examined presumptive risk-reducing dietary patterns in relation to prostate cancer risk were included in the CUP SLR. Two of these studies were based on predefined dietary patterns. A cohort study in the United States found a decreased risk of prostate cancer associated with a higher score on the Healthy Eating Index (HEI) and the alternate HEI, but only for cancers detected through PSA screening [171]. A cohort study in Korea, on the other hand, found that a dietary preference for vegetables rather than meat was not related to prostate cancer risk [58]. Two other cohort studies investigated data-derived (i.e., a posteriori) healthful eating patterns (generally characterized by high intakes of fruits, vegetables, and/or whole grains), and neither study found a significant association with prostate cancer risk [56,57]. Because the patterns investigated varied across studies, no meta-analysis was possible in the CUP SLR [52]. Since the CUP SLR, two additional cohorts have reported their findings. A cohort study in Sweden reported no association of prostate cancer incidence with a modified Mediterranean diet score, but an inverse association of prostate cancer incidence with a higher "low carbohydrate-high protein" score [60]. A cohort study of health professionals in the United States found no association between the traditional Mediterranean Diet and

advanced prostate cancer risk [61]. Thus, similar to the findings for presumptive high-risk dietary patterns, the data for presumptive low-risk dietary patterns do not suggest any association with prostate cancer incidence.

6 Foods and Beverages

a Vegetables

Intake of vegetables has been inversely associated with cancer risk at many sites. This has led to strong recommendations to consume significant quantities of these foods as part of a healthful diet. However, the evidence for a beneficial effect of vegetables on prostate cancer risk is not overwhelming. The CUP report placed vegetables in the "limited-no conclusion" category because of limited evidence. The meta-analyses for all vegetables in the SLR yielded a summary estimate of 0.99 (95% CI: 0.98, 1.00) per 100 g/day based on 13 cohort studies. When restricted to green leafy, yellow-orange, or cruciferous vegetables, summary estimates were not statistically significant. Since that SLR, reports on three prospective cohort studies also observed no relation [172–174]. Thus, even with the additional few studies since the CUP report, there is little evidence for an effect of vegetable consumption overall on prostate cancer risk. The findings for legumes, a vegetable subgroup, are considered separately (discussed later), and the findings for tomatoes are included in the later discussion of carotenoids.

Because vegetables contain numerous compounds that can act through a variety of mechanisms to inhibit carcinogenesis [175,176], an inverse association between vegetables and prostate cancer is plausible. Some of these mechanisms are discussed later with respect to specific food constituents.

b Fruits

The CUP report placed fruit consumption and prostate cancer risk in the "limited-no conclusion" category. The meta-analysis in the SLR yielded no significant association: the summary relative risk estimate was 1.00 (95% CI: 0.99, 1.01) per 100 g/day based on 16 cohort studies. Since that SLR, two cohort studies reported no association [172,173].

Fruits contain many of the same compounds with anticarcinogenic properties that are found in vegetables, such as various carotenoids and vitamin C [177]. Because most of the findings for this food group have been null, it does appear that fruit intake has no particular benefit with regard to the risk of prostate cancer.

c Legumes, Including Soy Products

Prostate cancer rates have traditionally been low in populations, such as those of Japan and China, in which the intake of soy products is relatively high. The CUP report concluded that the evidence was too limited to draw a firm conclusion regarding a role of legumes in increasing or decreasing the risk of prostate cancer. In the SLR, a dose–response meta-analysis was not conduced for legume and soy product intake due to the limited number of eligible cohort studies. Although previous meta-analyses supported an overall inverse association between soy foods consumption and prostate cancer risk [178–180], no recent studies have reported protective effects of soy foods against prostate cancer.

In the past, legumes were of interest in nutritional epidemiology primarily because of their important contribution to fiber intake. However, these foods also contain phytoestrogens, plant constituents that have mild estrogenic properties. Because estrogens are associated with lower risk of prostate cancer and are used in prostate cancer therapy, there is a good rationale for the hypothesis that phytoestrogen intake can protect against prostate cancer. Soybeans and many products made from soy, such as tofu, are rich in a class of phytoestrogens known as isoflavones (other classes of phytoestrogens include the coumestans and lignans). The main isoflavones found in soy include genistein, daidzein, and glycetein [181]. Several epidemiologic studies assessed the intake of dietary phytoestrogens, particularly isoflavones, and found inverse associations with prostate cancer risk [182–187]. Indeed, a meta-analysis suggested that higher phytoestrogen consumption (two cohort and nine case–control studies) and serum concentration (six case–control studies nested within cohorts and two population-based case–control studies) were related to a reduction in prostate cancer risk [188]. Furthermore, an analysis of urinary isoflavone excretion within a large cohort study showed inverse associations, suggesting that high intake of isoflavones may be protective against prostate cancer risk [189]. However, another nested case–control study did not confirm this result [190], and a subsequent large nested case–control study reported no association of prostate cancer with prediagnostic plasma genistein levels [191]. Thus, the evidence in support of a protective effect of legumes and phytoestrogens on prostate cancer risk remains limited and inconsistent.

The mechanism for a benefit of soy products on prostate carcinogenesis could entail the estrogenic effects of isoflavones, although other actions of these compounds, such as inhibition of protein tyrosine phosphorylation, induction of apoptosis, and suppression of angiogenesis, have also been proposed [192]. Laboratory data, based on human tissue as well as animal models, offer support for the hypothesis that soy products may protect against prostate cancer [193–196].

Although soy products and isoflavones are of particular interest, legumes contain other bioactive microconstituents, including saponins, protease inhibitors, inositol

hexaphosphate, γ-tocopherol, and phytosterols. Mechanisms by which each of these compounds can inhibit carcinogenesis have been proposed [192,193,197].

d Tea and Coffee

Due to limited evidence, the CUP report placed tea consumption in the "limited-no conclusion" category. The meta-analyses in the SLR found no support for an association based on five cohort studies. Since that SLR, a cohort study in the United States showed no relationship between daily tea consumption and prostate cancer risk [198], while a Netherlands cohort study found a decreased risk of advanced prostate cancer with black tea consumption [199]. A more recent meta-analysis, including seven prospective studies, did not show a protective effect of tea consumption on prostate cancer risk [200]. Thus, the evidence remains insufficient to draw firm conclusions regarding the effect of tea consumption on this cancer.

Tea contains polyphenols that are potentially anticarcinogenic because of their antioxidant properties, effects on signal transduction pathways, inhibition of cell proliferation, and other actions in the body [201,202].

The consumption of coffee has been examined in relation to prostate cancer risk, since it contains various components with potential anticancer properties. The CUP determined that the evidence for coffee and prostate cancer was "limited-no conclusion." The dose−response meta-analysis in the SLR showed a summary relative risk estimate of 0.99 (95% CI: 0.98, 1.01) per 1 cup/day for total prostate cancer incidence (based on eight cohort studies), and 0.97 (95% CI: 0.93, 1.00) for prostate cancer mortality (based on four studies). Since the CUP, two cohort studies observed no significant association [198,203], while another found a decreased risk [204]. Recently, several meta-analyses have been conducted to investigate the association between coffee and prostate cancer risk. Although one meta-analysis did not support [205], others suggest an inverse association between coffee consumption and prostate cancer [206−209], especially fatal tumors [207,210].

Potential mechanisms for anticancer effects of coffee phytochemicals include inhibition of oxidative stress and oxidative damage, regulation of DNA repair, phase II enzyme activity, apoptosis, inflammation, as well as having antiproliferative, antiangiogenetic, and antimetastatic effects [211].

7 Nutrients and Other Food Constituents

a Vitamin D

Evidence for a protective effect of vitamin D against prostate cancer is not convincing, and, though several studies examined this nutrient, the CUP report determined that the evidence was "limited-no conclusion" possible. However, because circulating vitamin D levels are substantially determined by the conversion of 7-dehydrocholesterol in the skin in response to solar UVB radiation, studies based on dietary vitamin D intake alone may be misleading [212,213].

Several cohort studies have examined the relationship of prediagnostic blood levels of 25-hydroxyvitamin D (25(OH)D), the most abundant circulating form of the vitamin, to subsequent development of prostate cancer. A dose−response meta-analysis in the CUP SLR showed no significant association: the summary risk estimate was 1.04 (95% CI: 1.00, 1.07) per 30 nmol/L based on 17 prospective studies. Since that SLR, a prospective study reported a decreased risk of prostate cancer with higher 25(OH)D concentration in blood [214]. On the contrary, a cohort study reported that lower levels of 25(OH)D in blood may reduce prostate cancer risk in older men [215]. Another study found that both low and high 25(OH)D concentrations were associated with increased risk of prostate cancer, and more strongly for high-grade disease [216]. A consortium of three European cohorts found that lower 25(OH)D concentrations were not significantly associated with increased incidence of prostate cancer [217]. Another consortium of six cohorts found no association between circulating 25(OH)D and fatal prostate cancer risk [218]. Thus, there is little epidemiologic data to support the hypothesis of a protective effect of vitamin D against prostate cancer, with some evidence even suggesting an adverse effect at high circulating levels of 25(OH)D.

The hormonal form of vitamin D, $1,25(OH)_2D$, reduces cell proliferation in the prostate (and other tissues) and enhances cell differentiation, both of which would be expected to lower the risk of cancer [134,219].

b Vitamin E

The CUP report concluded that evidence was too limited to draw a conclusion that vitamin E intake decreases or increases the risk of prostate cancer. In the CUP meta-analyses, the summary risk estimate was 1.01 (95% CI: 0.96, 1.06) per 10 mg/day for dietary vitamin E based on five cohort studies.

Several cohort studies have reported findings for vitamin E and prostate cancer based on prediagnostic blood levels. The CUP concluded that the evidence for an association between low plasma γ-tocopherol levels and increased prostate cancer risk was "limited-suggestive." Of 11 studies identified in the SLR, 8 reported an inverse association when comparing the highest versus the lowest γ-tocopherol concentration. A dose−response meta-analysis in the SLR yielded summary estimates of 0.99 (95% CI: 0.98, 1.00) per 1 mg/L of γ-tocopherol in blood based on nine cohort studies (Fig. 35.3) and of 0.97 (95% CI: 0.91, 1.04) per 1 mg/L of γ-tocopherol in blood based on seven cohort studies.

The CUP report concluded that the evidence for vitamin E supplements and prostate cancer risk was "limited-no conclusion": the summary relative risk was 1.00 (95% CI: 0.99, 1.01) per 100 IU/day for supplemental vitamin E based on seven cohort studies. Three clinical trials tested the efficacy of vitamin E in the prevention of prostate cancer. One trial reported that γ-tocopherol supplements protected against prostate cancer among male heavy smokers in Finland [228]. However, protection against prostate cancer was not a prespecified hypothesis in the trial. A later intervention trial of vitamins E (400 IU/alternate days) and C (500 mg/day) in 14,641 male physicians conducted in the United States provided no support for either an immediate or a long-term benefit of vitamin E supplements in the prevention of prostate cancer: relative risk was 0.97 (95% CI: 0.85, 1.09) during the intervention period [229] and 0.99 (95% CI: 0.89, 1.10) in the posttrial follow-up [230]. In another intervention trial of vitamin E (400 IU/day) and selenium (200 μg/day) among 35,533 healthy men, there was a statistically significant increase in risk (relative risk = 1.17; 95% CI: 1.004, 1.36) in the vitamin E group, suggesting that vitamin E supplementation actually increases the risk of prostate cancer among healthy men [231]. Thus, the weight of the existing epidemiological evidence on vitamin E intake, either dietary or through supplementation, does not support a protective effect against prostate cancer, though the data showing increased risk associated with low plasma levels of γ-tocopherol are suggestive. It is notable, however, that one intervention trial suggested that vitamin E supplementation may actually be harmful [231], especially among men with low selenium status [232].

Vitamin E inhibits prostate carcinogenesis in rats and mice [233,234] and the growth of human prostate cancer cells in nude mice [235–237]. Possible cancer prevention mechanisms include antioxidative and antiinflammatory activities, modulation of nuclear receptors, inhibition of cell growth, and induction of apoptosis [238].

c Carotenoids (β-Carotene and Lycopene)

The epidemiologic evidence related to β-carotene and prostate cancer is substantial and consistently null. Thus, the CUP report reached a firm conclusion that a substantial effect of β-carotene, either through food or supplements, on the risk of prostate cancer is unlikely. None of the 11 cohort studies identified in the SLR reported a statistically significant association when comparing the highest versus the lowest categories of dietary β-carotene. In the dose–response meta-analyses in the SLR, the summary risk estimate was 1.00 (95% CI: 0.99, 1.00) per 700 μg of dietary β-carotene per day based on 10 cohort studies. In addition, the SLR included three intervention trials of β-carotene supplements, none of which reported a significant effect on prostate cancer risk. The meta-analysis in the SLR also showed no significant association of β-carotene in prediagnostic blood with prostate cancer (summary risk estimate = 0.99; 95% CI: 0.95, 1.04) per 10 μg/100 mL based on nine prospective studies. Since that SLR, a Japanese cohort study found no association of β-carotene intake with prostate cancer [174].

A carotenoid of particular interest with regard to prostate cancer is lycopene, found primarily in tomatoes and tomato products (other food sources include watermelon, grapefruit, and guava). The CUP report placed lycopene

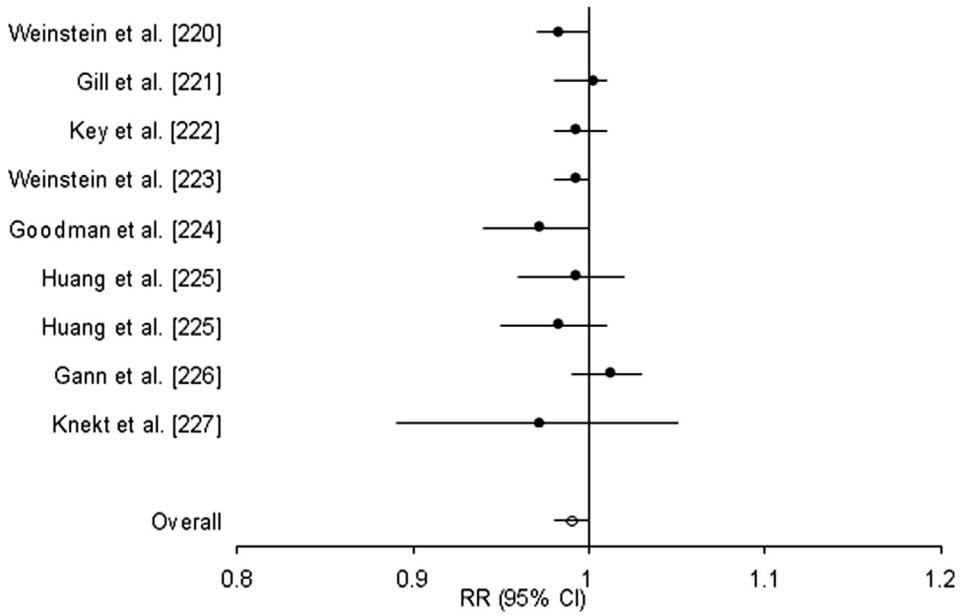

FIGURE 35.3 Circulating α-tocopherol and prostate cancer in prospective studies. *RR*, relative risk, per 10 μg/L; error bars indicate 95% CIs. *Adapted, with permission of the World Cancer Research Fund International, from World Cancer Research Fund International, Systematic literature review. The associations between food, nutrition and physical activity and the risk of prostate cancer. Available from: <http://wcrf.org/int/research-we-fund/continuous-update-project-findings-reports/prostate-cancer>, 2014.*

in the category "limited-no conclusion" due to limited evidence. The meta-analysis in the SLR yielded a nonstatistically significant summary relative risk estimate of 0.98 (95% CI: 0.93, 1.02) for dietary lycopene based on seven cohort studies, and 0.99 (95% CI: 0.79, 1.09) per 1 serving/day for tomatoes based on seven cohort studies [52]. In addition, a summary risk estimate based on 10 cohort studies that measured lycopene in blood was 0.99 (95% CI: 0.96, 1.01).

Since that SLR, one cohort study reported no association with dietary lycopene [95], while another cohort study reported that increasing tomato sauce intake was associated with a decreased risk of prostate cancer [239].

β-Carotene, lycopene, and other carotenoids are widely distributed in human tissues, including the prostate [240,241], where, as potent antioxidants, they help protect cell membranes, DNA, and other macromolecules from damage by reactive oxygen species. Other biological activities of carotenoids, such as the upregulation of gap-junctional communication [242], may also contribute to their anticarcinogenic effects. In three human prostate cancer cell lines (PC-3, DU 145, and LNCaP), β-carotene and lycopene significantly inhibited in vitro growth rates [243,244].

d Selenium

In the CUP, evidence for selenium supplements was too limited to draw any conclusions. In an early randomized intervention trial of a daily selenium supplement (200 μg) for men with a history of skin cancers, an incidental finding was a lower incidence of prostate cancer in men who received the intervention [245]. However, a large randomized intervention trial using supplemental selenium (200 μg/day) and vitamin E (400 IU/day) provided no evidence in support of a beneficial effect of selenium on prostate cancer risk [246]. A recent updated analysis from this trial reported that selenium supplementation increased the risk of high-grade prostate cancer among men with high selenium status at baseline [232]. Another randomized intervention trial of supplemental selenium (200 μg/day) in men at high risk of prostate cancer failed to support the hypothesis that selenium protects against prostate cancer [247]. Thus, there is no basis for recommending selenium supplementation to reduce prostate cancer risk.

On the other hand, the CUP report concluded that the evidence for an association of low plasma selenium concentrations with an increased risk of prostate cancer is limited, but suggestive. The SLR identified 17 relevant studies, and 7 reported an inverse association when comparing the highest versus the lowest categories. In the dose–response meta-analyses in the SLR, summary risk estimates for selenium in blood were 0.95 (95% CI: 0.91, 1.00) for total prostate cancer based on nine cohort studies (Fig. 35.4) and 0.95 (95% CI: 0.89, 1.00) for advanced cancer based on five cohort studies.

Since that SLR, a Danish cohort reported that plasma selenium was not associated with total or advanced prostate cancer risk, but higher selenium levels were associated with a lower risk of high-grade disease [256]. A recent meta-analysis of five studies showed a decreased risk of prostate cancer associated with higher toenail selenium concentrations (pooled odds ratio = 0.97, 95% CI: 0.95, 0.99 per 0.1 μg/g) [257].

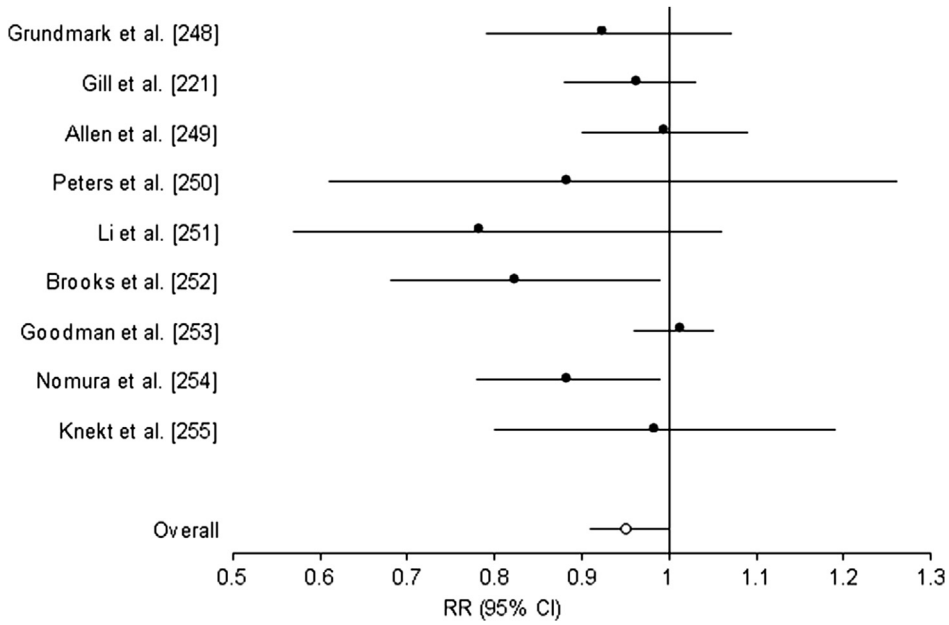

FIGURE 35.4 Circulating selenium and prostate cancer in prospective studies. *RR*, relative risk, per 10 μg/L; error bars indicate 95% CIs. *Adapted, with permission of the World Cancer Research Fund International, from World Cancer Research Fund International, Systematic literature review. The associations between food, nutrition and physical activity and the risk of prostate cancer. Available from: <http://wcrf.org/int/research-we-fund/continuous-update-project-findings-reports/prostate-cancer>, 2014.*

Selenium is a component of glutathione peroxidase, an important enzyme in certain antioxidative pathways. In in vitro experiments, selenium was shown to inhibit the growth of human prostate carcinoma cells [258,259]. Selenium may exert its anticancer effects through any of several proposed mechanisms, such as antioxidation, enhanced immune function, inhibition of cell proliferation, and induction of apoptosis [259].

e Isoflavonoids

The potential role of isoflavonoids in prostate carcinogenesis was discussed in the section on legumes.

8 Diet-Associated Protective Factors

a Physical Activity

The role of physical activity in human prostate carcinogenesis is unclear. Due to limited evidence, no conclusion on physical activity was reached in the CUP report. In the SLR, a summary relative risk estimate for the highest versus lowest level of physical activity was 0.97 (95% CI: 0.90, 1.04) for total physical activity based on 10 cohort studies, 0.87 (95% CI: 0.80, 0.95) for occupational physical activity based on 13 cohort studies, and 0.97 (95% CI: 0.90, 1.04) for recreational physical activity based on 21 cohort studies. Since that SLR, two cohort studies found no significant association for total [95,157], occupational, or recreational physical activity [157].

Because exercise influences androgen levels in the body, an effect of physical activity on prostate cancer risk is biologically plausible. Exercise lowers testosterone in the blood, and it also raises the level of sex hormone-binding globulin, which reduces the circulating free testosterone levels; both effects would be expected to lower prostate cancer risk [260–262].

IV GENETICS AND GENE–ENVIRONMENT INTERACTIONS

As noted previously, prostate cancer has a tendency to aggregate in families, and men whose fathers or brothers have had prostate cancer are at a two- or threefold increased risk of getting the disease compared to men without such a family history. The mapping by linkage studies of rare highly penetrant genes that could explain at least part of this familial aggregation identified a number of regions, including several loci on chromosomes 1 and X, but the results were not definitive [263,264].

Because diet (and other behaviors, such as physical activity [265]) can influence androgen, vitamin D, and IGF-I levels in the body, interactions may occur between dietary exposures and inherited susceptibilities in determining the actual risk for prostate cancer. Using linkage- and association-based strategies, many studies of single nucleotide polymorphisms in candidate genes have been reported, with largely disappointing results with regard to both the main effects of the genes and interactions between the genes and other exposures ("gene–environment interactions"). During the last decade, the research focus has been on genome-wide association studies (GWAS), which take an agnostic approach and require large consortial efforts to obtain sufficient numbers of cases. To date, the latter studies have identified approximately 100 distinct prostate cancer susceptibility loci associated with small differences in the risk of this disease [266,267]. One particular region on chromosome 8 (8q24) has been the source of considerable current research activity [268]. Unfortunately, overall, the GWAS-identified loci explain only a small portion of the variability in prostate cancer susceptibility [269].

V CONCLUSIONS AND IMPLICATIONS FOR PREVENTION AND TREATMENT

Considering the combined evidence from descriptive epidemiologic studies (especially the remarkable changes in migrant populations), analytic epidemiologic studies in widely varying populations, experimental studies in animals, and in vitro studies, the likelihood that certain dietary components or general patterns of eating influence the risk of prostate cancer remains high. However, no specific relationships have been established conclusively. Research on this topic should be continued because diet is a modifiable risk factor and because prostate cancer incidence is extremely high in many populations. In addition, further research on genetic polymorphisms that affect susceptibility to prostate cancer, and their possible interactions with dietary risk factors, may help identify high-risk subgroups of men who can be targeted for future preventive programs.

Currently, the primary treatment modalities for prostate cancer consist of surgery, radiation, and hormonal therapy. The fact that the findings for some dietary factors (e.g., saturated fat, well-done meat, calcium) were stronger in advanced or metastatic cases of prostate cancer implies that dietary effects can occur very late in the disease process [270]. This suggests that dietary interventions have the potential not only to reduce the incidence but also to improve the survival rates of the disease, providing another possible treatment modality. Indeed, one study of prostate cancer patients showed significantly worse survival for men in the upper tertile of saturated fat intake (>13.2% of calories) compared with men in the lowest tertile (<10.8% of calories) [271], whereas another study found that survival was improved in patients who consumed higher amounts of tomato products [272]. Explanations for such observations might be a beneficial effect of lower fat intake on circulating

androgen levels [273] or an inhibitory effect of lycopene on tumor growth rates [244].

Based on current knowledge, it is not prudent to make very specific dietary recommendations to prevent or treat prostate cancer. However, taken as a whole, the evidence is consistent with a diet that emphasizes vegetables, and is moderate or low in the consumption of processed meat and dairy products.

Chapter 36

Nutrition and Colon Cancer

Daniel D. Gallaher[1] and Sabrina P. Trudo[2]
[1]University of Minnesota, St. Paul, MN, United States, [2]University of Arkansas, Fayetteville, AR, United States

I INTRODUCTION

Colorectal cancer is the third most common cancer and third leading cause of cancer death in both men and women in the United States [1]. Approximately 71% of new cases arise in the colon and 29% in the rectum [1]. Epidemiologic evidence from migrant populations suggests there are some modifiable environmental risk factors, such as diet, in the etiology of colorectal cancer [2]. Hence, extensive research has probed the relationship between dietary components and altered colorectal cancer risk. Given that the majority of cases arise in the colon and evidence suggests some differences in etiology between colon and rectal cancers [3–5], this chapter will focus on the emerging evidence of dietary impacts on the risk of colon cancer.

Many approaches have been developed to examine how diet influences risk of colon cancer. Broadly, these include case–control studies, prospective cohort studies, intervention trials using putative intermediate markers of colon cancer risk, animal studies, and cell culture studies. Each approach has advantages and limitations. Epidemiologic studies, such as case–control and cohort studies, are observational studies that primarily demonstrate associations between two variables (e.g., a particular dietary component or dietary pattern and colon cancer risk). Observational studies are thus most useful for generating hypotheses or providing support to findings from intervention or animal studies. However, since they directly examine humans consuming their normal diets, epidemiologic studies are invaluable in identifying potentially beneficial or harmful foods or dietary patterns. Prospective cohort studies are typically considered stronger than case–control studies due to less susceptibility to recall and selection bias. In addition, data from multiple cohort and case–control studies are often combined to yield statistically stronger conclusions due to the combined larger number of study subjects, among other strengths of this approach; however, a primary drawback is that not all published cohort and case–control studies on a given topic provide sufficient data to be included in the meta-analysis.

Another approach for examining the role of nutrition in the etiology of colon cancer is the intervention trial. The advantages of these studies are that foods or dietary patterns being studied are well controlled and there is no question about applicability to humans. However, this approach requires an outcome measure other than the development of cancer, since trials are necessarily of shorter time than the induction period for colon cancer. Currently, there is no unequivocally validated intermediate marker for colon cancer. Recurrence of colon adenomas (polyps) after their removal has been used, but studies of polyp recurrence are long and expensive. Further, even polyps are not completely validated as a marker of colon cancer risk. However, there is reason for optimism, as some studies suggest the possibility that molecular markers collected from either rectal swabs [6] or fecal samples [7] may provide the long sought validated marker of elevated risk of colon cancer.

Animal studies represent a complementary approach that allows a more mechanistic examination to the study of diet and colon cancer. Although questions about the applicability of findings from animals to the human situation must continually be considered, there is no doubt that findings from animal studies provide insight into colon cancer in humans. Animal studies are often the best approach to examine how consuming different dietary components influence initiation events such as biotransformation of carcinogens, DNA adduct formation, DNA repair, and apoptosis, as well as postinitiation events such as changes in signaling pathways and eventual tumor formation.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00036-9

Cell culture studies are frequently employed for the study of how isolated compounds influence cancer cell growth and signaling pathways, among other aspects of carcinogenesis. Nonetheless, they are severely limited in that whole foods requiring digestion cannot be examined nor can food components that are normally metabolized after consumption. Consequently, for the purposes of this chapter, we shall focus on only animal, case–control, prospective cohort, and intervention studies related to nutrition and cancer. In discussion of the animal studies, we shall focus on those studies using whole foods and their effect on morphological endpoints of colon cancer, either adenomas (benign tumors that may progress to cancer), adenocarcinomas (cancerous tumors), aberrant crypt foci (ACF, believed to be precancerous lesions), or mucin-depleted foci (MDF, a subpopulation of ACF which are suggested to be highly dysplastic and are more immediate precursors to tumors than ACF) [8]. A representative image of ACF and MDF is shown in Fig. 36.1. For discussion of human studies, we will focus similarly on studies using colon cancer as the endpoint, with the exception of intervention trials. Emphasis will likewise be on studies of whole foods with a few exceptions.

The majority of these studies have investigated diet components that can be grouped into five categories: Fruits, Vegetables, and Legumes; Meats; Milk and Dairy Foods; Whole Grains; and Beverages. For each category we will summarize the proposed impact on colon cancer risk, including putative biological mechanisms for influencing cancer risk, and review the relevant animal and human data. Fig. 36.2 provides a representation of the process of carcinogenesis, and will provide a basis for understanding at what point(s) different diet components can influence this process.

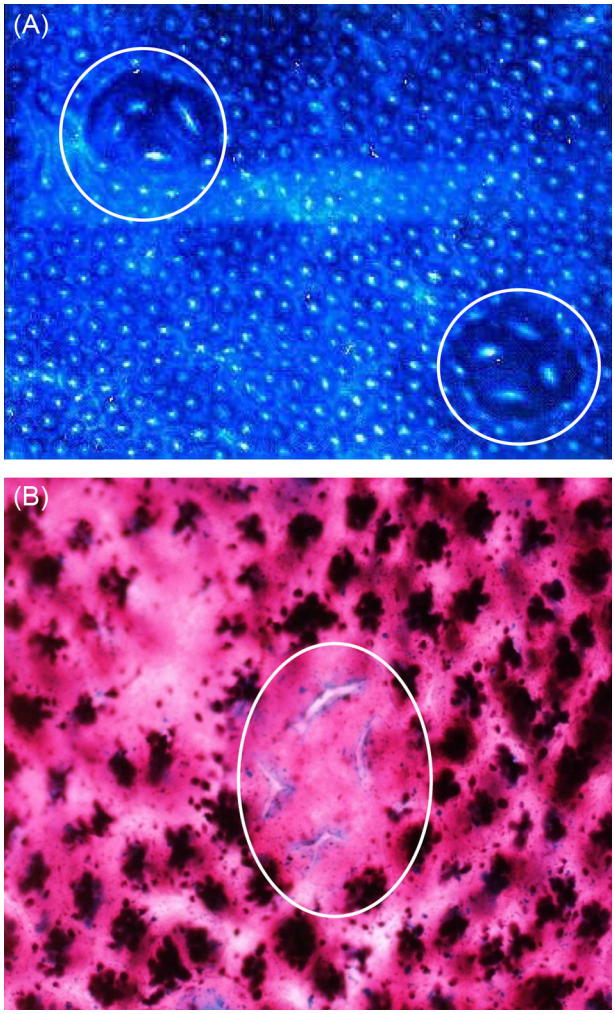

FIGURE 36.1 (A) Aberrant crypt foci (ACF) and (B) mucin-depleted foci (MDF) in rat colon. ACF are visualized by staining whole mounts of colon with methylene blue. MDF are ACF that show no mucin staining using high-iron diamine alcian blue. Normal crypts stain black.

II FRUITS, VEGETABLES, AND LEGUMES

Proposed mechanisms for influencing cancer risk. It has been hypothesized that plant foods protect against cancers such as colon cancer [9]. Thousands of phytochemicals have been identified in fruits, vegetables, and legumes, many of which are capable of modulating various processes related to colon cancer development. For example, apoptosis (or programmed cell death) is a means by which cells with DNA damage can be safely eliminated instead of becoming cancerous. Flavonoids that are found in many fruits and vegetables induce apoptosis in a variety of models [10,11]. Other phytochemicals that induce apoptosis include proanthocyanidins (apples, chocolate, grapes, berries, other fruits), resveratrol (grape skins, peanuts), isothiocyanates (derived from cruciferous vegetables like broccoli and cabbage), and limonene (citrus fruits, cherries) (reviewed in Refs. [10,12]).

Second, many of the naturally occurring compounds in plant foods also interfere with oxidative processes by acting as antioxidants or increasing antioxidant activity. Antioxidants inhibit or mitigate the damage to cells from reactive oxygen species (ROS) that can lead to carcinogenesis. Compounds shown to be antioxidants or to increase antioxidative activities include vitamin C, vitamin E, provitamin A and other carotenoids, flavonoids, proanthocyanidins, isoflavonoids (soy), isothiocyanates and indoles (cruciferous vegetables), and resveratrol (see reviews [10,12,13]).

A third major process modulated by phytochemicals is the metabolism of carcinogens. Several groups of biotransformation enzymes metabolize carcinogens by typically first exposing functional groups on the parent compound, referred to as phase I metabolism and, secondly, conjugating the metabolite with another molecule, called phase II metabolism. The net effect is usually a safer

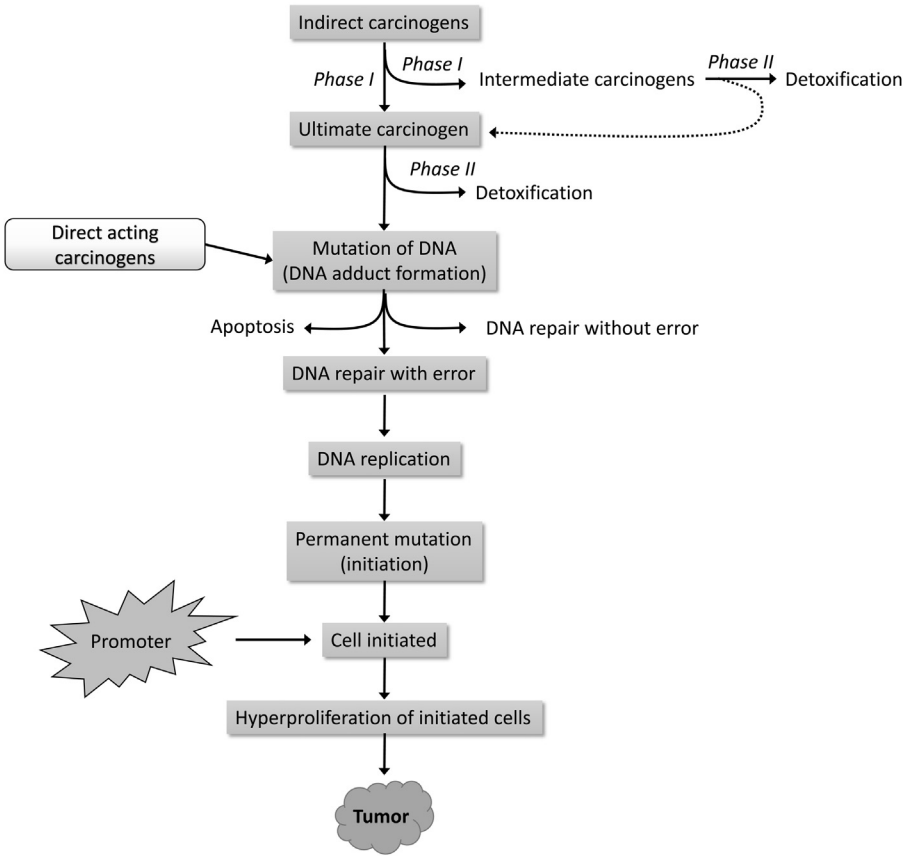

FIGURE 36.2 An overview of the pathway of chemical carcinogenesis. Indirect carcinogens can be detoxified through phase I and phase II metabolism, although for a few compounds, phase II metabolism can lead to carcinogen activation (dotted line). However, some indirect carcinogens are activated by phase I metabolism, leading to mutations in DNA through formation of DNA adducts. DNA repair mechanisms can remove the adducts. If mutation is extensive, this can result in cell death through apoptosis. However, if the DNA is not repaired correctly, and DNA replication occurs, this can lead to a permanent mutation, forming an initiated cell. Additional mutations or promoters of cell proliferation can lead to hyperproliferation and potentially a tumor. *Adapted from G.A. Belitsky, M.G. Yakubovskaya, Genetic polymorphism and variability of chemical carcinogenesis, Biokhimiya 73 (2008) 675–689, http://www.protein.bio.msu.ru/biokhimiya/contents/v73/full/73050675.html.*

and water soluble product that can be excreted. The cytochrome P450s (CYPs) are generally involved in the first step and the second step is mediated by conjugating enzymes such as glutathione *S*-transferases (GSTs), UDP-glucuronosyltransferases (UGTs), *N*-acetyltransferases, and sulfotransferases (SULTs). However, carcinogen metabolism by these collective enzymes is complex, in that the enzymes have broad substrate specificities and in some instances actually toxify the substrate instead of detoxifying it by the chemistry they mediate (i.e., activate procarcinogens). Given the number of phytochemicals that modulate biotransformation enzyme expression and activity, a widely investigated hypothesis is that diet could optimize biotransformation activity toward net detoxification of carcinogens. For example, CYP activity is influenced by isothiocyanates, furanocoumarins, and phenolic compounds [14,15]; GST activity is modulated by isothiocyanates and cruciferous vegetables [15,16]; many flavonoids, isoflavonoids, polyphenols, and some carotenes modulate UGT activity [17]; and evidence indicates that flavonoids and isoflavonoids inhibit several SULTs [18].

A fourth cancer-related process that is modulated by phytochemicals is inflammation. During promotion, cytokines and chemokines can serve as tumor growth factors and tumor survivor factors; proinflammatory cytokines can also regulate epithelial-mesenchymal transition and thus influence invasion and metastasis [19]. Flavonoids, proanthocyanidins, isothiocyanates, and resveratrol have demonstrated antiinflammatory activity [12,19].

Additionally, many plant foods are rich in folate, a water soluble B-vitamin. Folate aids in methylation of DNA, and methylation patterns are key in epigenetic regulation of gene expression. Finally, fruits, vegetables, and legumes provide fiber which may prevent colon cancer by increasing bulk of stool, decreasing transit time through the gut, and diluting carcinogens [20].

Animal studies. Few studies have examined the effect of whole fruits on colon carcinogenesis. Carcinogen-treated rats fed freeze-dried blueberries, blackberries, plums, or mangos, at 5% of the diet, had large reductions in ACF compared to the control group [21]. A similar finding was reported with freeze-dried black raspberries [22] and with whole apples [23]. Although feeding dried plum powder, produced by air drying, did not result in a reduction of ACF [24], feeding a puree of dried plums to carcinogen-treated rats did result in a highly significant reduction of ACF [25]. Thus, studies of fruit feeding have been mostly consistent in showing a reduction in colon cancer risk, although the manner of preparation of the fruit may be important.

Of the vegetables, cruciferous (*Brassica*) vegetables, such as cabbage, broccoli, Brussels sprouts, and cauliflower, have received the most attention for their chemopreventive properties. Cruciferous vegetables contain glucosinolates, which are hydrolyzed by the plant enzyme myrosinase after tissue damage, such as by chopping or chewing, to isothiocyanates and indoles, which evidence suggests are the active agents. Cruciferous vegetables fed to carcinogen-treated animals result in significant reductions in ACF [26]. Further, a tendency for reduction in ACF has been found with juices of garden cress [27] and Brussels sprouts [28], but not red cabbage [28]. Finally, carcinogen-treated mice that were fed cabbage had fewer adenomas, a benign tumor that can progress to a cancerous tumor [29]. Allium vegetables, such as garlic and onion, have also been examined. This family of vegetables is notable for high concentrations of organosulfur constituents, such as diallyl disulfide and *S*-allylcysteine. Studies of carcinogen-treated rats fed garlic have shown a reduction in either ACF [30] or MDF [31], as well as a reduction in tumor incidence [32]. Aged garlic extract reduced large ACF (>4 aberrant crypts/ACF) [33]. Aged garlic extract is prepared by prolonged extraction of fresh garlic, and is less irritating than fresh garlic. Dried onions also reduced ACF in carcinogen-treated rats [34]. Thus, vegetables from different botanical families, containing very different profiles of phytochemicals, appear to be chemopreventive in animal models.

Legumes commonly consumed by humans include soy, beans, peas, lentils, and peanuts. Of these, soy has received the most attention for colon cancer prevention due to evidence that isoflavones present in soy, which have phytoestrogenic activity, may be chemopreventive. Soy, however, is essentially never consumed as the whole bean. It is consumed as a myriad of processed products, including soy flour or protein isolates, tofu, and fermented forms such as tempeh and miso. Soy protein isolate fed to carcinogen-treated rats has reduced tumor incidence [35] and ACF number [36,37]. Soy flour has also reduced ACF number [38]. Interestingly, miso had no effect on ACF number or tumor incidence [39]. However, in contrast, a fermentation product of soybean, black bean, and green bean was found to reduce the growth of tumors resulting from injection of CT-26 colon cancer cells [40]. Few other legumes have been examined. In carcinogen-treated rats, garbanzo bean flour [38] and lentils [37] reduced ACF number whereas cooked navy beans had no effect on tumor incidence [41]. Thus, the evidence suggests that soy, as either a protein isolate or whole flour, is chemopreventive in animal models; too few studies have been reported to be confident about the effect of other legumes.

Human studies. While in vitro studies, animal studies, and many human intervention trials suggest mechanisms that are biologically plausible, cohort and case–control studies have been inconsistent regarding protection against colon cancer by plant foods. Most studies through the 1990s reported 30–40% reduction in risk in those with the highest vegetable intake relative to those with the lowest intake [9,42–46]. Accordingly, the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) reported in 1997 that, after critical review of the research literature by experts, the evidence for protection against colon cancer by diets rich in vegetables was "convincing" [47]. Subsequent studies, however, were less supportive. For example, the European Prospective Investigation into Cancer and Nutrition (EPIC) study observed in 2009 an inverse association for usual combined fruit and vegetable intake and colon cancer, however with adjustment for total fiber the risk estimate for colon cancer lost significance when comparing the highest with the lowest quintile of intake [48]. The reassessment of the evidence by the WCRF/AICR published in the 2011 Continuous Update Project (CUP) report for colorectal cancer indicated limited-suggestive evidence for risk reduction by fruits and nonstarchy vegetables [49]. Nevertheless, the 2011 CUP report does conclude that there is convincing evidence that foods containing dietary fiber do decrease the risk of cancers of the colon and rectum. Studies investigating the independent association of fruit and vegetable intake with colon cancer since the 2011 CUP have continued to report inconsistent results. After additional investigation in 2015 with longer follow-up within EPIC, study investigators reported that although there was suggestion of lower colon cancer risk with increased fruit and vegetable intake, the study did not support a clear inverse association [50]. EPIC was also used to assess the association with colon cancer of plasma concentrations and dietary intakes of carotenoids and vitamins A, C, and E which are generally found in high levels in fruits and vegetables. The authors concluded that although inverse associations with colon cancer were suggested, all of the inverse associations lost statistical significance after adjusting for multiple comparisons except for retinol [51]; the authors further suggested that the possible inverse association between fruit and vegetable intake and colon cancer may be due to compounds other than those investigated in the study. In the Shanghai Men's Health Study, a cohort of over 60,000 men, study investigators reported an inverse association between fruit intake and colon cancer, little evidence for an association between vegetable consumption and colorectal cancer, and an inverse association for legume intake [52]. Similarly, a systematic review and meta-analysis of cohort and case–control studies in the Japanese population found insufficient evidence of an association between vegetable intake and colorectal

cancer risk [53]. Other investigators have pursued more targeted assessment of the intake of specific vegetables. For example, Wu et al. [54] conducted a meta-analysis that included data from 24 case–control and 11 prospective studies to investigate the association of cruciferous vegetable intake and colon cancer risk; statistically significant inverse associations were observed particularly for distal colon cancer in both case–control and prospective studies. Likewise, the meta-analysis by Tse and Eslick [55] that included 33 studies also showed an inverse association between cruciferous vegetable consumption and colon cancer, particularly with broccoli. The 2011 CUP report concluded that garlic probably protects against colorectal cancer [49]; however, no evidence of a protective association was found in a 2014 meta-analysis that included studies specifically investigating allium vegetables (onion, garlic, leeks, etc.) [56].

In sum, the human data on fruits, vegetables, and legumes intake reducing colon cancer risk is inconsistent. The inconsistencies could be related to study design differences in population-based studies such as inconsistent discrimination between effects on proximal versus distal colon, low sample size and case numbers, low or narrow range of intake of plant-based foods in the population studied, types of plant foods consumed in different populations studied, and error in measuring dietary intake. Additionally, a possible explanation for existing discrepancies between animal data and population-based data is that animal studies frequently use purified phytochemicals as the interventions and there may be differences in net effects between phytochemical treatment versus treatment with the intact food source (see review by Liu [57]). Plant foods contain thousands of bioactive constituents that may interact or counteract each other as normally consumed in whole foods and complex diet patterns. Nonetheless, that individual phytochemicals show promise mechanistically in animal and in vitro studies gives impetus for continued work in identifying the role of plant foods in colon cancer prevention (Fig. 36.3).

III MEAT

Proposed mechanisms for influencing cancer risk. There are several components of meat whose consumption can plausibly be linked to enhancing the risk of colon cancer. Cooking meat at high temperature causes formation of heterocyclic aromatic amines (HAAs), which are known carcinogens in rodents [58]. HAA consumption produces chemical modifications of DNA [59], known as DNA adducts. The structures of two HAAs commonly found in foods and their DNA adducts are shown in Fig. 36.4. Formation of DNA adducts is generally considered to be a "necessary but not sufficient" event for tumor formation [60]. Although the failure to detect differences in colon cancer risk between populations consuming well-done meat versus normal meat [61] has caused some to question the role of HAAs in human colon carcinogenesis, a recent study in which dietary HAA intake was estimated for three HAAs found significant positive correlations between intake of several HAAs and colorectal tumors [62]. Thus, whether the HAAs present in grilled meat represents a colon cancer risk in human remains an open question. A second meat component suspected of increasing risk of colon cancer is heme, present in myoglobin, hemoglobin, and various heme proteins, which is suggested to act as a colon cancer promoter [63]. A large cohort study, in which heme iron intake was found to be significantly associated with an increased risk for tumors that carried G>A mutations in the APC gene [64], suggests a mechanism. Since G>A mutations are characteristic of

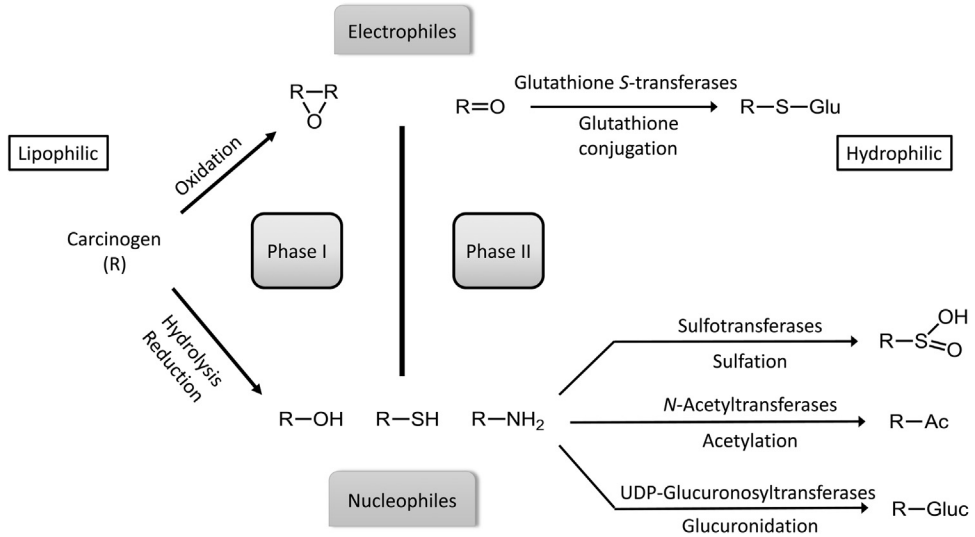

FIGURE 36.3 An overview of phase I and phase II metabolism. Carcinogens can undergo oxidation reactions that allow conjugation with glutathione by GSTs. Alternatively, carcinogens can undergo hydrolysis or reduction reactions, and subsequently be sulfated by SULTs, acetylated by *N*-acetyltransferases, or glucuronidated by UGTs. The result is a more hydrophilic compound that can be excreted in the bile or urine. *Adapted from https://commons.wikimedia.org/wiki/File:Xenobiotic_metabolism.png.*

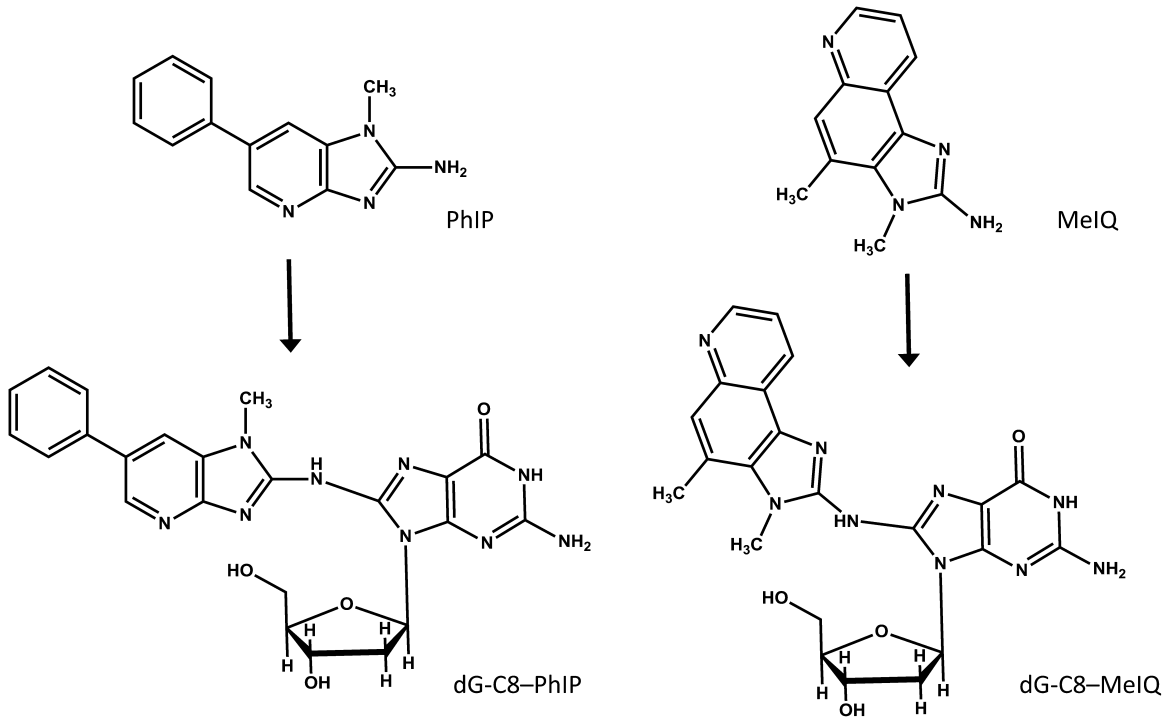

FIGURE 36.4 Structure of two foodborne HAAs, 2-amino-1-methyl-6-phenylimidazo(4,5-b)pyridine (PhIP) and 2-amino-3,4-dimethylimidazo[4,5-f] quinolone (MeIQ) and their DNA adducts *N*-(deoxyguanosin-8-yl)−PhIP (dG-C8−PhIP) and *N*-(deoxyguanosin-8-yl)−MeIQ (dG-C8−MeIQ).

DNA alkylating agents [65], heme may promote mutagenesis. However, in a study in which mice were fed heme-containing or heme-free diets for 18 months, no difference in either DNA alkyl adducts, such as O^6-methyl-2-deoxyguanosine, or tumor number were found between the groups [66]. Thus, a mechanism by which heme may increase colon cancer risk remains uncertain. Nitrite and *N*-nitroso compounds (NOCs) represent yet another class of compounds that are present primarily in processed meats (e.g., grilled bacon) and smoked fish, and have been shown to be carcinogenic in animal studies [67]. Further, nitrates and nitrites, which can give rise to NOCs endogenously, have been classified as probable human carcinogens by the International Agency for Research on Cancer (IARC) [68]. Finally, animal sources of dietary fat, primarily saturated fat, are implicated as a risk factor in epidemiologic studies [69,70]. How saturated fat may promote colon carcinogenesis remains very unclear. However, carcinogen-treated rats fed beef tallow were reported to have greater expression of β-catenin (part of the Wnt signaling pathway) and decreased apoptosis in the colonic mucosa [71], both of which are associated with greater colon cancer risk. Thus, saturated fat may shift intracellular signaling pathways toward a condition of greater cancer risk.

Animal studies. A large number of animal studies of the effect of red meat on colon carcinogenesis have been conducted. These include studies where the endpoints were either colonic tumors [72−74] or ACF [75] and where either carcinogen-treated animals or genetic models [76] of colon carcinogenesis were used. Overall, these studies do not support an effect of red meat on promoting colon carcinogenesis, and in some cases beef was protective [73,74,76]. For example, diets containing either 30% or 60% of freeze-dried beef, chicken, or bacon were fed to carcinogen-treated rats and ACF number determined after 100 days of feeding. These diets were compared to casein-based control diets that used either olive oil or lard as fat sources in order to approximate the fat content of the meat diets. There were no differences in the number of ACF among any of the diets [75]. Pence et al. examined the effect of lean beef versus casein at two levels of dietary fat (5% vs 20%) and two types of dietary fat (corn oil vs tallow) on tumor development in carcinogen-treated rats [74]. After 27 weeks of feeding, total incidence and the number of tumors were lower in the beef-fed rats than the casein-fed rats.

To explain why animal studies do not support a promotional effect of red meat whereas epidemiologic studies largely do (discussed below), Pierre et al. proposed that high calcium diets may protect against the promotional effect of red meat [77]. This was based on the observations that most rodent diets are relatively high in calcium, that heme added to the diets of rats promoted colonic epithelial proliferation [78], and that this heme-induced

proliferation was inhibited by high calcium [79]. This hypothesis was examined in carcinogen-treated rats fed diets containing 60% beef in the context of either a low or high calcium diet. A casein-based diet served as the control. Both ACF and MDF were increased in the low-calcium beef diet compared to the low-calcium casein diet. However, the high-calcium beef diet did not differ in ACF or MDF from the low-calcium casein group, supporting the hypothesis that calcium suppresses the promotional effect of red meat. Unfortunately, complicating the interpretation of these results was the finding that the high-calcium casein diet had ACF and MDF numbers equivalent to the low-calcium beef diet. The authors suggested that this unexpected finding may be due to the phosphate component of the calcium phosphate used as the calcium source in the diet. Further, a diet of 60% beef represents a concentration of beef in the diet well beyond what would be consumed by humans. In a subsequent study of the interaction of processed meat and calcium on colon cancer risk, carcinogen-treated rats were fed an air-exposed picnic ham containing nitrite (47% of the diet), in the context of a very low or high calcium diet [80]. Rats fed the high calcium diet had significantly fewer colonic MDF than those fed the low calcium diet, although the number of ACF did not vary between the two diets. These two studies suggest an important interaction between dietary red meat and calcium in terms of colon cancer risk that warrants further study.

Human studies. In the 2011 CUP by WCRF/AICR, the evidence was assessed as "convincing" for intake of red meat and processed meat (smoked, cured, salted, etc.) increasing the risk of colon and rectal cancer [49]. Moreover, on behalf of IARC, a working group of 22 scientists from 10 countries assessed over 800 epidemiological studies of the association between colorectal cancer and red meat and processed meat. They concluded in 2015 that consumption of processed meat is "carcinogenic to humans" with the largest body of evidence concerning colorectal cancer; they additionally concluded that red meat intake is "probably carcinogenic to humans" based on limited evidence in humans [81]. They define processed meat as meat that has been transformed (salting, curing, smoking, etc.) for enhanced flavor or improved preservation, and red meat as unprocessed mammalian muscle meat such as beef, pork, lamb, etc. However, other investigators critically reviewing the epidemiologic data on unprocessed red meat and colorectal and colon cancer contradictorily conclude that the data show weak associations, lack a clear dose−response trend, vary by gender, and are susceptible to the collinearity of meat intake with other dietary and behavioral factors which limits isolation of the independent effects of meat [82−84]; they also suggest that data from epidemiologic studies do not support that there is a clear underlying biological mechanism [84]. Interestingly, in a recent analysis of data from two large prospective cohorts (Nurses' Health Study, $n = 87{,}108$ women; Health Professionals Follow-up Study, $n = 47{,}389$ men) processed red meat was associated with higher risk of distal colon cancer while unprocessed red meat was associated with lower risk after adjusting for calcium, folate, and fiber intake [85]; the authors thus concluded that there was little evidence that unprocessed red meat substantially increases risk of colorectal cancer. In numerous prospective cohort and case−control studies of the association between poultry consumption and risk of colon cancer, results quite consistently indicate no association with colorectal or colon cancer risk [86]. This lack of an association has raised suspicion over the role of HAAs as an underlying mechanism of meat and colon cancer risk because, similar to red meat, poultry cooked at high temperatures is also a source of HAA. Potential challenges to finding consistency across human studies of meat and colon cancer may include accuracy in assessing cooking or processing methods of meats and level of doneness of meats (thus HAA exposure). Additionally, genetic polymorphisms, such as in genes involved in metabolism of HAAs or DNA repair, could modify the risk related to a putative mechanism [87−89].

IV MILK AND DAIRY FOODS

Proposed mechanisms for influencing cancer risk. A number of constituents in dairy foods have been investigated for their chemopreventive potential, with calcium and vitamin D having received the most attention. However, lipid components found in dairy fat, such as conjugated linoleic acid (CLA) and sphingolipids, as well as dairy proteins, particularly the whey proteins, have also been studied.

Perhaps the earliest suggestion for the chemopreventive action of dietary calcium was put forth by Newmark et al. [90], who suggested that calcium would precipitate fatty acids and bile acids within the colonic lumen, thereby reducing their ability to irritate the colonic epithelium. This irritation was suggested to be the manner in which they act as cancer promoters. This hypothesis received experimental support from studies showing that dietary calcium decreased the solubility of fatty acids and bile acids in the large intestine [91] and thereby reduced the cytotoxicity of the fecal water [92]. The calcium sensing receptor, which is involved in controlling differentiation of colonic epithelial cells, may also play a role. In cell culture studies, calcium increased transcriptional activity of the calcium sensing receptor and induced a less malignant phenotype in colon cancer cells, an effect also noted with $1,25(OH)_2D_3$, the active form of vitamin D [93].

Since the active form of vitamin D functions as a steroid hormone, functioning as a transcription factor bound

to the vitamin D receptor (VDR), it is understandable that the proposed mechanisms of action of vitamin D involve effects on gene expression. Since many sporadic colon cancers show mutations in the adenomatous polyposis coli gene (*Apc*) [94], several studies have examined the role of the active form of vitamin D on pathways related to *Apc*. Inactivation of *Apc* results in activation of the WNT pathway and accumulation of β-catenin in the nucleus which, through a complex series of events [95], leads to constitutive activation of target genes promoting proliferation of colonic epithelial cells. Subsequent mutations are thought to lead to tumor development. In mice with mutations in *Apc*, those also carrying a mutation in *VDR* accumulated more nuclear β-catenin [96], suggesting that 1,25-$(OH)_2D_3$ acts to modulate the WNT pathway. Severe deficiency of 1,25-$(OH)_2D_3$, created by knocking out 25-hydroxyvitamin D 1α-hydroxylase, the enzyme responsible for its formation, has been shown to induce significant colonic inflammation [97]. Chronic inflammation in the colon has long been known to increase colon cancer risk, as illustrated by the increased risk of colon cancer in patients with ulcerative colitis [98]. Whether the mild to moderate degrees of vitamin D deficiency encountered in human populations also result in colonic inflammation remains to be investigated.

CLA is a term for a group of isomers of linoleic acid that contains a conjugated double bond system. Dairy products represent a major dietary source of CLA, with the two major forms being *cis*9, *trans*11-CLA and *trans*10, *cis*12-CLA. Almost all studies examining the chemopreventive mechanisms of CLA have used purified CLA in cell culture studies. No clear mechanism has emerged from these studies. There is some evidence that *cis*9, *trans*11-CLA decreases cyclooxygenase-2 (COX-2) expression in breast cancer cell lines [99], a change associated with reduced cancer risk in the colon. Increased rates of apoptosis are associated with decreased colon cancer risk, and several studies showed induction of apoptosis with CLA [100,101]. Supporting a chemopreventive effect of CLA, a study in carcinogen-treated rats fed bitter gourd seed oil, which contains >50% CLA in the forms of α- and β-eleostearic acids, found statistically significant reductions in ACF and adenomas after 32 weeks of feeding. However, additional studies are necessary to establish the chemopreventive mechanism of CLA.

Sphingolipids are a category of structurally diverse lipids having a sphingoid base with long-chain fatty acids attached in an amide linkage and containing polar head groups. They are present in small amounts in most foods but are abundant in dairy products, particularly cream and cheese [102]. Sphingolipids, along with their digestion products (ceramides and sphingosines), are highly bioactive. A mechanism of chemoprevention by sphingolipids has not been conclusively identified, but ceramides are involved in cancer cell growth, differentiation, and apoptosis [103]; supplementing the diet with sphingolipid increases apoptosis in the colonic epithelium in carcinogen-treated mice [104]. There is also evidence that sphingolipids normalize aberrant Wnt/β-catenin signaling [105], a pathway that is frequently dysregulated in colon cancer. Thus, sphingolipid-induced changes in differentiation and apoptosis, as well as Wnt signaling, are likely to be involved in the chemopreventive action of sphingolipids.

Dairy proteins have several distinct properties that make them plausible dietary chemopreventive agents. Caseins, the most abundant group of dairy proteins at 80% of the total, have been shown to bind HAAs [106], which are known carcinogens. A casein hydrolysate was shown to inhibit β-glucuronidase activity [107]. Decreased β-glucuronidase activity has the potential to reduce colon cancer risk, as carcinogens can be inactivated by glucuronidation in the liver and excreted in the bile. However, colonic bacteria express β-glucuronidase activity, which hydrolyzes the glucuronide, releasing the active carcinogen. Inhibiting this bacterial β-glucuronidase activity could thus reduce carcinogen release in the colon. Whey proteins, the second most abundant group of dairy proteins, at 20% of the total, are notable as a rich source of the sulfur amino acid cystine. Feeding whey proteins to rats increases tissue levels of the cysteine-containing tripeptide glutathione [108]. This is significant for two reasons. First, glutathione is a potent intracellular antioxidant and can participate in the elimination of ROS, either directly or as a cosubstrate for glutathione peroxidase, which reduces lipid peroxides. ROS can damage cellular macromolecules including DNA, and high levels of ROS are believed to promote cancer. Second, glutathione is a cosubstrate for GST, an enzyme involved in detoxification of xenobiotics, including carcinogens. Animal studies show an inverse relationship between liver glutathione concentration and colon tumor incidence [72], suggesting that increasing tissue glutathione may be chemopreventive.

Animal studies. Tavan et al. [109] reported that carcinogen-treated rats given a diet containing 30% skim milk had a significant reduction in ACF relative to the control group. However, almost no additional studies have been conducted on milk and colon cancer risk in animal models. The focus has been almost exclusively on milk components, both major and minor. Whey proteins, which constitute approximately 20% of milk proteins, reduce tumor formation in carcinogen-treated rats [110] and partially hydrolyzed whey proteins reduce ACF number compared to casein-fed animals [111].

Another major milk component, milk fat, has been examined as two different fractions—the anhydrous milk fat and the milk fat globule membrane. This latter fraction is a protein−lipid complex, rich in sphingolipids, that surrounds the milk fat globules. In carcinogen-treated rats

the milk fat globule membrane, but not the anhydrous milk fat, reduced ACF number [112], pointing to the potential of sphingolipids as an important chemopreventive compound in milk. This is plausible, as a number of animal studies have demonstrated that sphingolipids show chemopreventive effects [10].

A large number of animal studies have examined the potential for calcium to reduce tumorigenesis. A meta-analysis of the studies through 2005 concluded that high calcium diets reduced tumor incidence in carcinogen-treated animals (Relative Risk = 0.91, $p = 0.03$) [113]. Animal studies conducted since 2005 continue to support a role for high calcium diets reducing carcinogenesis. A high calcium diet (5.2 g/kg diet) reduced ACF number in both mice and rats compared to a low calcium diet (1.4 g/kg diet) [114]. A relatively new animal model of colon carcinogenesis is the so-called new Western-Style diet (NWD), which is low in calcium and vitamin D and high in fat, and also has relatively low levels of folic acid, cysteine, and choline bitartrate. Long-term feeding (e.g., 18 months) of the NWD resulted in intestinal tumor formation, primarily in the large intestine [115]. Using this model, 2 years of feeding the NWD with added calcium and vitamin D resulted in no colon tumors compared to 27% of mice fed the NWD [116]. Since both calcium and vitamin D were added, this study cannot determine if either one alone would have had a comparable effect. Regardless, overall, animal studies strongly support a chemopreventive effect of dietary calcium.

Relatively few animal studies have been reported of the influence of vitamin D, independent of calcium (i.e., when dietary calcium was adequate), on tumorigenesis or precancerous lesion. In rats given the direct acting colon carcinogen *N*-methyl-*N*-nitrosourea and lithocholic acid (which acts as a tumor promoter), there were fewer tumors when 1-(OH)-D_3 was also administered [117]. In the Apc^{min} mouse, a genetic model of colon cancer, intraperitoneal injection of 1,25-$(OH)_2$-D_3, the active form of the vitamin, did not reduce the number of intestinal polyps. However, the total tumor load was significantly reduced compared to the control group that was not administered 1,25-$(OH)_2$-D_3 [118]. In carcinogen-treated rats, administration of 1,25-$(OH)_2$-D_3 prior to administration of the carcinogen reduced tumor formation by 50% [119]. The previously described studies examined supplemental vitamin D. In a study using carcinogen-treated rats, it was found that animals fed a high calcium diet had fewer colonic tumors per rat (tumor multiplicity), compared to a normal calcium diet. However, feeding a high calcium diet that was also vitamin D deficient resulted in the loss of the protective effect of the high calcium diet [120]. These few studies suggest that supplemental vitamin D may reduce colon cancer risk, and that vitamin D is necessary for the chemopreventive effect of high dietary calcium. However, in a recent study using both rats and mice with a defective *Apc* gene (Pirc rat and Apc^{min} mouse), supplemental vitamin D did not alter either tumor number or tumor multiplicity compared to animals given a normal amount of vitamin D in either species [121]. More recently, a similar study was conducted feeding a range of vitamin D concentrations as well as 25$(OH)D_3$ [122]. In addition to enumeration of tumors at the end of the study, the investigators followed tumor development endoscopically. No protection against development of the final number of colonic tumors was found. Thus, the results from animal studies are inconsistent and do not provide strong support for a chemopreventive effect of supplemental vitamin D.

Human studies. Based on evidence primarily from observational studies in Western countries, the WCRF/AICR concluded in the 2011 CUP report that intake of milk and calcium probably decrease the risk of colon cancer [49]; in regards to foods containing vitamin D, their conclusion was that there was "limited-suggestive" evidence for a protective association. In 2012, Aune et al. [123] published the results of their meta-analyses that included data from 19 cohort studies; total dairy intake and milk intake were each inversely associated with colon cancer in both men and women. No associations were observed for cheese or other dairy products. Subsequently, a meta-analysis that included 15 prospective studies reported an inverse association between milk intake and colon cancer risk, but in men only [124]. The authors speculated that observing the association in men only could be related to the higher incidence of colorectal cancer in men compared with women [124]. Consistent with the majority of studies on the association between dietary calcium and colorectal cancer risk, Zhang et al. [125] reported in 2016 that total calcium intake was associated with reduced risk of colon cancer in a large cohort of 88,509 women and 47,740 men. They also observed that results were similar for different sources of calcium (from all foods or dairy products only) and that the inverse association was linear and stronger for distal colon cancer than proximal [125]. Since the publication of the 2011 CUP report, evidence is still limited regarding vitamin D intake and colon cancer risk; a 2015 systematic review and meta-analysis utilizing six studies found inconsistent associations for colorectal cancer and vitamin D supplementation [126].

While not conclusive, the evidence is somewhat consistent for a protective effect from milk and calcium intake. The human data on vitamin D are not consistent and the relationship to colon cancer warrants further investigation.

V WHOLE GRAINS

Proposed mechanisms for influencing cancer risk. Whole grains include a heterogeneous collection of cereals,

including wheat, corn, barley, oats, rye, and rice, as well as less commonly consumed cereals such as sorghum, millet, and triticale. Whole grains represent the intact grain, containing the endosperm, germ, and bran. The endosperm is largely composed of starch with some protein, whereas the bran contains most of the dietary fiber and many compounds thought to be highly bioactive, including phenolic acids, flavonoids, and vitamin E. The germ is rich in vitamins, minerals, and oil, and also contains a variety of antioxidants, including vitamin E.

Unsurprisingly, cereals show great variation in their composition of components thought to have health benefits. For example, oats and barley contain substantial amounts of β-glucans, a viscous and highly fermentable type of dietary fiber, whereas wheat, corn, and rice have little β-glucans. There are similar wide variations in antioxidant capacity among the whole grains. Nevertheless, there are sufficient commonalities among the cereals that it is still useful to consider them as a group in terms of colon cancer prevention.

The dietary fiber from whole grains has long been postulated as providing protection from colon cancer by several different mechanisms. One long-standing hypothesis is that dietary fiber reduces contact of potential carcinogens or procarcinogens with the colon, either by dilution of potential carcinogens or procarcinogens due to fecal bulking or by reducing exposure due to a decreased colonic transit time. Another potential mechanism involves the increased production of short chain fatty acids within the colon due to greater quantities of fermentable substrate for colonic bacteria. Of the short chain fatty acids, butyrate has been of particular interest due to many in vitro studies showing that butyrate inhibits growth of cancer cells, causing normalization of cancer cells, or increases cancer cell elimination by increased apoptosis [127]. Yet another potential dietary fiber mechanism is the promotion of the growth of probiotic bacteria (such as bifidobacteria) by fructans (such as inulin). Although increasing probiotic bacteria in the colon by feeding prebiotics reduces colon cancer risk in animal models [128,129], it appears unlikely that humans consuming a normal cereal-containing diet could consume a sufficient quantity of fructans to significantly increase the colonic bifidobacteria population [130]. Therefore, this particular mechanism of chemoprevention may not be relevant to humans not consuming supplements of fructans.

Another oft-discussed potential mechanism of chemoprevention by whole grains is the delivery of antioxidants from whole grains. There are two issues with regard to this mechanism. First, the ability of antioxidants to reduce colon cancer risk is still in doubt. Trials in humans and animal models of colon cancer do not provide strong support for a reduction in risk by α-tocopherol, the form of vitamin E commonly found in supplements, although a mixture of tocopherols shows some promise [131]. For most other natural compounds present in foods, it is uncertain whether the chemopreventive benefit they provide is due to their antioxidant effect or some other property. The second issue is the often poor bioavailability of compounds in cereals with antioxidant activity. For example, ferulic acid, the major phenolic acid in cereals, displays antioxidant activity in vitro [132], but is almost entirely bound within the cereal matrix [133] and therefore poorly available for absorption. Consistent with this is the finding that in diabetic rats, who exhibit elevated levels of oxidative stress, feeding cereal-based diets had no effect on markers of oxidative stress [134].

A number of other compounds found in cereals have been shown, in purified form, to reduce colon cancer risk. These include phytic acid [135,136], sphingolipids [104], and lignans [137] (compounds with a diphenolic ring structure that have phytoestrogen activity). However, whether these compounds, either alone or in combination, contribute significantly to chemoprevention by cereals is difficult to ascertain, in part due to questions about bioavailability.

Thus, cereals contain a plethora of bioactive compounds that could explain any observed chemopreventive effects. As with other whole foods, determining which compound or combination of compounds is responsible for chemoprevention is a difficult task.

Animal studies. Very few studies have examined the effect of whole versus refined grains on colon cancer risk in animal models. Maziya-Dixon et al. [138] fed red and white flour, in both the whole and refined forms, to mice given a chemical carcinogen. After 40 weeks, mice fed the wheat-containing diets did not differ from the wheat-free control diet tumor incidence. Interestingly, though, mice fed the red wheat diets, regardless of refining state, had significantly lower tumor incidence that mice fed white flour, again regardless of refining state. In other words, it was wheat color, not the state of refinement, which influenced tumor incidence. The importance of wheat color, as opposed to state of refining, was confirmed in a study in carcinogen-treated rats, where feeding red wheat, either whole or refined, reduced colonic ACF relative to white wheat [139]. The importance of wheat color was confirmed and extended in a study where it was shown that carcinogen-treated rats fed refined red wheat had fewer MDF than those fed refined white wheat, when fed only in the late postinitiation stage (when the wheat diets were fed 54 days after carcinogen treatment), as well as less β-catenin, indicating less dysregulation of the Wnt signaling pathway [140]. In another study, whole and refined wheat were fed to rats given HAA as a carcinogen. No difference was found between the groups fed whole and refined wheat in the number of colonic ACF [141], although it should be noted that the number of

ACF per animal was extremely small. Thus, in the few studies investigating wheat, the evidence suggests that it is the color of the wheat, not whether it is whole or refined, that is most important in terms of chemoprevention.

Given the paucity of studies in which whole and refined grains have been directly compared, an alternative is to examine studies in which bran feeding has been investigated. This is an imperfect comparison, as whole grains differ from refined grains by the inclusion of both bran and germ in the whole grain. However, as germ represents only about 2.5% of the whole grain, in the case of wheat, this is likely a useful approach.

The vast majority of studies that used cereal bran examined wheat bran, usually at dietary concentrations of 15–20%. Using carcinogen-treated rats, most have found a reduction in colon tumor incidence [142–150]. A study using Min (multiple intestinal neoplasia) mice, which have a mutated *Apc* gene, similar to the mutation in familial adenomatous polyposis patients, and thus spontaneously develop intestinal tumors, reported fewer tumors after feeding brans of several wheat varieties. The efficacy of tumor number reduction inversely correlated with the orthophenolic content (e.g., ferulic acid) of the wheat from which the bran was derived [151]. In addition, several studies have reported a decrease in ACF in carcinogen-treated rats fed wheat bran, relative to rats fed a fiber-free or low fiber diet [148,152]. A study in carcinogen-treated mice found that a diet of 20% wheat bran reduced adenomas relative to a fiber-free control diet, but had no effect on adenocarcinoma incidence [153]. Several studies have even reported an enhancement in tumor incidence in carcinogen-treated rodents fed wheat bran. Carcinogen-treated mice fed 20% wheat bran, from either soft winter white or hard spring wheat, had a much higher incidence of colon tumors than animals fed a fiber-free diet [154]. Similarly, carcinogen-treated rats fed a 20% wheat bran diet also had a greater number of colonic tumors compared to animals fed fiber-free diet, but this was only observed when the wheat bran was fed during carcinogen administration [155]. Overall, however, studies in carcinogen-treated rodents support a reduction in tumor development with feeding of wheat bran.

Fewer studies have been carried out with brans of cereals other than wheat. Oat bran fed to carcinogen-treated rats resulted in a greater number of colonic tumors in the proximal colon, but not the distal colon, compared to a fiber-free control [156]. In Min mice, however, oat bran feeding had no effect on the development of intestinal tumors [157]. Feeding rye bran to carcinogen-treated rats resulted in fewer colon tumors and fewer ACF, compared to the cellulose-fed control group [158]. However, rye bran fed to Min mice resulted in either no effect [157,159] or an increase in intestinal tumors [160]. Barley bran was shown to reduce tumor incidence in carcinogen-treated rats compared to cellulose-fed control group [143], whereas corn bran increased colon tumor incidence in carcinogen-treated rats [142,161]. Finally, rice bran at 30%, but not 10% of the diet, reduced intestinal tumor number in Min mice compared to a cellulose-fed control group [162], but had no effect in carcinogen-treated rats [142].

Thus, animal studies provide considerable support for protection against colon cancer by wheat, primarily based on studies of wheat bran, although there are indications that the color of the wheat is more important than the state of refinement. For other cereals the studies are highly inconsistent and are too few to ascertain whether they have a chemopreventive effect or may even promote colon cancer.

Human studies. The evidence for an association between cereal grains and colon cancer was reported as limited according to the WCRF/AICR report of 2007 [20]; in the 2011 WCRF/AICR CUP report [49], whole grains are folded into the category of foods containing dietary fiber with the conclusion that there is convincing evidence that foods containing fiber decrease colon cancer risk. Specifically looking at whole grains, CUP meta-analyses showed a 16% decreased risk per three servings per day. Since the 2011 CUP report, Kyro et al. [163] reported that intake of whole-grain products, and specifically whole-grain wheat, was associated with lower incidence of colorectal cancer but not colon cancer in a large Scandinavian prospective cohort. However, in a cohort of Norwegian women whole-grain bread was not associated with colorectal cancer, but there was a weak protective association with proximal colon cancer [164]. Two other studies used plasma alkylresorcinols, a biomarker of whole-grain intake, to investigate the association of whole grains with colon cancer [165,166]. Alkylresorcinols are primarily found in the bran of wheat and rye and their concentrations in plasma have been used as an indicator of short-term and medium-term consumption specifically of whole-grain wheat and rye products. Both studies observed an inverse association between plasma alkylresorcinol concentrations and distal colon cancer incidence [165–167]. In sum, there is evidence that whole-grain wheat and rye may reduce colon cancer risk, that the effect may be specific to distal versus proximal colon cancer, and that use of the alkylresorcinol biomarker may increase precision in estimating risk compared to food frequency questionnaires. Further evidence that grains may influence risk of colon cancer includes studies where an increased risk was observed with intake of refined grains [168–170]. However, it should be noted that whole-grain intake is reported to be associated with various factors that could also be related to decreased risk of colon cancer, such as healthy lifestyle, socioeconomic, and dietary factors [171].

Using putative intermediary biomarkers of colorectal cancer, a few intervention trials have been conducted [172–175].

However, they typically used an isolated grain fraction such as the bran or fiber instead of actual whole-grain foods, or else combined high intake of whole-grain foods with other practices that may have an independent effect (e.g., low fat, high vegetable intakes) and thus make it difficult to assess effects attributable specifically to whole-grain intake.

VI BEVERAGES

Proposed mechanisms for influencing cancer risk. Three types of nonnutritive beverages have been studied extensively for potential protective effects against colon cancer (coffee and tea) and harmful effects (alcoholic beverages). The interest in coffee stems from evidence that coffee components such as dieterpenes (cafestol and kahweol) mitigate the genotoxicity of HAAs [176–178]; increase the activities of enzymes that generally detoxify carcinogens (UGTs and GSTs), decrease the activity of some carcinogen-activating enzymes (*N*-acetyltransferases and SULTs), and decrease HAA-mediated genotoxicity [176–181]. Additionally, cafestol and kahweol have antioxidant properties, and induce γ-glutamylcysteine synthetase (the rate limiting enzyme in glutathione synthesis) [182,183]. Human consumption of Italian-style coffee (or espresso) increases plasma glutathione and unfiltered French press coffee increases glutathione content in colorectal mucosa [184,185]. Moreover, coffee is rich in phenolic acids, flavonoids, and melanoidins, many of which have demonstrated antioxidant properties that can depend on degree of roasting [186–188]. In vitro studies suggest that chlorogenic and caffeic acids found in coffee may decrease cell proliferation, cell invasion, angiogenesis, and metastasis, further supporting the hypothesized chemopreventive potential of coffee [189–193].

Both green tea and black tea have also interested cancer prevention researchers. Theaflavin-2 (black tea polyphenol) exhibits antiinflammatory and proapoptotic activities [194]. Green tea polyphenols inhibit proliferation and invasiveness of colon cancer cells [195], induce apoptosis and demonstrate antioxidant activity [12,196], modulate GST activity [196], and are antiinflammatory [19].

Alcohol, on the other hand, may have detrimental effects. For example, it may enhance penetration of carcinogens by functioning as a solvent; be metabolized to reactive metabolites such as acetaldehyde; produce prostaglandins, lipid peroxidation, and free-radical oxygen species; and/or alter folate metabolism [20,197,198].

Animal studies. Very few studies have examined the effect of coffee on colon cancer in animal models. Mori and Hirono [199] examined the effect of coffee in rats treated with cycasin, a compound derived from the cycad sago palm that is metabolized to the colon carcinogen methylazoxymethanol. In their study, neither coffee nor cycasin alone induced a significant number of tumors. However, coffee and cycasin combined resulted in a high incidence of tumors, indicating that coffee promoted the carcinogenicity of cycasin. Recently, the influence of organic and conventional coffees, each at three different dietary levels (5, 10, and 20%), as well as 4% powdered coffee (eight coffee groups in all), was examined in carcinogen-treated rats [200]. The authors reported no significant effect of the coffee on ACF number. However, it should be noted that every coffee group had a greater number of ACF than the coffee-free control group, in most cases twice as many, raising the question as to whether further statistical analysis might have led to a different conclusion. In contrast, in a study in which 1% coffee was fed to carcinogen-treated rats, no difference in ACF number was found in the coffee group compared to the control group [201]. Since caffeine alone has been shown to increase tumor number and decrease long-term survival in rats treated with an HAA [202], it may be that the caffeine in coffee promotes carcinogenesis, but that phytochemicals within coffee counteract this effect when the quantity of caffeine is low.

Considerably more attention has been focused on the potential chemopreventive effects of tea, both green and black. In a study using an HAA as the carcinogen, green tea, but not black tea, was found to reduce ACF in rats [203]. However, in rats treated with azoxymethane as a carcinogen, the group fed black tea, but not green tea, had fewer adenomas [204]. There were also fewer cancers in the black tea group, but this reduction was not statistically significant. A second study using the colon-specific carcinogen azoxymethane reported that green tea did not reduce the number of ACF [205]. Further, Weisburger et al. [206] reported that extracts of black or green tea given to azoxymethane-treated rats had no influence on tumor development. In contrast, in mice treated with azoxymethane and fed a high fat background diet, mice given 0.6% green tea (0.6 mg tea solids/mL) had significantly fewer ACF relative to mice given only water [207]. White tea, which is the least processed type of tea, and therefore has the greatest quantity of the putative chemopreventive catechins, was found to greatly reduce ACF in rats administered an HAA as the carcinogen [208]. Yet, in a second study by the same investigators, white tea was found to *promote* the formation of colon tumors in rats administered an HAA [202]. Clearly, the results from animal studies on tea and colon carcinogenesis are highly inconsistent, and no conclusions can yet be drawn as to whether tea, in any form, is chemopreventive.

Animal studies examining the effect of fermented beverages such as beer and wine are very few. Feeding beer to carcinogen-treated rats led to a significant reduction in gastrointestinal tumor incidence, but not colon tumor incidence [209]. This finding is consistent with two studies in

which colonic tumor incidence was unaltered by beer consumption, although it led to a shift in tumor incidence from the right and transverse colon to the left colon [210,211]. However, in a more recent study, feeding freeze-dried beer, which contains no ethanol, nor the volatile components of beer, reduced ACF formation when fed in both the initiation and promotion phases of carcinogenesis [212]. When the freeze-dried beer was fed only in the promotion phase, the effect was somewhat attenuated. Ethanol alone had no effect on ACF formation. In contrast to the situation with beer, in which there are studies of feeding the beverage itself, there appear to be no studies in which wine was fed to carcinogen-treated animals. Studies with extracts from wine have been inconsistent. In one study, feeding an extract of complex polyphenols and tannins from wine did not reduce the number of ACF in carcinogen-treated rats [213]. Interestingly, in two subsequent studies by the same investigators, a polyphenolic extract of red wine reduced adenoma incidence in carcinogen-treated rats [214,215]. Given that the polyphenolic extract differs from wine itself, and that the results with the extracts were inconsistent, no conclusion can be drawn regarding the influence of wine consumption on colon carcinogenicity from animal studies.

Human studies. Historically, evidence for a protective association of coffee intake against colon cancer has been somewhat inconsistent. However, there is greater consistency in more recent reports from meta-analyses of prospective cohort and case−control studies, and have mostly been consistent in showing inverse associations between coffee intake and colon cancer risk [216−219]. In particular, the meta-analysis by Gan et al. [218] based solely on prospective cohort studies (19 studies with >22,600 cases combined), showed a threshold ≥5 cups/day as associated with decreased colon cancer risk, which is similar to the earlier suggestion of a nonlinear relationship and report by Tian et al. [220] that ≥4 cups/day is associated with decreased risk of colon cancer. Gan et al. posit that a nonlinear relationship is biologically plausible [218] given coffee's complex mixture of a thousand compounds, some of which may be detrimental (heterocyclic amines, aromatic hydrocarbons, acrylamide, caffeine) as well as the many bioactive compounds discussed earlier. Nonetheless, challenges persist in clearly determining the coffee and colon cancer relationship. For example, subgroups of populations may be more responsive to the effects of coffee, and insufficient measurement of the method of coffee preparation or type of coffee. Instant, filtered, and percolated coffee have negligible amounts of the bioactives cafestol and kahweol (paper filters significantly trap cafestol and kahweol) [221,222]; espresso has intermediate amounts; and Turkish, cafetière, and Scandinavian-type boiled coffees have large amounts [223]. Of note, Gan et al. detected stronger associations in older studies and put forth the notion that coffee preparation methods may have changed over time [218].

The majority of studies on tea have primarily focused on green tea, and frequently indicated a protective effect, but an assessment of the evidence was deemed limited and inconclusive in the WCRF/AICR 2007 report [20]; there have been no further updates on tea and colon cancer risk by WCRF/AICR. However, studies since 2007 seem to consistently report a protective association. Examples include an inverse relationship reported between green tea intake and colon cancer in a cohort of Chinese women [224]. Also, in a randomized control trial of 136 colorectal adenoma patients, adenomas were removed and patients randomized to 1.5 g green tea extract per day or no supplement for 1 year; there were fewer patients with metachronous adenomas in the supplement group ($p < 0.05$) and the size of relapsed adenomas was smaller in patients in the supplement group compared to the control group ($p < 0.001$) [225]. Conversely, in a Singapore cohort there was suggestion of an actual increased risk with green tea for advanced colon cancer in men and no association with black tea [226]. Using urinary biomarkers of tea polyphenols, Yuan et al. observed that in comparing the highest tertile of urinary epigallocatechin to undetected epigallocatechin there was an inverse association with colon cancer [227]; there was a similar inverse relation seen for 4′-*O*-methyl-epigallocatechin, and the strongest protective effect was observed for regular tea drinkers with high levels of both urinary polyphenols [227]. Lastly, in a cohort of Chinese men, green tea intake was associated with reduced risk of colon cancer in male nonsmokers [228]. However, a meta-analysis by Wang et al. [229] based on prospective cohort studies of green tea showed an inverse association with colon cancer only in the Shanghai population. A subsequent meta-analysis by Zhang et al. [230] of prospective studies of all kinds of tea showed no association between the green tea subtype and colon cancer risk.

Alcohol is one of a few dietary exposures with some of the most convincing human evidence for increasing risk of colon cancer [49]. For instance, results of a meta-analysis that included 16 cohort studies indicated that high intake of alcohol increased risk of colon cancer that was equivalent to a 15% increased risk of colon cancer for an increase of 100 g of alcohol per week [231]. A subsequent meta-analysis sought to clarify the dose-risk relation of alcohol to colorectal cancer and found a positive association with >1 drink per day, and the association of alcohol drinking with colorectal cancer did not differ by colon and rectal subsites [232]. A recent meta-analysis that utilized 12 case−control and 9 cohort studies that assessed the risk related specifically to beer intake, reported increased risk for colorectal cancer that

was stronger for rectal (30% increased risk) than colon cancer (5% increased risk) [233].

VII SUMMARY

With regard to fruits, vegetables, and legumes intake, there is some suggestion from animal studies of protection against colon cancer by fruit and soy, but not other legumes. The animal-based evidence for protective effects from vegetables is stronger. Evidence from human studies is inconsistent. While animal data are generally not supportive of meat increasing colon cancer risk, there may be an important interaction with dietary calcium, such that meat may promote colon cancer in the context of a low calcium diet. Human studies are more consistent with regard to meat consumption increasing colon cancer risk, although a clear mechanism is lacking. Strong data from animal studies are supportive of a protective effect from calcium, but the animal data is inconsistent for vitamin D and virtually absent for milk and dairy. There is some consistency in the human data regarding milk and dairy intake, and possibly calcium, but not regarding vitamin D. Relatively few studies with whole grains have been conducted in animals. Those examining wheat suggest that wheat color, not refining state (i.e., whole vs refined), is the important factor for reducing colon cancer risk. Studies using only wheat bran are supportive of a chemopreventive potential. There is little support from animal studies for other cereals being protective against colon cancer. Evidence in humans is limited on whole grains, but is generally encouraging of potential protection. Finally, with regards to nonnutritive beverages, few animal studies have been done on coffee and the tea and alcohol data are inconsistent. Likewise, human data are inconsistent for coffee and somewhat inconsistent for tea, but strong or convincing for alcohol increasing risk of colon cancer.

While this chapter presented the current state of the evidence for associations between food groups and colon cancer, it cannot be overlooked that foods are rarely eaten in isolation; they are consumed as part of a larger, complex dietary pattern. Interest and methodological developments are improving for assessment of the associations of different overall dietary patterns with colon cancer risk. For instance, a study in the United States (North Carolina) investigating risk modification of colon cancer identified three distinct dietary patterns and compared their associations with colon cancer [234]. The three dietary patterns were "Western-Southern" (high in red meats, fried foods, cheese dishes, sweets), "fruit-vegetable" (high in fruits, vegetables, legumes), and "metropolitan" (salad, seafood, pastas, Mexican foods, turkey, chicken, veal, lamb, cruciferous vegetables, alfalfa sprouts). The "fruit-vegetable" pattern was significantly inversely associated with colon cancer risk in Whites but not in African-Americans. A Canadian case–control study assessed three patterns: Meat-diet pattern (high intake of red and processed meat), Sugary-diet pattern (high intake of fruit pies, tarts, desserts, and sweets), and Plant-based pattern (fruits, vegetables, whole grains); increased risk of colon cancer was observed for the Sugary-diet pattern (proximal and distal) and the Meat-diet pattern (distal) [235]. In a large cohort of women in the United States, a diet pattern characterized by higher meat, fish, and sweetened beverage intake but lower coffee, high fat dairy, and whole-grain intake was associated with colon cancer in those who were overweight or sedentary [236]. For comparison, it was observed in a Japanese cohort that a high dairy, high fruit and vegetable, low alcohol dietary pattern was inversely associated with colorectal cancer, but only rectal cancer upon analyses by subsite; no associations were observed for a Japanese dietary pattern or an "animal food" pattern [237]. Lastly, a meta-analysis that included eight cohort studies and eight case–control studies found an increased risk of colon cancer associated with a "western" diet of high red and processed meat intake, and a decreased risk associated with a "healthy" pattern of high fruit and vegetable intake [238].

There is a general paucity of whole food studies in the body of literature on nutrition and colon cancer, which represents a severe limitation in diet and cancer research. People eat food as opposed to individual constituents or fractions and a presumption that there are no differences between pure individual constituents and intact foods is clearly false in some cases [57]. A greater use of foods in animal and human studies is needed to get us closer to developing appropriate dietary recommendations to make regarding cancer prevention. Additionally, there are relatively few whole food feeding intervention trials in humans. While of necessity they rely on intermediary markers of colon cancer, they could prove valuable in testing or confirming hypotheses and findings from population-based studies and animal studies [239]. Furthermore, future human studies may need to better account for genetic variation among individuals which can not only impact metabolism of carcinogens (as briefly mentioned earlier) but may impact tolerance, absorption, and metabolism of the putative chemopreventive constituents in the diet [240].

Chapter 37

Intestinal Microbiota and Diet in Health

Merlin W. Ariefdjohan, Abby Dilk, Onikia N. Brown-Esters and Dennis A. Savaiano
Purdue University, West Lafayette, IN, United States

I INTRODUCTION

The human gastrointestinal (GI) tract contains bacterial communities that are diverse and complex. This intestinal microbiota plays an important role in digestion and production of essential vitamins and protects the GI tract from pathogen colonization. Although the intestinal microbiota appears to be relatively stable, it can be altered by environmental factors such as disease, antibiotics, and diet. Furthermore, it has been postulated that dominant bacterial groups influence the well-being of their host by forming close interactions with the mammalian cells.

Over the past decade, there has been substantial progress in understanding the GI microbe−host relationship, primarily because of methodological advancements. Consequently, the mechanisms by which the intestinal microbiota influences human health and disease are becoming better understood. Scientific breakthroughs in this field have permitted researchers to move from observation to the prediction of disease using biomarkers based on the metabolic capabilities of intestinal microbiota. Dietary intervention strategies including the consumption of prebiotics, probiotics, and synbiotics have also been developed to enhance overall health and reduce disease incidence. Therefore, understanding the intricate relationship between GI tract microbiota and health is important for improving the quality of life for many.

This chapter serves to provide a comprehensive review of the following: (1) the concept of intestinal microbiota, (2) the methodology used to investigate the intestinal microbiota and their limitations, (3) the influence of diet on intestinal microbiota, and (4) future directions in the field.

II DISTRIBUTION AND DIVERSITY OF THE HUMAN INTESTINAL MICROBIOTA

When the word *ecosystem* comes to mind, most people conjure up images of the rain forest with its myriads of animals, plants, and insects or the oceans teeming with fish, algae, and phytoplankton. Rarely do we think of the ecosystem in our body in the form of bacterial communities residing on the skin, oral cavity, genitals, and GI tract. On average, the human GI tract (i.e., small intestine and large intestine [colon]) is 27 ft long. Its surface area is greatly enhanced by the formation of microvilli on the surface of each intestinal villus (Fig. 37.1). Because of this anatomical folding, the GI tract creates a large surface area for bacterial colonization (approximately 150−200 m^2 or 1614−2153 ft^2) [1]. As a comparison, the human skin covers only approximately 2 m^2 (21.5 ft^2). The adult GI tract is estimated to harbor up to 10^{14} bacteria/g of intestinal contents. This number easily exceeds the population size of other microbial communities associated with the human body. Remarkably, the microbial population in the GI tract is approximately 10 times greater than the total number of cells in the human body [2].

The intestinal microbiota of the adult GI tract is composed of all three domains of life—Bacteria, Archaea, and Eukarya, with bacteria having the highest cell densities [3]. The flora is distributed along the entire GI tract from the esophagus to the rectum (Fig. 37.2). The intestinal microbiota is also distributed in a vertical gradient within a specific part of the GI tract. Four microhabitats have been described (Fig. 37.3): the intestinal lumen, the unstirred water layer, the mucous layer at the surface of the mucosal epithelial cells, and the mucus layer in the intestinal crypts [4].

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00037-0

The population size and diversity of the intestinal microbiota are influenced by intrinsic factors such as pH, secretion of intestinal fluids, and transit time. The stomach and duodenum create a harsh environment for bacterial colonization. The former has low pH (ranging from 2.5 to 3.5) due to secretions of intestinal fluids (e.g., hydrochloric acid), and the latter has a short transit time. Consequently, approximately only 10^1-10^3 bacteria/mL of intestinal content reside in the stomach and duodenum, with a majority of them being transient. As the environment becomes less acidic and transit time gradually increases toward the distal end of the GI tract, the microbiota community flourishes both in number and in diversity (Fig. 37.2).

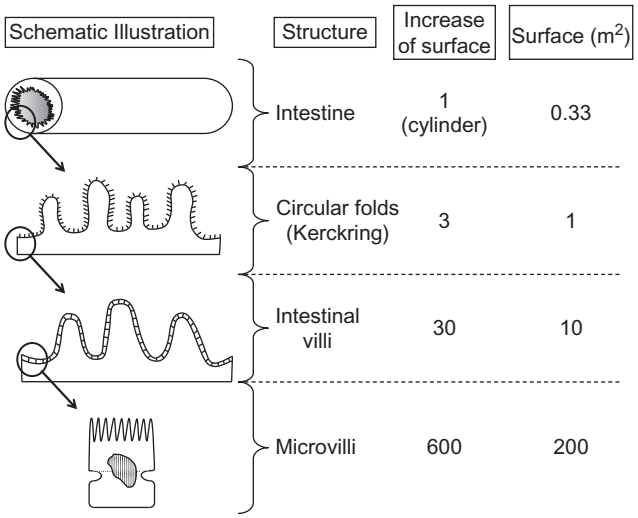

FIGURE 37.1 Folding on the intestinal mucosa significantly increased the surface area of the GI tract, providing a large surface area for bacterial colonization. *Modified from F. Waldeck, Funktionen des magen-darm-kanals, in: R. Schmidt, G. Thews (Eds.), Physiologie des Menschen, Springer, Berlin, 1990, p. 24.*

In comparison to the other parts of the GI tract, the colon has the slowest cell turnover rate, the lowest redox potential, and the longest transit time. Hence, the colon harbors the most diverse and the highest number of bacteria (Fig. 37.2). The colon is the major site for bacterial fermentation of nondigestible food components. Approximately $10^{10}-10^{12}$ bacteria/mL of intestinal contents reside in the colon. This microbial population includes more than 500 species belonging to more than 190 genera [5]. Because of the complexity of collecting samples from within the GI tract, most studies investigating the intestinal microbiota have been based on fecal sample analyses. Thus, our current understanding of the population size may not accurately reflect "true" species abundance and their relative importance in metabolic processes [6].

A few major groups of strict anaerobes dominate the colonic microbiota community, including *Bacteroides* spp., *Eubacterium* spp., and *Bifidobacterium* spp. [7]. Facultative aerobes such as *Enterobacter* spp., *Streptococcus* spp., and *Lactobacillus* spp. are also present as subdominant flora. Minor groups of pathogenic and opportunistic microbiota (e.g., *Clostridium* spp. and *Vibrio* spp.) are also present in low numbers [8]. The metabolic functions of many of the dominant bacterial species in the GI tract are not well understood. However, several studies indicate that *Bifidobacterium* spp. and *Lactobacillus* spp. are intestinal bacterial species that directly contribute to health [9] (Fig. 37.4).

III BACTERIAL COLONIZATION, SUCCESSION, AND METABOLISM

A Colonization and Succession

The GI tract of a fetus is believed to be sterile [10,11]. Bacterial colonization occurs immediately at delivery and gradually becomes more extensive as the newborn is introduced to the living environment and various foods [6,10–14]. Previous theories suggested that bacterial colonization of a breast-fed infant's gut was solely the result of contamination to the infant's oral cavity or from the mother's skin [15]. However, recent studies indicate that *Lactobacillus* spp. and *Bifidobacterium* spp. can translocate from the maternal GI tract, endogenously become incorporated into the mammary glands, and then reach the fetal GI tract where the bacteria can colonize. Furthermore, human milk oligosaccharides (HMOs) have been shown to enhance the growth of certain bacteria,

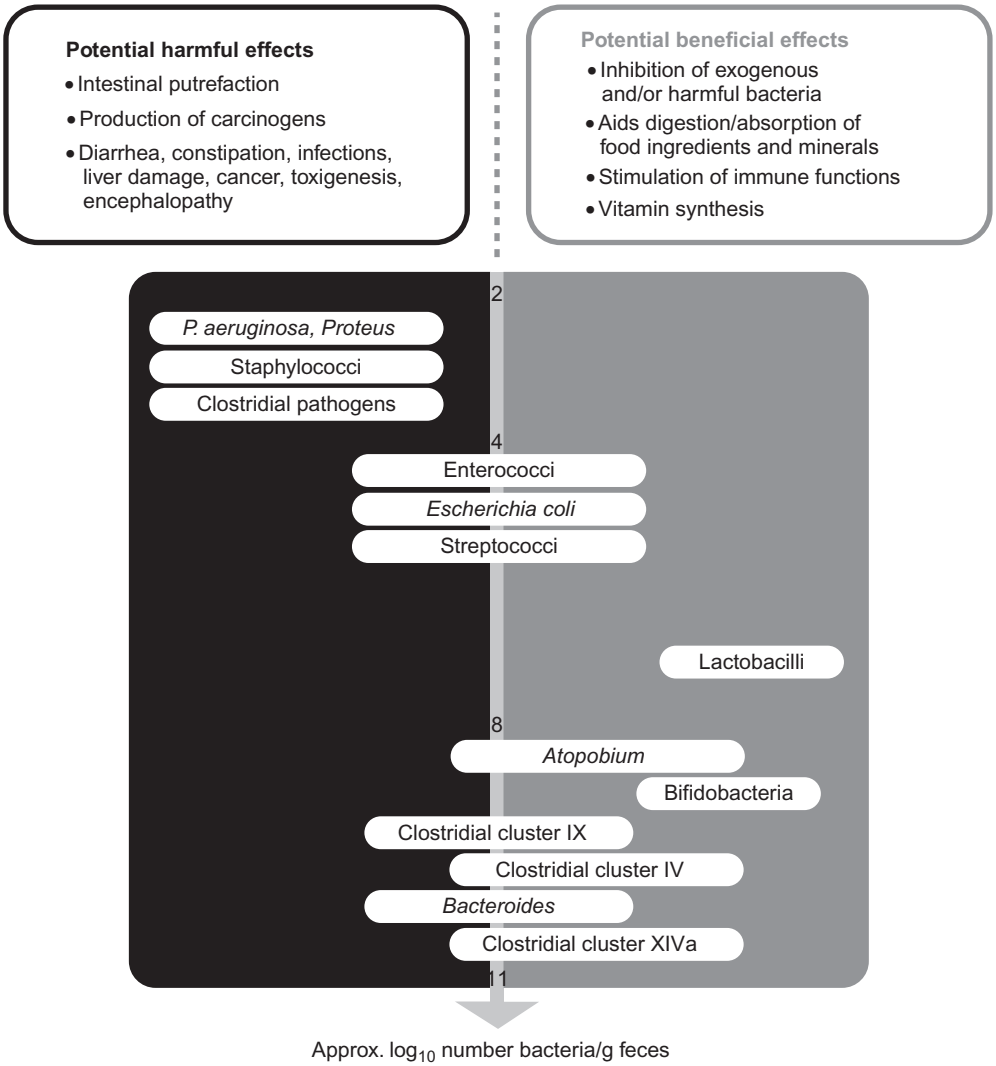

FIGURE 37.4 Dominant intestinal microbiota as categorized into potentially harmful or health-promoting groups. *Reprinted with permission from L. Thomas, M. Flower, A guide for healthcare professionals:* Lactobacillus casei *Shirota and Yakult, Science for Health, Yakult, UK, 2006.*

including *Bifidobacterium longum bioar infantis* [16]. HMOs also block pathogen adhesion, which can protect breast-fed infants from common infections, diarrhea, and even HIV transmission from the mother. This obstruction results from HMOs structural similarity to intestinal epithelial cell surface glycans that pathogens must attach to before invading the host. HMOs have also been shown to induce apoptosis and differentiation of intestinal epithelial cells. Bacterial colonization of the GI tract occurs in four phases [17,18]. Phase I, the initial acquisition phase, occurs between birth and 1 or 2 weeks. Phase II is considered a transitional period that takes place during lactation with either breast milk or formula. This event typically starts at the end of the second week after-birth and ends when supplementary feeding begins. Phase III is initiated with the introduction of other food sources, especially at weaning (e.g., when breast milk or formula is supplemented with solid foods). Phase IV follows once weaning is completed and the child is introduced to an adult diet.

In phase I, *Enterobacter* and *Streptococcus* appear to colonize the infant GI tract within 48 hours of birth. *Escherichia coli* follows soon after. These bacteria are thought to create a favorable environment for subsequent colonization by anaerobic bacteria including *Bacteroides* spp., *Bifidobacterium* spp., and *Clostridium* spp. This secondary colonization usually occurs within 4–7 days [6,19,20]. During later stages of phase I, a marked reduction in the levels of *E. coli* and *Streptococcus* was observed in the stools of exclusively breast-fed infants. This event was followed by a decrease in the levels of *Clostridium* and *Bacteroides* spp., whereas *Bifidobacterium* spp. gradually dominate. It appears that these trends are not as distinct in formula-fed infants [17]. Breast-fed infant GI microbiota appears to be more stable and predominantly populated by *Bifidobacterium* and *Bacteroides* spp., whereas formula-fed infant microbiota is more diverse but less stable, containing less *Bifidobacterium*, *Lactobacillus*, and *Staphylococcus* spp. but more *Bacteroides*, *Enterococcus*, and *Streptococcus* spp. [21]. The intestinal microbiota of formula-fed neonates also harbors members of the Clostridia class and Enterobacteriacae family, which are potential pathogens. However, the lesser diversity seen in breast-fed infants' intestinal microbiota is disadvantageous and may be associated with several diseases.

In phase II, *Bifidobacterium* spp. remain at high levels and become the dominant bacterial group in the intestinal microbiota of breast-fed infants [17]. Apparently, this is different from the intestinal microbiota profile of formula-fed infants, in whom relatively high numbers of *Bacteroides* spp., *Clostridium* spp., and *Streptococcus* spp. are present and *Bifidobacterium* spp. is no longer the dominant group [17].

The introduction of new foods to infants in phase III results in a major shift in microbial succession [12,13,17,20]. This shift is more significant in breast-fed infants. Following weaning, the intestinal microbiota of breast-fed infants gradually changes to resemble the community found in formula-fed infants. *Clostridium* spp., *Streptococcus* spp. and *E. coli* reappear, followed by *Bacteroides* spp. and other anaerobic gram-positive cocci such as *Peptococcus* spp. and *Peptostreptococcus* spp. [20]. At the end of phase III, differences in the intestinal microbiota of breast-fed and formula-fed infants are no longer observed.

Bacterial succession continues until weaning is completed (i.e., beginning of phase IV). This phase is denoted by a continued increase in *Bacteroides* spp. and anaerobic gram-positive cocci. Colonic levels of *Bifidobacterium* spp. continue to remain high. At this time, *Bifidobacterium* spp. is found in all individuals regardless of their starting diet [17]. *Escherichia coli* and *Streptococcus* spp. gradually decline to a typical adult level (i.e., approximately 10^6–10^8 bacteria/g of feces) [22]. *Clostridium* spp. is also present [22]. At the end of phase IV, the infant intestinal microbiota begins to resemble the bacterial community profile of an adult, which is typically diverse but relatively stable [12,13,18] (Fig. 37.5). Phase IV is usually attained by 2 years of age [12,13,20].

During adulthood, the intestinal microbiota can be modified by external factors including diet, environment, and medication. Due to reasons that are still unclear, the number of bacterial species residing in the GI tract declines with age [23–25] (Fig. 37.5). Typically, the population levels (in terms of $\log_{10}$ CFU1g) of *Bifidobacterium* spp. are markedly decreased and reduced to one or two dominant species, particularly *B. adolescentis* and *B. longum* [23,26]. In contrast, *Enterococcus* spp., *Lactobacillus* spp., *Bacteroides* spp., and *Clostridium* spp. are increased in GI tracts of the elderly [23,25].

B Metabolic Consequences of Bacterial Colonization and Succession

Changes in the intestinal microbiota of infants due to bacterial colonization and succession are reflected metabolically, especially in terms of fecal short-chain fatty acid (SCFA) profiles [27]. During the period when *Bifidobacterium* spp. predominate in the GI tract of breast-fed infants, acetic acid is the major SCFA detected [28,29]. Accumulation of acetic acid decreases the stool pH from values originally observed at birth. This trend is expected because *Bifidobacterium* spp. are a major producer of acetic acid. In formula-fed infants, however, lower levels of acetic acid are present and the stool pH tends to rise slightly. Therefore, changes in the fecal SCFA profile of breast-fed infants appear to be more profound than those in formula-fed infants [17,29]. Breast-

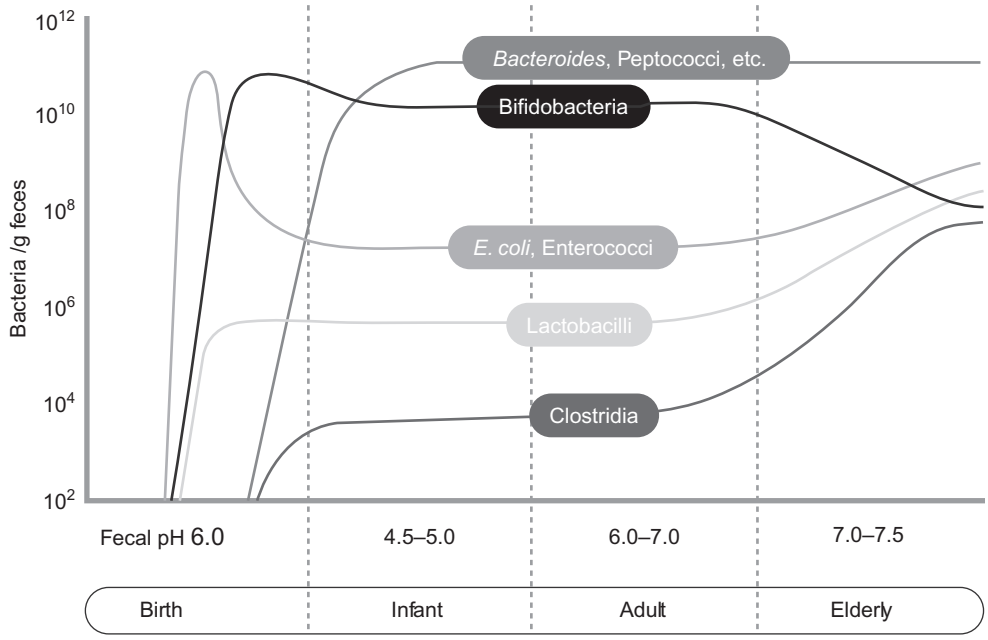

FIGURE 37.5 Bacterial succession throughout the lifetime. *Reprinted with permission from L. Thomas, M. Flower, A guide for healthcare professionals:* Lactobacillus casei *Shirota and Yakult, Science for Health, Yakult, UK, 2006.*

fed infants are also observed to exhibit a gradual increase in total SCFA. Concurrently, lactic acid decreases while acetic and propionic acid increase. At later stages of weaning, butyric acid production gradually increases as well. In contrast, changes in the fecal SCFA profile of formula-fed infants are less profound [17,29,30]. This may be attributed to fewer fluctuations in the GI microbiota in these infants.

The ability to ferment complex carbohydrates from diet may also reflect the variability in bacterial succession rate in breast-fed and formula-fed infants. Although variations exist among individual infants, fermentation capability appears to develop faster in formula-fed infants than in breast-fed infants [30]. This is expected because the colons of formula-fed infants are inhabited by more diverse bacterial strains and a greater population of gram-negative anaerobes, many of which are involved in the fermentation of complex carbohydrates. Unlike breast-fed infants, the colonic fermentation capacity of formula-fed infants does not vary significantly through weaning stages [30]. This observation suggests that the colonic microbiota of formula-fed infants matures faster than that of breast-fed infants and does not experience major shifts in composition [29–31].

C Factors Influencing Bacterial Colonization and Succession

In phase I of colonization, environmental factors introduce bacteria to the infant GI tract. With infants born by vaginal delivery, the length of the birthing process significantly influences the chance of detecting viable bacteria from the mouth and stomach of the newborn [32]. Infants born by cesarean section are exposed to and may acquire the mother's microbiota. However, initial exposure is most likely environmental (e.g., hospital condition, nursing staff, and other infants in the nursery) [33–36]. Cesarean sections may be associated with a 46% higher offspring risk of childhood obesity [37]. Furthermore, antibiotics used by the mother during the second or third trimester may be associated with a higher offspring risk of childhood obesity. Thus, these findings provide evidence that the gut microbiome influences health status later in life. In addition to mode of delivery, hygiene practices may influence the bacterial species introduced to the infant GI tract. For example, bacterial colonization of the GI tract of Pakistani infants born in poor areas with minimal sanitation occurred significantly earlier than in Swedish infants delivered in more sanitary conditions, regardless of delivery method [14].

There are numerous external and internal factors that shape the composition of the microbial community in the GI tract (Fig. 37.6). External factors include mode of birth, composition of the diet, sanitation of the living environment, and the use of medicines, especially antibiotics. Internal factors include changes in the physiological condition of the host (e.g., stress, health status, and aging) and conditions in the GI tract (e.g., pH, substrate availability, redox potential, transit time, flow of enteric fluid, and IgA secretions) [6]. A disruption of the "normal" intestinal bacteria may lead to the growth of those that are potentially harmful and physiologically manifest as a disease. Studies show that changes in diet, climate, aging, medication, illness, stress, and/or infection generally lead

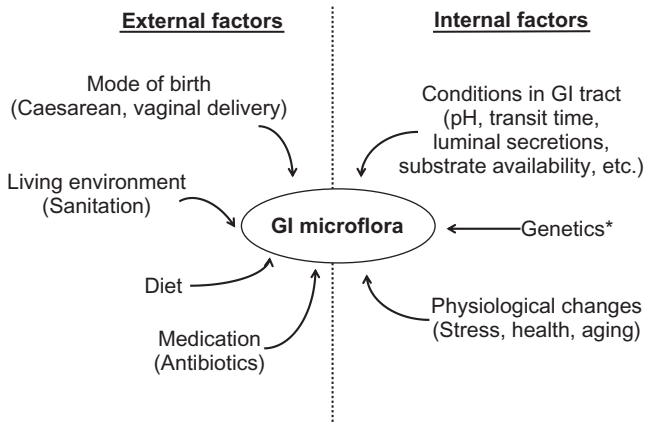

FIGURE 37.6 External and internal factors influencing bacterial succession in the GI tract. *Genetics has been speculated to play a role in intestinal microbiota succession, but the current body of literature has not provided strong evidence for it.

to an increase in anaerobes and *E. coli* in the small intestine and to an increase of *Enterobacter* and streptococci in the colon, with a concurrent decrease of *Bifidobacterium* spp. [37,38]. Although predicting the occurrence of a disease based on intestinal microbiota profile is currently not possible, it is hypothesized that a marked decline in intestinal bacteria that are beneficial to health, such as *Bifidobacterium* spp., will ultimately influence the health of the host.

IV FUNCTIONS OF THE GI TRACT MICROBIOTA

A Production of Vitamin K

Prothrombin, which is involved in blood clotting, is activated by vitamin K. Food sources of vitamin K are liver, eggs, milk, and spinach. However, this vitamin can also be synthesized by bacteria in the GI tract. Administration of antibiotics eradicates intestinal bacteria and consequently may diminish de novo vitamin K production. Newborn infants, whose GI tracts are typically devoid of bacteria, may be given an injection of vitamin K at birth to counter deficiency until their vitamin K-producing bacteria are established [39]. Another vitamin that is exclusively synthesized by bacteria is vitamin B_{12} (cobalamin) [40], which is important for the formation of red blood cells.

B Protection Against Pathogens

Colonization of the GI tract by the intestinal microbiota confers protection on the human host. A fully established GI tract microbiota community can "outcompete" pathogens for carbon and other energy sources, as well as for adhesion sites on the intestinal mucosa. Consequently, pathogens are less able to establish themselves on the intestinal mucosa and thus are prevented from causing physiological damage to the host [41]. Complex microbiomes may result in high expression of RegIIIγ by epithelial cells, which is a C-type lectin that restricts pathogen-epithelium contact [42]. This effect is likely dependent on IgA due to its ability to prevent bacterial adhesion and epithelial stimulation. Some species of indigenous intestinal microbiota may also produce bacteriocins that kill pathogens [43].

C Enhanced Histological and Physiological Development of the GI Tract and the Immune System

Intestinal microbiota plays a role in the development of intestinal mucosa and gut-associated lymphoid tissue (GALT). Evidence for this role was provided by comparative assessments of histological and physiological data from germ-free (GF) mice and conventionally raised (CONV-R) mice. GF mice are devoid of intestinal microbiota because they are delivered by cesarean and raised in a sterile environment. On the other hand, CONV-R mice are delivered and raised in a standard environment in order to acquire a "normal" intestinal microbiota. Histological data show that CONV-R mice have a higher epithelial cell turnover rate than that of GF mice (i.e., 2 days in CONV-R vs 4 days in GF). In addition, the secondary lymphatic organs of GF mice (e.g., GALT and spleen) are significantly less developed than those of CONV-R mice [3]. Other morphological abnormalities seen in GF mice include an enlarged cecum, larger enterochromaffin cell area, reduced intestinal surface area, and small villi thickness [44]. The intestinal microbiota has also been found to stimulate the development of immune tissues in the GI tract such as the lamina propria, Peyer's patches, and mesenteric lymph nodes. In the absence of the intestinal microbiota, these tissues do not fully develop and become less "primed" to fight infection. The serum of GF mice contains lower concentrations of immunoglobulins than that of CONV-R mice; GF mice have a reduced immune function, are more susceptible to severe infection, and usually have poorer survival.

In humans, differences in the composition of intestinal microbiota have also been suggested to influence immune function. Interleukin-22, Reg3γ, IgA, and interleukin-17 immune responses are likely influenced by the microbiome's production of polysaccharide A, SCFAs, and α-galactosylceramide and tryptophan metabolites [42]. *Bacteroides fragilis* can produce polysaccharide A in outer membrane vesicles, which can then be detected by dendritic cells and prevent inflammation of the colon [45]. *Bacteroides fragilis* also releases α-galactosylceramide, which is a glycosphingolipid that can bind with CD1d

proteins and subsequently activate invariant natural killer T cells. Furthermore, GI microbiota have been shown to impact lamina propria dendritic cells and whether their response will be inflammatory or antiinflammatory to specific antigens [42]. Evidence for this is derived from comparing the prevalence of allergies and atopic diseases in infants [46]. GI tracts of infants born and raised in developing countries (i.e., assumed to have a low level of sanitation) appear to be colonized at an early stage by gram-negative bacteria and variable enterobacterial strains. On the other hand, infants in developed countries (i.e., assumed to have a high level of sanitation) acquired gram-negative bacteria later and more stable enterobacterial strains. Such differences in the intestinal microbiota composition have been associated with a higher prevalence of allergies and atopic diseases in infants born and raised in developed countries than those in developing countries [46]. A study that compared the intestinal microbiota profiles of children in Europe observed that Swedish and Estonian toddlers with low counts of *Lactobacillus* spp., *Bifidobacterium* spp., *Bacteroides* spp., and *Enterococcus* spp., but having higher levels of clostridia and *Staphylococcus aureus*, were more prone to allergies than were healthy infants [47,48]. Much remains to be learned about intestinal colonization, immune function, and disease in humans.

D Production of SCFAs

Food components that are not digested in the small intestine travel to the colon. These nondigestible elements are substrates for fermentation by the intestinal microbiota. By-products of fermentation include carbon dioxide, hydrogen, and methane gases. Nongaseous by-products include SCFAs such as acetate, propionate, and butyrate (Fig. 37.7). Butyrate is mainly produced by *Clostridium* spp. and *Eubacterium* spp. [49]. *Roseburia intestinalis*, *Eubacterium rectale*, and *Faecalibacterium prausnitzii* have also been identified as butyrate producers [50,51]. Acetate is produced by *Lactobacillus* spp. and *Bifidobacterium* spp. [49].

Approximately 40–50% of the available energy from carbohydrate in the diet is converted into SCFAs by the colonic microbiota [52]. These volatile fatty acids provide energy for cellular maintenance and metabolism by being passively absorbed by the colonic epithelium (butyrate), liver (propionate), and muscle (acetate) [49,53,54]. Studies suggest that butyrate plays an important role in cellular differentiation and proliferation in the colonic mucosa by inducing apoptosis and may confer protection against colitis and colorectal cancer by modulating oncogene expression [55,56]. Production of SCFAs also lowers intestinal pH, which increases the solubility of minerals such as calcium and magnesium [57,58] and consequently enhances absorption [59]. Furthermore, reduction of colonic pH by accumulation of SCFAs has been hypothesized to protect the intestinal mucosa from being colonized by pathogens that are less tolerant of an acidic environment (e.g., *Helicobacter pylori*) [60]. Additional benefits of SCFAs are outlined in Fig. 37.8.

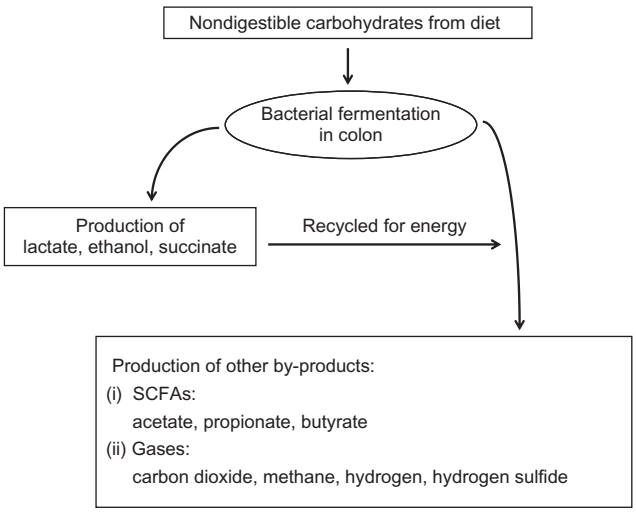

FIGURE 37.7 Bacterial fermentation of nondigestible food components.

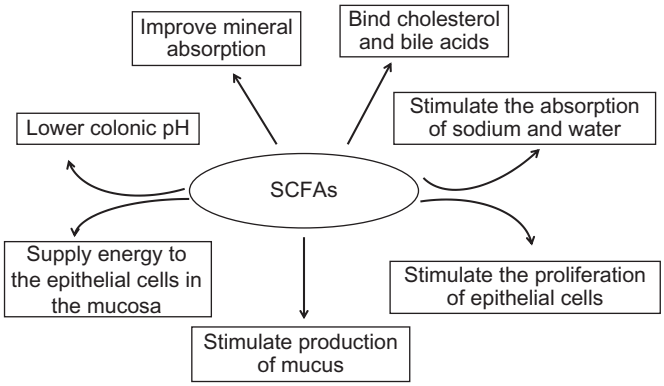

FIGURE 37.8 Benefits of SCFA.

The GI microbiota have been shown to change in composition during pregnancy, which may affect fermentation in the gut and the subsequent production of SCFAs in both peripheral blood and the cecum throughout gestation [61]. Furthermore, fatty acid receptor-2 (Ffar2), a G protein-coupled receptor that binds SCFAs, may be more highly expressed in pancreatic islets during pregnancy. Mice lacking Ffar2 have demonstrated fasting hyperglycemia and impaired glucose tolerance, suggesting that increased SCFA uptake into cells as a result of alterations in the intestinal microbiota contributes to gestational glucose homeostasis.

E Utilization of Nutrients

Absorption of nutrients from food is largely dependent on the action of various digestive enzymes. However, numerous food components cannot be digested. For example, stachyose (a tetrasaccharide) and raffinose (a trisaccharide) are long-chain carbohydrates (i.e., commonly termed oligosaccharides) found in soy. The unique α-(1−6) galactose linkage present in stachyose and raffinose can be broken down by α-galactosidase, which is not secreted by the human intestinal mucosa. As a result, these oligosaccharides (and other nondigestible food components) pass to the large intestine, where they become fermentation substrates for the colonic microbiota. Fructo-oligosaccharides (FOS), transgalacto-oligosaccharides, and galacto-oligosaccharides (GOS) are other types of nondigestible oligosaccharides that can be fermented by the colonic microbiota. Thus, the intestinal microbiota salvages a significant amount of energy from an otherwise nonavailable source [49,52−54].

Evidence that the intestinal microbiota plays an important role in fermenting nondigestible foodstuffs is based on studies using GF and CONV-R mice [3,62]. The latter were more efficient in nutrient absorption than GF mice because they had acquired "normal" intestinal microbiota. CONV-R mice gained more body weight, grew faster, and had as much as 40% more body fat than their GF counterparts even though they were maintained on the same diet. This growth difference was present even though CONV-R mice consumed less chow per day [3]. In order for GF mice to achieve the body weight of the CONV-R counterparts, they had to consume approximately 30% more calories [62]. However, following inoculation of GF mice with the intestinal microbiota of CONV-R mice, GF mice quickly gained body fat to levels equivalent to those of CONV-R mice without having to consume additional chow [62].

GI microbiota also affect fat and micronutrient absorption to such a degree that GF rodents may require a higher caloric intake to maintain proper body weight as compared to mice with colonized GI tracts [63]. Increased pancreatic lipase-related protein-2, colipase, apolipoprotein A-IV, and fatty acid-binding adipose factor, which are all involved in lipid absorption, have been shown to result from microbiome colonization. Furthermore, expression of fasting-induced adipose factor, which is repressed upon fat feeding, is likely to be decreased in GF rats. Additionally, proteins that sequester heavy metals, such as epithelial copper transporter, metallothioneins I and II, and ferritin heavy chain, have been shown to be threefold and five- to sixfold more abundant, respectively, in colonized GI tracts, thereby suggesting that the microbiome may also affect micronutrient absorption.

F Generation of Bioactive Metabolites (Conversion of Isoflavones)

Soy isoflavones, phytochemicals classified as "nonnutritive components," are predominantly derived from soy products. Currently, soy is the only recognized nutritionally relevant source of isoflavones. The primary isoflavones in soy are genistin and daidzin. Following ingestion, these glycosides are hydrolyzed by intestinal glucosidases and converted to the aglycone form of genistein and daidzein. These aglycones are further converted by certain intestinal microbiota into specific metabolites, such as equol. Chemically, equol is similar to the hormone estradiol. Results of in vitro animal studies indicate that equol has a higher estrogenic effect than its precursor, daidzein [64]. Hence, equol has garnered much attention for its potential in the prevention and/or treatment of chronic diseases or conditions associated with estrogen levels (e.g., breast cancer, osteoporosis, and menopause) [65].

In humans, the conversion of soy isoflavones (genistein and daidzein) to the more potent metabolite (equol) appears to be dependent on the composition of the intestinal microbiota. Evidence for this conversion comes from animal and clinical studies. First, all rodents are equol producers, except those that are bred GF. Second, infants fed soy-based formulas do not form a substantial amount of equol for the first 4 months of life, coinciding with intestinal microbiota development. In addition, individuals who are known to be equol producers have significantly lower equol excretion after antibiotic treatment [66]. It appears that the large interindividual variability in the intestinal microbiota composition results in only 30−40% of individuals producing equol after soy consumption [64,67−69]. In 2000, Hur and colleagues [70] identified two strains of bacteria from human feces that can produce primary and secondary metabolites from the natural isoflavone glycosides daidzein and genistin, but it is still unclear whether the ability to convert daidzein to equol can be induced in nonproducers [71].

G Communication With the Nervous System

Gut microbiota and the central nervous system have been found to display bidirectional communication via the microbiota−gut−brain axis [72]. The vagus nerve, humoral components of the immune system, and the hypothalamus-pituitary-adrenal axis are believed to mediate this interaction. Disruption of this axis has been shown to be an underlying cause of irritable bowel syndrome (IBS) and other functional bowel disorders. Furthermore, stress-related psychiatric disorders such as depression and anxiety usually coincide with IBS, which provides additional evidence to support the theory of the microbiota−gut−brain axis. Additionally, changes in gut microbiota have been indicated in autism, and early-life stressful events have been shown to alter brain neurochemistry and the composition of GI microbiota, as well as increase in visceral sensitivity.

A lack of bacterial colonization in the gut during development in GF mice has been linked to higher levels of corticosterone and adrenocorticotrophin levels in response to stress [72]. GF mice were found to have genetic alternations related to the citric acid cycle, steroid hormone metabolism, cAMP signaling, and long-term potentiation [73]. Monoamines such as epinephrine, serotonin, and melatonin have also been shown to exhibit decreased turnover rates as a result of GF GI tracts, as well as decreased production of brain-derived neurotrophic factor, a protein that supports and encourages the growth of neurons and synapses in the brain.

H Promotion of Angiogenesis

Intestinal microbiota colonization likely affects the development and regulation of intestinal angiogenesis via Paneth cells [74]. Bacterial colonization in the intestine and the development of villi blood vessel networks are coinciding after-birth events. Paneth cells are located in intestinal crypts and secrete antimicrobial peptides such as lysozymes and secretory phospholipase A_2, which ultimately affect the ecology of microbes found in the intestinal lumen. Paneth cells can produce factors that promote angiogenesis of the intestine even in the absence of intestinal microbiota; however Paneth cells and microbiota are likely needed in conjunction in order for proper angiogenesis to occur.

V METHODOLOGY FOR STUDYING INTESTINAL MICROBIOTA

A Conventional Methodology and Its Limitations

Our knowledge of intestinal microbiota is largely based on classical approaches of cultivation, direct microscopic observation, and biochemical analysis [75]. Results obtained using these conventional methodologies have improved our understanding of the intestinal microbiota. However, many intestinal bacteria are difficult to culture because the media may not be specific (i.e., causing overestimation) or may be too selective (i.e., resulting in underestimation or absence of growth) for culturing the particular bacteria of interest [76]. It is estimated that only 20−40% [77−79] of the total intestinal microbiota can be cultured and identified using conventional microbiological methods. Thus, evaluating intestinal microbiota using conventional methods will bias our knowledge in favor of those genera that are most easily grown under laboratory conditions [80]. In addition, media preparation and biochemical analyses associated with these approaches are also time-consuming.

B Molecular Analysis of the Human Intestinal Microbiota

In the past two decades, novel analytical approaches based on the manipulation of 16S rDNA and other genetic materials have been developed to analyze bacterial communities in environmental samples (e.g., soil, lakes, oceans, and hydrothermal vents). These methods have been adapted to evaluate bacterial communities in the GI tract [9,81]. Molecular techniques do not require the presence of viable bacteria [9,82,83]. Furthermore, the use of genetic materials (e.g., DNA and RNA) allows species that cannot be cultured using current standard laboratory protocols to be detected. Thus, data derived from molecular techniques depict a more complete and real picture of the bacterial community. These molecular methods have shown a great potential to overcome the limitations associated with conventional techniques and have become increasingly favored [82,83]. Many molecular techniques, especially after being optimized, are now being developed as rapid assays, allowing large-scale studies with high-throughput analyses. Biological samples can now be frozen at the site of collection and then transported to laboratories for analyses. However, because RNA is degraded more easily than DNA, sample storage and handling largely depend on the choice of method and outcome measures.

Molecular techniques can be categorized as follows:

1. Direct molecular detection and/or enumeration: dot blot hybridization, fluorescent in situ hybridization (FISH), and real-time polymerase chain reaction (RT-PCR);
2. Molecular fingerprinting techniques to monitor changes in the composition of bacterial community: terminal restriction fragment length polymorphism (T-RFLP) and denaturing gradient gel electrophoresis (DGGE);

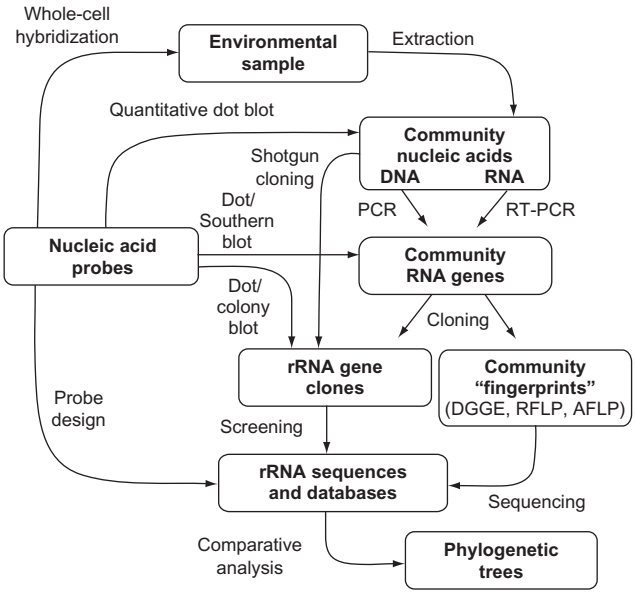

FIGURE 37.9 Various molecular methods and analytical approaches that are applicable for studying the intestinal microbiota communities. *Reprinted with permission from P. Lawson, Taxonomy and systematics of predominant gut anaerobes, in: G.R. Gibson, M.B. Roberfroid, Colonic Microbiota, Nutrition and Health, Kluwer, Dordrecht, the Netherlands, 1999, pp. 149–166.*

3. Genotyping: rapid amplification polymorphic DNA–polymerase chain reaction (RAPD-PCR), enterobacterial repetitive intergenic consensus–polymerase chain reaction (ERIC-PCR), multilocus sequence typing, plasmid profile analysis, repetitive extragenic palindromic, ERIC, ribotyping, as well as amplified fragment length polymorphism (ALFP), RFLP, and RAPD techniques;
4. Other novel molecular methods under development: microarray, magnetic-immuno PCR, and *recA* gene analysis.

Other molecular techniques have been developed to study microbial communities in the environment. Fig. 37.9 outlines several common methods of analysis.

C Limitations Associated With Molecular Techniques

Despite their superiority to conventional microbiological approaches, molecular techniques do have limitations. The main drawback of molecular techniques, which significantly influences downstream analytical processes, is their reliance on cell lysis efficiency and the quality of DNA recovered from the environmental samples. DNA isolation methods that contribute to insufficient cell lysis or shearing of DNA bias PCR amplification [84–87]. Inhibitors in feces, such as bile salts and complex polysaccharides, will create similar problems [84,88,89]. Furthermore, special equipment and reagents are needed for sample processing and analyses (e.g., thermal cycler, RT-PCR unit, DGGE setup, bead-beating equipment for lysing cells, and DNA or RNA extraction kits). Thus, initial laboratory setup may be costly, especially for novice researchers. However, research in this field has advanced rapidly in approximately the past decade. Technological progress has significantly reduced costs as well as improved quality and performance of equipment and reagents. Note that some molecular techniques are semiquantitative (DGGE and TGGE) and may lack sensitivity (e.g., dot blot hybridization and FISH). Primer bias may also occur in PCR reactions. In addition, almost all of these molecular techniques rely on primers and oligonucleotide probes to detect bacteria. Hence, the choice of primers and probes in analyses is crucial for detecting the bacteria of interest. Although primer and probe availability may be limited, their numbers are steadily increasing as interest in this field grows. Despite these limitations, molecular techniques are continually being developed and modified to increase efficiency and sensitivity in analyzing the diverse bacterial community in environmental samples, including those found in the GI tract and feces.

VI INFLUENCE OF DIET ON INTESTINAL MICROBIOTA

Several bacterial genera make up a large majority of the intestinal microbiota (Figs. 37.2 and 37.4). However, external and internal factors can modify the overall number and dominant species within the community (i.e., the concept of microbial succession; Fig. 37.6). One of the most studied external factors that influences microbial succession is diet.

A Can Diet Alter the Intestinal Microbiota?

Comparative analyses of fecal samples from breast-fed and formula-fed infants have shown differences in the composition of their intestinal microbiota as a response to the diet (Figs. 37.10 and 37.11). The intestinal microbiota of adults is more diverse and stable than that of infants; however, it can still be modified by diet. In 1974, Finegold et al. [90] compared the fecal flora of subjects who consumed a traditional Japanese diet to that of those who consumed a Western diet. In this study, a significantly higher number of *Clostridium* spp., *Eubacterium* spp., and *E. coli* were recovered in the feces of subjects on the traditional Japanese diet than in those on the Western diet. On the other hand, *Bacteroides* spp. (especially *B. infantis* and *B. putredinis*) and *Bifidobacterium* spp. were more prevalent in the fecal samples of subjects on the Western diet. In addition, differences in intestinal bacterial profiles were also found to vary by ethnicity (e.g., Asians, North Americans, and Europeans),

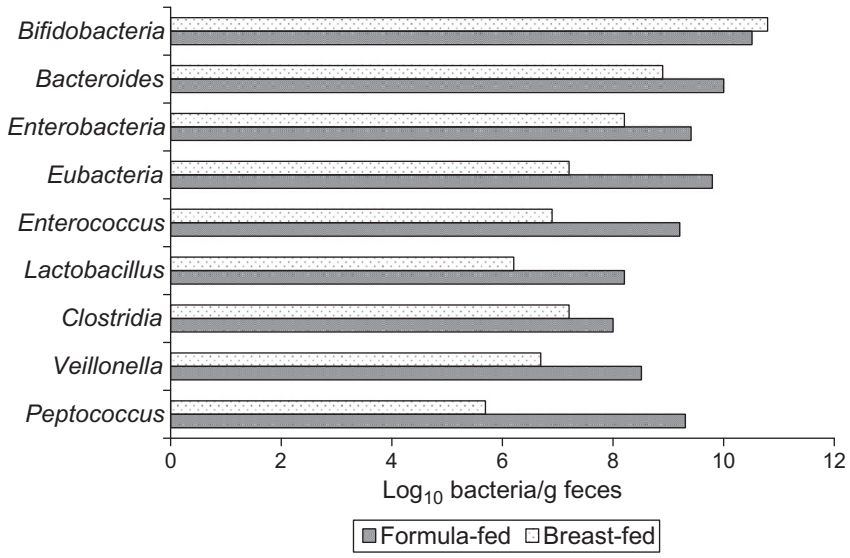

FIGURE 37.10 Comparison of bacterial populations in breast-fed versus formula-fed infants. *Data adapted from Y. Benno, K. Sawada, T. Mitsuoka, T., The intestinal microbiota of infants: composition of fecal flora in breast-fed and bottle-fed infants, Microbiol. Immunol. 28 (1984) 975–986.*

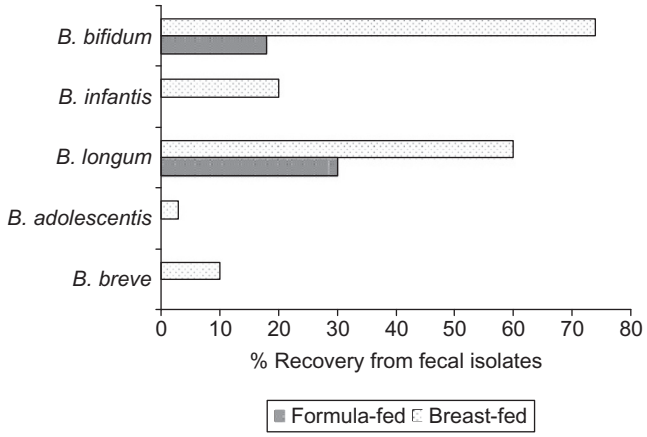

FIGURE 37.11 Differences in the *Bifidobacterium* spp. isolated from fecal samples of breast-fed versus formula-fed infants. *Data adapted from H. Beerens, C. Romond, C. Neut, Influence of breast-feeding on the bifid flora of the newborn intestine, Am. J. Clin. Nutr. 33 (1980) 2434–2439.*

implicating regional dietary habits [37]. Hence, from these observational studies, it appears that dietary patterns influence intestinal microbiota communities.

Intervention studies provide more direct evidence of the ability of diet to modify intestinal microbiota. We conducted unpublished experiments in which diet was strictly controlled and modified from basal, free-living diet. Asian adolescents participated in two 3-week sessions of supervised clinical camp. The "camp" diet comprised food items such as peanut butter-and-jelly sandwiches, pasta, and pizza, but without the addition of probiotics, prebiotics, and other high-fiber food. Meals were given such that all subjects consumed the same types of food at any given meal time (i.e., controlled diet). Changes in intestinal microbiota profile were assessed based on fecal samples using the DGGE method. It was observed that the bacterial community shifts to a different profile within 2–4 days of consuming the new diet and the profile is maintained as long as the diet remains largely unchanged. The intestinal microbiota profiles of these subjects changed from "basal" profile to "camp" profile in the first session of camp, reverted to "basal" profile during the wash-out period, and then slipped back to "camp" profile in the second session of camp [91]. However, intersubject variability remained high, indicating that regardless of dietary changes, each individual maintains his or her unique intestinal microbiota profile [91,92]. Intestinal microbiota profile can also be altered when one type of food is consumed at a higher than usual intake [93,94]. The number of *Bacteroides* spp. and *Staphylococcus* spp. was elevated during periods of high-meat consumption, whereas the number of these bacteria decreased when the diet was devoid of meat. In addition, the number of *Eubacterium* spp., *Bifidobacterium* spp., and *Lactobacillus* spp. was much lower following a high-meat diet compared to a meat-free diet [93]. A high intake of cruciferous vegetables has also been shown to cause a major shift in the intestinal microbiota composition compared to the intestinal microbiota profile of subjects maintained on a fruit- and vegetable-free diet [94].

B Altering the Intestinal Microbiota Using Food Supplements

1 Probiotics

Probiotics contain viable microorganisms that are proposed to improve the health of the host primarily by altering its intestinal microbial communities. Various probiotic bacterial strains are available, but the genera *Lactobacillus* spp.,

Bifidobacterium spp., and *Streptococcus* spp. are the most commonly used. Yogurt, kefir, and capsules containing freeze-dried probiotic bacteria are examples of commercially available probiotics.

The beneficial effects of consuming probiotics, which include improvement in lactose tolerance and a reduction in the risk and severity of diarrheal symptoms (i.e., as a side effect to antibiotics, traveler's diarrhea, or induced by rotavirus as in the case of gastroenteritis), have been observed in clinical studies. Inflammatory bowel disease (IBD), which is characterized by chronic or recurring intestinal inflammation, has been postulated to be caused by abnormal host immune responses to certain members of the intestinal microbiota and/or from a defective mucosal barrier [95]. Some clinical studies have indicated that probiotics can treat IBD (e.g., ulcerative colitis, Crohn's disease, and pouchitis; Table 37.1). Probiotics may also be a treatment for intestinal infection caused by pathogens (e.g., *Clostridium difficile* and *H. pylori*) (Table 37.1). Furthermore, it is hypothesized that regular consumption of probiotics may reduce the levels of secondary bile acids and other mutagens that are involved in colon carcinogenesis [96]. Other studies outlining the efficacy of probiotics in various clinical applications are summarized in Table 37.1.

The efficacy of probiotics remains unproven. Mixed results raise concerns regarding the suitability of the strains, effective dosage, toxicity levels, and the viability of the bacteria in the product. Furthermore, mechanisms by which these bacteria colonize the intestinal tract have not been described [97–99]. Colonization success of the ingested probiotic bacteria is questionable because probiotic bacteria typically are not able to permanently colonize the GI tract. Hence, colonization and benefits are usually transient in nature [100,101].

2 Prebiotics

Prebiotics are defined as nondigestible and fermentable food components that selectively stimulate the growth and/or activity of certain colonic bacteria that bring beneficial health effects to the host. Unlike probiotics, where one attempts to introduce beneficial bacteria into the GI tract, prebiotics attempt to stimulate the growth of endogenous beneficial bacteria by providing specific fermentable substrate(s). Examples of prebiotics are inulin, FOS, GOS, and lactulose.

It has been proposed that a food component has to satisfy the following criteria to be recognized as a prebiotic: (1) resistant to the acidic condition of the stomach, (2) unable to be broken down in the small intestine, (3) transferable to the colon as a fermentable substrate, and (4) able to stimulate the growth of a selective group of beneficial colonic bacteria (e.g., *Bifidobacterium* spp. and *Lactobacillus* spp.) [102]. Clinical studies investigating the effects of prebiotics such as inulin, FOS, GOS, and lactulose are listed in Table 37.2. Although most of these studies resulted in the enhancement of *Bifidobacterium* spp., few of them were able to correlate bacterial data with health-related biomarkers. It is speculated that increases in the colonic levels of *Bifidobacterium* spp. modulate immune function, inhibit pathogen colonization, and augment the production of SCFA (Fig. 37.12).

VII MICROBIOME-ASSOCIATED BIOMARKERS

Given that intestinal microbiota are known to be involved in metabolism and utilization of nutrients, it is not surprising that biomarkers for metabolic syndrome and obesity have been found in the microbiome [103]. A high-fat diet is more likely to result in abundant propionate and acetate producing bacterial species such as *Phascolarctobacterium*, *Proteus mirabilis*, and Veillonellaceae, whereas normal-fat diets are associated with higher prevalence of *Lactobacillus intestinalis*. Furthermore, body weight and fat mass have been found to be negatively correlated with an abundance of *L. intestinalis*, which provides evidence that the composition of the microbiome can help predict obesity risk. Additionally, low bacterial diversity in the gut is associated with increased overall adiposity, triglycerides and free fatty acids, insulin resistance, inflammatory responses, and weight gain over time [104]. These characteristics can then be used to predict the risk of prediabetes, type 2 diabetes, and ischemic cardiovascular disorders.

The gut microbiome also provides biomarkers for asthma, atopic dermatitis, and autoimmune diseases. High fecal calprotectin, a biomarker for intestinal inflammation, was found to be associated with an increased risk of atopic dermatitis and asthma by the age of 6 [105]. It has been proposed that impaired monocyte IL-10 activation due to the lack of *E. coli* colonization is linked to this finding.

VIII CHALLENGES IN THE FIELD

The study of the human intestinal microbiota is a relatively new field. Interest in this field has been stimulated by the active marketing of probiotics and prebiotics for intestinal health. In addition, concerns about the effects of antibiotics (i.e., due to a medical treatment or residues in animal products) have focused research on the GI microbiota.

Given the unknown role that the GI tract plays in maintaining overall health, efforts to advance our knowledge of the complex interaction between host and microbiota are needed. As a first goal, the diversity of the intestinal microbiota needs to be characterized. With better basic knowledge, we can move toward elucidating microbe–microbe and host–microbe interactions. Investigations of the effects of age, gender, host genotype, various components of diet,

TABLE 37.1 Clinical Studies Investigating Various Applications of Probiotics

Intestinal Condition	Probiotic	Reference
Lactose intolerance	*Lactobacillus acidophilus*	[106]

TABLE 37.2 Clinical Studies Investigating Alterations in Intestinal Microbiota as a Response to Prebiotics

Prebiotic	Dose and Duration	Microbiota Modulation	Reference
Inulin	8 g/day, 14 days	Increase in bifidobacteria, slight increase in clostridia	[225]
Inulin	Up to 34 g/day, 64 days	Increase in bifidobacteria	[226]
Inulin	15 g/day, 15 days	Increase in bifidobacteria	[227]
Inulin	20 g/day, 19 days	Increase in bifidobacteria, decrease in enterococci and enterobacteria	[228]
FOS	15 g/day, 15 days	Increase in bifidobacteria, decrease in *Bacteroides*, clostridia, and fusobacteria	[229]
FOS and PHGG	6.6 g/day FOS, 3.4 g/day PHGG, 21 days	Increase in bifidobacteria	[230]
FOS	0–20 g/day, 7 days	Increase in bifidobacteria	[231]
FOS	4 g/day, 42 days	Increase in bifidobacteria	[232]
FOS + GOS	0.04 g/L, 0.08 g/L, 28 days	Increase in bifidobacteria and lactobacilli	[233]
FOS + GOS	10 g/L, 28 days	Increase in bifidobacteria	[234]
Lactulose	10 g/day, 26 days	Increase in bifidobacteria	[235]
Lactulose	3 g/day, 14 days	Increase in bifidobacteria, decrease in lactobacilli	[236]
Lactulose	2 × 10 g/day, 4 weeks	Increase in bifidobacteria and lactobacilli	[237]
Lactulose	5 g/L and 10 g/L, 3 weeks	Increase in bifidobacteria, decrease in coliforms	[238]
GOS	0–10 g/day, 8 weeks	Increase in bifidobacteria and lactobacilli	[239]
GOS	2.5 g/day, 3 weeks	Increase in bifidobacteria, decrease in *Bacteroides* and clostridia	[240]

FOS, fructo-oligosaccharides; GOS, galacto-oligosaccharides; PHGG, partially hydrolyzed guar gum.

and the environment on intestinal microbial community are additional goals. Reliable methods to detect alterations in the composition of the intestinal microbiota are required to meet these objectives. Molecular methods hold much promise in this regard [72,73].

Chapter 38

Gut Microbial Metabolism in Health and Disease

Wei Jia[1,2] and Cynthia Rajani[1]

[1]University of Hawaii Cancer Center, Honolulu, HI, United States, [2]Shanghai Jiao Tong University School of Medicine, Shanghai, China

I INTRODUCTION TO THE GUT MICROBIOTA

In the early 1980s, researchers at the University of Notre Dame, Indiana, reported that germ-free (GF) mice could survive without microbe colonization; however, they had higher nutritional demands in terms of quantity of food and composition [1]. GF mice required 30% more energy in their diet as well as supplementation with vitamins K and B to maintain their body weight. Furthermore, they did not develop normal anatomy or physiology and were more susceptible to infections. Combined, these effects provided clear evidence that gut bacterial communities were important components of the host defense barrier [2]. GF mice were found to have smaller intestines of decreased surface area, thinner lamina propria (LP), larger cecums, fewer plasma cells and intraepithelial lymphocytes, lower IgA levels, as well as underdeveloped secondary lymphoid structures such as smaller Peyer's patches and mesenteric lymph nodes than conventional animals [3]. Thus, while microbial colonization is not essential for life, it is important for normal growth, development, and immunity.

Knowledge that the gut microbiota may be important for human health prompted scientists to seek ways to identify and classify those microbes present in the gastrointestinal (GI) tract. Amongst other factors, the strict anaerobic nature and the symbiotic interactions between species of bacteria and the host have made it challenging to culture beyond a minority of these organisms. In 1977, Woese and Fox made the discovery that the nucleotide sequence of 16S ribosomal RNA (16S rRNA), a component of the 30S small subunit of prokaryotic ribosomes, present in every bacterial and archaeal cell, contained regions that were highly conserved and that these sequences flanked regions that were variable among the different bacterial species which allowed their phylogenetic classification [4]. Only recently have high-throughput sequencing techniques, such as phylogenetic DNA microarray, whole genome, and next-generation sequencing, been developed which allow taxonomic classification of gut bacteria via comparison with 16S rRNA sequence databases such as the National Center for Biotechnology Information (NCBI; http://www.ncbi.nlm.nih.gov/nucleotide) [5].

The classical understanding of inflammation is that of a normal physiologic response to an infectious threat or tissue injury that leads to tissue repair, resolution, and restoration to original tissue homeostasis. Chronic, noncommunicable inflammatory diseases such as metabolic syndrome (MS), type 2 diabetes (T2D), irritable bowel syndrome (IBS), obesity, and neurodegenerative disorders do not really fit this model as there is no acute threat nor is the inflammation resolved. Instead, there is an adaptation to a new set of conditions, a "shift" in the balance perhaps brought about by a change in diet, overuse of antibiotics, or other environmental insults that alter the nutritional interrelationship between the host and microbiota metabolisms. This adaptation results in altered gut colonization patterns or "dysbiosis," a common, central theme found in these chronic inflammatory conditions [6]. In this chapter the relationship between the gut microbiota and incidence of chronic noncommunicable inflammatory diseases will be reviewed including a discussion on the impact of microbial metabolism and metabolomics approaches used in these investigations.

A The Gut Microbiota and Diet

Changes in dietary patterns and habits are some of the most important lifestyle decisions that can affect a person's health. These changes are second only to cessation of smoking for disease prevention [7]. It is believed that a healthy population of commensal bacteria is essential for optimal host−microbiota mutualism and overall human health. Thus, an increasingly important question is how can the microbiota be shaped throughout life and from meal-to-meal to prevent, cure, or alter the progression of a disease? Overall, dietary fiber is the main source of energy for bacteria in the colon [8]. As such, a key factor that affects the composition of microbiota is the availability of glycans (derived from fiber) in the lower intestine. Human hosts are capable of fully digesting only starch, lactose, and sucrose glycans each of which contain only one or two different linkages. However, a much more diverse array of glycans can be derived from the diet in the form of both plants and animal sources. Microbial fermentation of these otherwise indigestible glycans converts them into short-chain fatty acids (SCFA) which are well known to serve as nutrients for the GI epithelial cells. Individual microorganisms are able to preferentially metabolize different glycans and thus, selective human consumption could potentially influence which microbiota populations will flourish. Whereas dietary glycans may vary, endogenous *N*-linked glycans produced by shed GI epithelial cells and *O*-linked glycans attached to mucus cells provide a more stable source. However, the ability of certain microbes to interact closely with the mucosal layer and utilize endogenous glycans may negatively affect mucosal barrier function and colonic health, especially under conditions of dysbiosis [9].

The human gut microbiota is initially seeded from the microbes presented at birth and is believed to become established within the first few days. Breast-fed infants are exposed to a unique mixture of complex human milk oligosaccharides (HMOs) not present in the milk of other mammals. These HMOs are not digested by human enzymes and, it has been suggested, that they evolved to serve as natural prebiotics and guide development of infant microbiota by serving as selective substrates for specific bacterial species and communities (e.g., *Bifidobacterium longum* biovar. *infantis*) [10]. The fact that HMOs are indigestible by the infant through normal digestion means they will be the most abundant macromolecule reaching the lower intestine and those bacteria that can selectively utilize these substrates to aid in establishing specific community profiles will thrive. HMOs are complex, containing a diverse array of sugars. *Lactobacilli* sp., also preeminent in the infant gut, prefers monosaccharide components of the HMOs suggesting that selection of individual components of HMO may contribute to broader microbial community structure [9]. Formula-fed (cow's milk) infants were found to have lower amounts of *Lactobacilli* and *Bifidobacteria* but showed increased abundances of *Clostridium*, *Bacteroides*, and members of the Enterobactericeae. Cow's milk lacks the diversity and amounts of oligosaccharides when compared to human milk and does not contain the unique HMOs [9,11].

At approximately 6 months, the composition of the human diet begins to incorporate complex foods, such as cereals, fruits, and vegetables, that diversify the digestible and indigestible carbohydrate portion of the diet. This in turn induces a shift in the microbiota to gram-negative Bacteriodetes and other species of Firmicutes become more abundant. These two phyla numerically dominate the adult microbiota. When a fully omnivorous diet is established, there is microbiota stabilization with fewer temporal changes, although the ratio of Bacteriodetes/Firmicutes can change with diet. A third phylum, Actinobacteria, is also frequently found in adult microbiota [9].

Direct evidence for the effect of diet on gut microbiota was reported in a study that involved two populations of children. One was a population from Burkina Faso (BF), who had a diet high in fiber content similar to that of early human agricultural settlement and was compared to European (EU) children on a typical western, high fat/low fiber diet. The 16S rRNA sequencing and biochemical analysis revealed that BF children had enriched amounts of Bacteroidetes and depletion of Firmicutes with an abundance of *Prevotella* and *Xylanibacter*. The last phylum contains many genes for cellulose and xylan hydrolysis and was completely lacking in EU children. Significantly higher concentrations of SCFAs were found in BF children along with significantly reduced populations of *Shigella* and *Escherichia* which would be protective against inflammation (Fig. 38.1) and irritable bowel disease (IBD) [12].

Dietary supplementation with particular carbohydrates may be another means of eliciting changes in species abundance. Prebiotics are defined as a selectively fermented substance, typically carbohydrates, that allows specific microbiota changes that confer benefits upon host health. Resistant starch (RS) is an example of a potential prebiotic dietary component. RS is dietary starch that is inaccessible to human digestive enzymes and therefore traverses to the colon and is made available to the microbiota. RS can be divided into four types: (1) RS1, starch found in whole grains or partially milled grains and legumes; (2) RS2, granular starch that is tightly packed and dehydrated; (3) RS3, cooked and reassociated starch with limited accessibility to host enzymes, and (4) RS4, chemically or enzymatically modified starch. Within the RS3 type, different X-ray diffraction patterns based on amylose content have also been found which favor particular bacteria. For example, typical cereal starches exhibit an A-type pattern (*Atopobium* spp.) while tuber and other starches with high amylose content favor a B-type pattern

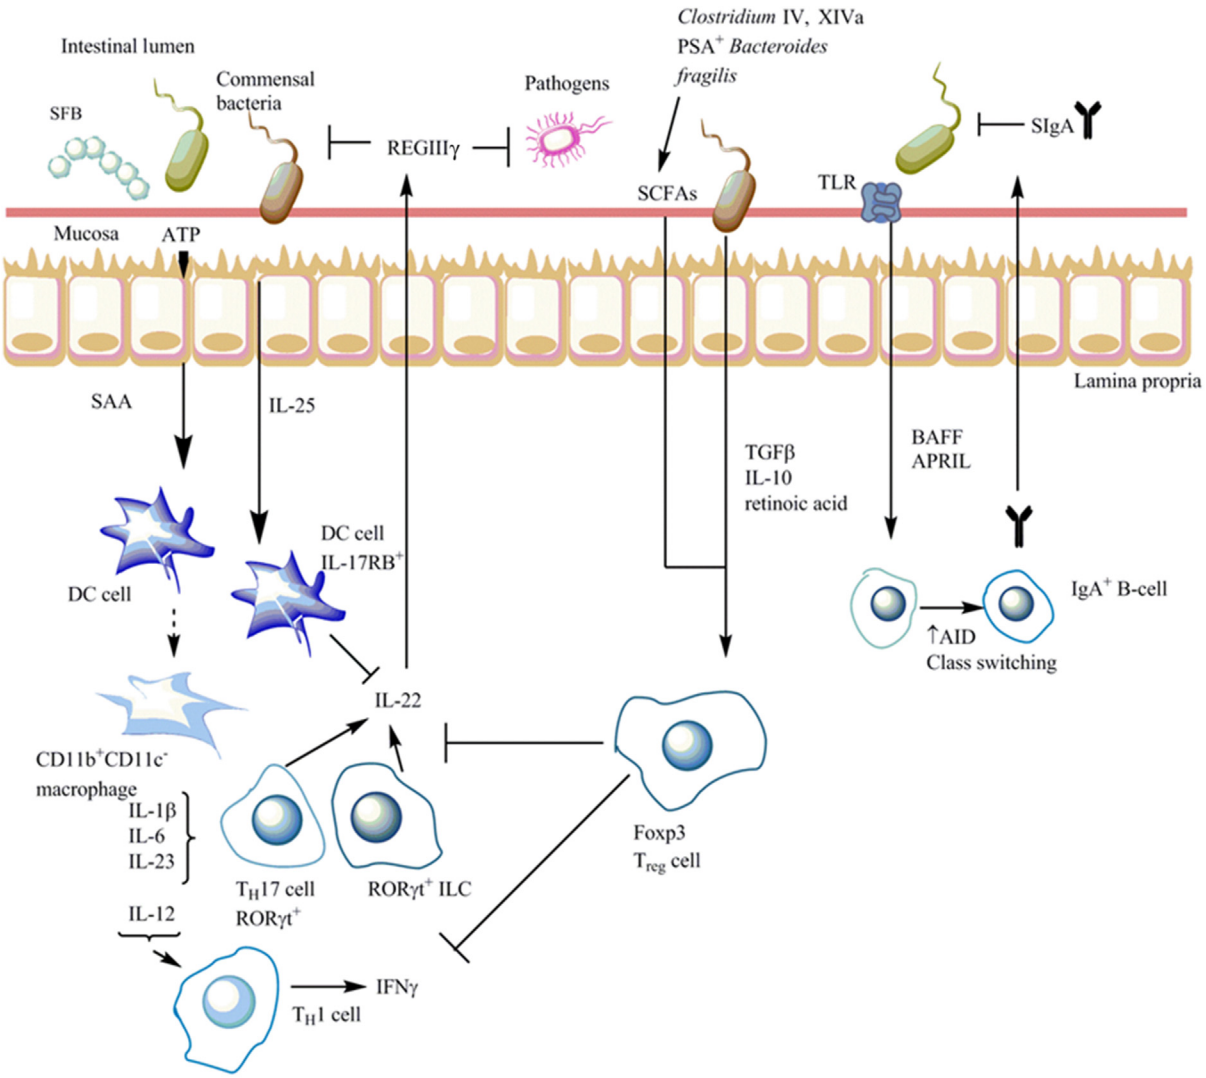

FIGURE 38.1 Gut microbiota shape the immune system to promote microbiota−host mutualism. Abbreviations: IL, interleukin; T_H, T-helper cell; T_{reg}, T-regulatory cell; PSA, polysaccharide A (see text also).

(*Bifidobacterium* spp.). B-type pattern starches favored higher butyrate production indicative of differences in the bacterial species that were enhanced with this supplementation [8]. Based on human feeding studies, RS supplementation was also reported to increase the amount of butyrate, a common metabolite of Firmicutes, that is, not only a nutrient for the mucosal epithelium but is also thought to be antiinflammatory via its ability to increase differentiation of T_{reg} cells (Fig. 38.1) [13].

Hemicellulose is another major category of dietary fiber that includes arabinoxylans, xyloglucans, glucomannans, galactomannans, and β-glucans. Arabinoxylooligosaccharides (ARS), the hydrolyzate of arabinoxylan and β-glucan have been shown to stimulate the growth of *Bifidobacteria* spp. in the human colon and thus there is interest in using them as prebiotics. In a simulator of intestinal microbial ecosystem (SHIME), the degree of polymerization (DP) of ARS was found to influence which species of bacteria fermented it and where fermentation occurred in the colon [14]. Interestingly, in a protein-rich environment, decreases in the proteolytic markers, phenol and *p*-cresol, were discovered and continued to decrease after the 3-week treatment with arabinoxylin-oligosaccharides (AXOS) was discontinued indicating a longer term effect on microbiota. Proteolysis can lead to higher levels of tryptophan (TRP) and increased inflammation via its metabolism along the TRP → KYN pathway (Fig. 38.2). Increased amounts (25−48%) of two beneficial SCFAs, butyrate and propionate, were also observed in all colonic vessels [14]. Higher DPs (≥60%) in humanized rats provided some different results highlighting the importance of molecular size for the efficacy of AXOS as a prebiotic [15]. The molecular size of β-glucan has also been shown to play

a role in favoring specific bacterial groups (Table 38.1). Fructans can also be used as prebiotics and comparison studies have been performed for inulin (DP 3−60) and one of its enzymatically hydrolyzed products, oligofructose (DP 2−20) using the SHIME. Inulin took longer to establish a prebiotic effect but its effect was more pronounced with respect to fermentation activity and microbial community composition changes than was seen with the shorter chain oligofructose (Table 38.1) [16].

It is important to consider that dietary carbohydrates and other nutrients can fluctuate from meal-to-meal. Recently, human subjects fed either high-fat/low-fiber or low-fat/high-fiber diets in a controlled experiment showed detectable shifts in microbiota after just 24 hours suggesting that some proportion of human microbiota are constantly fluctuating in response to feeding [17]. Another important factor with respect to meals and potentially microbiota is circadian rhythm. It has been shown that not only amount and content of food but time of ingestion is also critical for health. A well-known medieval quote is as follows, "Eat like a king in the morning, a prince at noon, and a peasant at dinner." Because a large fraction of the microbiota is located in the intestine which also has a powerful circadian clock that participates in daily cycles of food digestion, it is not surprising that studies have shown that the intestinal epithelial cells (IECs) circadian clock can be disrupted by depletion of microbiota. Therefore, changes in microbiota induced by different dietary and life patterns likely differentially regulate the gut microbial communities and circadian rhythm [18].

In summary, the lower intestine harbors a large portion of the overall gut microbiota. Undigestible carbohydrates (fiber) have been shown to be influential in both shaping and maintaining a healthy gut microbiota. This has led to the formulation of dietary supplements and foods with prebiotics to aid individuals in the establishment and

maintenance of "healthy" microbiota. An imbalance in this system, gut dysbiosis, is a central theme in the non-communicable inflammatory diseases, obesity, IBS, mental health, and age-related neurodegeneration disorder (ARNDD) that will be discussed further.

B The Gut Microbiota and the Mucosal Barrier Immune System

Mucosal surfaces in the intestine represent the largest area through which microorganisms and the environment interact with the immune system. The recognition that the gut microbiota impact not only metabolism and immunity in the intestine but also systemically including the brain has given rise to the concept of a gut-liver and gut-brain axis in humans [19]. Microbiota are involved in microbe–host epithelium interactions which have the effect of shaping intestinal immune systems. Fig. 38.1 summarizes how the gut microbiota control key populations of dendritic cells (DCs) that give rise to three major classes of T-cells, T_H1, T_H17, and T_{reg}, as well as an important IgA secreting type of B-cell. Microbiota-induced intestinal immunity functions to prevent overgrowth of bacteria and prevents colonization by pathogens thereby maintaining the integrity of the mucosal barrier.

A central strategy employed by the host is to minimize contact of both pathogens and commensal microbes with the epithelium. To control bacterial overgrowth, segmented filamentous bacteria (SFP) adhere to the host epithelium and upregulate serum amyloid protein A (SAA). SAA is then actively transported using ATP and triggers the differentiation of particular DCs into $CD11b^+/CD11c^-$ macrophages which produce IL-1β, IL-6, and IL-23 that effect T-cell differentiation into T_H17 cells. Alternatively, these same macrophages can produce IL-12

which causes T-cell differentiation to T_H1 cells. T_H17 cells produce IL-22 that interacts with epithelial enterocytes to produce regenerating islet-derived protein 3γ (REGIIIγ), an antibacterial protein, that blocks microbial proliferation via a proinflammatory immune response. IL-22 can also be produced by innate lymphoid cells (ILCs) that express retinoic acid receptor-related orphan receptor-γt (RORγt+) to act on epithelial REGIIIγ production. T_H1 cells produce antiviral interferon gamma (IFNγ). Microbes such as *Clostridium cluster IV*, *VIVa* strains and PSA^+ *B. fragilis* can adhere to the epithelium and activate the transforming growth factor β (TGFβ) pathway or, alternatively, activate DCs to produce retinoic acid and IL-10 which together promote T-cell differentiation to Forkhead box-P3 ($Foxp3^+$) T_{reg} cells. T_{reg} cells negatively regulate the effects of T_H17 cells by causing antiinflammatory immunosuppression thus preserving host−microbe homeostasis [20−22]. Carbohydrate metabolites including the SCFA butyrate produced by commensal microbiota such as the *Clostridium* IV cluster can selectively expand the population of $Foxp3^+$ T_{reg} cells [23].

Prevention of pathogen colonization relies not only on protection via antibacterial peptides such as REGIIIγ, but also via regulation of B-cell differentiation [24]. B-cells that differentiate to secrete IgA are important for mucosal barrier integrity. When IgA is secreted into the lumen (soluble IgA, SIgA) both commensal bacteria and other soluble antigens are coated to prevent their binding and penetration of the epithelium [25]. In the intestine, binding of bacteria to toll-like receptors (TLRs) on the surface of the epithelium leads to secretion by the epithelial cells of two important factors, B-cell activating factor (BAFF) and a proliferation-inducing ligand, APRIL, to promote the differentiation of B-cells via their increased expression of activation-induced cytidine deaminase to an IgA^+ B-cell [20,25].

Comparison between GI homeostatic and inflammatory conditions (Table 38.2) shows a definite shift in the ratios of T-cell subtypes. Inflammation results in increased numbers of T_H17 cells and suppression of T_{reg} cells, IL-10, and REGIIIγ. In IBD there is an increase in the T_H17/T_{reg} ratio [20]. The result is increased commensal bacteria loss (gut dysbiosis) [26]. Under homeostatic conditions, intestinal macrophages are hyporesponsive, but respond to overproduction of microbial products by secreting proinflammatory cytokines (PICs) [20,27].

C The Gut Microbiota and TRP Metabolism

Serotonin (5-HT) is a key neurotransmitter that allows bidirectional communication between the central nervous system (CNS) and the GI tract. There is strong evidence that gut microbial influence on TRP metabolism is an important regulator of the "gut-brain" axis [28]. Table 38.3 lists the important effects of serotonergic metabolism.

TRP, an essential amino acid obtained from the diet, is first proteolyzed from ingested protein by gut microbiota (Fig. 38.2A) and then converted by GI enterochromaffin (EC) cells to 5-HT:

$$\text{TRP} \xrightarrow{\text{TRP hydroxylase}} \text{5-hydroxy-tryptophan (5-HTP)} \xrightarrow[\text{(AAAD)}]{\text{aromatic amino acid decarboxylase}} \text{5-HT} \rightarrow \text{Melatonin}$$

Certain bacterial species including *Lactobacillus plantarum*, *Streptococcus thermophilis*, *E. coli K-12*, and *Klebsiella pneumoniae* have TRP synthase enzymes and can directly produce 5-HT from TRP [29]. However, the main fate of TRP is not 5-HT but rather 95% ends up being shunted down the kynurenine (KYN)

TABLE 38.3 Important Physiologic Effects of Serotonergic Metabolism [28]

metabolic pathway (Fig. 38.2B) [28]. The rate-limiting enzyme for KYN formation is indoleamine 2,3-dioxygenase (IDO) which is ubiquitously expressed except in liver, astrocytes, microglia, microvascular endothelial cells, and macrophages. The other enzyme that can convert TRP to KYN is TRP 2,3-dioxygenase (TDO) which is expressed mostly in the liver but is also found in kidney and brain. IDO is activated by PICs and TDO is activated by stress hormones such as cortisol. KYN metabolism leads to four important acids and production of NAD. Xanthurenic acid, which has been implicated in insulin resistance (IR), kynurenic acid, an antagonist for both α7-nicotinic-acetylcholinergic (α7-nAcR) and *N*-methyl-D-aspartate (NMDA) receptors and picolinic/quinolinic acids which are known to produce PICs as well as NAD [30].

The use of GF mice has revealed that the gut microbiota is essential for normal brain development and behavior. Relative to conventional (CON) mice, GF mice had increased plasma levels of TRP and 5-HT and a decreased KYN/TRP ratio (used as an indicator of IDO or TDO enzyme activity) which was normalized following introduction of microbiota [31]. Administration of *L. johnsonii* to rats was found to reduce serum KYN concentrations along with an increase in hydrogen peroxide (H_2O_2) in their ileum lumens. Further testing of H_2O_2 on IDO levels in HT-29 human IECs showed decreased enzyme activity that was attributed to oxidation and inactivation of the enzyme [32]. Given that many *Lactobacillus* sp. and other lactic acid producing bacteria can produce H_2O_2, this is a plausible way in which the microbiota can affect TRP metabolism. Comparisons have also been made between GF, specific pathogen-free (SPF) and CON mice with respect to motor ability and anxiety behaviors. It was found that GF mice had less anxiety and traveled longer distances at both slow and fast speeds than SPF and CON mice. There were no differences between SPF and CON mice for any of the tests. Introduction of microbiota early in GF mice produced CON mice that behaved like SPF mice whereas when adult GF mice were conventionalized, they did not become like SPF indicating that there was a window for achieving certain behavior patterns. The differences found in this study were increased amounts of two key proteins related to synaptic vesicle maturation, synaptophysin, and PSD-95 which were increased in early CON mice but not those conventionalized as adults. Early CON mice also had 2.8-fold increases in plasma 5-HT levels relative to GF mice. This postnatal change induced by microbiota may thus change peripheral 5-HT pools in ways that influence behavior and brain development in an early-life sensitive window [33].

The gut microbiota can also directly utilize TRP thus limiting its availability to the host. Certain bacterial strains such as *B. fragilis* can produce indole from TRP via tryptophanase enzymes [34].

$$\text{TRP} \xrightarrow{\text{tryptophanase}} \text{Indole} + \text{Pyruvate} + \text{Ammonia}$$

Prokaryotes, unlike eukaryotes, can also synthesize TRP utilizing TRP synthase enzymes and thus provide an additional source of TRP to the host [28,35]. Certain strains of *Lactobacilli*, *Streptococci*, *E. coli*, *Morganella* and *K. pneumoniae* can produce 5-HT from TRP [28,29]. It has also been reported that certain gram-positive bacteria are sensitive to increased concentrations of 5-HT. This is evidenced by their negative response to administration of selective serotonin reuptake inhibitors [36]. Therefore, TRP levels available to the host are not only derived directly from the diet but also rely on the balance between microbial TRP utilization and metabolism, microbial 5-HT production, direct microbial synthesis of TRP, and antimicrobial response to exogenous 5-HT. Finally, because the TRP-KYN pathway is driven by PICs (Fig. 38.2) and the microbiota control the mucosal production of PICs such as TNFα, IFNγ, IL-1β, IL-23, IL-25 and IL-6 (Fig. 38.1), they can indirectly control TRP metabolism along the KYN pathway via their role in mucosal immunity.

D Gut Microbiota and Bile Acid Metabolism

As noted previously, gut microbial compositions can be altered by diet, antibiotic treatment, and presence of disease. Bile acids (BAs) appear to be a major regulator of the commensal microbiota. The liver is responsible for the synthesis of hydrophilic, glyco- or tauro-conjugated primary BAs [37]. Commensal bacteria, via bile salt hydrolase enzymes, convert the primary conjugated BAs of hepatic origin into unconjugated BAs, thereby reducing their toxicity allowing for improved bacterial survival and growth in the colon [38,39]. In the colon, select *Clostridium* species further transform the primary unconjugated BAs, chenodeoxycholic acid (CDCA) and cholic acid (CA) into the secondary BAs, lithocholic acid (LCA) and deoxycholic acid (DCA) [38].

BA pool size and composition appear to be important factors in regulating mammalian gut microbial community structure. BAs have direct antimicrobial effects on gut microbiota [40] and may affect microbial compositions through farnesoid-x receptor (FXR)-induced antimicrobial peptides (AMPs) [41] and metabolism of BAs. For example, the microbial metabolite of CA, DCA has antimicrobial activity an order of magnitude greater than that of CA [40]. Rapid and significant changes in the microbiome community structures are observed when rats are fed BAs. Increased BAs in the gut appear to favor gram-positive members of the Firmicutes, such as *Clostridium*

cluster XVIa, and conversely, decreased intestinal levels of BAs lead to a depletion of this taxonomic group in the gut.

While the composition of the mammalian microbiota is a product of nature, it is clear that our environment, particularly diet and lifestyle, shapes the composition of our commensal microbiota. High fat diets (HFDs) increase the levels of BAs excreted to the intestine. Such increase in BA concentration in the large intestine leads to an increase of taxa including BA 7α-dehydroxylating species. On the other hand, an altered gut microbial community structure will profoundly impact BA metabolism that are central to regulation of lipid and glucose metabolism.

Evidence for the effect of commensal bacteria on BA synthesis originated from studies of mice raised in the absence of commensal bacteria where fewer secondary and more conjugated BAs presented in fecal matter [42,43]. Convergent data for human IBD, a condition characterized by diminished microbial diversity and decreased amounts of bacteria of the Firmicutes phylum especially, *Faecalibacterium prausnitzii* showed significantly higher conjugated and lower secondary BA levels relative to healthy controls. Interestingly, increased amounts of 3-OH-sulfated secondary BAs were also detected [44–46]. Sulfation eliminates the ability of secondary BAs to activate the antiinflammatory BA receptor, FXR [43]. The BAs act as receptor agonists for FXR with the following rank order: CDCA > LCA = DCA > CA [39,47]. Therefore, loss of commensal bacteria may result in a diminished ability to produce unconjugated and secondary BAs that are preferred ligands for FXR, as well as increased BA deactivation via sulfation. This can lead to a negative effect on the ability to control intestinal inflammation. On the other hand, retention of commensal bacteria such as Firmicutes species (i.e., *Clostridium* sp.) allows for increased production of butyrate and subsequent promotion of antiinflammatory T_{reg} cell expansion and important nutrition for the enteric mucosal cells [23].

Hepatic FXR activity is normally responsible for maintaining BA levels in the biliary tree and intestine while limiting BA accumulation in the liver. Normal intestinal FXR activity causes increased efflux of BAs back into the portal vein and decreased BA reuptake via apical sodium-dependent bile salt transporters (ASBT) into the enterocyte and thus limits the amount of BAs in the enterocytes [48]. Decreased FXR signaling in the enterocyte can result in a decreased expression of the BA carrier protein, ileal-BA binding protein (I-BAP) which acts to shuttle BAs from the luminal to the serosal side of the intestinal enterocyte. This is combined with the ability to downregulate organic solute transporters-α and -β. The result is reduced flow of BAs back into the portal vein and accumulation of BAs in the intestinal enterocyte. There is also decreased fibroblast growth factor (FGF19) production which causes an increase of BA synthesis in the liver which in turn contributes to cholestasis and hepatic inflammation via nuclear factor kappa B (NF-κB) activation, PIC production, and subsequent inhibition of hepatic FXR. Decreased FXR signaling in the liver causes decreased expression of most of the BA transporters and diminishes BA transport both into and out of the liver resulting in poor enterohepatic circulation. This disruption of BA transport in combination with increased BA synthesis in the liver ultimately leads to cholestasis in the liver and an increased degree of hepatic inflammation [49,50].

E Gut Microbiota and Obesity

The first evidence for the influence of microbiota on body mass came from studies using GF mice which consumed 30% more food to maintain a specific weight. However, upon colonization with microbiota these mice experienced a body weight increase of 60% within 2 weeks. In addition, GF mice fed a high fat, sugar-rich diet were protected from diet-induced obesity and had better insulin sensitivity [51,52]. One important difference between GF and CON mice is the increase in energy harvest that is possible due to the microbiota's ability to ferment complex dietary polysaccharides to SCFAs which not only provide 10% of daily energy supply but also act as signaling molecules that may influence appetite and metabolism. The IEC expressed G-protein coupled receptors, GPR43 and GPR41, play important roles in host–microbiota mutualism (Fig. 38.3A). GPR43 when activated by either of the SCFAs, acetate or propionate, promotes secretion of the hormone, glucagon-like peptide-1 (GLP-1). This hormone is known to increase insulin release and decrease glucagon secretion resulting in a decrease in blood glucose. GLP-1 acts to decrease GI motility potentially resulting in an increase in energy harvest and feelings of satiety [53]. GPR41, which is activated by butyrate or propionate, increases plasma levels of peptide YY (PYY) that also has the effect of decreasing gut motility and increasing energy harvest and feelings of satiety [52]. Activation of either of these two receptors causes a decrease in the secretion of ghrelin, which has the effect of decreasing appetite [54]. In the situation of over-nutrition, however, increased energy harvest and decreased transit time through the colon can lead to weight gain.

Peroxisome proliferator-activator receptor-γ (PPARγ) is highly expressed in the colon and can become activated by SCFAs of microbial origin resulting in an increased secretion of angiopoietin-like-4 (ANGPTL4), a circulating inhibitor of lipoprotein lipase (LPL). The result is inhibition of cellular fatty acid (FA) uptake, decreased adipose

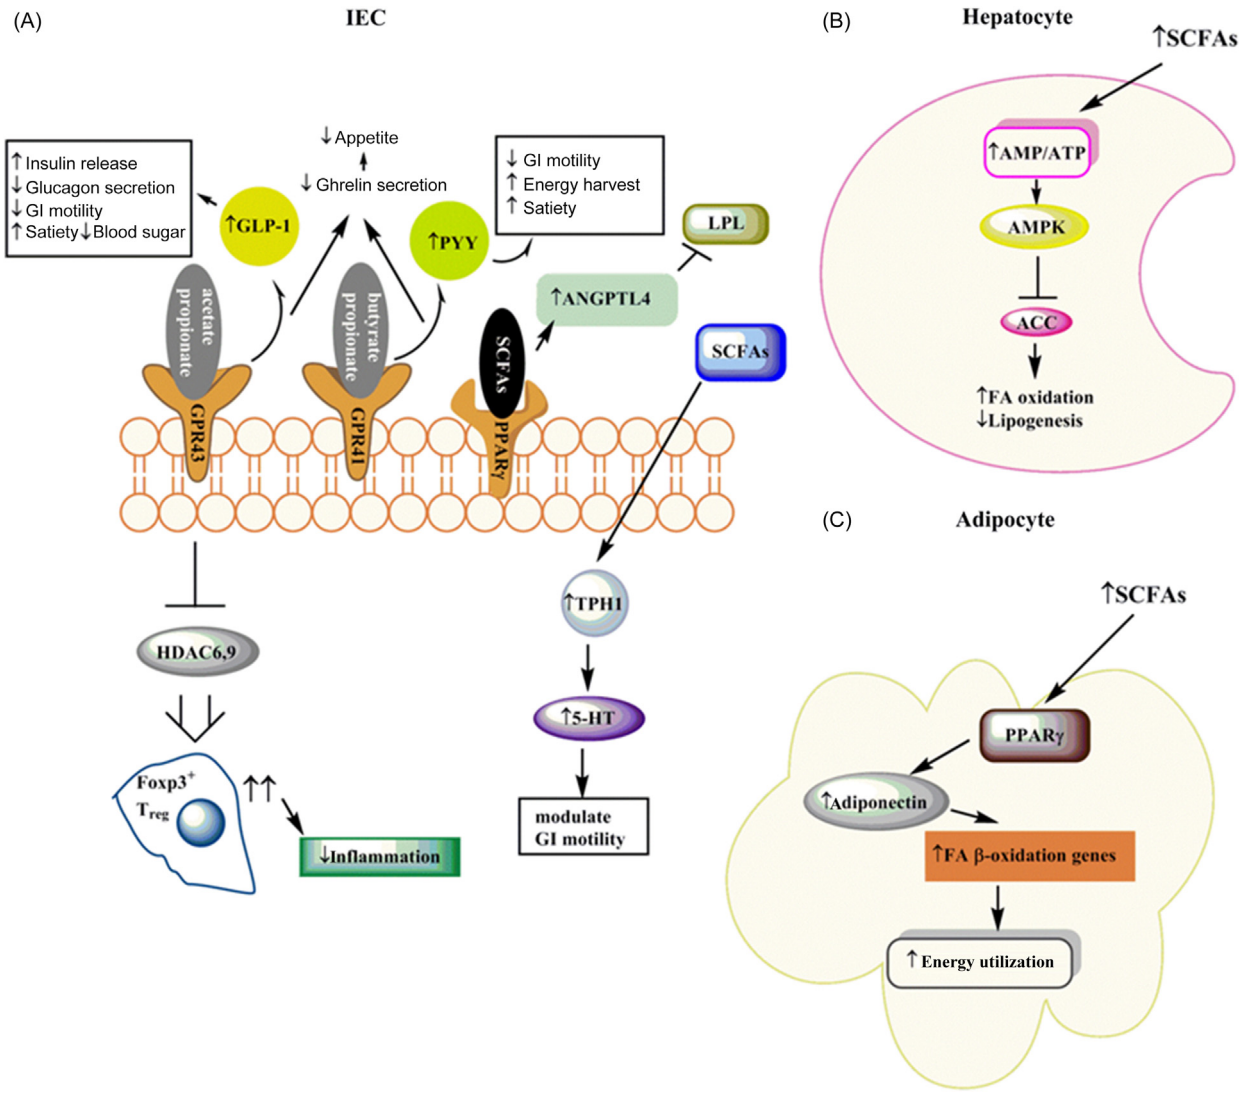

FIGURE 38.3 (A) The effect of SCFAs in IEC, (B) liver, and (C) WAT (see text for details). Abbreviations: HDAC, histone deacetylase; ACC, acetyl-CoA decarboxylase.

triglyceride accumulation, and less fat storage [55]. Confirmation for the effect of ANGPTL4 on lipid storage has come from studies of GF ANGPTL4$^{-/-}$ mice which showed the same degree of adiposity as wild-type (WT) controls [51]. Microbial SCFAs can also directly interact with IECs to cause increased expression of TRP hydroxylase-1 (TPH1), the rate-limiting enzyme for 5-HT synthesis. This means increased synthesis of 5-HT in the gut as a result of the microbiota (Fig. 38.3A). 5-HT modulates GI motility and affects energy harvest which, if stored, leads to weight gain [56].

Microbial SCFAs also impact the liver by increasing the hepatic ratio AMP/ATP. This causes increased activation of AMP-activated protein kinase and therefore, blocks acetyl-CoA carboxylase causing increased expression of enzymes for FA β-oxidation. The result is decreased de novo hepatic lipogenesis and increased energy utilization [57]. This effect affords protection against liver steatosis (Fig. 38.3B).

In the adipocyte, SCFAs can activate PPARγ in white adipose tissue (WAT) to cause upregulation of adiponectin which, in turn, increases expression of FA β-oxidation genes thereby increasing energy utilization and preventing triglyceride accumulation in WAT [58] (Fig. 38.3C). To summarize, SFCA production by gut microbiota modulates host metabolism by increasing energy harvest, decreasing blood sugar, increasing energy utilization, decreasing appetite, and either increasing or decreasing lipid storage. Over-nutrition in combination with increased energy harvest may cause weight gain and these changes may be directly related to shifts in the patterns of gut microbial communities that alter SCFA production.

A recent study of 4 female human twin pairs discordant for obesity involved fecal sampling from each twin and subsequent transplantation of the fecal samples into 8–9 week old male GF mice. Mice were then fed sterilized chow that was low in fat (4% by weight) and high in plant polysaccharides. Fecal pellets from each mouse were obtained at various time points postcolonization which were then analyzed for microbiota composition. The results showed that obesity and lean phenotypes could be transmitted to GF mice from human microbiota. Cohousing of mice given lean versus obese twin's fecal content prevented the obese phenotype. Analysis via 16S rRNA techniques revealed that in the case of cohousing there was invasion of microbiota from the lean mice into the obese but not vice versa. The most prominent invaders from lean inoculate mice to obese inoculate mice that prevented obesity were *B. cellulosilyticus*, *B. uniformis*, *B. vulgates*, *B. thetaaiotaomicron*, and *B. caccae* as well as, *Alistipes putredinis*, and *Parabacteroides merdae*. This study of humanized mice provided some strong evidence that the gut microbiota composition can directly influence adiposity [59].

In other research, genome sequencing of 16S rRNA from obese, lean, and WT mice fed the same polysaccharide-rich diet revealed that obese mice had a 50% reduction in Bacteriodetes and a proportional increase in Firmicutes compared to lean mice. Similar results were observed in humans further suggesting that the Bacteriodetes/Firmicutes ratio approached the lean phenotype after 52 weeks of induced weight loss [60]. These results have been replicated, but differences between the two phyla for obese versus lean individuals were not observed [61,62]. This led to examination of lower taxonomic levels such as genera and even specific species to define individual organisms that could be associated with obesity. One example of this is a study that showed *L. casei* and *L. plantarum* to be associated with weight loss but *L. reuteri* was associated with obesity in humans [63]. The *Lactobacillus* strain dependent effect on weight loss has brought into question the efficacy of using common probiotics in management of obesity and their therapeutic use for obesity has not to date been recommended [64]. However, the use of prebiotics has shown some promise in assisting individuals with weight loss [65]. In a study of 10 healthy volunteers of normal body mass, the effects of prebiotics (Orafti Synergy-1 from Beneo-Orafti, Belgium) on satiety and related gut-derived hormones were determined after 2 weeks of treatment. The results were increased gut microbiota fermentation, improved satiety, glucose tolerance test results, and increased plasma GLP-1 and PYY concentrations [66].

Gut dysbiosis has also been associated with the development of low-grade inflammation in obese individuals and progression from obesity to MS and IR [52]. One possible culprit for the origin of obesity-related inflammation is lipopolysaccharide (LPS), a membrane component of gram-negative bacteria. LPS is constantly produced in the gut through lysis of gram-negative bacteria and is recognized by TLR4 pattern recognition receptors in both macrophages and epithelial cells. Binding of LPS to TLRs initiates a proinflammatory cascade of events (Fig. 38.4) [67]. LPS transport from the intestinal lumen to TLR receptors has been shown to be facilitated by IEC synthesized chylomicrons after HFD feeding. Mice fed a HFD for 2 weeks showed significant increases in plasma LPS. Continuous subcutaneous low-rate

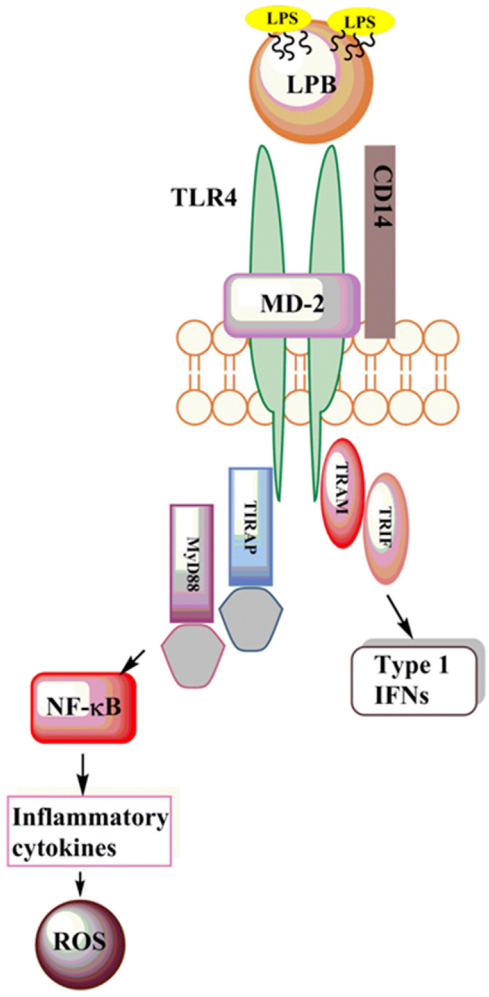

FIGURE 38.4 TLR4 activation. LPS binds to LPB and then to the CD14 accessory protein. LPS is then transferred to the next TLR4 accessory molecule, MD-2. Two TLR4/MD-2/LPS complexes must then dimerize to initiate the internal cell signaling pathways. There are two pathways for TLR4, MyD88 dependent and MyD88 independent, which lead to production of inflammatory cytokines/ROS and IFNs, respectively. Abbreviations: CD, cluster of differentiation; LPB, liposaccharide-binding protein; MD-2, myeloid differentiation factor; MyD88, myeloid differentiating primary response gene 88; TIRAP, toll-interleukin 1 receptor domain containing adaptor protein; TRIF, TIR-domain-containing adaptor-inducing interferon-B; TRAM, toll-like receptor adaptor molecule 2.

infusion of LPS into mice was sufficient to cause the HFD phenotype, that is, excessive weight gain, hyperglycemia, steatosis, WAT macrophage infiltration, and IR, thus demonstrating a link between HFD, elevated LPS, and development of MS [68]. In order to demonstrate a definite link between the TLR4 receptor for LPS and the development of obesity and MS, CD14 (Fig. 38.4) knockout mice and also TLR4-deficient mice were found to be protected from HFD-induced obesity and MS [68]. Notably, plasma LPS levels have been reported to be higher in humans with obesity and T2D than in normal controls [69]. Major LPS-producing bacteria within the phylum Proteobacteria such as Enterobacteriaceae and Desulfovibrionaceae have been found to be enriched in obese humans [65].

Does diet have any influence over activated TLR4-induced inflammation? One way in which to reduce levels of LPS is to control the population of T_H17 cells (Fig. 38.1; Table 38.2) by increasing the population of Foxp3 T_{reg} cells (Figs. 38.1 and 38.4A). Activation of GPR43 receptors by microbially derived SCFAs causes inhibition of HDAC6 and 9 that, in turn, upregulates differentiation of Foxp3 T_{reg} cells, an immunosuppressive response against the bacteria-killing T_H17 cells (reduce LPS).

Another source of obesity-related inflammation comes from TRP metabolism both by host and microbiota (Fig. 38.2). HFD and overfeeding in general can cause increased plasma concentrations of TRP from the metabolism of protein and yet morbidly obese individuals have low plasma TRP [70]. This is because 95% of TRP is metabolized along the TRP → KYN pathway and results in the increased production of substances such as COX-2 and 5-LOX which are precursors for PGEs and leukotrienes that are synthetic precursors for PICs, IFNs, and TNFα. Increased production of IFNs and TNFα cause upregulation of IDO (Fig. 38.2B) thus creating a cycle of chronic inflammation. The plasma KYN/TRP ratio is an indicator of IDO enzyme activity. TRP depletion results as IDO activity increases and this leads to less availability for 5-HT production. CNS 5-HT regulates carbohydrate and fat intake, relieves stress (caloric intake trigger) and inhibits neuropeptide Y (NYP), a potent orexigenic peptide in the hypothalamus [70]. Therefore, decreased CNS 5-HT contributes to both development and maintenance of obesity. Decreased CNS 5-HT also means less BAT further compounding the obesity situation (Fig. 38.2A) [71]. There is also lower production of melatonin, a substance important for sleep cycles. Sleep deprivation upregulates orexin activity causing NYP activation and hunger [30].

Increased peripheral 5-HT, generated from microbial metabolism in the gut (Fig. 38.2A), can activate 5-HT receptors 2B and 3A in the pancreas to cause increased glucose-stimulated insulin secretion and increased β-cell proliferation. If this situation persists, the protein translation overload associated with cellular proliferation in the pancreas can lead to increased ER stress and result ultimately in β-cell loss and IR (Fig. 38.2A) [15,60]. This will translate to development of MS and T2D. Increased IR can also be a product of the TRP → KYN pathway via the formation of xanthurenic acid (Fig. 38.2B) which is known to form a "pseudoinsulin" by reacting with insulin to form a product that is antigenetically indistinguishable from insulin but inactive, thus decreasing insulin sensitivity [30].

An important question is whether the inflammatory status can be switched back to a normal homeostasis that existed prior to the onset of obesity. It was found in one study that for postbariatric surgery patients, TRP depletion could not be prevented despite significant loss of weight and that there continued to be diminished 5-HT functions leading to unchanged satiety dysregulation and a reward-deficiency-syndrome [72]. Perhaps, there is a point of no return for chronic inflammation alleviation in the morbidly obese or perhaps the cure cannot come from bariatric surgery alone but must involve a remodeling of the gut microbiota to restore normal TRP metabolism and decreased populations of LPS-producing bacteria. Consistent with previous discussions, obesity is thus strongly influenced by the microbiota via TRP metabolism, modulation of the immune system to control inflammation, microbiota metabolic products such as SCFAs as well as compositional differences in the microbiota populations themselves.

F Gut Microbiota and IBS

IBS is one of the most common GI disorders and it is characterized by chronic abdominal pain, bloating, and abnormal defecation. Direct evidence for microbiota involvement in IBS comes from epidemiology studies which revealed that 6−17% of patients with IBS-D report an acute onset following enteric infection with *Salmonella enteridis*, *Camphylobacter jejuni,* or *Shigella flexneri* [73]. Furthermore, the use of probiotics incorporating *Bifidobacterium* spp. and *Lactobacillus* spp. and nonabsorbable antibiotics such as neomycin or rifaximin can ameliorate some of the symptoms of IBS such as bowel habits and visceral pain [74,75]. Relative to normal controls, at the phylum level, a consistent finding for IBS-D has been reported to be enrichment of Firmicutes and reduced abundance of Bacteroidetes with the Firmicutes/Bacteroidetes ratio twofold higher for IBS patients [76] along with overall lower microbiota diversity [77,78]. IBS-C, on the other hand, presents with higher levels of *Methanobrevibactor smithii*, a prolific methane-producing bacterium. Enteric methane slows intestinal

transit time and also produces ileal contractions that are nonpropulsive in nature [79]. Hydrogen sulfide, produced by sulfate-reducing bacteria, also exerts a relaxation effect on intestinal smooth muscle through an agonist action on a potassium channel resulting in decreased transit times and constipation [80].

IBS is considered a stress-related disorder and dysregulation of the gut-brain axis has been proposed as a suitable model for this disease [74]. The brain communicates with the gut via the autonomic nervous system which includes the vagus nerves (VNs), sacral parasympathetic pelvic nerves, and the sympathetic splanchnic nerves (SNs) (Fig. 38.5). The VNs transmit information to the CNS regarding luminal osmolarity, carbohydrate levels, mechanical distortion of the mucosa, and the presence of bacterial products. The afferent SNs transmit visceral pain. In addition, there are organs outside the blood brain barrier such as the adrenal gland, hypothalamus, area postrema, and the pituitary gland that respond to vascular contents of circulating cytokines and interleukins [81]. Fig. 38.5A is a diagram of the brain-gut axis. The response of the GI tract to stress can include modifications of motility, secretion, visceral sensitivity, mucosa permeability, and inflammatory responses. Mast cells (MCs) of the intestinal mucosa release PICs (Fig. 38.5A) in response to stress and induce mucosal barrier

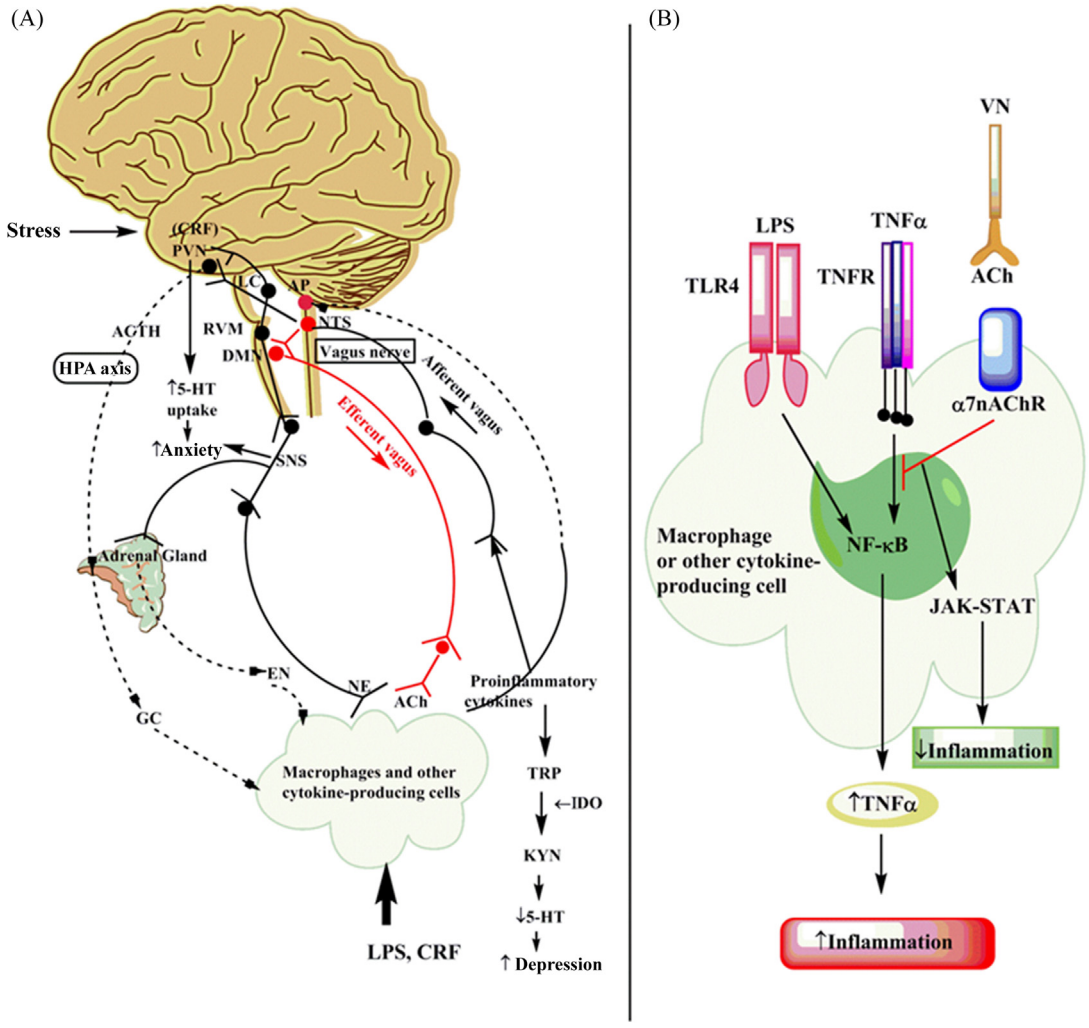

FIGURE 38.5 (A) The gut-brain axis. (B) The antiinflammatory effect of the VN via the cholinergic pathway. ACh is released at the distal end of VN efferent fibers which activates the α7nAChR receptor in macrophages. The activation of α7nAChR causes inhibition of TNFR receptor activation by TNFα thus preventing downstream activation of NF-κB signaling. Additionally, activation of α7nAChR causes activation of a JAK-STAT mediated antiinflammatory pathway [81]. Abbreviations: TNFR, tumor necrosis factor receptor; CRF, corticotrophin-releasing factor; JAK, Janus kinase; STAT, signal transducer and activator of transcription. ACTH, adrenocorticotropic hormone; DMN, dorsal motor nucleus of the vagus (origin of VN efferents); EN, epinephrine; LC, locus ceruleus (the primary brain noradrenergic nucleus located in the pons and involved in the stress response); NE, norepinephrine; PVN, paraventricular nucleus of the hypothalamus (source of corticotrophin-releasing factor, CRF); RVM, rostral ventrolateral medulla; NTS, nucleus tractus solitarii (termination point for vagus efferents).

hyperpermeability along with further activation of mucosal immunity (Fig. 38.1). This, in turn, can lead to loss of microbiota and increased amounts of bacterial products such as LPS [82]. MCs are in close contact with SNs and these afferent nerves respond to MC products via adrenergic receptor activation causing stress-induced increases in both peripheral and central PICs. This ultimately activates the NF-κB signaling pathway leading to the continued maintenance of the inflammation [83].

The VNs, on the other hand, are antiinflammatory and their activation by PICs such as IL-1β, IL-6, and TNFα results in activation of the HPA axis which, in turn, stimulates the release of glucocorticoids to reduce mucosal inflammation (Fig. 38.5A) [84]. Acetylcholine (ACh), which is released by VN efferent fibers, can decrease the macrophage production of PICs such as TNFα via activation of the α7nAChR in macrophages (Fig. 38.5B) [85]. Stress decreases VN efferent outflow of ACh and therefore favors SN-induced inflammation [86].

The gut-brain axis thus responds to stress by attempting to maintain a balance between PIC activation of VNs and SNs to produce either ACh or CRF which suppresses inflammation or increased amounts of PICs to amplify inflammation, respectively. If this balance is perturbed, IBS may result. Relative to normal patients, IBS patients have higher plasma levels of PICs such as IL-6, IL-1β, and TNFα, providing support for an inflammatory status in IBS. It has also been demonstrated that there are increased numbers of MCs in the colonic mucosa in IBS patients indicating increased activation of mucosal innate immunity and furthermore, number of MCs correlated with severity of fatigue and depression, clearly implicating MC immunomodulation of the gut-brain axis (Fig. 38.5A). Further evidence for innate immune activation in IBS comes from the observation of increased AMPs, such as β-defensin-2, secreted by IECs in response to PICs. Increased density of mucosal T-lymphocytes has also been commonly observed for IBS, implicating increased activation of mucosal adaptive immunity which can be impacted by the microbiota (Fig. 38.1) [87]. Additionally, altered TLR expression has been reported in IBS patients with specific increases in LPS-activated TLR4 (Fig. 38.5B), TLR2, and TLR5 (latter two respond to bacterial lipoproteins, flagellin, and peptidoglycans) and decreases in TLR7 and TLR8 (virus, DNA, RNA recognition). Microbial activation of TLRs 2, 4, and 5 all lead to activation of proinflammatory NF-κB signaling (Fig. 38.4) [75]. Enhanced activation of NF-κB also leads to inhibition of FXR in the intestine and the liver leading to decreased enterohepatic circulation which can lead to small intestine bacterial overgrowth a condition commonly reported for IBS-D [88].

5-HT is widely distributed in the gut and is stored mainly in ECs. IBS-D patients have been shown to release higher amounts of 5-HT postprandial relative to normal controls with the reverse being true for IBS-C patients. 5-HT release causes increased GI secretions and propulsion and if pronounced, diarrhea. Inflammation is associated with increased amounts of CD4 + T_H17 and T_H1 lymphocytes (Fig. 38.1) and it has been shown in both animal models and for human IBS-D patients that increased amounts of these cells cause EC hyperproliferation [89,90]. In addition, bacterial SCFAs can stimulate the IECs to upregulate TPH1, the rate-limiting enzyme for EC 5-HT synthesis (Figs. 38.2 and 38.4A). The SCFAs acetate and propionate have been found to be significantly increased in IBS patients of all three classifications relative to normal controls. Higher levels of acetate and propionate were correlated with increased GI symptoms, decreased quality of life, and increased negative emotions [91]. This has led to recommendations for limiting the use of prebiotics and restriction of fermentable carbohydrates (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols; FODMAP diet) for IBS patients [74]. Thus intestinal transit time can be linked to the availability of TRP (from diet, microbiota proteolysis, and direct synthesis) (Fig. 38.2) as well as microbiota-directed mucosal immunity (Fig. 38.1) and SCFA production (Fig. 38.3) for increased production of 5-HT.

The effects of altered 5-HT signaling on IBS symptoms via the CNS include increased reaction to visceral pain via 5-HT activation of 5-HT_3 receptors, an increased stress response due to enhanced CRF-induced 5-HT activation of upregulated 5-HT2A receptors (Fig. 38.5A; Table 38.3) which causes increased anxiety. The combination of this increased 5-HT turnover and metabolism along with enhanced CRF-induced production of cytokines (Fig. 38.5A) can cause increased stimulation of the TRP/KYN pathway (Fig. 38.2B) eventually culminating in 5-HT depletion and depression in chronically inflamed IBS patients [92]. Clinical evidence for this comes indirectly from the utilization of the antibiotic minocycline to modulate depression [93]. Notably, minocycline has an effect of indirectly inhibiting IDO activity without affecting 5-HT turnover [94].

When TRP is metabolized to KYN in the CNS, it can be further metabolized to quinolinic acid, an NMDA receptor agonist that acts to increase excitotoxicity at glutaminergic synapses in the striatum and hippocampus where NMDA receptors are the most abundant. The result is diminished cognitive processes such as learning and memory (Fig. 38.2B) [95]. Quinolinic acid can also upregulate iNOS and this ultimately leads to increased amounts of proinflammatory PGEs and leukotrienes which can continue to fuel GI inflammation as well as sustain production of more KYN [81]. KYN can also be metabolized to kynurenic acid which is an antagonist to the α7-nAChR. CNS antagonism of this receptor results

in decreased cognition and increased depression (Fig. 38.2B) [30]. Peripheral antagonism of α7-nAChR interferes with VN release of ACh and this, in turn, can increase activation of NF-κB to favor inflammation in IBS (Fig. 38.5B) [81]. Therefore, the microbiota, via its control of TRP and SCFA availability may have a profound effect on IBS psychological symptoms and contributes to the microbiota-gut-brain dysregulation associated with IBS. Although clinical evidence is limited, one study showed that in healthy volunteers administered a probiotic consisting of *L. helveticus*, a homofermentative species that produces only lactic acid, and *B. longum*, also a lactic acid producing bacteria that has also been shown to be antiinflammatory, produced alleviation of psychological distress including an index of depression [28,96].

From the preceding discussion of IBS, it is clear that a major way to prevent/control this disease is to ameliorate stress whenever possible. Stress is the primary trigger for release of CRF (Fig. 38.5A) and activation of the HPA pathway. If the individual cannot compensate for HPA activation with VN stimulated responses, then it results in the dysregulation of the gut-brain axis. Therefore stress-reducing changes in lifestyle including changes in diet and physical activity may be able to help these patients via effects on their microbiota. More work is needed to characterize changes in microbiota that are associated with treatments that have been shown to be helpful in IBS, such as minocycline antibiotics, prebiotics, and selective serotonin reuptake inhibitors. Changes in gut microbial profiles before and after treatment may provide clues for further therapeutic targets such as identification of microbial species that are restorative of the mucosal barrier, can aid in controlling GI inflammation, and thus shift the balance of the microbiota-gut-brain axis to a balanced, noninflammatory status.

G The Gut Microbiota and ARNDD

Aging is often accompanied by regression of key physiological functions that enhance susceptibility to inflammatory diseases. "Inflammageing" is a chronic low-grade inflammatory status caused by age-related decline in the immune system, "immunosenescence" [97], thought to begin at an earlier time-point in the GI relative to other systemic compartments [98]. In the intestine, the immune response originates from gut-associated lymphoid tissue (GALT) that contain all of the cells necessary to effect antigen-specific B- and T-cell responses. After induction, immune cells migrate to the "effector site" in the LP (Fig. 38.1) where they undergo further differentiation before migration to other sites [99]. Specialized GALTs known as Paneth cells in the small intestine are the major source of AMPs and both their number and secretion functions decline with age [99].

The LP is separated from the luminal environment by a single layer of IECs which form part of the mucosal barrier via their tight junctions (TJs). In a study done in primates, aging in the absence of any overt inflammation was shown to cause increased IEC production of proinflammatory IL-6, TNFα, and IL-1β cytokines which in turn, caused aberrant TJ protein expression [100]. IL-6 has been shown to decrease murine zona occluding-1 (ZO-1) expression [101]. IL-1β has been shown to downregulate occludin in Caco-2 IECs and decrease transepithelial resistance [102]. Increased IL-6 and IL-1β have been detected in the plasma in selected healthy (65−72 years) elderly humans [103]. An upregulation of a microRNA, miR-29a, was observed in the primate study and was related to decreased expression of ZO-1, occludin, and junctional adhesion molecule-A (JAM-A) which together function in the adherence of TJ [100]. Fig. 38.6A is a diagram of the epithelial cell TJ and Fig. 38.6B shows a proposed mechanism for the effect of cytokines on TJ [104,105]. A preinflammatory state of "leaky" mucosal barrier thus opens up the possibility of increased barrier translocation of bacteria and bacterial products to eventually induce overt inflammation (Fig. 38.1) and also affect the microbiota composition.

In the brain, inflammageing manifests itself by constitutive activation of perivascular macrophages as well as parenchymal microglia that continually express PICs. This is accompanied by an increased number of astrocytes which have been shown to be capable of secreting the neurotransmitter, glutamate (GLU), an important ligand for activation of the NMDA receptor [106]. Neurodegenerative diseases such as Parkinson's disease (PD), Alzheimer's disease (AD), and Huntington's (HD) are all characterized by altered GLU homeostasis and increased excitotoxicity involving the agonist action of quinolinic acid, a product of TRP metabolism, on the NMDA receptor in brain [107,108]. Enhanced production of PICs in the brain is accompanied by increased production of reactive oxygen and nitrogen species that leads to neurodegeneration and eventually loss of neurons via KYN metabolism to 3-hydroxykynurenine (3-HK) (Fig. 38.2B) [30]. Fig. 38.7 illustrates the development of neuroinflammation from a peripheral inflammatory response [109].

The microbiota in people >65 years has been characterized by increased amounts of opportunistic aerobes such as *Staphylococcus*, *Streptococcus*, and Enterobacteriaceae, potentially pathogenic species associated with hospitalization and antibiotic treatments [110] and also decreased amounts of *Clostridium* cluster IV, XIVA, known for SCFA production, maintaining colonic pH [111], and *Bifidobacterium* (vitamin synthesis, support immune function, epigenetic effects to control cell proliferation) [111]. Aging of the gut

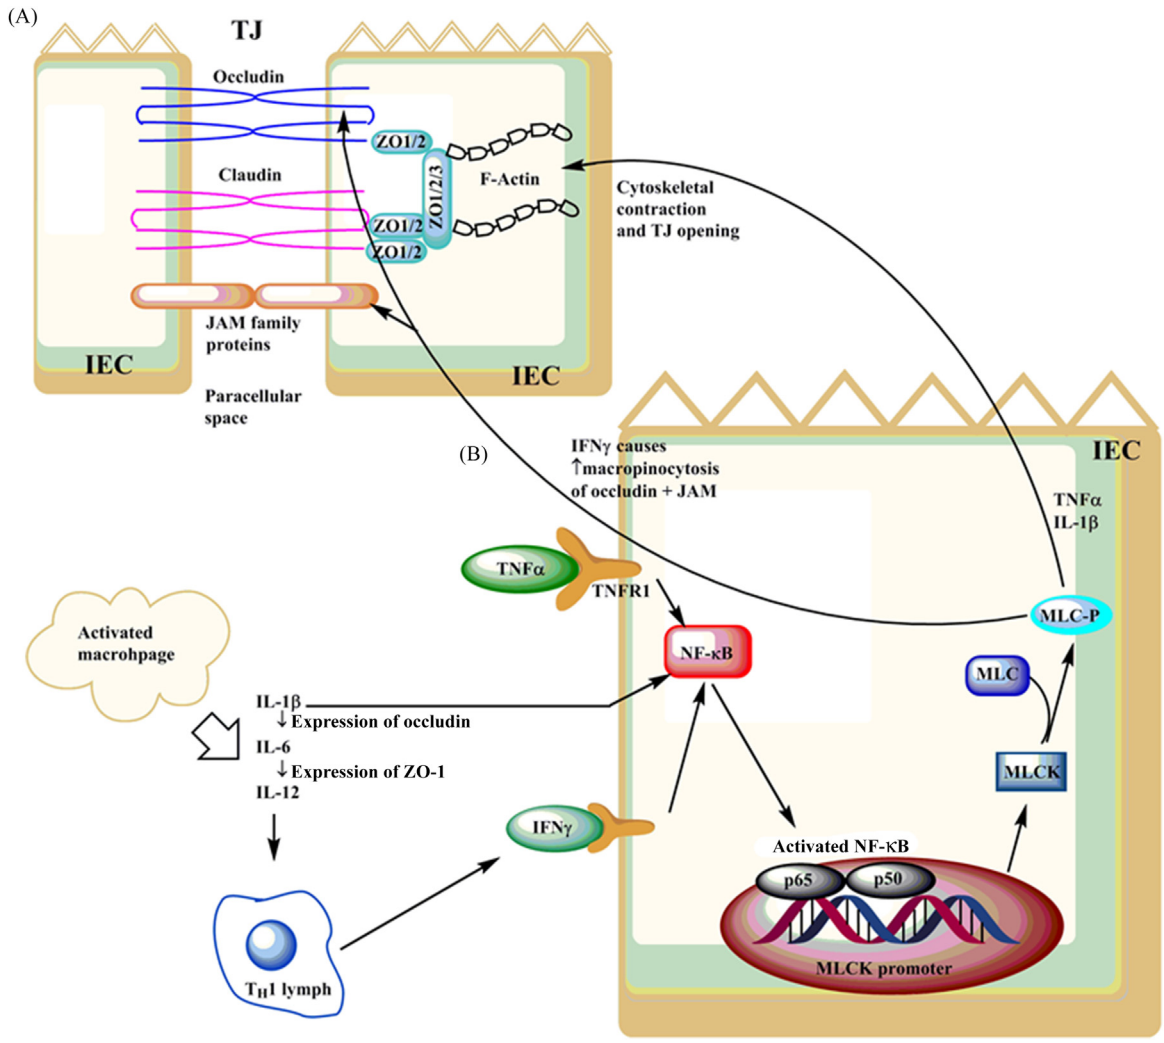

FIGURE 38.6 (A) Structure of the TJ between adjacent IECs. Transmembrane proteins occludin, claudin, and JAM family proteins seal the paracellular space between IECs. Plaque proteins such as ZO family proteins bind to one another to form a stabilizing scaffold and a direct link to the cytoskeleton via ZO-1 binding to F-actin. (B) The effect of PICs that have been found to be increased in healthy, normal weight seniors on the TJ. Activated macrophages (Fig. 38.1) produce TNFα, IL-1β, and IL-6 as well as IL-12. IL-12 goes on to stimulate production of T_H1 cells that secrete IFNγ. TNFα binds to the TNFR1 receptor on IECs and causes activation of NF-κB and its subsequent translocation to the nucleus where it acts as a transcription factor for the MLCK promoter resulting in production of MLCK protein. MLCK then phosphorylates MLC to MLC-P which then acts on F-actin to cause cytoskeletal contraction and opening of the TJ. IL-1β has been shown to downregulate the expression of occludin and also acts via NF-κB → MLC-P to cause TJ opening. IL-6 has been shown to decrease expression of ZO-1 causing disruption of the TJ stabilizing scaffold. IFNγ, also via MLC-P, has been shown to increase IEC macropinocytosis of occludin and JAM proteins, thus removing them from the paracellular space. The culmination of all of these effects is a "leaky" mucosal membrane. Abbreviations: MLCK, myosin light chain kinase; MLC, myosin light chain protein; TNFR1, tumor necrosis factor receptor-1.

microbiota has also been shown to exhibit diminished bacterial diversity with increased amounts of proteolytic bacteria and decreased amounts of saccharolytic bacteria [36,112]. Increased proteolytic bacteria allow for more TRP production and decreased populations of saccharolytic bacteria implies less production of SCFAs (Figs. 38.2 and 38.5A). The former leads to activation of proinflammatory pathways (Fig. 38.2) and the latter can adversely affect IEC health and augment inflammation via diminished effects on T_{reg} cell populations (Fig. 38.1).

Investigators have started to examine changes in gut microbiota in PD and AD patients. In a study of 72 subjects and age-matched controls, PD subjects showed higher counts of Enterobacteriaceae and a 77% reduction in Prevotellaceae, relative to controls. The latter is known to be saccharolytic, providing SCFAs as well as, thiamine and folate. Decreased amounts of thiamine and folate could potentially result in decreased production of vitamins necessary for important gut hormone secretion [113,114]. Certain cyanobacteria normally present in small

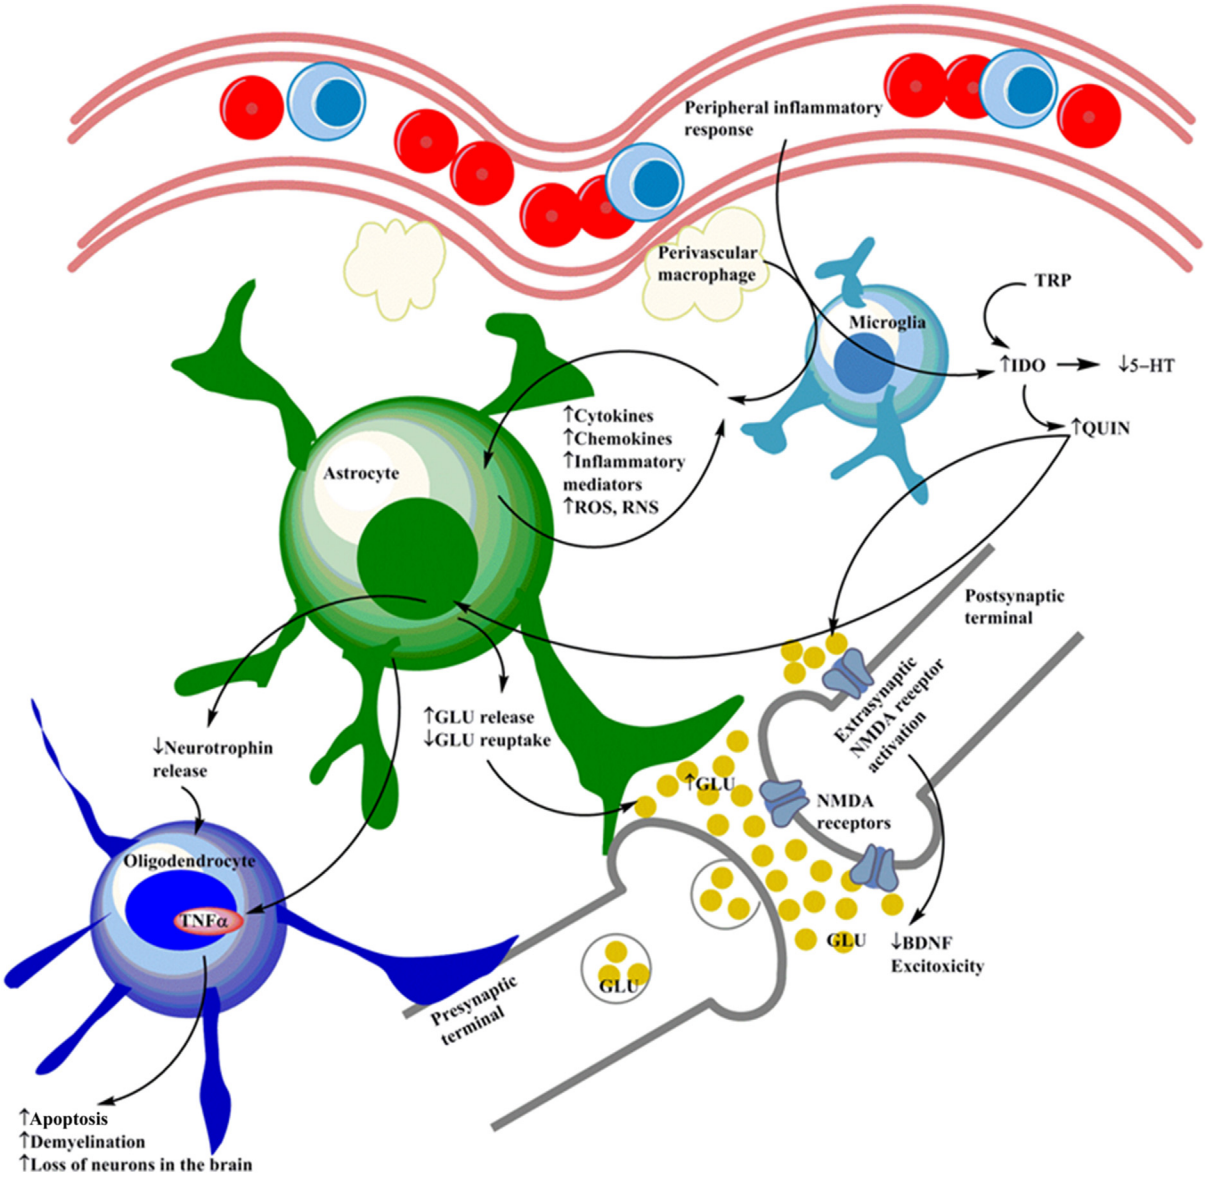

FIGURE 38.7 Inflammageing in the brain. An inflammatory response initiated in the GI can result in circulatory transport of proinflammatory substances such as LPS which can activate perivascular macrophages and microglia to upregulate IDO and the TRP/KYN pathways resulting in increased production of neural PICs, ROS, and RNS. Increased TRP metabolism causes decreased levels of 5-HT and increased levels of QUIN. QUIN is an agonist for the excitatory NMDA receptor and thus stimulates release of glutamate (GLU). Multiple functions of astrocytes are compromised due to excessive cytokine exposure resulting in a decrease of GLU reuptake and an increased release of GLU along with decreased trophic support for oligodendrocytes. Oligodendrocytes are very sensitive to PICs, especially TNFα. Exposure to excess TNFα leads to oligodendrocyte apoptosis and eventual loss of neurons in the brain. Overall, inflammageing causes a disruption of neural plasticity through glutaminergic excitotoxicity involving the NMDA receptor with subsequent degeneration and apoptosis of neurons.

numbers in the GI tract produce β-*N*-methylamino-L-alanine (BMAA) which has been found to be elevated in the brains of AD and PD patients. BMAA is an excitotoxin that activates metabotropic glutamate receptor 5 causing depletion of the antioxidant, glutathione, and defective glial cell control of neuronal ROS and RNS. BMAA has also been implicated in the protein misfolding and aggregation seen in PD and AD patient brains [114,115].

Bacteria also have the capacity to generate neurotransmitters. Certain *Lactobacillus* sp. and *Bifidobacterium* sp. produce gamma-aminobutyric acid (GABA); *Escherichia*, *Bacillus*, and *Streptococcus* spp. produce NE; *Candida*, *Streptococcus*, *Escherichia*, and *Enterococcus* spp. produce 5-HT; *Bacillus* produces dopamine (DA); and *Lactobacillus* can generate ACh [116]. It should be noted here that GABA-producing strains of *L. helveticus R0052*

and *B. longum R1075* in a probiotic formulation have shown efficacy in alleviating depression symptoms in both animal studies and human volunteers [96]. GABA is significant because it is an inhibitory neuromodulator in the CNS and hence works to counter the effects of excitatory GLU signaling [117].

TRP metabolism alterations play a large role in aging. Aging has been associated with elevated cortisol production as a result of HPA axis hyperactivation (Fig. 38.5A). This hyperactivation results in enhanced production of cortisol which upregulates TDO (Fig. 38.2B). Another consequence of enhanced cortisol production is desensitization of glucocorticoid receptors which diminishes the antiinflammatory effect of glucocorticoids. Thus, the activation of not only IDO but also TDO (Fig. 38.2B) causes an increased risk for depression in the elderly via TRP metabolism to KYN and increased inflammation [118]. Evidence for age-related TRP depletion has been found in several studies, one of which revealed increased amount of genes for TRP metabolism [119]. Another study of centenarians revealed plasma TRP depletion [120]. Two independent studies of elderly patients detected increased KYN/TRP ratios indicating increased TRP metabolism to KYN relative to younger patients [121]. Neurodegenerative disorders associated with aging such as PD and AD have long been associated with depression accompanied by TRP, 5-HT, and melatonin depletion [122,108]. Additionally, HD, a neurodegenerative genetic disorder that affects early aging at 35−45 years of age has also been associated with the TRP depletion [107,123]. In fact, a point of similarity for all three of these neurodegenerative disorders is that there is a decreased amount of kynurenic acid (thought to be neuroprotective) but increased amounts of 3-hydroxykynurenine (3-HK) and quinolinic acid indicating a preferred metabolism of KYN to quinolinic acid, a known NMDA receptor agonist, which is consistent with the NMDA excitotoxicity and oxidative stress that is associated with these conditions (Fig. 38.2B) [108].

Thus, the homeostatic balance in the brain that is disrupted as a result of gut microbiota-induced inflammation that starts in an aged "leaky gut" is the balance between excitatory (GLU) and inhibitory (GABA) neurotransmitter signaling in the brain. The homeostatic shift in the balance is toward glutaminergic excitotoxicity and this leads to a progression from depression to neurodegenerative diseases. The reason for this shift is due to another shift in the balance, that is, a shift toward KYN metabolism to QUIN away from KYN metabolism to kynurenic acid. The use of probiotics that replace the diminished *Lactobacillus* and *Bifidobacterium* spp., a situation commonly found in the aged population, has shown some promise in alleviating depression perhaps by their ability to produce the neuroinhibitory neurotransmitter, GABA. The fact that neuroinflammation is the driving force in depression is evident from the fact that antioxidants such as melatonin, NSAID, and more recently, antiinflammatory antibiotics such as minocycline show efficacy in treatment [109,124,125]. Therefore, correcting the gut dysbiosis as early as possible may be the key to prevention of age-related dementias.

H The Metabolomic Approach to the Study of Microbiota

Metabolomics is a new omics approach aimed at qualitatively and quantitatively describing all of the metabolites in cells, tissues, or body fluids. The ultimate goal of an analysis is identification of a complete panel of metabolites that reflect important changes resulting from disease acquisition or progression. A targeted approach is used to examine a predefined set of metabolites. Liquid chromatography (LC) and/or gas chromatography (GC) interfaced to a mass spectrometer are the most widely used techniques, while nuclear magnetic resonance spectroscopy is growing in its use in metabolomics. The general steps in a typical metabolomics analysis include sample collection and processing, instrumental analysis including separation and detection of individual metabolites, data analysis, and interpretation [126]. GC is useful for compounds that are volatile and also thermally stable enough to survive higher than ambient temperatures. LC is employed for higher MW compounds and thermally sensitive substances. It is not uncommon for both techniques to be applied on aliquots of the same sample to broaden the metabolic profiling capacity. Some key differences in protocols for metabolomics also concern with sampling and pretreatment (i.e., body fluid vs cell lysate) as well as instrumental parameters (column selection, GC vs LC, temperature and solvent gradients, etc.). Metabolomics is a powerful tool that can be used to identify microbial metabolites, test the efficacy of a therapeutic intervention [127], reveals an underlying cause for a disease state [128,129] or to predict disease acquisition risk [130].

A specific example of the application of metabolomics to characterization of microbial activity and metabolism is the examination of metabolic impact on host metabolism in mice with their gut microbiota ablated using a broad spectrum antibiotic and measurements of their metabolic phenotype were done at multiple time-points. Zheng et al. first reported a panel of 202 urinary and 223 fecal metabolites derived from gut microbial−mammalian cometabolism, which includes TRP metabolites, SCFAs, organic acids such as hippuric acid, amino acids such as tyrosine and phenylalanine, and oligopeptides [129]. These differentially expressed metabolites were identified in a rat model treated with beta-lactam antibiotic

imipenem/cilastatin sodium for 4 days followed by a 14-day recovery period. Increased amounts of TRP, tryptamine, and melatonin along with decreased amounts of indole and other TRP metabolites such as 3-HK were observed in urine and feces. Neurotransmitters such as DA, NE, and epinephrine were also perturbed in both urine and feces. These results lend credence to the impact of gut microbiota on the gut-brain axis [129].

Another approach of identifying microbial metabolome is the direct measurement of metabolites produced by bacteria. A recent study examined the effect of different sizes of arabino-oligosaccharides (AOS) on six different human fecal communities from healthy subjects in an in vitro experiment [127]. The AOS substrates were obtained from sugar beet and were separated using HP size exclusion LC to recover the original AOS base-extract (BE), an enriched low MW component (LA) and an enriched high MW component (HA). Fecal samples from six healthy volunteers were then collected in airtight containers and fecal slurries prepared anaerobically were then mixed with BA, LA, or HA. Bacterial DNA was extracted and was measured by qPCR using 16S rRNA targeting primers. Metabolites were measured by LC-mass spectrometer. Comparisons were made between the two time-points (before and after bacterial fermentation), and to a control with no AOS added. BE and LA fermentations yielded similar results while HA was distinct in yielding higher amounts of *Bifidobacterium* spp. and *Desulfovibrio* spp. The importance of this study was not only identification of HA as a potential prebiotic but correlations made with specific metabolites thus expanding the repertoire of potentially useful bacterial metabolites other than SCFAs. For HA samples, these included increased amounts 3-oxaloalanine, tyramine, and homoveratic acid. On the other hand LA and BE had higher levels of cysteine, aminobenzoic acid, hypoxanthine, and 3-octadecanoic acid. By using metabolomics, the efficacy of a potential prebiotic therapy as well as baseline levels of potentially beneficial plant metabolites for a healthy microbiota were obtained.

II CONCLUSION

In this chapter we have presented some specific examples of the way gut microbiota influence human health and how they may contribute to the development of noncommunicable inflammatory disease such as obesity, IBS, and ARNDD. The gut microbiota modulate inflammation via their effect on immunity, their own populations, availability of neurotransmitters, key metabolites for host health, and the enterohepatic circulation via BA metabolism for GI tract homeostasis. Future therapeutic targets for noncommunicable inflammatory diseases may have to go beyond treatment of inflammation in order to control the epidemic that developed countries are now facing with respect to the topics covered in this chapter and other chronic inflammatory conditions such as cardiovascular disease and T2D. Knowledge of how to reestablish the original homeostatic condition may require a more detailed dissection of the combination of environmental and dietary factors that give rise to the gut dysbiosis now believed to be important in the etiology of most of these conditions. Only by resetting the "shift" in the homeostatic balance can these conditions be said to be truly "cured." A better understanding of the microbiota composition and its response to conventional treatments already in use may provide clues to design better pro- and prebiotic strategies to correct dysbiosis along with "prescription diets" to encourage a healthy, diverse population of commensal bacteria. A key component to this will be the application of metabolomics to evaluation of clinical improvements as a result of therapeutic intervention in an effort to provide key information linking host metabolism with changes in the gut microbiota.

Chapter 39

Nutritional Management of Inflammatory Bowel Disease and Short Bowel Syndrome

Jennifer L. Barnes[1] and Kelly A. Tappenden[2]
[1]Illinois State University, Normal, IL, United States, [2]University of Illinois at Urbana-Champaign, Urbana, IL, United States

I INFLAMMATORY BOWEL DISEASE

Crohn's disease (CD) and ulcerative colitis (UC) are the two most common forms of inflammatory bowel disease (IBD). Although the precise etiology is not known, evidence suggests that the body launches an immune response to a healthy, normal intestinal environment, resulting in inflammation (Fig. 39.1). Inflammatory episodes range from mild to very severe and are often relapsing. Over the last several decades, the prevalence of IBD, particularly CD, has been on the rise, suggesting an environmental contribution, with evidence for a genetic component [1]. It has been suggested that individuals in Western countries including North America and Europe are more likely to develop IBD, but perhaps not coincidentally; this is also where the greatest number of population-based studies are performed. Recent estimates suggest an incidence of 19.2 UC cases per 100,000 people in North America and 20.2 cases per 100,000 people for CD [2] with a prevalence of 1.3 million IBD sufferers in North America alone [3]. Caucasians and individuals of Jewish descent show a greater incidence of IBD; females are at increased risk of CD compared to males, whereas UC is slightly more common in men [2,3].

The cause of IBD is yet to be elucidated, but it is likely due to unusually aggressive innate and adaptive immune responses. This immune response is thought to be in response to interactions with the gut microbial communities, which may be mediated by genetic predispositions [1,4,5]. The gastrointestinal (GI) tract is continually exposed to numerous antigens, presented from the diet, microbiota, and other environmental factors, each with the potential to activate an abnormal immune response, thereby initiating an IBD episode. These interactions are an active area of research, with emphasis on the possibility of a microbiota dysbiosis being of particular etiological importance.

IBD significantly impacts the patient's health, quality of life, nutritional status, and relationship with food. Nutrition is a key component of any IBD care plan. Food choices can trigger or exacerbate, and even reduce the symptoms of IBD. During active disease and following surgery, adequate nutrition is critical to prevent deficiencies. This chapter will review IBD and short bowel syndrome (SBS). Topics covered for each will include variants of the diagnosis, etiology, a brief orientation to medical management, and an in depth discussion of the medical nutrition therapy.

A Characteristics of IBD

CD and UC both result from a robust, cytokine-driven inflammation of the GI tract [6]. The prolonged and dysfunctional inflammatory response results in changes in intestinal mucosal architecture, strictures, bowel thickening, ulcerations, altered motility, and malabsorption [6–8]. Symptoms of fatigue, intestinal and extraintestinal pain, bloating, diarrhea, steatorrhea, weight loss, malnutrition, and increased risk of colon cancer are manifestations of increased local and circulating levels of cytokines and other products of inflammation [9,10]. Impaired intestinal permeability, local edema, ulceration, and damage to the intestinal structures may occur. Secretions, digestion, absorption, and motility may be abnormal, especially in

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00039-4

active stages, and the normal barrier function may be compromised [6,7]. Malabsorption results in macro- and micronutrient deficiencies with consequences such as anemia and metabolic bone disease. Some CD and UC patients experience arthritis and dermatologic manifestations due to the widespread inflammation. Many of these symptoms are shared by the two inflammatory conditions, but others are unique to either CD or UC.

The most important differentiating characteristic between CD and UC is that patients with CD can present with inflammation occurring through the length of the GI tract that is not limited to the mucosa. Indeed, inflammation in CD is transmural, affecting the full thickness of the tissue. The anatomical location of the disease may change over time, but is most commonly found in the distal small intestine. Specifically, at diagnosis CD is located in the ileum 47% of the time, in the colon 28% of the time, and both ileum and colon together 21% of the time [7,11]. Diseased tissue is often intermittent and surrounded by healthy tissue. Malabsorption, mucosal thickening, strictures, obstruction, abscess and fistula formation, and kidney stones are also more common with CD (see Fig. 39.2). Unlike CD that is associated with more proximal and transmural inflammation, UC is confined to the colon and inflammation affects the mucosa only. Progression of UC differs from that of CD in that it

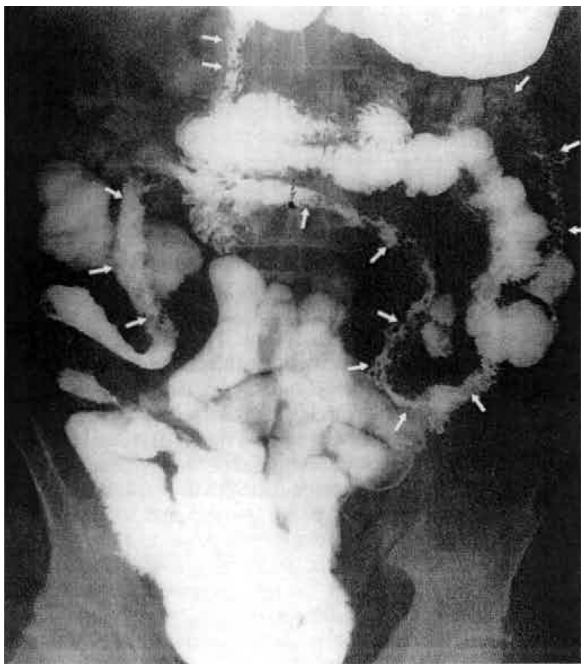

FIGURE 39.2 Radiologic image of patient with CD. White arrows indicate areas of narrowed small intestine. *Reprinted from M. Sleisenger, M. Feldman, Sleisenger and Fordtran's Gastrointestinal and Liver Disease, seventh ed., W.B. Saunders, 2002, with permission from Elsevier.*

TABLE 39.1 Characteristics of CD and UC

Crohn's Disease	Ulcerative Colitis	Both
• Can occur in length of GI • Transmural • Healthy mucosa interrupted with diseased mucosa • Fistulas • Strictures • Nausea and vomiting	• Bloody diarrhea • Anemia • Limited to the colon • Mucosal ulceration	• Relapse and remission • Abdominal pain • Diarrhea • Tenesmus • Loss of appetite • Fatigue • Weight loss, growth failure • Systemic inflammation • Fever • Increased risk of colorectal cancer

characteristically begins at the most distal tissue and extends proximally in a continuous fashion. The hallmark of UC is bloody diarrhea and mucus (see Fig. 39.3) [7,8,12]. See Table 39.1 for common disease characteristics.

B Variables Triggering Onset or Exacerbation of IBD

IBD is a chronic disease characterized by relapse and remission. Environmental factors can trigger relapse or help maintain remission and knowledge of these factors are important for clinical management. However, the potential triggers are many, including genetic and environmental contributions, and often difficult to predict [13]. In addition, a number of years may elapse between histological onset, symptoms, and IBD diagnosis. Microscopic or endoscopic evidence of the disease may occur long before clinical symptoms become apparent. Normal reactions to dietary indiscretions may cause GI symptoms (gas, bloating, pain, cramping, diarrhea) and may be confused with active disease. Dietary factors considered to provoke active disease include high added sugar intake [14], specific lipids, lack of dietary fiber (fruits and vegetables) [12,15–18], abnormal metabolism of sulfur-containing amino acids as in hyperhomocysteinemia [17,19], inadequate micronutrient status such as folate [19,20] and vitamin D [21], and individual food intolerances or food allergies [13]. Breastfeeding and consumption of fruits, vegetables, dietary fiber, and *n*-3 lipids are considered protective [7,12,18,22].

C Medical Management of IBD

Several classes of medications are utilized to control complications and induce/maintain remission of IBD, but there is no cure [23]. The most common categories of medications include antiinflammatory agents, immunomodulator or immunosuppressive compounds, biologic agents, and antibiotics [23,24]. Drugs are also prescribed or recommended to treat specific symptoms, including antidiarrheals, antiemetics, analgesics, and antibiotics [23,24]. While often helpful in managing IBD, in some cases medications are not effective at inducing or maintaining remission even at high doses and for prolonged periods of time [24]. A nutrition professional must always

TABLE 39.2 Medical Management of IBD

5-Aminosalicylic acid (antiinflammatory)
• mesalamine, sulfasalazine
Corticosteroids
• prednisone, prednisolone
Immunosuppressives
• azathioprine, 6-mercaptopurine, methotrexate
Biologicals
• infiximab, adalimumab, etanercept, certolizumab
Antibiotics
• antimycobacterial, metronidazole

be aware of medications prescribed to patients to monitor for any potential drug−nutrient interactions. See Table 39.2 for a listing of medications commonly used in IBD.

D Surgical Treatment of IBD

When management of IBD through medications ceases to be adequately effective, surgical intervention is often utilized to control CD and/or cure UC. Specific indications for surgery include severe, unrelenting disease, strictures, obstruction, hemorrhage, increasing risk of cancer, repair of fistulas, and failure of other medical therapy [12,25]. As UC is restricted to the colon, a complete colectomy eliminates any further relapse and is considered curative. It is estimated that approximately 25−30% of patients with UC have surgery during their lifetime [26−28]. The most common surgical intervention is colectomy with the creation of an ileoanal pouch. This pouch develops the microbiota and serves to some degree as a colonic/rectal reservoir.

Unlike UC, surgical resection of severely involved segments of small or large bowel in CD does not bring resolution of the disease and duration of clinical remission varies greatly. In fact, many patients experience relapse which may occur in months, whereas other patients appear to remain in remission for years. Approximately 70−90% of patients with CD eventually have at least one surgery during their lifetime with 40−50% requiring additional operations [29−31]. Strictureplasty is a procedure to relieve narrowed segments of bowel generally caused by fibrous tissue. This procedure may be preferable as it helps to preserve intestinal tissue [32]. However, in some cases, patients with prolonged or severe episodes of CD have multiple resections resulting in SBS and the host of new nutritional considerations associated with that diagnosis (covered later in this chapter).

E Nutrition Assessment in IBD

Nutrition assessment in IBD should follow the standard approach including collection of anthropometrics, biochemical measures, clinical evaluation, and dietary intake data in order to fully evaluate nutrition status and risk. Standard anthropometric measurements including growth rate for age in children, weight and history of weight changes, body mass index, and body composition assessment when available are important in IBD. Biochemical laboratory data should be evaluated for protein-energy and micronutrient status. Evaluation of the patient's medical and surgical history including duration and severity of the disease, presence of strictures, fistulas, resections, and ostomies are necessary to identify nutritional risk. Symptoms including diarrhea (stool volume, frequency, and duration) or malabsorption (increased fecal fat), very low serum cholesterol, abdominal cramping, bloating, or distention also significantly affect nutritional status. A careful diet history of typical food intake, quantity and quality of food choices, and intolerance and aversions to various foods and food allergies provides insight into macro- and micronutrient intake. IBD patients may utilize botanical or other complementary medicines [33] in addition to prescriptions and over-the-counter medications, which may or may not influence the nutrition management of the disease. The nutrition assessment should also include an evaluation of the patient's knowledge and understanding of his or her nutritional status, needs, problems, and therapeutic options.

1 Energy Balance

When conducting the nutrition assessment, close consideration must be paid to energy balance and weight status as patients with IBD often experience anorexia and malabsorption as a consequence of the widespread inflammation [34−38]. Individuals may also avoid food due to symptoms and perceived food intolerances, negatively impacting the amount and quality of food consumed. Weight loss, muscle wasting, growth failure, and delayed maturation are some of the most common problems in adults and children with IBD, particularly CD. Evidence of protein-energy malnutrition may include decreased levels of transport proteins such as albumin, transferrin, or prealbumin [39]. Decreased intake is further confounded by increased fecal loss of macronutrients during IBD flares. Growth failure is common in children suffering from IBD, particularly CD [40−42]. The etiology of growth failure is similar to that of weight loss and wasting in adults where anorexia and malabsorption are the primary causes [43].

2 Fluid and Micronutrients

Diarrhea is one of the most common symptoms exhibited in IBD [7,12]. Dehydration and electrolyte imbalances may occur in flares of IBD and after significant small bowel resections in CD. Micronutrient deficiencies

secondary to malabsorption and/or inadequate intake including vitamin B_{12}, folate, zinc, calcium, iron, magnesium, selenium, copper, and vitamin A, D, and E have all been reported in IBD [39,44–47]. Further, anemia may result from lack of one or several of these micronutrients resulting from inadequate intake, malabsorption, increased requirements, and drug–nutrient interactions. As many as 70% of children and 40% of adults with IBD are anemic [44]. UC patients may be at increased risk for iron-deficiency anemia due to blood loss in feces, while CD patients are at greater risk following intestinal resection [48,49]. Overall, micronutrient deficiencies may be more profound in CD patients, especially those who have undergone surgical resection [50,51]. Depending on the location of resection and severity of malabsorption, intravenous supplementation of micronutrients, particularly iron and B_{12}, may be indicated [52,53].

F Medical Nutrition Therapy in IBD

1 Goals of Medical Nutrition Therapy

The primary nutritional goals in IBD are to restore, support, and maintain nutrition status, help control symptoms, and decrease inflammation. Inadequate intake of protein, energy, and micronutrients, independent of a diseased state, are known to effect changes in GI barrier function and digestive functions, modulate immune function, and alter microbial populations [54]. Further, individual dietary components are well-established antioxidants and may serve as precursors to inflammatory mediators in the GI tract. These may be implicated in remission maintenance [55,56]. More specifically to IBD, nutritional rehabilitation may be required after acute or prolonged reduction in the quantity or quality of dietary intake. Special diets and supplements may be recommended to provide adequate nourishment with complications such as SBS, strictures, or fistulas especially in CD. Patients may experience severe malnutrition, particularly following aggressive bouts of the disease, or after surgical procedures if adequate preoperative nutrition care and education was unavailable. Indeed, focusing on achieving optimal nutrition status prior to surgical interventions has been shown to improve patient outcomes [57]. Nutrition counseling can also aid the patient in identifying and avoiding foods that exacerbate symptoms. Intolerances are highly individualized and should be treated on a case-by-case basis. In addition, patients may choose to avoid foods they perceive as responsible for adverse symptoms such as diarrhea, abdominal pain, nausea, and bloating. Finally, medications can influence appetite and GI-related symptoms, resulting in decreased intake, increased malabsorption, and/or alter requirement for nutrients. Potential drug–nutrient interactions should be closely monitored and discussed with their health professionals.

2 Energy and Protein Requirements

There is no evidence to suggest that patients with IBD have increased energy requirements, unless nutrition status restoration or weight gain is warranted. Other complications known to increase resting energy expenditure may simultaneously occur resulting in elevated energy needs such as sepsis or fever. Regardless, the presence of active disease alone does not appear to raise energy requirements appreciably [58,59]. Protein needs may be increased significantly because of GI nitrogen losses, the ongoing/established inflammatory response, and the anabolic synthesis of new tissue for healing postoperatively, weight gain, and/or growth.

3 Parenteral Nutrition During Active IBD

In previous years, parenteral nutrition (PN) was a primary therapy in IBD, particularly CD. It was observed that patients on PN appeared to enter remission. This initiated a protocol wherein PN was provided as a means of "bowel rest" with the rationale of decreasing the antigen load presented to the mucosa [60–63]. However, the concept of bowel rest is no longer in favor. According to the 2009 European Society of Parenteral and Enteral Nutrition (ESPEN) Guidelines on PN in Gastroenterology, PN is not indicated as a primary therapy in the treatment of CD or UC [64]. PN is indicated in patients with obstruction, perforation, complicated fistula, SBS, or a nonfunctioning GI tract that precludes adequate enteral nutrition (EN). Withholding oral/EN is considered undesirable because it may compromise gut integrity including atrophy of the intestinal mucosa [65,66]. In addition, PN does not contain the balance of phytochemicals typically present in plant foods and complex diets that may interact with the inflammatory response. Further PN is being associated with greater cost and increased risk of sepsis [67].

4 EN During Active IBD

EN is the route of choice for nutrition support whenever possible. In almost all studies, CD appears to be more amenable to enteral treatment than UC, although different forms of nutrition interventions (other than standard enteral formulas) may be of value in UC. Guidelines from ESPEN [68] cite that enteral feeding is first-line therapy in CD and should be used as sole therapy in adults when treatment with steroids is not feasible. Undernourished patients with CD or UC should receive oral or tube-fed supplements.

The most recent and robust evidence-based reviews of the CD literature [68,69] indicate that medicinal corticosteroid treatment is more effective than EN for the acute phase of UC and CD. However, when considering EN, a clear superior choice among elemental and polymeric formulas is not seen [70]. Exclusive enteral feeding appears

to be more effective than partial EN, while lower fat formulas are more favorable. Remission rates in the individual studies ranged from 20% to 84%. Overall, enteral diets have the advantage of providing/restoring nutritional status and reducing the risks of medications. The majority of reports indicate that mucosal healing is more likely to occur with enteral feeding than with steroids due to a decrease in mucosal cytokine production [71,72]. The possible mechanisms for these benefits include an altered antigen load, positive alterations in the GI microbiota resulting in improved structure and function of the mucosal layer. EN is not generally recommended for UC patients during active disease; however, patients with poor oral intake or deficiencies may be candidates [68].

5 Emerging Nutrients Therapies and Bioactives

Specific nutrients and other dietary interventions may aid in managing acute IBD exacerbations and inducing and maintaining remission. This is an emerging area of research with probiotics, prebiotics, short-chain fatty acids (SCFAs), and omega-3 fatty acids being the most commonly investigated. In each instance, the mechanism of action is believed to be a reduction in the immune regulatory response.

a Probiotics

Probiotics are live microorganisms that when ingested in adequate amounts, confer health benefits on the host [73]. Probiotics are of interest to modify the microbiota population, modulate intestinal immunity and inflammation, and their ability to influence antigen tolerance, cytokine levels, and adhesion mechanisms [74–77]. UC and probiotics have been more thoroughly investigated compared to CD. VSL #3, a probiotic supplement containing *Bifidobacterium breve*, *B. longum*, *B. infantis*, *Lactobacillus acidophilus*, *L. plantarum*, *L. paracasei*, *L. bulgaricus*, and *Streptococcus thermophilus*, has shown efficacy in decreasing evidence and symptoms of active disease and inducing remission [78,79]. Similar effects, including decreased markers of inflammation, are reported with *L. delbrukeii* and *L. fermentum* in UC [80]. A recent meta-analysis concluded that probiotics are better at maintaining remission of UC compared to placebo [81]. Probiotics in the meta-analysis included VSL #3, *Bifidobacterium* species, *Lactobacillus* species, and *Escherichia coli* Nissle 1917. It is important to note that probiotic supplementation often occurs in tandem with traditional medicinal therapy; however, studies investigating *E. coli* Nissle 1917 suggest that it is an acceptable alternative to 5-aminosalicylic acid, an anti-inflammatory [82]. Unlike UC, results of the human intervention trials with probiotics for inducing or maintaining remission CD have not been as successful or as thorough as concluded by Cochrane Reviews [83–85]. Probiotics, including VSL #3, *L. rhamnosus*, and *Bifidobacterium*, also have considerable evidence for effectiveness in maintaining remission from pouchitis, the inflammatory state that occurs in the "pouch" surgically created from distal loops of ileum after colectomy [86–89].

b Prebiotics and SCFA

Prebiotics are functional polysaccharides that selectively stimulate growth of beneficial gut microbiota and are fermented to SCFA [90]. SCFA, specifically butyrate, have been shown to decrease markers of inflammation, primarily through decreasing NF-κB [91–94]. However, a recent study investigating the efficacy of fructooligosaccharides, a prebiotic, on active CD found no benefit compared to placebo [95]. Synbiotics, the combination of pre- and probiotics, have exhibited promising effects in both CD and UC [96–98].

c Omega-3 Fatty Acids

Fatty acids are unique in their ability not only to provide energy, but also to influence the inflammatory state in IBD and other inflammatory diseases. The Western diet greatly favors *n*-6 polyunsaturated fatty acids compared to *n*-3 fatty acids. Omega-6 and omega-3 fatty acids are incorporated into cell membranes and affect the physical, chemical, and functional properties of the cell and cell wall [99–101]. The lipids also serve as precursors for potent mediators in many physiologic reactions including the immune and inflammatory response. The *n*-6 and *n*-3 polyunsaturated fatty acids are metabolized to eicosanoids which are important in regulating the inflammatory state. Eicosanoids produced from *n*-6 fatty acids are proinflammatory and encourage blood clotting and thrombosis. Conversely, eicosanoids produced from *n*-3 fatty acids are antiinflammatory and decrease cellular adherence. Data from animal and human studies show that consumption of a high *n*-6:*n*-3 fatty acid ratio result in increased peripheral proinflammatory cytokines TNF-α, IL-6, and IL-1 concentrations, membrane permeability, edema, and increased reactive oxygen species, all consistent with an increased inflammatory state [102]. Similarly, diets containing *n*-3 fatty acids have been shown to decrease gene expression of inflammatory cytokines, increase anti-inflammatory resolvins, and alter signaling pathways in the inflammatory response, with the majority of the data in cardiovascular disease.

Clinical trial evidence for *n*-3 fatty acids in the management of IBD is conflicting. The recent Cochrane evidence-based reviews concluded that omega-3 fatty acids in both CD and UC did not improve maintenance of remission [103,104]. A trial by Nielsen and colleagues,

however, reports a decrease in proinflammatory cytokines after omega-3 supplementation compared to omega-6 during active CD [105]. Turner et al. recommend that future investigations utilize enteric coated capsules to insure intact delivery of the biologically active fatty acids to the inflamed tissue in the gut [104].

G Nutrition in IBD Remission

The majority of patients with IBD can achieve a full oral diet during disease remission. Individuals with extreme short bowel after surgical resection secondary to CD are the primary examples of who may require additional support to maintain nutritional status (see Section II on SBS). Characteristics of a healthy diet during IBD remission are similar to an individual without IBD. Fruits and vegetables are excellent sources of antioxidant nutrients and phytochemicals which may help to reduce oxidative stress. A low omega-6:omega-3 fatty acid ratio encourages production of antiinflammatory eicosanoids. Consuming sources of fermentable fiber will increase fermentation and therefore SCFA, including butyrate, production in the large intestine. Foods that are not well tolerated should be identified on an individual basis. Nutrition professionals can not only help identify food items that increase symptoms, but also offer suggestions on alternatives and label reading. Pre- and/or probiotics may be indicated for some patients. Small frequent meals can also help to increase tolerance. Individuals continuing to suffer from malabsorption or who are unable to consume and/or absorb adequate nutrients from food in their diet may require supplementation of macro- and micronutrients. CD patients in remission may benefit from EN support [106].

II SHORT BOWEL SYNDROME

A Definition

SBS is best defined functionally rather than by anatomical length of residual intestine. SBS is due to surgical resection of intestinal tissue resulting in a decrease in functional surface area and malabsorption [107–109]. Intestinal failure (IF) is defined as a decrease in functional intestinal mass below the amount required for digestion and absorption to meet the body's needs, be it growth in pediatric patients or maintenance in adult patients, and results in dependence on PN [110,111]. SBS is a common cause of IF wherein an individual's previously normal enteral nutrient intake is not enough to support growth and/or maintain weight due to malabsorption of macronutrients, micronutrients, fluid, electrolytes, and endogenous secretions. Deficiencies are common with the severity of such depending upon the amount and location of intestinal resection, age, and disease activity in the remaining tissue. The long list of complications attributed to SBS include weight loss, growth retardation, diarrhea, dehydration, electrolyte imbalances, loss of bone mass, renal oxalate stones, gallstones, lactic acidosis, and bacterial overgrowth, depending on the anatomical nature of the resection, function of the residual intestine, and age/growth status of the patient (see Fig. 39.4) [112,113].

B Causes

In adults, the most common causes of SBS are mesenteric infarction, dysmotility, CD, obstruction, trauma, and radiation [114–117]. Causes of pediatric SBS can be prenatal, neonatal, or postnatal and include atresia, volvulus, Hirschsprung's disease, necrotizing enterocolitis, and IBD [110,111]. See Table 39.3 for causes of pediatric SBS.

C Predictors of the Severity and Prognosis in SBS

The prognosis for SBS can range from a temporary condition with less extreme intestinal resections or permanent in instances where little functional intestinal tissue remains. Symptoms appear immediately after resection and continue until sufficient adaptation occurs and/or

medical, nutritional, or surgical interventions are successful. The length, location, and function of the remaining intestinal tissue and overall health of the patient greatly impact the need for nutrition support, the severity and duration of symptoms, and survival. Patients who survive without PN tend to have fewer adverse symptoms and are at decreased nutritional risk. It is well established that the ileum maintains a greater compensatory capacity when compared to the jejunum [118–120]. In addition, the ileocecal valve plays an integral role in releasing chyme from the small intestine to the large intestine and maintaining the balance of gut microbial populations in the colon [121]. Therefore, the patients with the following qualities have the best prognosis; patients who are very young have remaining distal ileum and ileocecal valve, have colon-in-continuity, and are otherwise healthy and well-nourished. Alternatively, qualities of a poor prognosis include loss of terminal ileum and ileocecal valve, advanced age at resection, loss of the colon in addition to small bowel, and/or presence of residual GI disease [112,122]. These patient attributes often result in dependence on large volumes of PN support, increased nutritional risk, and decreased quality of life.

D Intestinal Adaptation

Following intestinal resection, the remaining intestine undergoes dynamic structural and functional adaptation to compensate for the loss in tissue. Much of the data detailing intestinal adaptation is in animal models and includes lengthening and dilation of the residual bowel and increased proliferation [123–125]. This results in greater absorptive surface area through increased villus height and crypt depth (see Fig. 39.5). Importantly, nutrient transport is also unregulated. These adaptations are also observed in humans [119,126,127]. As mentioned previously, the ileum has the greatest potential for adaptation, although adaptation does occur through the length of the residual intestine [118,120].

Langnas, Short-bowel syndrome in children and adults, Gastroenterology 113 (5) (1997) 1767–1778, with permission from Elsevier.*

E Massive Intestinal Resections in Infants

The same risk factors for increased morbidity apply in infants, including loss of ileum, ileocecal valve, and colon, except that infants adapt significantly better after resections than do adults. Healthy infants and children experience incredible intestinal growth from in utero until early adulthood. According to Weaver and colleagues, the small intestine doubles in length from 20 to 40 weeks gestation and nearly doubles again from term (275 cm) to age 10 (500 cm) [128]. Infants are reported to survive independent of PN with as little as approximately 30–60 cm of small bowel if the children have retained the ileocecal valve, and as little as 30–100 cm without the ileocecal valve [128,129]. When the ileocecal valve is lost, retained colon becomes more important for the

maintenance of electrolyte balance, adequate hydration, and to salvage malabsorbed substrates. For pediatric patients with extremely short lengths of residual functional intestine, who cannot fully adapt, several options exist. They can remain on PN, undergo small bowel lengthening procedures, or good candidates may receive a small bowel transplantation. PN, although lifesaving, imposes on the quality of life for the patient and caretakers and carries increased risk of infection, cholestasis and hepatic failure, gallstone formation, and nutrient deficiencies [130].

F Medical Management of SBS

Patients with SBS may be treated with several medications to improve symptoms, decrease GI secretions, delay gastric emptying, slow intestinal transit, and/or bind bile acids [131]. Antisecretory/antidiarrheal drugs such as proton pump inhibitors or histamine-2 receptor blockers are used in the initial stages of gastric acid hypersecretion that follows intestinal resection. Cholestyramine may aid in decreasing diarrhea by binding bile acids within the intestinal lumen and reduce the osmotic load present within the distal intestine [111]. Antimotility agents are utilized to slow transit time and extend the window of absorption. Conversely, prokinetic agents may be necessary to relieve symptoms such as abdominal distention and vomiting. Small intestine bacterial overgrowth is most commonly managed with antibiotic therapy. See Table 39.4 for a list of common medications utilized in SBS.

Glucagon-like peptide 2 (GLP-2) is an intestinotrophic hormone secreted from the distal intestine. A GLP-2 analog, teduglutide, was approved in 2012 by the United States Food and Drug Administration for use in SBS patients dependent on PN. GLP-2 or teduglutide has shown efficacy through increased villus height, crypt depth, urine output, wet weight absorption, with a decreased stomal energy output, PN volume, and overall increased body weight and lean body mass [132–137].

G Surgical Interventions in SBS

Although total PN is a lifesaving measure and has improved the prognosis for SBS and IF patients, serious complications exist including catheter sepsis and PN-associated liver disease. Surgical procedures will be considered when intestinal adaptation has been maximized and PN is still required. Currently, there are several surgical procedures performed to lengthen the residual intestine, which as a group are deemed autologous gastrointestinal reconstruction. In longitudinal intestinal lengthening and tailoring (LILT) or the Bianchi procedure, the dilated bowel is divided in half longitudinally, creating two loops of bowel, which are anastomosed together, doubling the intestinal length [138]. The serial transverse enteroplasty (STEP), first reported in a porcine model in 2003, is another lengthening procedure. STEP is similar to LILT with less handling of the mesentery and involves stapling the dilated bowel in a zigzag pattern to increase absorptive surface area [139,140]. Spiral intestinal lengthening and tailoring is a new procedure wherein the residual intestine is cut in a spiral pattern, stretched, and sutured to create a longer, narrower segment [141]. This procedure, while only performed in a few cases to date, has been successful in weaning or significantly decreasing PN requirements [142,143]. Small intestinal and multivisceral transplants have now become more successful and are indicated when patients experience PN failure with persistent complications including catheter-related infections and PN-associated liver disease [144]. There are several forms of small bowel transplant including small intestinal segments alone, liver-intestinal transplants, and multivisceral transplants [145].

H Nutrition Assessment in SBS

Nutrition assessment in the SBS patient is similar to that outlined for IBD, and indeed, many other clinical states. Determining the level of intestinal function in the residual tissue is a challenge in the clinical setting but assessing steatorrhea and fecal levels of macronutrients is possible [146]. Fecal or stoma output, serum electrolytes, and urine sodium content can also help establish hydration status [112,147]. Serum proteins such as albumin, transferrin, prealbumin, and hematological assessment can assist in establishing nutrition status and adequacy of macronutrient intake and absorption. Surgical history and radiologic examination can be utilized to determine the anatomical location and length of residual bowel, as this will significantly impact the patient's nutrition status. Careful consideration of the anatomical location of

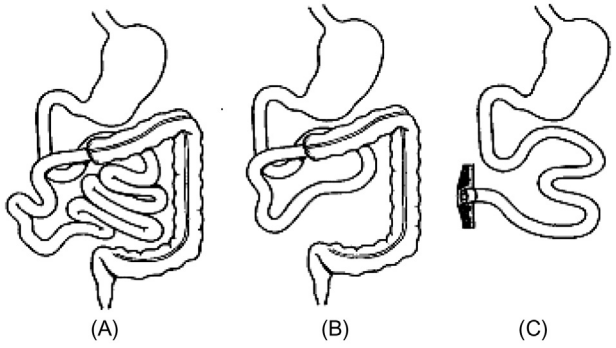

FIGURE 39.7 Common types of intestinal resection include (A) jejunal resections; (B) ileal resections; (C) end jejunostomy with resection of the ileum and colon. *Reprinted from M. Sleisenger, M. Feldman, Sleisenger and Fordtran's Gastrointestinal and Liver Disease, seventh ed., W.B. Saunders, 2002, with permission from Elsevier.*

resection and corresponding digestive and absorptive function is necessary for optimal nutrition therapy in SBS (see Fig. 39.6). Indeed, SBS is classified based on resected tissue, which aids in predicting the severity and nutritional risk and is discussed in the next section (see Fig. 39.7) [148].

I Medical Nutrition Therapy in SBS

The majority of SBS patients require PN following surgical resection, especially individuals with an end jejunostomy. The ultimate goal of nutrition support in the immediate postoperative phase is to restore and maintain hydration status. Depending on the stability of the patient and the amount of residual intestine, small amounts of oral nutrients may be provided [64]. During this time, urine volume, urine sodium content, and blood glucose should be monitored closely [149]. Enteral and/or oral nutrition should be initiated as soon as they are tolerated, with continued parenteral support as needed. Although there is no clearly superior formula in the literature, elemental enteral formulas may be beneficial in patients with rapid transit and severe malabsorption [68,150,151]. Electrolytes including sodium, potassium, and magnesium should be closely monitored.

Many patients, particularly those with an intact colon, progress to a fully oral diet. However, weaning from PN should not be considered until all other aspects of care are stabilized including medications and fluid management [152]. DiBaise and colleagues recommend patients achieve 80% of energy needs orally before complete PN weaning is initiated. Educational counseling with goal setting should occur before weaning is attempted. Individuals with colon-in-continuity are more likely to achieve independence from PN although patients without a colon may also be successful [153]. However, the colon does help in maintaining fluid balance and salvaging energy via fermentation by the gut microbiota. Depending on location of resection, micronutrients may need to be supplemented and should be closely monitored. Certain micronutrients such as magnesium and vitamin B_{12} may need to be administered intravenously if absorption is not adequate. Oral nutrition solutions or enteral feedings may be recommended if oral whole food intake is inadequate [68]. Adaptive hyperphagia, or oral consumption at least 1.5 times greater than calculated energy needs, occurs in most patients with SBS and may be helpful in the adaptive process and maintaining energy balance [154]. This biologic compensatory action should be encouraged, based on tolerance. The following sections discuss specific considerations for each type of SBS, depending on location of resection and remaining tissue.

1 Jejunoileal Anastomosis

The jejunum is the primary site of absorption for lipids, monosaccharides, peptides, and amino acids as well as a host of vitamins and minerals. As mentioned previously, the ileum has the capacity to adapt and restore much of the lost functionality over time [118,120]. With this in mind, jejunoileal anastomosis patients experience relatively mild malabsorption as long as the patient and the remaining GI tract are healthy. PN may be initially required but small frequent snacks and beverages may also be provided, as the presence of enteral nutrients encourages adaptation of the remaining intestine. Patients may experience a decreased lactose tolerance due to less lactase production from the resected jejunal tissue but restrictions should be recommended on an individual

basis depending on tolerance [148,155]. Ultimately, the patient should be able to consume oral meals with limited restrictions and minimal compromise in digestive and absorptive capacity.

2 Jejunocolic Anastomosis

Ileal resections present greater nutrition challenges compared to jejunal resections due to the decreased adaptive potential of the jejunum. Macronutrient and water malabsorption are more common. Although the ileum is not the major site of digestion and absorption of most nutrients, it is critical for vitamin B_{12}, remaining fat soluble vitamins, bile salts, and select acids. Because of these specialized ileal functions, B_{12} supplementation is often necessary [156] and the presence of steatorrhea and fat-soluble vitamin deficiencies must be monitored [156,157]. Since the colon remains in continuity, these patients may benefit from a higher complex carbohydrate diet through maximizing energy salvage by bacterial fermentation [158,159]. This increase in carbohydrates corresponds with a decrease in total energy from fat, which may be associated with decreased fluid and electrolyte fecal losses [159]. Fat intake from medium chain triglycerides may further improve absorption [160]. While adults consume approximately 2 L of fluid daily, the proximal small intestine secrete a much greater volume of 7–9 L per day [161]. While the healthy intestine is capable of reabsorbing the majority of this fluid, ileal resections result in increased risk of diarrhea and dehydration. Patients should be counseled to avoid high osmolarity fluids to decrease diarrheal exacerbations [162].

Patients with ileal resections are at increased risk of developing kidney stones. Under normal conditions, dietary oxalate binds calcium and other divalent cations, forming insoluble complexes. Following surgery, free oxalate becomes available for absorption in the colon. Kidney stones occur when the concentration of calcium and oxalate increase in the urine. Supplemental calcium and dietary oxalate restriction is often indicated to reduce absorption of oxalate and improve colonic fluid and electrolyte absorption [112,163]. Dietary sources of oxalate include berries, chocolate, coffee, tea, nuts, and green leafy vegetables such as kale and spinach.

3 Jejunostomy

Jejunostomy patients will face the greatest challenge to maintain energy and hydration status as loss of both the ileum and colon results in chronic malabsorption of macronutrients, micronutrients, and water, with relatively little possibility for adaptation. The same problems exist compared to jejunocolic SBS patients regarding nutrients that are absorbed specifically in the ileum including vitamin B_{12} and bile salts, but without the benefit of colonic energy salvage and fluid absorption. The fecal output contains large amounts of sodium and other electrolytes, resulting in increased risk of hypovolemia, hypokalemia, hypomagnesemia and other forms of nutrient depletion [112,115,163]. Jejunostomy patients should be encouraged to take in a greater amount of fluid than is lost from the ostomy and may benefit from oral rehydration solutions [163,164]. Ultimately these patients are likely to require long-term PN support [165].

J Nutrients for Intestinal Adaptation

There is great interest in strategically formulating the diet in SBS patients to maximize intestinal adaptation. Beginning soon after resection and continuing for months to several years, intestinal adaptation is a dynamic process that can be influenced by nutrition [130]. Much of the data for specific interventions is in animal models and includes adaptations such as increased bowel length and dilation, enhanced mucosal architecture including villus height and crypt depth yielding increased absorptive surface area, as well as increased nutrient transport [123–125]. There is also a body of evidence supporting these adaptations in humans [119,126,127].

1 Monomeric Versus Polymeric Enteral Formulas

Monomeric formulas consist of hydrolyzed amino acids while polymeric formulas contain whole proteins. An intermediate, semielemental formula is composed of oligopeptides averaging 4–5 amino acids in length. When considering monomeric and polymeric enteral formulas, the optimal enteral composition is controversial [110] and data are conflicting. Elemental formula has been reported to aid in weaning from PN in a small sample size of 4 pediatric SBS patients [166]; however a randomized, crossover double-blind trial of 10 pediatric SBS patients failed to detect a difference between a hydrolyzed and intact nutrient formula [167]. No clear choice between monomeric and polymeric formula emerges from the current literature, but polymeric formulas are generally more affordable and less likely to cause osmotic diarrhea [148].

2 Glutamine and Growth Hormone

Glutamine is an important energy source for enterocytes and has been investigated for inducing adaptation in SBS; however glutamine alone does not seem to be efficacious [168]. Glutamine is often supplemented in combination with growth hormone and benefits are reported in animal models such as increased remnant bowel length and improved architecture [169,170]. Human studies indicated an increase in plasma proteins, weaning from PN in a portion of studied patients and increased macronutrient and

electrolyte absorption [171–174]. Studies reporting no beneficial effect [175,176] and/or a return to baseline following treatment cessation also exist in the literature [172,177]. Adverse events attributable to growth hormone are also commonly reported [174–177]. In all, the evidence from an intestinal adaptation perspective is not promising and is not recommended [148]. In fact, a commercial growth hormone pharmaceutical targeted for SBS, Zorbtive, has seen limited success [178].

3 Fish Oil

Linolenic acid is an essential omega-3 fatty acid found in fish oil and is necessary to synthesize eicosapentaenoic acid (EPA) and docosahexenoic acid (DHA). EPA serves as a precursor to eicosanoids including thromboxanes, prostaglandins, and leukotrienes, which modulate inflammation and thrombosis, as discussed in the Section I. Pediatric IF-associated liver disease is a life-threatening complication associated with PN; however, promising evidence suggests that fish oil lipid emulsions may reduce the risk and even reverse the disease [179–182]. Fish oil, delivered both enterally or systemically, is also being investigated for its potential intestinotrophic properties. Studies utilizing intestinal resection rat models demonstrate an increase in structural and functional adaptation [183–185]. Fish oil as an intestinal adaptation modulator is a new concept, therefore well-designed human trials are lacking, with most studies being observational.

4 Butyrate

Acetate, propionate, and butyrate are the primary SCFAs produced in the human intestine through fermentation of otherwise nondigestible carbohydrates (including select prebiotic fibers) by anaerobic bacteria. Butyrate is a key energy source for colonocytes, and is absorbed with sodium and water and has intestinotrophic properties. Human studies are lacking, but strong animal data suggest that butyrate stimulates structural and functional adaptations of the residual intestine [186–189]. While the mechanism remains to be determined, it is hypothesized that GLP-2 may be involved.

5 Pre- and Probiotics

Pre- and probiotics are used alone and in combination in SBS, specifically for use in adaptation and managing small intestine bacterial overgrowth. Probiotic supplementation in rats including a mixture of *L. acidophilus*, *Bifidobacteria*, *S. thermophiles*, and *L. rhamnosus* GG (LGG) alone resulted in increased indices of intestinal architecture such as villus height and crypt depth [190,191]. Few intervention trials have been completed in humans with SBS; however, a double-blind, placebo-controlled, crossover clinical trial in pediatric SBS patients observed no effect of LGG on intestinal permeability [192]. A pediatric case study reports successful treatment of small intestine bacterial overgrowth with the synbiotic combination of *B. breve*, *L. casei*, and the prebiotic, galactooligosaccharides [193]. Interestingly, two other studies utilizing the same synbiotic treatment report decreased pathogenic bacteria in the feces, increased fecal SCFA, accelerated weight gain, and decreased nutrition support [194,195]. While these trials showed no negative impact of probiotic supplementation, there is concern about bacterial translocation, particularly with compromised barrier function in PN-dependent patients [196,197]. Overall, this evidence is not strong enough to support pre- and/or probiotic recommendations in SBS patients at this time [148].

III CONCLUSIONS

IBD and SBS are GI diseases with profound nutritional consequences. CD and UC are inflammatory conditions with an etiology yet to be determined while SBS is a functional disorder as the result of intestinal resection. Continued scientific advances in medicine and nutrition science provide a rich and ever-evolving body of knowledge that continues to improve the prognosis for individuals with IBD and SBS. In both IBD and SBS, diseases medical and surgical treatments are often necessary and can impact nutritional status. Medical nutrition therapy often takes the form of parenteral and/or EN but, in most cases, is temporary. Emerging research suggests that select nutrients can aid in decreasing inflammation in IBD and increase adaptation in SBS. It is imperative that clinicians carefully follow the nutrition intervention research in IBD and SBS to stay up-to-date on the most effective treatments.

I INTRODUCTION

Ingestion of a large single dose of lactose (e.g., 50 g, the quantity in a quart of milk) by lactose maldigesters commonly results in diarrhea, bloating, and flatulence [1]. The wide dissemination of this information has led some of the lay population and a fraction of the medical community to attribute common gastrointestinal symptoms to lactose intolerance, independent of the dose of lactose ingested. As a result, a segment of the population avoids dairy products in the belief that even trivial doses of lactose will induce diarrhea or gas. However, multiple factors affect the ability of lactose to induce perceptible symptoms, including residual lactase activity [2], gastrointestinal transit time [3], lactose consumed with other foods [4], lactose load [5], and colonic fermentation [6]. The estimated 25% of adults in the United States who maldigest lactose are composed mainly of the Hispanic, Asian, and African-American populations (Table 40.1). These race/ethnic groups are rapidly growing segments of the population. Thus, the overall number of lactose maldigesters will grow in the United States in coming years. A major challenge for diet therapy of lactose maldigesters is to ensure adequate intakes of calcium, vitamin D, and other nutrients found largely in dairy products while at the same time minimizing the occurrence of lactose intolerance symptoms that would tend to limit milk consumption.

This chapter reviews the pathophysiology of lactose maldigestion, attempts to correct common misconceptions concerning the frequency and severity of lactose intolerance symptoms, and provides dietary strategies to minimize symptoms of intolerance.

II LACTOSE IN THE DIET

Lactose is the primary disaccharide in virtually all mammalian milks. It is unique among the major dietary sugars because of the β-1→4 linkage between its component monosaccharides, galactose and glucose. Lactose production in nature is limited to the mammalian breast, which contains the enzyme system (lactose synthase) necessary to create this linkage [7]. Human milk contains approximately 7% lactose by weight, which is among the highest lactose concentrations of all mammalian milks [5]. Cow's milk contains 4 or 5% lactose. Lactose, being water soluble, is associated with the whey portion of dairy foods. Thus, hard cheeses (with the whey removed from the curds) contain very little lactose compared with fluid milk. Table 40.2 shows the lactose content of selected foods.

In addition to food sources of lactose, small amounts of lactose are found in a wide variety of medications because of the excellent tablet-forming properties of lactose [5]. However, lactose is usually present in milligrams, rather than grams, quantities in most medications, and the amount is biologically insignificant for lactose maldigesters.

III DIGESTION OF LACTOSE

The small intestine is normally impermeable to lactose. Lactose must first be hydrolyzed to glucose and galactose, which are subsequently absorbed. Inability to digest lactose is referred to as *lactose maldigestion*. Lactose digestion is dependent on the enzyme lactase-phlorizin hydrolase (LPH), a microvillar protein that has at least three enzyme

activities: β-galactosidase, phlorizin hydrolase, and glycosylceramidase [8,9]. Synthesis of LPH occurs in enterocytes, with the highest and most uniform synthesis being in the jejunum in humans [10]. The LPH gene is located on chromosome 2 and directs the synthesis of a pre-proLPH that is processed intracellularly (and possibly by pancreatic proteases) into the mature form that is anchored in the cell membrane at the brush border [11,12]. Lactase activity develops late in gestation compared to other disaccharidases. Lactase activity in a fetus at 34 weeks is only 30% that of a full-term infant, rising to 70% of the full-term activity by 35–38 weeks [13].

IV LOSS OF LACTASE ACTIVITY

Full-term infants possess high lactase activity, except for *congenital lactase deficiency*, in which lactase is completely absent at birth. Holzel et al. [14] first described congenital lactase deficiency in 1959. It is a very rare condition, such that even in Finland, where it is

TABLE 40.2 Lactose Content of Selected Foods

Product	Portion Size	Lactose Content (g/portion)
Milk, full fat	1 cup (244 g)	11
Milk, reduced fat (2%)	1 cup (244 g)	9–13
Milk, nonfat	1 cup (244 g)	12–14
Milk, chocolate	1 cup (244 g)	10–12
Buttermilk, fluid	1 cup (245 g)	9–11
Half and half	1 T. (15 g)	0.6
Yogurt, low fat	8 fl. oz. (227–258 g)	11–15
Cheese (blue, Camembert, cheddar, Colby, cream, Gouda, Limburger, grated Parmesan)	1 oz. (28 g)	0.1–0.8
Cheese, pasteurized processed (American, pimento, Swiss)	1 oz. (28 g)	0.4–1.7
Cottage cheese, whole	1 cup (210 g)	5–6
Cottage cheese, 2% fat	1 cup (226 g)	7–8
Butter	2 parts (10 g)	0.1
Ice cream, vanilla, regular	1 cup (133 g)	9
Ice milk, vanilla	1 cup (131 g)	10
Sherbet, orange	1 cup (193 g)	4

most common, only 42 cases were diagnosed from 1966 to 1998 [11]. Lactase activity in jejunal biopsy specimens from infants with congenital lactase deficiency is reduced to 0–10 IU/g protein, and severe diarrhea results from unabsorbed lactose [11]. Treatment with a lactose-free formula eliminates symptoms and promotes normal growth and development [15].

Primary acquired hypolactasia, in which there is up to a 90–95% reduction in lactase activity, is much more common than congenital lactase deficiency (alactasia) [16]. The preferred term for this type of hypolactasia is *lactase nonpersistence* (LNP). It is estimated that approximately 75% of the world's population are LNP (see Table 40.1), with the exception of northern Europeans and a few pastoral tribes in Africa and the Middle East that maintain infantile levels of lactase throughout life [17]. Thus, LNP is not a "lactase deficiency" disease but is the normal pattern in human physiology, similar to the physiology of other mammalian species. This permanent loss of lactase occurs sometime after 3–5 years of age [9,18].

Lactase persistence is inherited as a highly penetrant, autosomal-dominant characteristic [17]. It has been hypothesized that individuals with a genetic mutation coding for lactase persistence would have gained a selective evolutionary advantage over LNP individuals in areas where dairy farming developed several thousand years ago [19,20]. Under marginal nutritional conditions, the individual with lactase persistence would be able to comfortably consume dairy products, deriving greater nutritional benefit. A key question has been whether the lactase persistence mutation in humans occurred before (the reverse cause hypothesis) or after (the cultural–historical hypothesis) the advent of dairying. DNA studies on the skeletal remains of predairy farming Neolithic Europeans [21] indicate that the most common allele for lactase persistence in Europeans (−13910*T) was not present, arguing for the cultural–historical hypothesis (this mutation is discussed in more detail in the following section). In addition, Tishkoff et al. [22] have identified three single-nucleotide polymorphisms (SNPs) for lactase persistence that developed in African populations as few as 3000 years ago. This date corresponds well with archeological data suggesting that cattle domestication came to different areas of Africa 3300–9000 years ago. These SNPs developed independently of the European mutation, providing striking evidence of both convergent evolution and the strong and relatively recent impact of a cultural practice such as dairy farming on the genome.

The genetic regulation of LPH has been studied extensively. Most evidence supports reduced levels of lactase mRNA in lactose maldigesters, suggesting that regulation is primarily at the level of transcription [23–26]. However, hypolactasia is sometimes present even when lactase mRNA is abundant, suggesting that posttranscriptional factors play a role [10,27,28]. One potential reason for conflicting results is the intestinal segment examined (duodenum vs jejunum). Lactase expression is higher and more uniform in the jejunum compared to the duodenum [29,30]. Another potential discrepancy is the age of the subjects studied. A poor correlation between lactase mRNA and lactase activity was reported in intestinal biopsies from children, although the biopsy specimens in this study were from duodenal sites [28]. Lactase activity in the jejunal enterocytes is found in a "mosaic"-type pattern [31]. In hypolactasic individuals, some jejunal enterocytes produce high amounts of lactase, whereas others, even those sharing the same villus, do not produce lactase [10]. Thus, rather than a uniform reduction in lactase production among all enterocytes, a hypolactasic individual may have a "patchy" distribution of lactose-producing enterocytes that are low in number relative to the nonlactase-producing enterocytes. In lactase-persistent individuals, all villus enterocytes may produce lactase. Current evidence suggests that the regulation of lactase is accomplished primarily at the level of transcription, although posttranscriptional factors (e.g., degradation of mRNA and posttranslational processing of the LPH protein) could be important in some individuals.

Secondary hypolactasia occurs as the result of damage to the enterocytes via disease, medications, surgery, or radiation to the gastrointestinal tract (Table 40.3) [5,32,33]. For example, the prevalence of microsporidiosis, which is associated with hypolactasia, can be as high as 50% in HIV-infected patients [34]. Seventy percent of HIV-infected patients showed evidence of lactose maldigestion compared to only 34% of controls [35]. In addition, the severity of lactose maldigestion increases in the more advanced stages of the disease. In general, secondary hypolactasia is reversible once the underlying cause is treated, but this reversal may require 6 months or more of diet therapy [5].

V DIAGNOSIS OF LACTOSE MALDIGESTION

A Genetic Testing

Historically, biochemical and/or symptom tests (described in Section V-B: Direct Assessment of Lactase Activity and Section V-C: Indirect Assessment Methods for Lactose Maldigestion) have been used to diagnosis lactose maldigestion. In approximately the past 5–10 years, however, the focus has been the development of genetic tests to identify markers of lactose maldigestion. These types

TABLE 40.3 Potential Causes of Secondary Hypolactasia

Disease		
Small Bowel	**Multisystem**	**Iatrogenic**
HIV enteropathy	Carcinoid syndrome	Chemotherapy
Regional enteritis (e.g., Crohn's disease)	Cystic fibrosis	Radiation enteritis
Sprue (celiac and tropical)	Diabetic gastropathy	Surgical resection of intestine
Whipple's disease (intestinal lipodystrophy)	Protein energy malnutrition	Medications
Ascaris lumbricoides infection	Zollinger–Ellison syndrome	Colchicine (antigout)
Blind loop syndrome	Alcoholism	Neomycin (antibiotic)
Giardiasis	Iron deficiency	Kanamycin (antibiotic)
Infectious diarrhea	Aminosalicylic acid (antibiotic)	
Short gut

Scrimshaw, E.B. Murray, The acceptability of milk and milk products in populations with a high prevalence of lactose intolerance, Am. J. Clin. Nutr. 48 (1998) 1083–1159; and D.A. Savaiano, M.D. Levitt, Milk intolerance and microbe-containing dairy foods, J. Dairy Sci. 70 (1987) 397–406.

of tests have several advantages over present methods. First, the measurements can be done on buccal cell samples, which are rapidly and easily obtained and require little or no preparation on the part of the individual being tested. Second, because the symptoms of lactose intolerance may often be confused with other gastrointestinal disorders, such as irritable bowel syndrome or Crohn's disease, genetic testing would allow for the ready differentiation of lactose maldigestion (resulting from LNP) from other gastrointestinal conditions. Enattah et al. [36] isolated two SNPs that are strongly associated with LNP in a primarily Finnish population. Both of these SNPs are located in a region adjacent to the lactase gene (LCT) on chromosome 2q21. The first, a substitution of cytosine for thymine 13,910 base pairs upstream of the 5′ end of LCT (termed C/T_{-13910}), was completely associated with biochemical evidence of LNP in 236 individuals. The second, g/A_{-22018}, was found in 229 of 236 cases. A subsequent study of intestinal biopsy samples showed that these SNPs coincided with low levels of mRNA for LPH consistent with transcriptional regulation [37]. It is likely that the C/T_{-13910} mutation impairs the binding of transcription factor Oct-1 [38]. The association between C/T_{-13910} and LNP was also observed in a study of children [39]. The presence of C/T_{-13910} had 100% specificity and 93% sensitivity in children older than 12 years compared with intestinal biopsy. Although these findings caused a great deal of excitement regarding the possibility of widespread genetic testing for LNP, other researchers have argued that genetic testing for LNP, based on C/T_{-13910}, is premature. In two reports of genetic testing of LNP among sub-Saharan African subjects, the C/T_{-13910} variant was extremely rare, and the authors suggested that other SNPs may be responsible for the LNP found in these populations [38,40]. The DNA regions encompassing the C/T_{-13910} LP/LNP variant have become the obvious targets in the search for additional lactose-persistent variants in such populations. T/G_{-13915} and G/C_{-14010} have been associated with lactose persistence in African populations [41,42], and Oct-1 has been shown to interact with T/G_{-13915} [43]. Novel substitutions are being continually found, and further studies are required to confirm the possible relationships of these substitutions to the lactose persistent trait [44,42]. The fact that individuals who are digesters have been found to carry no recognized causative allele is indicative of the fact that many more unidentified variants are in existence [45]. More research is required to determine the appropriate genetic markers of LNP in different populations before genetic testing becomes commonplace.

B Direct Assessment of Lactase Activity

Lactose digestion can be assessed directly or indirectly. The direct method involves obtaining a biopsy specimen of intestinal tissue and assaying for lactase activity or by intestinal perfusion studies [46]. Although these tests can accurately measure lactase activity, they are invasive and seldom used clinically.

C Indirect Assessment Methods for Lactose Maldigestion

The metabolic basis for different indirect tests of lactose maldigestion is shown in Fig. 40.1. Several indirect methods for assessing lactose digestion are available, including blood, urine, stool, and breath tests. Blood tests involve feeding a standard 50 g lactose dose and measurement of plasma glucose every 15−30 minutes over a period of 30 minutes to 2 hours. A rise in blood glucose of at least 25−30 mg/dL (1.5−1.7 mmol/L) is indicative of normal lactose digestion [41]. Unfortunately, blood glucose levels are subject to a variety of hormonal influences, reducing the reliability of this test. A blood test for galactose has been developed to correct this problem. The lactose dose is administered with a 500 mg/kg dose of ethanol (to prevent conversion of galactose to glucose in the liver) [46]. The galactose test is more reliable than the glucose test, but the ethanol exposure and somewhat invasive blood sampling are disadvantages.

A test has been devised to simultaneously measure intestinal lactose digestion (lactose digestion index [LDI]) and intestinal permeability (sugar absorption test [SAT]) [47]. The LDI/SAT consists of the oral administration of a 250-mL solution containing 25 g ^{13}C-lactose, 0.5 g ^{2}H-glucose, 5 g lactulose (a nonabsorbable disaccharide of galactose and fructose), and 1 g L-rhamnose. For the LDI test, the blood levels of ^{13}C-glucose and ^{2}H-glucose are measured before and at several time intervals after the LDI solution, and a low ^{13}C glucose:^{2}H-glucose ratio (<0.60) indicates significant failure to hydrolyze lactose. Urine collections more than 10 hours after the solution are obtained for measurements of the lactulose:rhamnose ratio, with a higher ratio indicating increased intestinal permeability. The LDI test was shown to outperform other measures of lactose digestion in one study [48] and it is less invasive than an intestinal biopsy, but it still has a number of limitations. The test requires the use of expensive isotopes and analytical equipment, involves both blood and urine collection, and has not been evaluated in persons with mucosal damage that might increase intestinal permeability.

A sometimes-used urine test involves the measurement of galactose in the urine, rather than the blood, during the lactose tolerance test with ethanol. Another urine test is conducted by simultaneously administering lactose and lactulose [46]. Small amounts of lactose (up to 1% of the ingested dose) and lactulose diffuse unmediated across the intestinal mucosa and are excreted in the urine. The ratio of lactose to lactulose in the urine (collected over 10 hours) is determined by the hydrolysis of lactose. A value of less than 0.3 indicates normal lactose digestion, and a ratio approaching 1.0 is observed in hypolactasia [46].

The measurement of stool pH and reducing substances in the stool has been used to assess lactose digestion in children. The analyses are easy to perform and convenient for the individuals being tested. However, stool pH has been shown to be unreliable in the diagnosis of hypolactasia in children and adults [46]. Furthermore, changes in gut motility and water excretion can alter the level of reducing substances in the stool. Thus, diagnosis of hypolactasia should not be based on stool tests alone [46].

Breath tests are the most widely used method for diagnosing carbohydrate maldigestion/malabsorption. The principle behind breath tests is that lactose, which escapes digestion in the small intestine, is fermented by bacteria in the colon, producing short-chain fatty acids (SCFAs) and hydrogen, carbon dioxide, and methane (in some

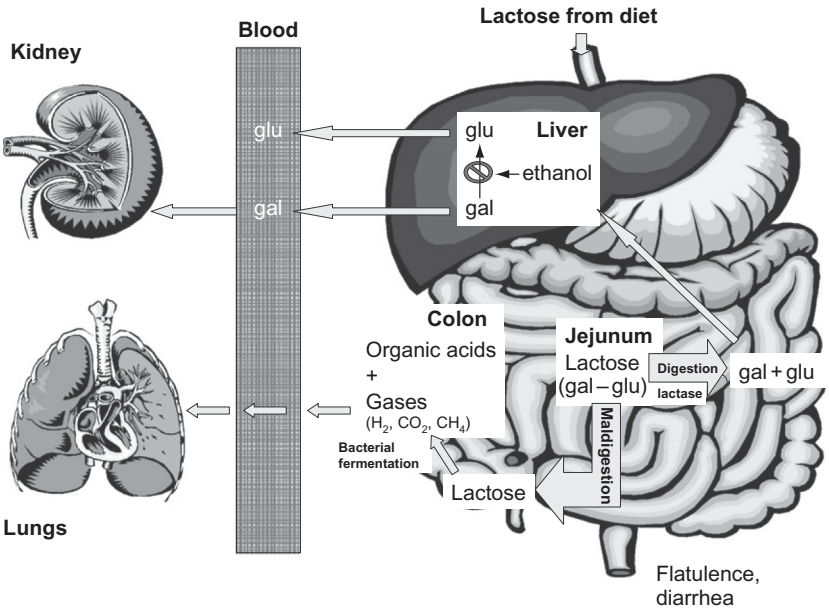

FIGURE 40.1 Metabolic background for understanding the diagnosis of lactose maldigestion and intolerance. gal, galactose; glu, glucose. *Adapted with permission from H. Arola, Diagnosis of hypolactasia and lactose malabsorption, Scand. J. Gastroenterol. 29 (Suppl. 202) (1994) 26−35.*

individuals). One breath test measures the amount of $^{13}CO_2$ excreted in the breath following administration of ^{13}C-lactose [46]. This stable isotope test has a safety advantage over older tests employing radioactive ^{14}C-lactose, but the high cost of the equipment prohibits widespread use of this method.

The current "gold standard" for diagnosis of carbohydrate maldigestion/malabsorption is the breath hydrogen test. Bacterial fermentation is the only source of hydrogen gas in the body. A portion of the hydrogen gas produced in the colon diffuses into the blood, with ultimate pulmonary excretion [49]. The hydrogen breath test is widely used because it is noninvasive and easy to perform. Typically, a subject is given an oral dose of lactose following an overnight (~12 hours) fast. Breath samples are collected at regular intervals for a period of 3–8 hours. In early studies, 50 g of lactose was used as a challenge dose. Almost all lactose maldigesters will experience intolerance symptoms following a dose of lactose this large [32], and yet many will be able to tolerate smaller, more physiologic doses of lactose. Doses of lactose that are in the range of 1 or 2 cups (240–480 mL) of milk (12–24 g lactose) have been more frequently used in recent years [50]. The dose of lactose used in the breath hydrogen test influences the diagnostic criterion for lactose maldigestion. Early studies with 50 g lactose showed perfect separation of lactose digesters from maldigesters using a rise in breath hydrogen of greater than 20 parts per million (ppm) above the fasting level [51]. Strocchi et al. [52] evaluated different criteria for diagnosis of carbohydrate maldigestion, using small doses of carbohydrate (10 g lactulose). Using a cut point of a 10-ppm or greater rise in breath hydrogen above fasting over an 8-hour period resulted in improved sensitivity (93% vs 76%) and only a slight decrease in specificity (95% vs 100%) compared to the 20-ppm cutoff. Furthermore, it was shown that using a sum of breath hydrogen values from hours 5, 6, and 7 and a 15-ppm or greater rise above fasting cut point resulted in 100% sensitivity and specificity.

Despite the advantages of breath hydrogen testing, care must be taken to ensure an accurate test. First, it is important to establish a low baseline breath hydrogen value, to which subsequent values are compared. This is accomplished by fasting before and after consumption of the lactose dose. In addition, it has been shown that a meal low in nondigestible carbohydrate (e.g., white rice and ground meat) the evening before the test results in lower baseline hydrogen [53]. Second, it is possible that some individuals may have a colonic microflora that is incapable of producing hydrogen. However, these individuals are rare, and the possibility of a nonhydrogen-producing flora can be ruled out by the administration of lactulose [52]. Third, approximately 40% of adults harbor significant numbers of methane-producing bacteria in the colon [49]. Because methanogenic bacteria consume four parts of hydrogen to produce one part methane [54], some authors have suggested that simultaneous measurement of methane will improve the accuracy of breath hydrogen testing in methane-producing subjects [55]. The availability of gas chromatographs that can analyze both hydrogen and methane in breath samples eliminates this potential problem. Finally, a number of factors (sleep, antibiotics, smoking, bacterial overgrowth of the small intestine, and exercise) may complicate the interpretation of breath hydrogen tests [46]. Therefore, standardization of the breath test protocol and appropriate controls are important.

Breath testing has been employed as a comparison to assess the clinical value of genetic testing. Positive breath tests have been correlated with both the C/T_{-13910} [56] and the g/A_{-22018} polymorphisms [57]. However, better correlation has been identified between the lactase-persistent genotype and a negative breath test [58]. Genetic testing does not provide information on actual patient symptoms, and the current usefulness of this test in populations with unestablished LP/LNP variants is questionable.

VI LACTOSE MALDIGESTION AND INTOLERANCE SYMPTOMS

A positive breath hydrogen test is indicative of lactose maldigestion. However, reduced lactase levels do not necessarily lead to intolerance symptoms. Symptoms of intolerance occur when the amount of lactose consumed exceeds the ability of both the small intestine and the colon to effectively metabolize the dose. Unhydrolyzed lactose passes from the small intestine to the large intestine, where it is fermented by enteric bacteria, producing the gases that are partially responsible for causing intolerance symptoms. The intensity of symptoms varies with the amount of lactose consumed [33,59–61], the degree of colonic adaptation [6,62], and the physical form of the lactose-containing food [63].

The correlation between lactose maldigestion and reported intolerance symptoms is unclear. Most maldigesters can tolerate the amount of lactose in up to 1 or 2 cups of milk without experiencing severe symptoms. However, some lactose maldigesters believe that small amounts of lactose, such as the amount used with coffee or cereal, cause gastrointestinal distress [64]. Individual differences observed in symptom reporting may reflect learned behaviors, cultural attitudes, or other social issues.

Lactose maldigesters, unselected for their degree of lactose intolerance, tolerated a cup of milk without experiencing appreciable symptoms [65–67]. However,

the results of these studies did not gain general acceptance, in part because of failure to enlist subjects with "severe" lactose intolerance. In 1995, Suarez et al. [64] conducted a study of 30 self-described "severely lactose intolerant individuals." Initial breath hydrogen test measurements indicated that approximately 30% (9 of 30) of the subjects claiming severe lactose intolerance were digesters and, thus, had no physiological basis for intolerance symptoms. These findings further demonstrate how strongly behavioral and psychological factors influence symptom reporting. Additional research is necessary to evaluate the psychological component of symptom reporting in lactose maldigesters.

VII LACTOSE DIGESTION, CALCIUM, AND OSTEOPOROSIS

Individuals who are lactose intolerant can generally tolerate moderate amounts of lactose with minimal or no gastrointestinal discomfort [64,68]. However, some lactose maldigesting individuals may unnecessarily restrict their intake of lactose-containing, calcium-rich dairy foods, thus compromising calcium intake. Milk and milk products contribute 73% of the calcium to the U.S. food supply [69]. Lactose maldigestion is associated with lower calcium intakes and is more frequent in osteoporotic cases than in controls [70–73]. For example, Newcomer et al. [70] found that 8 of 30 women with osteoporosis were lactose maldigesters compared to only 1 of 30 controls. In addition, calcium intakes of postmenopausal women positive for LNP in this study were significantly lower than in the lactase-persistent women (530 vs 811 mg/day). Interestingly, in this report, and another by Horowitz et al. [71], few of the LNP subjects reported a history of milk intolerance and yet they still restricted milk intake. The lower milk intakes in these subjects may have been due to factors other than lactose intolerance. However, it is also possible that these subjects restricted their milk intakes because of lactose intolerance in childhood, forgot that they had done so, and simply maintained that pattern of milk intake throughout life.

Another potential explanation for the increased prevalence of osteoporosis among lactose maldigesters is that maldigestion of lactose might decrease the absorption of calcium. Human and animal studies suggest that lactose stimulates the intestinal absorption of calcium [69]. However, there is considerable disagreement regarding the influence of lactose and lactose maldigestion on calcium absorption in adults. This disagreement results from a number of factors, including the dose of lactose given, the choice of method for assessing calcium absorption (single isotope, double isotope, and balance methods), prior calcium intake of the subjects, and the form in which the calcium is given (milk vs water).

Kocian et al. [74], using a single-isotope (^{47}Ca) method, demonstrated improved absorption of a 972-mg calcium dose from lactose-hydrolyzed milk compared to milk containing lactose in lactose maldigesters. Conversely, the regular milk resulted in increased calcium absorption versus the lactose-hydrolyzed milk in lactose digesters. Another study—using dual-isotope methods, a 50 g lactose load, and 500 mg of calcium chloride in water—found similar results [75]. Total fractional calcium absorption was decreased in maldigesters and increased in digesters with lactose feeding. However, the doses of lactose given in these studies (39–50 g or the equivalent of 3 or 4 cups of milk) were unphysiologic and may have resulted in more rapid intestinal transit than would be observed with more physiologic amounts of lactose.

Several studies have been conducted with physiologic doses of lactose. Griessen et al. [76], using dual-isotope methods, found that lactose maldigesters ($n = 7$) had a slightly, but not statistically significant, greater total fractional calcium absorption from 500 mL of milk compared to 500 mL of lactose-free milk. They also observed a nonsignificant decline in fractional calcium absorption in normal subjects ($n = 8$) when comparing lactose-free milk with regular milk. In another dual-isotope study, lactose maldigesters absorbed more calcium from a 240 mL dose of milk than did digesters ($\sim$35% vs 25%), which was thought to be due to lower calcium intakes in the lactose maldigesting group [77]. Most important, however, no difference was observed in fractional calcium absorption between lactose-hydrolyzed and regular milk in either group of subjects. Calcium absorption from milk and yogurt, each containing 270 mg of calcium, was studied using a single-isotope method [78]. No significant differences were observed in calcium absorption between milk and yogurt in either the lactose maldigesting or digesting subjects. Interestingly, yogurt resulted in slightly, but significantly ($p < 0.05$), greater calcium absorption in lactose maldigesters compared to lactose digesters.

Differences in study methodology (milk vs water, dose of lactose, and the choice of method for determining calcium absorption) may explain contrasting results. Physiologic doses of lactose (e.g., amounts provided by up to 2 cups of milk) are not likely to have a significant impact on calcium absorption. The increased prevalence of osteoporosis in lactose maldigesters is most likely related to inadequate calcium intake rather than impaired intestinal calcium absorption.

VIII DIETARY MANAGEMENT FOR LACTOSE MALDIGESTION

It is difficult for lactose maldigesters to consume adequate amounts of calcium if dairy products are eliminated from the diet. Fortunately, lactose intolerance is easily

TABLE 40.4 Dietary Strategies for Lactose Intolerance

Factors Affecting Lactose Digestion	Dietary Strategy	Reference
Dose of lactose	Consume a cup of milk or less at a time, containing up to 12 g lactose.	Suarez et al. [64]
		Hertzler et al. [6]
		Suarez et al. [68]
Intestinal transit	Consume milk with other foods, rather than alone, to slow the intestinal transit of lactose.	Solomons et al. [85]
		Martini and Savaiano [4]
		Dehkordi et al. [86]
Yogurt	Consume yogurt containing active bacteria cultures. One serving, or even two, should be well tolerated. Lactose in yogurts is better digested than the lactose in milk. Pasteurized yogurt does not improve lactose digestion; however, these products, when consumed, produce few to no symptoms.	Kolars et al. [93]
		Gilliland and Kim [100]
		Savaiano et al. [63]
		Shermak et al. [99]
		Savaiano et al. [63]
		Kolars et al. [93]
		Gilliland and Kim [100]
Digestive aids	Over-the-counter lactase supplements (pills, capsules, and drops) may be used when large doses of lactose (>12 g) are consumed at once. Lactose-hydrolyzed milk is also well tolerated.	Moskovitz et al. [119]
		Lin et al. [114]
		Ramirez et al. [120]
		Nielsen et al. [126]
		Biller et al. [131]
		Rosado et al. [128]
		Brand and Holt [124]
Colon adaptation	Consume lactose-containing foods daily to increase the ability of the colonic bacteria to metabolize undigested lactose.	Perman et al. [138]
		Florent et al. [62]
		Hertzler et al. [6]

managed. Dietary management approaches that effectively reduce or eliminate intolerance symptoms are discussed next and shown in Table 40.4.

A Dose–Response to Lactose

There is a clear relationship between the dose of lactose consumed and the symptomatic response. Small doses (up to 12 g of lactose) yield no symptoms [1,64,66–68], whereas high doses (>20–50 g of lactose) produce appreciable symptoms in most individuals [1,79–81]. In a well-controlled trial, Newcomer et al. [1] demonstrated that more than 85% of lactose maldigesters developed intolerance symptoms after consuming 50 g of lactose (the approximate amount of lactose in 1 quart of milk) as a single dose. The frequency of reported symptoms may be attributed to the nonphysiologic nature of the lactose dose and the physical form of lactose load administered. A lactose dose of 15–25 g produces appreciable symptoms in some subjects [30,74]. The incidence of symptom reporting generally remains higher than 50% with intermediate doses. However, the frequency varies from less than 40% to greater than 90% [32]. In a double-blind protocol, Suarez et al. [64] demonstrated that feeding 12 g of lactose with a meal resulted in minimal to no symptoms in maldigesters. Interestingly, in unblinded studies [82,83], lactose maldigesters more frequently reported intolerance symptoms after consuming lactose loads similar to those given by Suarez et al. Subsequently, Suarez et al. [68] provided further evidence that individuals who are lactose intolerant can consume lactose-containing foods without experiencing appreciable symptoms by

feeding lactose maldigesters 2 cups of milk daily. One cup of milk was given with breakfast, and the second was given with the evening meal. The symptoms reported by maldigesters after consumption of 2 cups of milk a day were trivial.

Symptoms from excessive lactose in the intestine may increase out of proportion to dose, which raises the possibility that the absorption efficiency decreases with increased loads. Fractional lactose absorption is most likely influenced by dose, with more effective absorption of small loads and less effective utilization of larger doses. Hertzler et al. [60], using breath hydrogen as an indicator, suggested that 2 g of lactose is almost completely absorbed, whereas there was some degree of maldigestion when a 6 g load was ingested. The only study directly measuring the lactose absorption efficiency in lactose maldigesting subjects is that of Bond and Levitt [84], who intubated the terminal ileum and then fed the subjects ^{14}C-lactose mixed with polyethylene glycol, a nonabsorbable volumetric marker. Analysis of the ratio of ^{14}C-lactose to polyethylene glycol passing through the terminal ileum allowed researchers to calculate the percentage of lactose absorbed. On average, maldigesters absorbed approximately 40% of a 12.5 g lactose load, whereas the other 60% passed to the terminal ileum. However, sizable differences were seen in absorption efficiency among lactose maldigesters. These differences may represent differences in residual lactase efficiency and/or gastric emptying and intestinal transit time.

B Factors Affecting Gastrointestinal Transit of Lactose

Consuming milk with other foods can minimize symptoms from lactose maldigestion [4,85,86]. A probable explanation for these findings is that the presence of additional foods slows the intestinal transit of lactose. Slowed transit allows more contact between ingested lactose and residual lactase in the small intestine, thus improving lactose digestion. It is also possible that additional foods may simply slow the rate at which lactose arrives in the colon because a delay in peak breath hydrogen production, rather than a significant decrease in total hydrogen production, has been reported [4]. The slower fermentation of lactose might allow for more efficient disposal of fermentation gases, reducing the potential for symptoms.

The energy content, fat content, and added components such as chocolate may influence gastrointestinal transit of lactose and subsequent lactose digestion. Leichter [87] showed that 50 g of lactose from whole milk (1050 mL) resulted in fewer symptoms (abdominal discomfort, bloating, and flatulence) compared to 50 g of lactose from either skim milk (1050 mL) or an aqueous solution (330 mL). However, only blood glucose was measured to determine lactose digestion, and no statistical evaluation of symptoms was done in this study. Other studies have demonstrated that higher fat milk may slightly decrease breath hydrogen relative to skim milk [86] but not improve tolerance [86,88,89]. Furthermore, increasing the energy content or viscosity of milk has not been effective in improving lactose digestion or tolerance [90,91].

Chocolate milk has been recommended for individuals who are lactose intolerant. Apparently, chocolate milk empties from the stomach more slowly than unflavored milk, possibly because of its higher osmolality or energy content [3]. Two reports [86,92] have demonstrated improved lactose digestion (i.e., reduced breath hydrogen) following consumption of chocolate milk. One of these studies [92] documented fewer symptoms in subjects.

Clearly, consumption of milk with other foods results in improved tolerance compared to consumption of milk alone. Therefore, consuming small amounts of milk routinely with meals is a recommended approach for individuals who are lactose intolerant to obtain sufficient calcium from dairy products. These individuals may also try chocolate milk to improve tolerance.

C Yogurt

The lactose in yogurt with live cultures is digested better than lactose in milk and is well tolerated by those who are lactose intolerant [93]. In fact, Kolars et al. [93] reported only 20% of participants who had consumed yogurt experienced diarrhea or flatulence, as compared to 80% of participants given a similar quantity of lactose in milk. Prior to fermentation, most commercially produced yogurt is nearly 6% lactose because of the addition of milk solids to milk during yogurt production. However, as the lactic acid bacteria (*Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus salivarius* subsp. *thermophilus*) multiply to nearly 100 million organisms per milliliter, 20–30% of the lactose is utilized, decreasing the lactose content of yogurt to approximately 4% [94]. During fermentation, the activity of the β-galactosidase (lactase) enzyme substantially increases. Casein, calcium phosphate, and lactate in yogurt act as buffers in the acidic environment of the stomach, thus protecting a portion of the microbial lactase from degradation and allowing the delivery of intact cells to the small intestine [95,96]. As yogurt enters the small intestine, the increasing pH accompanied by a slower transit time maintains the activity of bacterial lactase, thereby allowing for adequate lactose digestion and the prevention of lactose maldigestion symptoms [97]. In the duodenum, once the intact bacterial cells interact with bile acids, they are disrupted, allowing substrate access to enzyme activity.

Yogurt consumption results in enhanced digestion of lactose and improved tolerance [63,93,98–100]. In 1984,

Kolars et al. [93] and Gilliland and Kim [100] reported enhanced lactose digestion from yogurt in lactose maldigesters. In both studies, breath hydrogen excretion was significantly reduced with the consumption of live culture yogurt. Furthermore, Kolars et al. found that an 18-g load of lactose in yogurt resulted in significantly fewer intolerance symptoms reported by subjects compared to the other forms of lactose given. Also in 1984, Savaiano et al. [63] demonstrated that yogurt feeding resulted in one-third to one-fifth less hydrogen excretion compared to other lactose-containing dairy foods with no symptoms. Shermak et al. [99] reported that a 12 g load of lactose in yogurt resulted in lower peak hydrogen in children with a delay in the time for breath hydrogen to rise compared to a similar lactose load given in milk. These children experienced significantly fewer intolerance symptoms with yogurt consumption.

Yogurt pasteurization following fermentation has been somewhat controversial [100]. One advantage of pasteurizing yogurt is a longer shelf life. However, removing the active cultures that are partly responsible for improved lactose digestion may increase intolerance symptoms and cause lactose maldigesters to avoid yogurt products. Further, galactose absorption and intestinal lactase activity were enhanced in rats fed live culture yogurt as compared to rats fed pasteurized yogurt [101]. Pasteurizing yogurt increases the maldigestion of lactose [63,99,100]. However, pasteurized yogurt is moderately well tolerated, producing minimal symptoms [63,98,99]. Because pasteurized yogurt is relatively well tolerated, other factors such as the physical form, or gelling, and the energy density of yogurt may play a role in tolerance. The level of the β-galactosidase enzyme in yogurt may not be the limiting factor for improving lactose digestion because not all yogurts have the same level of lactase activity [102]. Martini et al. [102] fed yogurts with varying levels of microbial β-galactosidase. The remaining characteristics of the test yogurts (pH, cell counts, and lactose concentrations) were similar. Despite the different levels of β-galactosidase activity, all yogurts improved lactose digestion and minimized intolerance symptoms.

Whether yogurt is flavored or unflavored is an impactful characteristic in regards to lactose digestion [103]; via breath hydrogen measurements, unflavored yogurt resulted in hydrogen production of 37 ppm/hour in lactase-deficient individuals, whereas flavored yogurt produced an intermediate hydrogen reading of 77 ppm/hour. This difference may be attributed to an increased osmotic effect of sugar in the stomach, dilution of the yogurt via flavoring or sugar, or inhibition of glucose as the end product of digestion. Despite the increased breath hydrogen readings for lactase-deficient individuals who consumed flavored yogurt, they had no symptoms.

D Kefir

Kefir is a fermented dairy beverage that originated in Eastern Europe and has been made for centuries. Unlike yogurt, it is drinkable, and the kefir grains used to culture the milk contain a wider variety of starter culture microorganisms. Hertzler and Clancy [104] investigated the effect of kefir ingestion on lactose maldigestion and intolerance symptoms in a group of lactose maldigesters. The kefir used in the study contained *S. lactis*, *L. plantarum*, *S. cremoris*, *L. casei*, *S. diacetylactis*, *Saccharomyces florentinus*, and *Leuconostoc cremoris* (as per label information) as the starter cultures. Feeding a 20 g lactose load as plain kefir reduced breath hydrogen excretion (8-hour area under the curve) by nearly threefold and decreased flatulence symptoms by 50% compared with the same amount of lactose from milk. The response to yogurt was similar to that observed with kefir.

E Unfermented Acidophilus Milk

Individuals who are lactose maldigesters may consume unfermented milk containing cultures of *L. acidophilus* in an effort to consume adequate amounts of calcium and avoid intolerance symptoms [105–107]. Various strains of *L. acidophilus* exist; however, strain NCFM has been most extensively studied and used in commercial products. Unfermented acidophilus milk tastes identical to unaltered milk because the NCFM strain does not multiply in the product, provided that the storage temperature is below 40°F (5°C) [105,106,108]. *Lactobacillus acidophilus* strain NCFM is derived from human fecal samples [95] and contains β-galactosidase. The effectiveness of acidophilus milk on improving lactose digestion and intolerance symptoms has been evaluated. Most evidence suggests that unfermented acidophilus milk does not enhance lactose digestion or reduce intolerance symptoms [63,109–111], primarily because of the low concentration of the species in the milk. Improved lactose digestion has been observed by some [111]; however, the test milk in this study contained a much higher concentration of *L. acidophilus* than is normally used to produce commercial acidophilus milks.

Furthermore, the microbial lactase from *L. acidophilus* may not be available to hydrolyze the lactose in vivo [103,106,110]. *Lactobacillus acidophilus* is not a bile-sensitive organism [95,105]. Therefore, once the intact bacterial cells reach the small intestine, bile acids may not disrupt the cell membrane to allow the release of the microbial lactase. However, sonicated acidophilus milk improved lactose digestion by reducing breath hydrogen [112]. Thus, if less bile-resistant strains were developed and used in adequate amounts, these strains may allow the β-galactosidase to be released, possibly yielding an

effective approach to the dietary management of lactose maldigestion.

Finally, fermented and unfermented milks containing bifidobacteria may also be useful in the management of lactose intolerance. Studies of milks treated with *Bifidobacterium bifidus* GD428 [103] and *B. longum* (strains B6 and 15708) [113] revealed lower breath hydrogen excretion and flatulence symptoms compared with milk in lactose maldigesters. However, the beneficial effects, as with acidophilus milk, were still less than those observed with yogurt.

F Lactase Supplements and Lactose-Reduced Milk

Lactase pills, capsules, and drops contain lactase derived from yeast (*Kluyveromyces lactis*) or fungal (*Aspergillus niger* and *A. oryzae*) sources. Common brands include Lactaid and Lacteeze. Dosages of lactase per pill or caplet vary from 4000 to 9000 FCC (Food Chemical Codex) units [114–116]. Since 1984, these over-the-counter preparations have been given generally recognized as safe status by the U.S. Food and Drug Administration [117]. Lactase pretreated milks (100% lactose hydrolysis) are available from Lactaid and Dairy Ease [115,118].

A number of studies have evaluated the effectiveness of these products. Doses of 3000–6000 FCC units of lactase administered just prior to milk consumption decrease both breath hydrogen and symptom responses to lactose loads ranging from 17 to 20 g [114,119,120]. The decrease in breath hydrogen and symptoms is generally dose dependent. Doses up to 9900 FCC units may be needed for digestion of a large lactose load, such as 50 g of lactose [114,121,122].

Lactose-hydrolyzed milks also improve lactose intolerance symptoms in both children and adults [80,81,123–133]. A by-product of lactose-hydrolyzed milk is increased sweetness due to the presence of free glucose [64]. This increased sweetness may increase its acceptability in children [126].

G Colonic Fermentation and Colonic Bacterial Adaptation of Lactose

The colonic bacteria ferment undigested lactose and produce SCFA and gases. Historically, this fermentation process was viewed negatively as a cause of lactose intolerance symptoms. However, it is now recognized that the fermentation of lactose, as well as other nonabsorbed carbohydrates, plays an important role in the health of the colon and affects the nutritional status of the individual.

The loss of intestinal lactase activity in lactose maldigesters is permanent. Studies from Israel, India, and Thailand have reported that feeding 50 g of lactose or more per day for periods of 1–14 months has no impact on jejunal lactase activity [17,134,135]. Despite this observation, milk has been used successfully in the treatment of malnourished children in areas of the world where lactose maldigestion is common. In Ethiopia, for example, 100 schoolchildren, aged 6–10 years, were fed 250 mL of milk per day for a period of 4 weeks [136]. Although the children initially experienced some degree of gastrointestinal symptoms, the symptoms rapidly abated and returned to pretrial levels within 4 weeks. Similar results were observed with schoolchildren in India [134]. Finally, a study of African-American males and females aged 13–39 years who were lactose maldigesters and lactose intolerant showed that 77% of the subjects could ultimately tolerate 12 g or more of lactose if lactose was increased gradually and fed daily over a period of 6–12 weeks [137]. Approximately 80% of the subjects (18 of 22) had rise in breath hydrogen of at least 10 ppm above baseline at the maximum dose of lactose tolerated, suggesting that improved digestion of lactose in the small intestine was not responsible for the increased tolerance. Therefore, the authors proposed that colonic bacterial adaptation was a likely explanation for these findings.

Evidence for colonic bacterial adaptation to disaccharides (lactulose and lactose) is substantial. Perman et al. [138] fed adults 0.3 g/kg lactulose per day for 7 days and observed a decrease in fecal pH from 7.1 ± 0.3 to 5.8 ± 0.6. The breath hydrogen response to a challenge dose of lactose (0.3 g/kg) fell significantly after lactulose adaptation. Employing the same experimental design and doses of lactulose, Florent et al. [62] measured fecal β-galactosidase, colonic pH, breath hydrogen, fecal carbohydrates, SCFA, and ^{14}C-lactulose catabolism in subjects before and after the 7-day lactulose maintenance period. Fecal β-galactosidase was six times greater after lactulose feeding, and breath hydrogen fell significantly. Breath $^{14}CO_2$ (indicating catabolism of ^{14}C-lactulose) increased and fecal outputs of lactulose and total hexose units were low after the lactulose feeding. Symptoms were not measured; however, a follow-up study showed that adaptation to lactulose (40 g/day for 8 days) reduced symptoms of diarrhea induced by a large dose (60 g) of lactulose [139]. Breath hydrogen decreased significantly, and fecal β-galactosidase activity increased as in the previous study.

Several feeding trials directed to adapting lactose maldigesters to lactose have been reported. The first was a blinded, crossover study conducted at the University of Minnesota [6]. Feeding increasing doses of lactose (from 0.3 to 1.0 g/kg/day) for 16 days resulted in a threefold increase in fecal β-galactosidase activity, which returned to baseline levels within 48 hours after substitution of dextrose for lactose. Furthermore, 10 days of lactose feeding (from 0.6 to 1.0 g/kg/day), compared to dextrose

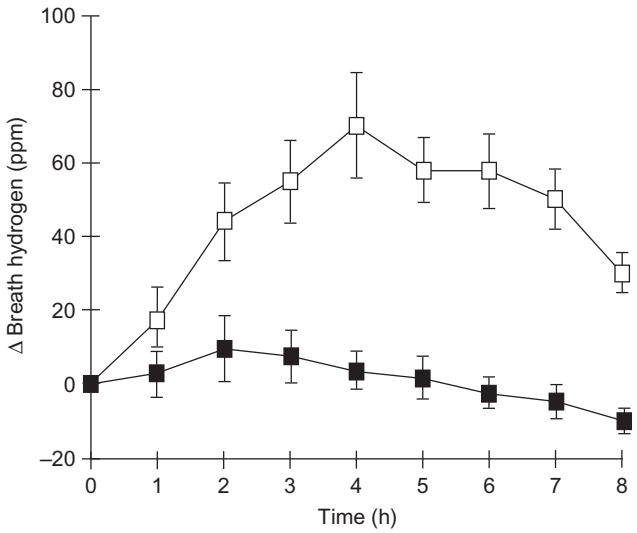

FIGURE 40.2 Breath hydrogen response to a lactose challenge after lactose (□) or dextrose (■) feeding periods. Data are the means ±SEM, $n = 20$. *Reprinted with permission from S.R. Hertzler, D.A. Savaiano, Colonic adaptation to daily lactose feeding in lactose maldigesters reduces lactose intolerance, Am. J. Clin. Nutr. 64 (1996) 232–236.*

feeding, dramatically decreased the breath hydrogen response to a lactose challenge dose (0.35 g/kg; Fig. 40.2). After lactose adaptation, the subjects no longer appeared to be lactose maldigesters, based on a 20-ppm rise in breath hydrogen above fasting. The large doses of lactose fed during the adaptation period (averaging 42–70 g/day) resulted in only minor symptoms. In addition, the severity and frequency of flatus symptoms in response to the lactose challenge dose were reduced by 50%.

The second study was a double-blind, placebo-controlled trial conducted in France with a group of 46 subjects who were lactose intolerant [140]. Following a baseline lactose challenge with 50 g of lactose, subjects were randomly assigned to either a lactose-fed group ($n = 24$) or a sucrose-fed control group ($n = 22$). Subjects were fed 34 g of either lactose or sucrose per day for 15 days. Fecal β-galactosidase increased and breath hydrogen decreased as a result of lactose feeding. Clinical symptoms (except diarrhea) were 50% less severe after lactose feeding. However, the sucrose-fed control group also experienced a comparable decrease in symptoms, despite no evidence of metabolic adaptation. Thus, these authors concluded that the improvements in symptoms resulted from familiarization with the test protocol rather than from metabolic adaptation.

Lactose digesters and maldigesters who reported milk aversion could improve their status of milk consumption as the result of a 21-day intervention [141]. The intervention called for having participants consume 1/2 cup of milk twice a day during the first week, 2/3 cup of milk twice a day during the second week, and 1 cup of milk during the third week. All participants had a decrease in symptoms associated with lactose maldigestion including abdominal pain, bloating, diarrhea, flatulence, and headache. Most notably, however, maldigesters experienced a decrease in symptoms to a greater degree than digesters. Three months following the intervention, participants increased milk consumption by approximately 10 servings per month, which improved their calcium intake category from poor (<700 mg/day) to far (700–1000 mg/day). Milk consumption decreased slightly to 6 servings per month at the 6-month follow-up; however, the behaviors and feelings participants' had toward milk became more consistent. Thus, a similar intervention could be implemented for individuals who maintain their avoidance of dairy products after experiences with lactose intolerance during childhood.

Colonic bacteria develop an increased ability to ferment lactose (indicated by increased fecal β-galactosidase) following prolonged lactose feeding. Because hydrogen gas is an end product of fermentation, it might be expected that the increased ability to ferment lactose would result in an increase, rather than the observed decrease, in breath hydrogen. However, breath hydrogen excretion represents the net of bacterial hydrogen production and consumption in the colon [54]. A decrease in net production of hydrogen could result from either decreased bacterial production or increased consumption. To examine the mechanism for decreased breath hydrogen after lactose adaptation, Hertzler et al. [142] employed metabolic inhibitors of bacterial hydrogen consumption (methanogenesis, sulfate reduction, and acetogenesis) to obtain measures of absolute hydrogen production. Subjects were fed increasing amounts of lactose or dextrose in a manner similar to previous studies. Fecal samples were assayed in vitro for absolute hydrogen production and hydrogen consumption. Absolute hydrogen production after 3 hours of incubation with lactose was threefold lower after lactose adaptation (242 ± 54 mL) compared to the dextrose feeding period (680 ± 7 mL, $p = 0.006$). Fecal hydrogen consumption was unaffected by either feeding period. These findings tend to support the hypothesis that prolonged lactose feeding favors the growth or metabolic activity of bacteria (e.g., bifidobacteria and lactic acid bacteria) that can ferment lactose without the production of hydrogen. Feeding lactose, lactulose, and nonabsorbable oligosaccharides stimulates the proliferation of lactic acid bacteria in the colon [143–145]. In addition, high populations of bifidobacteria inhibit the growth of known hydrogen-producing organisms, such as Clostridia or *Escherichia coli* [146].

Colonic bacterial adaptation to lactose does occur. Although the role of colonic adaptation in improving symptoms is not firmly established, it is clear that many individuals who are lactose intolerant can develop a tolerance to milk if they consume it regularly. This may represent a simpler and less expensive solution than the use of lactose digestive aids. A product called Lactagen has been marketed as a therapy for lactose intolerance, largely based on the colonic adaptation hypothesis. Lactagen is a powder containing lactose, *L. acidophilus*, fructo-oligosaccharides, and small amounts of calcium and phosphorus. It is recommended by the manufacturer that the product be taken for a 38-day period, which is said to be sufficient to permanently "recondition" the intestinal microflora for lactose tolerance. One double-blind study of this product, published only as an abstract [147], reported that 80% of lactose-intolerant subjects had reductions in lactose intolerance symptoms compared with 19% in the placebo group. However, objective evidence of improved lactose digestion or altered colonic bacterial fermentation of lactose (e.g., decreased breath hydrogen) was not obtained in this study. Furthermore, longer term follow-up studies to assess the permanence of the symptom reductions were not conducted.

H A2 β-Casein Milk

Cow's milk typically contains A1 and A2 types of β-casein, the former of which may yield the peptide β-casomorphin-7 (BCM-7) upon digestion [148]. Adverse gastrointestinal effects such as inflammation and discomfort, which resemble lactose intolerance, have been suggested to result from A1 β-casein and its subsequent metabolite, BCM-7. Proposed effects of BCM-7 include increased gastrointestinal transit time, reduced total fecal SCFA content, and slowed cognition. Either or both of the A1 and A2 types of β-casein can be present in cow's milk depending on its genetic makeup. It has been suggested that lactose maldigesters may better tolerate cow's milk containing solely A2 β-casein. However, further evidence that A2 β-casein is associated with improved tolerance is needed.

IX GENE THERAPY FOR LACTOSE INTOLERANCE

Although conventional dietary therapies for lactose intolerance exist, the possibility of gene therapy for LNP was examined by During et al. [149]. An adeno-associated virus vector was orally administered to hypolactasic rats to increase lactase mRNA. The adeno-associated virus vector is a defective, helper-dependent virus, and the wild type is nonpathogenic in humans and other species. Following a single administration of a recombinant adeno-associated virus vector expressing β-galactosidase, all rats treated with this vector ($n = 4$) were positive for *lacZ* mRNA in the proximal intestine within 3 days. There was no lactase mRNA in the rats treated with the control vector. On day 7, following vector administration, the rats were challenged with a lactose solution. The treated rats had a rise in blood glucose from 114 ± 4 to 130 ± 3 mg/dL after 30 minutes, whereas the control rats had a flat blood glucose curve. Furthermore, the treated rats still displayed similar lactase activity when challenged with lactose 6 months later. Thus, the potential of gene therapy for lactose intolerance is an interesting prospect, but this has not been studied in humans.

X PREBIOTICS AS TREATMENT FOR LACTOSE MALDIGESTERS

Prebiotics, specifically galacto-oligosaccharides (GOS), have been shown to alter gastrointestinal microflora, which can improve lactose digestion [150]. Due to the glycosidic bonds in GOS, it is able to avoid hydrolysis by salivary and intestinal salivary enzymes. Thus, GOS reaches the colon intact, where it promotes the growth of lactose-metabolizing bacteria already existent in the digestive tract such as *Bifidobacterium* spp. and *Lactobacilli* spp. A randomized double-blind clinical trial involving 61 participants demonstrated improved lactose digestion following GOS treatment, as evidenced by fewer symptoms of lactose intolerance posttreatment. Furthermore, long-term treatment with GOS is not necessary as long as the affected bacterial colonies are continually exposed to lactose.

XI SUMMARY

A majority of the world's population and approximately 25% of the U.S. population are lactose maldigesters. Milk and milk products not only contain lactose but also are important sources of calcium, riboflavin, and high-quality protein. Some maldigesters may avoid dairy products because of the perception that intolerance symptoms will inevitably follow dairy food consumption. Avoiding dairy products may limit calcium intake and bone density, thus increasing the risk for osteoporosis. Avoidance of milk and milk products is unnecessary because moderate lactose consumption does not usually produce a symptomatic response in maldigesters. In addition, various dietary strategies effectively manage lactose intolerance by reducing or eliminating gastrointestinal symptoms. Dairy food consumption is possible for individuals who are lactose intolerant if simple dietary management strategies are incorporated into daily living.

Chapter 41

Nutritional Considerations in the Management of Gluten-Related Disorders*

Maureen M. Leonard[1,2], Pamela Cureton[1,2] and Alessio Fasano[1,2]
[1]*MassGeneral Hospital* for *Children, Boston, MA, United States,* [2]*Harvard Medical School, Boston, MA, United States*

I INTRODUCTION

Gluten-related disorder celiac disease (also spelled coeliac disease in the European literature) has been known by many names in the medical literature in the past, including gluten-sensitive enteropathy, gliadin-sensitive enteropathy, and celiac sprue (to differentiate it from tropical sprue). Celiac disease occurs in genetically predisposed individuals who develop a permanent immunologic reaction to gluten, found in wheat, rye, and barley. When individuals with celiac disease ingest gluten, the result is malabsorption of sugars, proteins, fats, vitamins, and other minerals. Individuals with celiac disease have a permanent intolerance to the gliadin fraction of wheat protein and related alcohol-soluble proteins (called prolamins) found in rye and barley. Susceptible individuals who ingest these proteins develop an immune-mediated enteropathy, which self-perpetuates as long as these gluten-containing grains are in the diet. Removal of gluten from the diet, in the majority of people with celiac disease, leads to both resolution of symptoms and improvement in the intestinal damage. However, in some individuals, there may be a primary lack of response or secondary loss of response to the gluten-free diet (called "nonresponsive" or "refractory sprue") and intense nutritional support and immune-suppressing medications may be required.

Symptoms of celiac disease in childhood include gastrointestinal symptoms such as diarrhea, abdominal pain, or constipation [1]. Extraintestinal manifestations include short stature, anemia, dental enamel hypoplasia, and children may also present with clinically silent disease [1]. In the United States, and worldwide, many individuals are being diagnosed with celiac disease as adults [2]. They may present with gastrointestinal symptoms, such as diarrhea, gastroesophageal reflux, or constipation. Adults may also present with symptoms outside the gastrointestinal tract; including joint pain, rash, infertility, and abnormalities of the hematologic, musculoskeletal, and neurologic systems [1]. Individuals with celiac disease, and their family members, often have other autoimmune diseases, such as type 1 diabetes, inflammatory bowel disease, and thyroid disease [1]. The diagnosis of celiac disease is often delayed for years due to the presence of nonspecific complaints.

Serum antibodies are useful as a screening method for celiac disease. However, a small-intestinal biopsy, done by endoscopy, must be obtained to confirm a diagnosis of celiac disease. A patient's clinical response to a gluten-free diet is also used to provide important information about the diagnosis. Individuals with untreated disease are at risk for complications, such as iron-deficiency anemia, vitamin deficiencies, osteoporosis, infertility, and gastrointestinal cancers. The long-term maintenance of a gluten-free lifestyle is challenging. Individuals diagnosed with celiac disease benefit most from a team approach, which includes regular supervision by a physician, nutritional counseling by a dietitian, and access to support groups knowledgeable about celiac disease and the gluten-free diet.

II SYMPTOMS OF CELIAC DISEASE

The clinician must have a high index of suspicion for celiac disease because its symptoms can affect almost

* Adapted from Michelle Pietzak.

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00041-2

every organ system of the body, and its clinical features can be highly variable. The disease may present at any age [2]. Likewise, the severity of the presentation of celiac disease can be highly variable, with some patients experiencing severe diarrhea and weight loss, and others having no gastrointestinal symptoms whatsoever. Because celiac disease is a multisystem disease, it can affect not only the gastrointestinal tract but also the neurologic, endocrine, musculoskeletal, reproductive, and hematologic systems. Thus, it is not uncommon that a patient with celiac disease may be seen by multiple physicians over many years before the disorder is correctly identified.

A Intestinal Manifestations

1 Pediatric

Infants and toddlers may present with gastrointestinal complaints as early as 12 months of age, after the introduction of gluten-containing foods into the diet. The onset is usually insidious, with "failure to thrive" and obvious physical signs of wasting over a period of weeks to months. Symptoms include diarrhea, weight loss, abdominal distention, gassiness, and foul-smelling stools due to carbohydrate (primarily lactose) and fat malabsorption. Parents will often report that the child becomes irritable after meals, and the child may also develop a secondary anorexia due to the pain associated with the diarrhea and abdominal distention. These children exhibit classic signs on physical exam of protein-calorie malnutrition: hypotonia, poor muscle bulk, peripheral edema, decreased subcutaneous fat stores, abdominal distention, and ascites in severe cases. Anemia is common. The anemia is usually microcytic, due to iron malabsorption. However, if the disease is long standing, and small bowel involvement is severe, a macrocytic anemia can develop as a result of folate or vitamin B_{12} malabsorption. Radiographs can show osteopenia due to vitamin D and calcium malabsorption.

2 Adolescents and Adults

School-age children, adolescents, young adults, and even the elderly often complain of mild to intermittent diarrhea, gassiness, urgency, and abdominal distention and cramping. A presenting patient may also complain of chronic abdominal pain; constipation rather than diarrhea; and upper gastrointestinal tract symptoms such as nausea, dyspepsia, indigestion, gastroesophageal reflux, and chronic vomiting. Rather than being examined for celiac disease, these patients often are labeled as having irritable bowel syndrome (IBS), lactose intolerance, recurrent abdominal pain of childhood, or even an inflammatory bowel disease such as Crohn's disease. Patients are therefore treated with lactose-free or high-fiber diets, medications to treat constipation or IBS, or medications to suppress gastric acid or the immune system. Not surprisingly, the celiac patient will not get relief from these treatments. Some of these therapies, such as a high-fiber diet, which often contains a great deal of gluten, may increase symptomatology. Many patients will have upper and lower endoscopies performed by a gastroenterologist, and the results may look visually normal without obvious ulcers or cancers; thus, biopsies for celiac disease will not be taken. Because of this, the diagnosis of celiac disease is often missed.

B Extraintestinal Manifestations

Celiac disease is a multisystemic immune-mediated disorder and thus it can present with signs and symptoms outside the gastrointestinal tract [1]. Organ systems affected can include the musculoskeletal system, skin and mucous membranes, reproductive system, hematologic system, hepatic system, and central nervous system.

1 Musculoskeletal System

One of the most common presenting features in childhood in the musculoskeletal system is idiopathic short stature. In European studies [3–5], it is estimated that approximately 1 of 10 children whose height is far below his or her genetic predisposition for unclear reasons is short because of celiac disease. Short stature can be an isolated feature of this condition. The children often have delayed onset of puberty, and stimulation testing may reveal growth hormone deficiency [6]. The potential to achieve normal stature and bone mineralization is good if these patients are diagnosed with celiac disease before puberty and placed on a gluten-free diet in a timely fashion [7]. However, after the growth plates have closed, individuals will have short stature for life.

Dental enamel defects are common in children affected by celiac disease during the toddler years. They may experience caries at an early age and in atypical locations. One report has noted that up to 30% of older patients with celiac disease have enamel hypoplasia [8]. If gluten is in the diet, these enamel defects affect only the permanent (secondary) dentition that is forming before the age of 7 years. The primary dentition or "baby teeth" are formed in utero, which is a gluten-free environment, and thus the primary dentition is unaffected. The dental enamel defects are linear and occur symmetrically in all four quadrants [9]. The precise cause of these defects is unknown.

Joint pain is a common complaint among both adolescents and adults with undiagnosed celiac disease. The joints are often only painful, and not red, hot, or visibly

swollen. The pain often resolves with the implementation of a gluten-free diet. Clubbing of the fingers and toes (broad digits with abnormally curved nails) has also been reported. Interestingly, and to confuse the issue further, celiac disease is also seen in higher incidence in patients with rheumatologic disorders such as systemic lupus erythematosus and rheumatoid arthritis [10–12]. In an adolescent, arthritis may be the only presenting symptom [13].

One of the most serious causes of morbidity in older individuals diagnosed with celiac disease is fractures associated with osteoporosis. The potential health implications are grave and include vertebral fractures, kyphosis, hip fractures, and Colles' fracture of the lower radius in the arm [14]. These problems can begin in childhood, when radiographs may reveal delayed bone age, rickets, or osteomalacia, which left untreated may lead to osteoporosis. It is believed that early interventional therapy with a gluten-free diet may prevent progression and may even reverse bone loss [15]. However, severe osteoporosis associated with celiac disease diagnosed very late in life will not revert on the gluten-free diet after a critical point in time [16].

2 Skin and Mucous Membranes

Often overlooked, the skin and mucous membranes can be obvious sites for the expression of symptoms from celiac disease. The classic skin manifestation of celiac disease is a skin rash called dermatitis herpetiformis, often abbreviated as DH. It occurs primarily in adults and is rarely seen in children before puberty. This skin rash is classically pruritic (itchy) and symmetrical and does not respond to topical creams and medications. The rash begins as flat, red lesions, which then progress to erythematous, fluid-filled blisters. They usually occur on the face, elbows, back, buttocks, and knees. The lesions initially can be confused with urticaria (hives) or varicella (chickenpox). Patients will often scratch and pick at the lesions, so that the skin will then develop an eczematous appearance. A biopsy of the normal-appearing skin next to the affected area demonstrates the characteristic histology of granular immunoglobulin A (IgA) deposits [17]. DH is now known to be the pathognomonic skin rash for celiac disease, and once a skin biopsy has proven the diagnosis of DH, an intestinal biopsy for celiac disease is unnecessary. If a patient with DH does have a small-intestinal biopsy, the majority of the time there will be intestinal damage [18]. For complete resolution of DH, a gluten-free diet is required. Some patients with DH also require an antiinflammatory antibiotic, in addition to a gluten-free diet, during acute onset of DH. The skin lesions, or just the pruritis of DH, may appear when gluten is intentionally or inadvertently ingested. This should alert the affected individual to scrutinize the diet for gluten contamination.

Celiac disease can have many other manifestations in the skin and mucous membranes, including urticaria, psoriasis, and oral aphthous stomatitis [18–20]. Oral aphthous stomatitis ("fever sores" or "canker sores"), which can appear on the cheeks, tongue, gums, and lips, usually correlates with histological changes in the small intestine. However, because aphthous ulcers are also seen with common viral infections (such as herpes viruses) and other types of autoimmune and inflammatory diseases of the gastrointestinal tract (particularly Crohn's disease), they are not pathognomonic for celiac disease.

3 Reproductive System

The reproductive systems of both women and men can be affected by celiac disease. Compared to the general population, women with undiagnosed celiac disease have greater difficulty becoming pregnant [21] and a higher risk for spontaneous abortions [22,23]. Men with undiagnosed celiac disease may also experience infertility due to gonadal dysfunction [24]. Adult patients with undiagnosed celiac disease may often undergo exhaustive and expensive infertility studies, without discovery of an etiology. Many of these infertile women will also give a history of delayed menarche, anemia, and IBS symptoms, similar to the pediatric patients described previously with short stature and delayed puberty. Women with undiagnosed and diagnosed celiac disease have infants with higher rates of neural tube defects because of folic acid deficiency, as well as more infants with intrauterine growth retardation [25–27]. Whether these individuals experience reproductive challenges because of nutritional factors, or having an undiagnosed autoimmune disease, or a combination of both is unclear.

4 Hematologic System

Iron-deficiency anemia is one of the most common micronutrient deficiencies in the undiagnosed celiac patient. In addition to anemia, leukopenia (low white blood cell count) and thrombocytopenia (low platelet count) have also been reported. The anemia in celiac disease is usually microcytic and hypochromic, due to iron deficiency [28]. However, a macrocytic anemia should warrant an investigation into gut malabsorption of vitamin B_{12} or folic acid. Because fat-soluble vitamins are also malabsorbed in this disorder, vitamin K deficiency may occur, resulting in an increased risk for bruising and bleeding. Vitamin E deficiency may also occur, resulting in a hemolytic anemia and jaundice.

5 Liver

In children and adults with celiac disease, diseases of the liver, such as autoimmune hepatitis and chronic transaminasemia (liver enzymes), have been reported [28–31].

In children initially diagnosed with celiac disease with elevated aspartate transaminase and alanine transaminase liver enzymes at presentation, these biochemical markers of hepatocyte damage returned to normal with strict adherence to a gluten-free diet [32]. Autoimmune liver diseases, such as autoimmune hepatitis, sclerosing cholangitis, and primary biliary cirrhosis, are all more likely to occur in the individual with celiac disease [33]. Patients with celiac disease who have evidence of chronic liver disease that has not responded to a gluten-free diet require an evaluation for these autoimmune liver diseases.

6 Central Nervous System

There is evidence that patients with celiac disease have increased rates of both neurologic and psychiatric disorders. Their associations are not always clear: some symptoms can be attributed to nutritional deficiencies; others perhaps related to autoimmunity; and many are hypothesized to be due to yet-unproven pathways by which gluten may cross the blood–brain barrier and interact with endogenous neurotransmitter receptors or cause neuroinflammation. Neurological complications have been reported in association with established celiac disease for decades [34], and gluten sensitivity can present with neurological dysfunction as its sole symptom [35].

In the neurologic system, patients with celiac disease are 20 times more likely than the general population to have epilepsy and have been reported with associated cerebral and cerebellar calcifications imaged by both computed tomography and magnetic resonance imaging [36]. In children with celiac disease, focal white matter lesions in the brain have been reported and are thought to be either ischemic in origin as a result of vasculitis or caused by inflammatory demyelination [37].

Gluten-associated ataxia is the most common neurological manifestation of gluten sensitivity [38] and presents as difficulty with speech, movement, and balance due to atrophy of the cerebellum. It rarely occurs before puberty, has a mean age of onset in the late 40s, and has a paucity of gastrointestinal symptoms [39]. Emerging evidence indicates that early initiation of a gluten-free diet is beneficial for treating the symptoms of both ataxia and peripheral neuropathy, even in the absence of intestinal damage [40].

In both treated and untreated persons with celiac disease, psychiatric comorbidities, such as depression, dementia, and schizophrenia, are common. In children, behavioral changes such as irritability, increased separation anxiety, emotional withdrawal, and autistic behaviors have improved, by parental report, on a gluten-free diet [41]. Although not scientifically validated, the gluten-free diet, along with a casein-free diet, is now also being advocated by several groups for a subset of children with autism [42–44]. Children with Down syndrome and other genetic syndromes are at higher risk for celiac disease [45]. It is important to note that only a proportion of patients presenting with neurological dysfunction associated with gluten sensitivity will also have biopsy-proven intestinal damage [46].

C Associated Conditions

There are several groups of patients who are at substantially increased risk of having celiac disease: those with another autoimmune disorder, those with certain syndromes, and relatives of biopsy-diagnosed patients. These associated conditions are further described in Table 41.1. Patients with other autoimmune diseases, such as type 1 diabetes, as well as relatives of persons with biopsy-diagnosed celiac disease, are more likely to carry the human leukocyte antigen (HLA) haplotypes that put them at risk for the disease. It has been demonstrated that patients diagnosed with celiac disease early in life, and treated early with a gluten-free diet, have a significantly lower risk of developing other autoimmune disorders than do individuals diagnosed later in life [71].

Persons with both Down and Turner syndromes classically have short stature and are at increased risk for skeletal and other autoimmune diseases such as diabetes mellitus, Crohn's disease, and thyroid disease [72], which makes the diagnosis in this population exceptionally difficult. A multicenter study from Italy strongly suggested the need for screening all children with Down syndrome, regardless of the presence or absence of gastrointestinal symptomatology [58]. It is unclear why individuals with certain syndromes are at higher risk for celiac disease. However, because several of these syndromes have as part of their constellation poor growth and short stature, anthropometric measures are poor screening tools for malabsorption in these populations. The NIH Consensus Development Conference on Celiac Disease, held in June 2004, recommended that patients with Down, Turner, or Williams syndrome should be offered screening for celiac disease at least once [73].

D Asymptomatic Disease

It can be debated whether or not there is truly an "asymptomatic" form of celiac disease. The medical literature describes patients lacking the signs and symptoms occurring in the gastrointestinal tract or extraintestinal systems as "asymptomatic." With a more detailed history, physical exam, and laboratory investigations, these asymptomatic patients may have revealed evidence of trace mineral deficiencies, anemia, short stature, low bone density, and low serum fat-soluble vitamin levels. These patients may be identified through mass serologic screenings and are

TABLE 41.1 Conditions and Syndromes at Increased Risk for Celiac Disease

Condition	% Diagnosed with Celiac Disease	Increased Risk	Reference
Arthritis	1.5–7.5	3- to 10-fold	[1,10,47,48]
Cardiomyopathy (idiopathic dilated)	5.7		[49]
Dental enamel defects	19–30	19-fold	[8,9,50]
Dermatitis herpetiformis	100		[17,51,52]
Diabetes type 1	3.5–10	4- to 10-fold	[53–57]
Down syndrome	4–20	17- to 50-fold	[1,58–60]
Epilepsy	2		[36,61]
IgA deficiency	7	31-fold	[62]
Infertility (idiopathic)	6.3		[1]
Iron-deficiency anemia	4.2	16-fold	[1,28]
Osteoporosis	2.6		[1]
Primary biliary cirrhosis	6		[33]
Relatives, first- or second-degree	2.6–20	18-fold	[1,63,64]
Short stature (idiopathic)	4–10	23-fold	[1,3–5]
Sjögren's syndrome	2–3		[1,65]
Thyroid disease (autoimmune)	4		[66]
Turner syndrome	4–8		[67–69]
Williams syndrome	9.5		[70]

often first- and second-degree relatives of a patient with biopsy-diagnosed disease. A family history of gastrointestinal cancers or other autoimmune disorders is often elicited [74–77].

E Potential Celiac Disease

Patients with the potential celiac disease have positive antibodies for the condition but an initial normal intestinal biopsy. The evidence regarding the likelihood of developing celiac disease and factors useful in predicting whether overt celiac disease develops is still debated. Pediatric studies report that the majority of patients with potential celiac disease do not go on to develop overt celiac disease; however, factors predictive of developing the disease have not been identified [78]. A prospective study examining 175 asymptomatic children with potential celiac disease with serology tests and intestinal biopsies every 2 years found that at 3, 6, and 9 years of follow-up, the number of cases that remained potential were 86%, 73%, and 67%, respectively [79]. While the true prevalence of potential celiac disease and the frequency with which it develops into overt celiac disease are unknown, studies indicate the prevalence, like overt celiac disease, is rising [80].

III DIAGNOSIS OF CELIAC DISEASE

A Serologic and Genetic Screening Tests

The tests of choice to screen for celiac disease are serum immunological markers with high sensitivity and specificity. The classic screening tests that are used for other gastrointestinal malabsorption disorders, such as fecal fat, glucose tolerance tests, D-xylose uptake, serum carotene levels, and permeability tests (e.g., lactulose/mannitol ratios), are poorly specific for celiac disease and should not be used in place of the serologic markers that are discussed hereafter. The clinician must remember, however, that no screening test is perfect, and that the "gold standard" to confirm the diagnosis of celiac disease remains a small-intestinal biopsy and the patient's clinical response to a gluten-free diet. Any patient with suggestive symptoms should have a small-bowel biopsy, even if the serology is negative.

There are three frequently used commercially available serologic tests (antibodies): anti-endomysial or

anti-endomysium (EMA or AEA), antitissue transglutaminase (tTG), and antideamidated gliadin antibody (DGP). Sensitivity, specificity, and positive and negative predictive values can vary widely for each antibody, depending on the age of the patient, the population being studied, the substrates and laboratory kits being used to run the assays, and the proficiency of the laboratory performing the test [81]. Therefore, the IgA tTG is the first line screening test and the EMA is sometimes used to confirm the tTG findings before moving forward with endoscopy. Conditions that may yield false negative antibody results include a patient who makes low levels of IgA, young children who may not manufacture autoimmune antibodies, an inexperienced laboratory, and testing while the patient is already on a gluten-free diet. DGP antibodies of IgG class have been introduced with a sensitivity and specificity close to IgA anti-tTG. The DGP test is recommended in limited circumstances most notably, the immunoglobulin G (IgG) DGP antibody test is recommended for use when IgA is low (<7). False positive tests can also be seen with these antibody tests, as delineated later, in normal individuals with other gastrointestinal disorders and in other autoimmune disorders.

1 Anti-Endomysium Antibodies

The serologic test currently commercially available with the highest sensitivity and specificity is the anti-endomysium IgA immunofluorescent antibody (EMA). The EMA was discovered in the early 1980s and rapidly gained use as part of a screening "celiac panel" by commercial laboratories in combination with AGA IgG and AGA IgA. False-negative EMA can be seen in young children, those with IgA deficiency, and in the hands of an inexperienced laboratory because of the subjective nature of the test [81]. Also, the substrate for this antibody was initially monkey esophagus, making it expensive and unsuitable for screening large numbers of people. Human umbilical cord is now used as an alternative to monkey esophagus in most commercial laboratories [82].

2 Tissue Transglutaminase Antibodies

Tissue transglutaminase (tTG) was described in 1997 as the autoantigen of EMA [83]. The initial tTG ELISA was guinea pig IgA, with a lower sensitivity and specificity than EMA [84,85]. However, commercial labs now use human recombinant tTG, which has improved sensitivity and specificity and correlates better with EMA IgA and intestinal biopsy results [83–86]. The tTG IgA ELISA represents an improvement over the EMA IgA assay because it is less expensive, is less time-consuming, is not a subjective test, and can be performed on a single drop of blood using a dot-blot technique, making this an ideal test for mass serologic screenings. Positive tTG results may be seen in other autoimmune diseases, such as type 1 diabetes, autoimmune liver disease, autoimmune thyroid disease, and inflammatory bowel disease.

3 Genetic Testing

Although celiac disease is the only autoimmune disease for which we know the environmental trigger, gluten, we also know that there is a strong genetic influence. For example, as discussed under Section II-C, Associated Conditions, in first- and second-degree relatives, there can be up to a 26% disease prevalence [1,63,64,80]. Also, identical twins have a 75% concordance rate for celiac disease (one of the highest rates reported for any disease), whereas nonidentical twins do not differ from siblings [87]. This again indicates a genetic, in addition to an environmental, component.

Celiac disease is a complex genetic disorder, but the actual "celiac genes" have not yet been identified. The strongest genetic determinant of risk for celiac disease appears to be the presence of certain HLA alleles. The presence of these HLA alleles, DQ2 and DQ8, is thought to account for up to 40% of the genetic load of the familial risk for celiac disease [88]. The HLA are markers that help identify cells as "self" versus "nonself." The HLA prevent the immune system from attacking "self." HLA DQ2 or DQ8 are found in more than 95% of celiac patients. It is extremely rare for a celiac patient to have neither of these genes. However, if an individual has these HLA alleles, it does not mean that the individual has celiac disease because these alleles are found in 39.5% of the general population [89–91]. This is a great source of confusion for patients and physicians because it is counterintuitive to other types of genetic testing, where the presence of the gene confirms the disease.

The value of genetic testing is that it has a high negative predictive value to rule out celiac disease for a patient's lifetime. Negativity for HLA DQ2 and DQ8 excludes the diagnosis of celiac disease with 99% confidence. However, positivity for DQ2 or DQ8 has limited diagnostic value because of the high prevalence of these genotypes in the general population. The strength of genetic testing is that the patient does not need to be on a gluten-containing diet to be tested because the presence of these genes is not affected by diet. Therefore, genetic testing can evaluate

- Infants not yet exposed to gluten;
- Young children who may not make all of the antibodies;
- Patients who have self-imposed a gluten-free diet;
- Patients with serology or biopsies that were not conclusive;
- Relatives of biopsy-diagnosed individuals with celiac disease.

4 Current Guidelines on the Use of Serologic and Genetic Testing to Screen for Celiac Disease

As described previously, the IgA class human anti-tTG antibody, coupled with a determination of total serum IgA to rule out deficiency, currently is the most cost-effective way to screen for celiac disease in an otherwise healthy adult. EMA should be used as a confirmatory, prebiopsy test, whereas IgG DGP determinations should be restricted to the diagnostic workup of individuals with IgA deficiency. Given the high prevalence of the HLA haplotypes associated with celiac disease in the general population, genetic testing is not recommended as a routine screening test for celiac disease. Additionally, most insurance companies will not cover the test making it quite expensive. The practitioner should remember that serologic tests are screens and that to confirm the diagnosis of celiac disease, a small bowel biopsy must be performed, as discussed next.

B The Intestinal Biopsy

Confirmation of either a clinical suspicion of celiac disease or a positive serologic screen requires a small-intestinal biopsy. Before the advent of fiberoptic and chip technology for endoscopes, biopsies of the jejunum were obtained using a Crosby spring-loaded capsule, passed orally under fluoroscopic guidance. Biopsies today are performed using a flexible endoscope, passed orally under either conscious sedation or general anesthesia. This has the advantages of allowing direct visualization of the mucosa with a camera to look for changes suggestive of small bowel damage, such as notching or scalloping of the small bowel folds or lymphonodular hyperplasia [92]. Endoscopy also allows the endoscopist to look for other lesions, such as ulcers, esophagitis, or gastritis, which may help explain the patient's symptomatology.

The detailed description of the characteristic small bowel changes seen in celiac disease that was given by Marsh in 1988 has become accepted as the standard [93]. The Marsh criteria describe four patterns of mucosal pathology: type 0 (preinfiltrative), which is without detectable inflammation or changes in the crypt/villous architecture; type 1 (infiltrative), with an increase in the intraepithelial lymphocytes (IELs) but without detectable changes in the crypt/villous architecture; type 2 (hyperplastic), with inflammation, villous blunting, and an increased crypt/villous height ratio; and type 3 (destructive), with severe inflammation, flat villi, and hyperplastic crypts. The clinician, however, needs to be aware that villous atrophy (shortening of the finger-like projections in the small bowel, which increase absorptive surface area) can be caused by a wide variety of gastrointestinal diseases and infections, and that correlation with serology and the patient's response to a gluten-free diet is imperative to confirm the diagnosis. In rare instances, a gluten challenge may be necessary to confirm that the villous atrophy was due to celiac disease and not a concomitant gastrointestinal infection. In cases in which serology is suggestive, the biopsy is confirmative, and the patient has had a clinical response to the gluten-free diet, a gluten challenge and repeat small bowel biopsy are no longer required [94]. However, a repeat small bowel biopsy in order to confirm intestinal mucosal healing should be considered in pediatric and adult cases.

IV TREATMENT OF CELIAC DISEASE WITH A GLUTEN-FREE DIET

The only known treatment for celiac disease is a gluten-free diet. This was first discovered after World War II in children with celiac disease when the toxicity of wheat proteins was established after the bread shortages resolved in Europe [95,96]. Gluten is important in baked goods because it plays an important role in leavening, in forming the structure of the dough, and in holding the baked product together [97]. Removal of gluten from the diet of a biopsy-diagnosed person with celiac disease results in complete symptomatic and histologic resolution of the disease in the majority of patients. The identified agents responsible for the immune-mediated response and intestinal damage are prolamins, storage proteins located in the seeds of different grains. Gluten is the general name for the prolamins found in wheat (gliadin), rye (secalin), barley (hordein), and oats (avenin) [97].

The prolamin of oats, avenin, accounts for only 5–15% of the total seed protein, as opposed to gliadin, which comprises approximately 50% of wheat proteins [98]. This oat prolamin is thought not to elicit the same immune response as gliadin and is thought by some to be safe for patients with celiac disease to ingest [51]. The risk that oats are contaminated with wheat in the United States is great because oats are often crop-rotated, harvested, and milled with wheat. For this reason, patients are instructed to use only labeled gluten-free oats when including oats in their diet. A study in the United States in newly diagnosed children with celiac disease who were allowed to eat oats found that these children had symptomatic and histologic resolution of the disease comparable to children who were denied oats [99]. Prolamins are also found in corn and rice, but they likewise do not elicit an immune reaction in the intestines of individuals with celiac disease [97].

Table 41.2 provides some basic dietary guidelines for persons following a gluten-free diet. Although not all-inclusive, it is meant to serve as a starting point for

TABLE 41.2 Basic Dietary Guidelines for Individuals Following a Gluten-Free Diet

Allowed	Not Allowed	Questionable
Fruits and Vegetables		
Grains/Starches: corn (maize), corn bran, corn starch, corn meal, corn flour, corn germ, corn gluten, rice, rice bran, rice flour, glutinous white rice, rice polish, soy (soya), arrowroot, pure wild rice, sago, potato starch, potato flour, sweet potato flour, legume flours (garbanzo, chickpea, garfava, lentil, pea, whole bean), nut flours (almond, chestnut, hazelnut), flax seed, flax seed meal, sorghum, tapioca (also called cassava or manioc), buckwheat, millet, teff, amaranth, quinoa	Grains: wheat, rye, triticale, barley, wheat flour, wheat germ, wheat bran, graham flour, gluten flour, durum flour, wheat starch[a], bulgur, farina, semolina, couscous, spelt, kamut, einkorn, emmer, farro, orzo, atta Oats (in any form) unless uncontaminated and labeled gluten-free oats	Packaged rice mixes Rice pilaf-may contain Italian vermicelli (a wheat-based pasta) and other gluten-based ingredients Buckwheat flour (pure buckwheat is gluten-free but buckwheat flour may be a blend of buckwheat and wheat)
Meat/Protein Foods		
Fresh, plain, frozen, and smoked meat (beef, pork), poultry, fish, seafood without added, unidentified natural flavorings or seasonings Veggie burgers and meat substitutes that are labeled gluten-free and do not contain any questionable ingredients Processed meat or poultry products (such as deli or luncheon meats) labeled gluten-free or free of gluten-containing ingredients Fresh eggs (in the shell) Most cholesterol-reduced liquid egg products Lentil, chickpea (garbanzo), dried peas, soybean, garfava (garbanzo and fava), whole dried beans (navy, pinto, black) Most peanut and nut butters Plain tofu Plain soy miso, rice miso Plain nuts (almond, walnut, chestnut, hazelnut, etc.) Plain peanuts Plain seeds (sesame, sunflower, chia, pumpkin, hemp, flax) Tempeh (made without gluten-containing ingredients)	Canned fish, poultry, or meat basted containing hydrolyzed wheat protein Most veggie burgers and many vegetarian meat substitutes—most contain gluten in the form of soy sauce made from wheat, texturized wheat protein, seitan, wheat gluten, bulgur wheat, wheat flour, or oats Roast beef or prime rib with au jus (many beef sauces/gravies contain hydrolyzed wheat or wheat flour) Processed, prepared, or preserved meat and meat products (luncheon meats, hot dogs, sausages, etc.), processed poultry products (seasoned chicken breast, etc.), and processed mixed food products (that generally contain more than 3% raw meat or 2% or more cooked meat or poultry meat) that contain modified food starch, dextrin and/or starch derived from gluten or other gluten-containing ingredients are present Processed egg products (dried, frozen, or liquid eggs with or without added ingredients) that contain modified food starch, dextrin, and/or starch derived from gluten	Any meat, poultry, or fish product containing unidentified natural flavoring or seasonings (beef, fish, or chicken burgers may contain fillers such as wheat flour, wheat starch, bread crumbs) Seasonings may include ingredients derived from wheat, barley, or rye Ham (ready to cook)—glaze may contain wheat protein, wheat flour, or wheat starch Poultry, fish, or meat marinades—may be made with soy sauce, malt vinegar, or other gluten-containing ingredients Surimi (imitation crab/seafood) Imitation bacon Reduced fat and flavored peanut and nut butters—check for gluten-containing ingredients Flavored/seasoned tofu—may be made with soy sauce or other gluten-based ingredients Miso (may be barley based)
Milk Products		
Milk: whole, low fat, skim, plain powdered, evaporated, or condensed Soy, hemp, nut (almond), coconut, rice, and sunflower seed-based milk substitutes labeled gluten-free	Malted milk Yogurt with gluten-based mix-ins (cookie crumbs, granola, etc.)	Soy, hemp, nut (almond), coconut, and rice-based milk substitutes—may contain barley flavoring and/or barley-derived enzymes Chocolate drinks and mixes—may contain barley malt or other gluten-containing ingredients
Buttermilk		
Cream, half & half, nondairy creamer Regular sour cream Plain yogurt		
Fruits and Vegetables		
All plain fresh, frozen, and canned fruits Pure fruit juices—all plain fresh, frozen, dried, and canned vegetables Pure vegetable juices Plain tomato sauce	Breaded or batter-dipped vegetables, tempura, vegetables with sauces containing wheat-based soy sauce, teriyaki sauce, or unknown ingredients Frozen potato products made with wheat starch or flour	Canned fruit pie filling—may contain gluten-containing ingredients Dried fruit (esp. dates)—may be dusted with flour or starch to prevent sticking Bulk bin dried fruit—may be contaminated with items from other bins

(*Continued*)

TABLE 41.2 (Continued)

Allowed	Not Allowed	Questionable
Fruits and Vegetables		
Plain tomato paste Spaghetti sauce made with allowed ingredients Fresh potatoes Gluten-free French fries cooked in dedicated fryer		French fries—"seasoned" or flavored fries—often contain wheat starch or wheat flour Restaurant/fast food fries—often cooked in oil used to cook gluten-containing foods (i.e., onion rings, breaded chicken fingers) Scalloped potatoes are usually made with flour Potato mixes may contain gluten-based ingredients
Miscellaneous		
Butter, margarine, shortening, all vegetable oils (olive, sunflower, safflower, canola, grape seed, etc.) except wheat germ oil Most ice cream and frozen yogurt, sherbet, sorbet, popsicles, gelatin, Italian ice, whipped cream Pure chocolate, honey, maple syrup, jelly, jam, marmalade, molasses, sugar (white and brown), coconut, fructose, powdered/confectioner's sugar (if corn starch based), artificial sweeteners, pure cocoa powder, pure carob chips and pure carob powder, marshmallows, most chocolate syrups, some rice syrups Most relish, ketchup, prepared mustards, olives, salsa Many salad dressings Mayonnaise Most vinegars (except malt vinegar) All pure spices and herbs, pure black pepper, mustard flour (ground mustard seeds), tahini Soy sauce and marinades made without wheat or gluten-containing ingredients (labeled gluten-free) Salt MSG (monosodium glutamate) Pure or artificial vanilla extract Baking soda, yeast (except Brewer's yeast), most baking powder, cream of tartar, corn starch Corn gluten, corn malt Gluten-free Communion wafers Gums: xanthan, guar Pure tea, most herbal tea, unflavored coffee (instant or ground), pure cocoa powder, soft drinks, cider (without gluten-containing ingredients) Most distilled alcoholic beverages (i.e., rum, whiskey, vodka) without added gluten-containing flavorings Wine Water Most hot chocolate mixes, most liqueur, some soy beverages Beer labeled gluten-free and made from gluten-free grains (such as sorghum)	Wheat germ oil, nonstick baking spray containing flour, fats/oils that have been used to cook gluten-containing foods Ice cream or frozen yogurt containing gluten-based ingredients, and/or mix-ins made from gluten-based ingredients (such as cookie crumbs) Candies, candy bars, and chewing gum containing malt flavoring or other gluten-containing ingredients Licorice candy unless labeled gluten-free Soy sauce made from wheat Teriyaki sauce, Tamari, or shoyu made from wheat Malt vinegar Sauces, marinades, or gravies made with wheat flour, wheat starch, or other unknown ingredients Salad dressings containing wheat-based soy sauce, malt vinegar, or other gluten-containing ingredients Salsa containing malt vinegar or other gluten-containing ingredients Barley malt, barley flavoring, malt flavoring, or malt extract Regular Communion wafers Brewer's yeast Autolyzed yeast and autolyzed yeast extract unless the source is identified as gluten-free or the product is labeled gluten-free Malted beverages, beer, ale, lager Herb tea containing roasted barley, barley malt Postum or other grain-based coffee substitutes Beer made with gluten-containing grains—"processed or treated or crafted to remove gluten." *Note*: The gluten content of these products cannot be verified	Pudding, custards, flan, lemon curd (homemade or from mix)—may be made with flour "Flourless" cakes—may be baked in pans dusted with flour Chocolate with crisped rice—may contain malt flavor Chocolate bars may contain barley malt extract/flavoring, wheat starch, or wheat flour Butterscotch morsels—may contain barley flavoring Confectioner's sugar—may contain wheat as an ingredient Spice blends or seasoning mixes (i.e., taco seasoning mix)—may contain wheat starch or hydrolyzed wheat protein Steak sauce, Worcestershire sauce, BBQ sauce, and marinades (poultry, fish, or meat)—often contain malt vinegar, wheat-based soy sauce or other Salad dressing—may contain wheat-based soy sauce or gluten-based ingredients Prepared mustards—some made with wheat flour Restaurant sauces, gravies—most thickened with flour or use flavoring ingredients containing gluten Flavored or herb tea—may contain barley Flavored coffee—may contain gluten-containing ingredients Chocolate drinks and mixes, coffee flavored mixes—may contain barley malt or other gluten-based ingredients Alcoholic beverages containing unknown flavorings added after distillation

[a]*Except in labeled gluten-free foods.*

Source: This table has been modified with permission from The Celiac Center and Nutrition Services at Beth Israel Deaconess Medical Center.

discussion between patients and health care practitioners. Many newly diagnosed individuals are not aware that "gluten-free" does not mean just eliminating bread and pastries from the diet, because gluten (especially wheat) can be identified on food labels and in restaurants by many other names. For example, triticale (a combination of wheat and rye), kamut, and spelt are all forms of wheat and are considered toxic [100]. Other forms of wheat, such as bulgur, couscous, einkorn, farina, and semolina (durum), are also not permitted on the gluten-free diet. Any food product that contains rye, barley, or malt (a partial hydrolysate of barley) has prolamins that are considered harmful [101]. In general, a food product that includes wheat in its name (e.g., cracked wheat, wheat bran, wheat grass, wheat germ, or whole wheat) or malt in its name (barley malt, malt extract, malt flavoring, or malt syrup) is considered to contain gluten. One notable exception, however, is buckwheat, which is not directly related to *Triticum* and is considered safe to consume. Distilled ingredients (e.g., vinegar and alcohol) are allowed because gluten does not pass into the distillate. Malt vinegar is a fermented product and must be avoided as well as beverages made with barley (e.g., beer, ale, lager, and some rice and soy drinks) [97].

Food labeling in the United States has undergone some changes. The Food Allergen Labeling and Consumer Protection Act (FALCPA) was signed into law in August 2004. It requires food labels to clearly state if a product contains any of the top eight food allergens: milk, eggs, fish, crustacean shellfish, tree nuts, peanuts, soybeans, and wheat. All food products manufactured and sold in the United States after January 1, 2006, are required to have updated labels declaring the presence of any of the top eight food allergens in the product. FALCPA was primarily passed to benefit individuals with food allergies. However, it is also of tremendous value to those with celiac disease because wheat is often hidden on ingredient labels as "modified food starch," "flavorings," "seasonings," or "dextrin" (Table 41.2). Wheat is often used as a flavoring in candy, sauces, seasonings, soups, and salad dressings [97,102]. Because wheat is the most commonly used grain in the United States, by clarifying the source of ingredients and identifying "wheat," approximately 90% of labeling concerns are resolved for celiac and gluten-sensitive patients.

The law also called for the Food and Drug Administration (FDA) to issue rules, by 2008, detailing what it means when a product is labeled "gluten-free." Unlike Europe, Canada, and Australia, the United States did not have a defined standard for "gluten-free" foods, causing a great deal of confusion over what it means when an American manufacturer puts "gluten-free" on a product's label. The FDA rule establishing the definition of "gluten-free" was finally passed and was enacted as of August 2013. The rule establishes a standard that will increase consumer confidence in the safety of products labeled gluten-free. A summary of the FDA gluten-free label rules enacted in August 2013 include:

- A food label gluten-free must:
  - Be inherently gluten-free (raw vegetables, water, 100% juice);
  - Does not contain an ingredient that is a gluten-containing grain such as wheat, rye, barley;
  - Does not contain an ingredient derived from a gluten-containing grain that has not been processed to remove gluten;
  - May contain an ingredient derived from a gluten-containing grain that has been processed to remove gluten (wheat starch) as long as the food does not contain more than 20 ppm gluten;
  - The food product contains less than 20 ppm gluten.
- Applies to foods that are regulated by the FDA:
  - Does not cover pet food, cosmetics, drugs, foods regulated by the USDA and beverages regulated by Alcohol Tobacco Tax and Trade Bureau.

Manufactures are not required to test either the ingredients or the end product.

Toiletries, such as shampoos, conditioners, and skin care products, are thought not harmful as long as they are not ingested. Patients with open skin lesions that cover a large body surface area, such as with DH, may have reactions on the skin or systemically if gluten gets into an open wound.

In addition to carefully selecting foods that are gluten-free, one must also protect these foods from coming in contact with gluten-containing foods to prevent cross contact. Examples of problematic cross contact would include, taking the bun off the hamburger patty, eating the toppings from a gluten-containing pizza, using the same toaster for both gluten-free and gluten-containing bread products, and French fries made in the same oil as other breaded products such as chicken nuggets.

The education of the person newly diagnosed with celiac disease should consist of a team approach between the patient (or parents), the gastroenterologist, the primary care physician, the dietitian, and local branches of support groups. Medical management primarily consists of monitoring for compliance with the gluten-free diet, confirming mucosal recovery, and screening for the well-known complications to be discussed later. After the gastroenterologist who performed the biopsy confirms the diagnosis, the patient should be immediately referred to a knowledgeable dietitian for medical nutrition therapy [103]. Physicians and dietitians should encourage the patient to join support organizations, which can aid in finding local resources, such as supermarkets, food manufacturers,

literature, and restaurants, that are familiar with the gluten-free diet.

Lifelong compliance with the gluten-free diet is challenging. Numerous barriers face those following a strict gluten-free diet, including availability of gluten-free foods, taste and quality of the safe foods, and the high cost of specialty gluten-free items. These products can be 3–5 times more expensive than their gluten-containing counterparts. The most important factors in achieving compliance are patient education, close supervision by an interested physician, and regular nutritional counseling by a registered dietitian with expertise in this area [103]. Compliance can be improved even in adolescents if they are seen by a physician on a regular basis [104,105]. One of the best and least expensive markers for dietary compliance is assessment by a trained interviewer (either a physician or a dietitian) because of the low cost and noninvasive nature of dietary assessment. There is a strong correlation between self-reported intake of foods containing gluten and intestinal damage [105].

V MANAGEMENT OF THE COMPLICATIONS OF CELIAC DISEASE

Patients with undiagnosed and untreated celiac disease as well as those with nonresponsive or refractory celiac disease have increased morbidity and mortality due to associated conditions, including osteoporosis, nutritional deficiencies, extraintestinal manifestations, other autoimmune diseases, and cancer. These patients also incur increased health care costs because of being chronically ill, the need to see multiple subspecialists, and the tests performed on them until the correct diagnosis is obtained [106]. Corrao and other investigators of the Club del Tenue Study Group formed a prospective cohort study that included 1072 adults with diagnosed celiac disease and 3384 first-degree relatives. These individuals were followed for 32 years. The number of deaths between the two groups was compared and expressed as the standardized mortality ratio (SMR) and relative survival ratio. Two times the number of persons with celiac disease died compared to the relatives (SMR, 2.0; 95% confidence interval, 1.5–2.7). The greatest excess of deaths occurred during the first 3 years after diagnosis. These results suggest that prompt and strict dietary treatment may decrease premature mortality among persons with celiac disease [107].

The primary reason for the increased mortality is the association with gastrointestinal malignancies, primarily intestinal lymphoma, which has been reported in up to 10–15% of adult patients who have been noncompliant with the diet [108]. The odds ratio overall for non-Hodgkin's lymphoma associated with celiac disease compared to first-degree relatives was reported to be 3.1, with odds ratios of 16.9 for gut lymphoma and 19.2 for T cell lymphoma, respectively [109]. The good news is that the reported risk for lymphoma decreases to that of the general population on the gluten-free diet [110].

A Nonresponsive and Refractory Celiac Disease

The majority of individuals with celiac disease will have a substantial improvement within the first weeks or months of being on a gluten-free diet; however, 7–30% of celiac disease patients may continue to have symptoms and intestinal damage despite being on a gluten-free diet [111,112]. Nonresponsive or refractory celiac disease is defined as persistent or recurrent signs or symptoms and/or persistent villous atrophy, despite maintenance of a strict gluten-free diet for 1 year. This may be a primary nonresponse to a gluten-free diet meaning someone who initially fails to respond to a gluten-free diet or a secondary loss of response or a relapse in symptoms after an initial improvement. The most common cause of persistent symptoms in patients with celiac disease is largely caused by inadvertent gluten exposure accounting for up to 50% of the nonresponsive celiac disease [113,114]. Patients with celiac disease may be unintentionally exposed to up to 2 g of gluten per day. Therefore, given the challenges of a gluten-free diet, a thorough dietary history should first be taken to exclude inadvertent (or intentional) ingestion of gluten. In any celiac patient with persistent symptoms, one should refer to the gastroenterologist for a repeat intestinal biopsy [115]. The gastroenterologist will also consider other common causes of associated symptoms such as IBS, other food intolerances like lactose or fructose, small-intestinal bacterial overgrowth in addition to nonresponsive or refractory celiac disease. Additional reasons for nonresponsiveness to the gluten-free diet include pancreatic insufficiency and T cell lymphoma, both of which may be associated with celiac disease [116,117].

1 Nonresponsive Celiac Disease

Patients with nonresponsive celiac disease may present at any age and typically have gastrointestinal or extraintestinal manifestations or they may be clinically asymptomatic and still have persistent intestinal damage. Patients with persistent enteropathy despite maintaining a gluten-free diet may respond to a gluten-free diet free from processed foods called the gluten contamination elimination diet [118]. The goal of this diet, followed for 3–6 months with the guidance of a dietitian is to eliminate exposure to any possible source of gluten cross contamination from packaged or processed foods, including those labeled

gluten-free. A retrospective study which evaluated 17 patients with nonresponsive celiac disease found that after approximately 4.3 months on this diet 81% of patients had resolution of symptoms, 82% had a serological or histological improvement, and 79% were able to successfully return to a traditional gluten-free diet [118]. Patients with persistent enteropathy which does not improve after 3–6 months on the gluten contamination elimination diet (as measured during repeat endoscopy) are diagnosed with refractory celiac disease.

2 Refractory Celiac Disease

Persistent villous atrophy, despite maintenance of a strict gluten free diet for 1 year after possible gluten contamination or other causes of villous atrophy have been excluded, is defined as refractory celiac disease. Refractory celiac disease is further divided into type one in which the IELs carry a normal phenotype, and type two in which there is an abnormal clonal expansion of IELs that lack surface CD3, CD8, and T cell receptors [119]. Patients with type 1 refractory celiac disease may present at any age with symptoms such as diarrhea, abdominal pain, fatigue, and others. These patients do not respond to the gluten contamination elimination diet and instead frequently require immunosuppressing medications, such as steroids including budesonide, azathioprine, and cyclosporine [111,120–124], in addition to a gluten-free diet. Despite the need for medication in addition to a gluten-free diet, patients have a 5-year survival of nearly 100% [125].

Patients with refractory celiac disease type two have a severe presentation compared to those with type one. Typically, patients present after the age of 50 years with severe diarrhea and weight loss that often requires hospitalization and support with parenteral nutrition [126]. Patients with refractory celiac disease type two are likely to be homozygous for DQ2 and often present in the fifth decade with severe protein-losing enteropathy that is unresponsive to medical management [127]. Patients with refractory celiac disease type two have a 5-year survival of 44–58% as up to half may go on to develop enteropathy-associated T cell lymphoma [119,128]. Patients respond poorly to available treatment options such as Remicade, cladiribine, and other immunosuppressant agents [129,130].

B Long-Term Monitoring

All patients with celiac disease are at risk for nutritional deficiencies. Children should be examined for protein-calorie malnutrition, linear growth failure, and delayed puberty. All patients should be screened at diagnosis for the nutritional deficiencies that can accompany this malabsorptive disorder, such as iron deficiency anemia, B_{12} deficiency, and 25-hydroxy-D. Patients should also be monitored yearly once stable on a gluten-free diet by a knowledgeable gastroenterologist for common extraintestinal complications, including osteoporosis, neurologic complaints, and the development of other autoimmune diseases, especially of the thyroid and liver [131,132]. Bone density should be measured in the newly diagnosed celiac patient because numerous studies have documented low bone density in both children and adults at the time of initial diagnosis of celiac disease. Osteopenia can improve with the gluten-free diet, and progression of osteoporosis can be halted with strict adherence to the diet and, when necessary, appropriate supplementation [133–136]. Osteopenic patients should be evaluated for deficient intake and absorption of vitamin D and calcium and the development of secondary hyperparathyroidism [137].

1 Type 1 Diabetes and Celiac Disease

Special considerations need to be given to patients who have both celiac disease and type 1 diabetes because many of the well-known complications of type 1 diabetes can be exacerbated by nutritional deficiencies. Nocturnal hypoglycemia with seizures and recurrent, unexplained hypoglycemia with a reduction in insulin requirements should prompt the physician to investigate for celiac disease [138,139]. In the young child, growth failure and delayed sexual maturation may be seen. Vitamin A deficiency may aggravate retinopathy; deficiencies of vitamins E and B_{12} may cause peripheral neuropathy; iron and folic acid deficiencies may lead to complications of fertility and pregnancy; and vitamin D can complicate dental disease, limit joint mobility, and cause osteopenia and osteoporosis. There is also an increased incidence of other autoimmune diseases in type 1 diabetics who have celiac disease [140,141]. The gluten-free diet presents additional challenges to the diabetic patient, who may see acute hyperglycemia and a steady rise in hemoglobin A1c on initiation of this diet. This can be due to intestinal healing and better absorption, as well as gluten-free food substitutes, which can be corn-, rice-, or potato-based and have a higher glycemic index.

Once the patient has undergone initial counseling, the gastroenterologist and dietitian should follow up with the patient in 3 months and again at 6 months to discuss compliance with the diet and reinforce its importance. The gastroenterologist should repeat the screening laboratory study (IgA tTG) at 6 months and again 12 months after the initial diagnosis of celiac disease. After 1 year on a gluten-free diet, a repeat endoscopy with biopsy to assess for mucosal recovery should be considered in patients with celiac disease. Once mucosal recovery is confirmed in patients with celiac disease they should be followed

annually by a gastroenterologist. At the annual visit, a detailed dietary history should be elicited, and serum antibodies can be measured. First-degree relatives should be offered serologic screening. The gastroenterologist will perform a detailed history and physical aimed at screening for nutritional deficiencies and searching for signs and symptoms of other autoimmune disorders, gastrointestinal cancers, and refractory sprue. If the patient is doing well without clinical symptoms and has normal antibody titers, he or she should continue to be followed annually. If the patient is doing poorly, indicated by symptoms, nutritional deficiencies, or elevated antibodies, they should again be evaluated by the gastroenterologist with consultation with a knowledgeable dietitian [103]. This patient will also require closer monitoring for the development of the aforementioned nutritional, autoimmune, and possibly malignant complications.

The reader is invited to review separate chapters in this book about additional nutritional considerations in colon cancer, type 1 diabetes, gastroesophageal reflux disease, diarrhea, constipation, lactose intolerance, liver disease, food allergy, osteomalacia, and osteoporosis, all of which can complicate celiac disease.

VI SUMMARY

The astute clinician must have a high index of suspicion to make the diagnosis of celiac disease. Although this condition is very common, it is under diagnosed because of its protean manifestations. The diagnosis of this disease is further complicated by its presentation at any age with a variety of symptoms ranging from joint pain to infertility and anemia. Serum antibodies are an excellent screening tool for this disease. However, confirmation requires a small bowel biopsy performed by a gastroenterologist via an upper endoscopy. Celiac disease is the only autoimmune disease for which we know the trigger: gluten. Removal of gluten from the diet results in complete histological and symptomatic recovery in the majority of patients. Not uncommon complications of celiac disease can include vitamin and mineral deficiencies, the development of other autoimmune diseases, and a higher risk for osteoporosis and gastrointestinal cancers. We now recognize that up to 15% of pediatric patients and nearly 2/3 of adult patients with celiac disease may have persistent autoimmune enteropathy even after 2 years on a gluten-free diet [142,143]. Living gluten-free is challenging socially and the potential for contamination of foods by wheat, rye, and barley is high. The patient benefits best from the involvement of a physician, a dietitian, and a support group who are up-to-date about the diet as well as the latest literature and advances in the understanding of the complex interactions between gluten and the immune system.

Chapter 42

Nutrition and Cystic Fibrosis

Zhumin Zhang, Lyanne H. Chin and HuiChuan J. Lai
University of Wisconsin, Madison, WI, United States

I OVERVIEW OF CYSTIC FIBROSIS

Cystic fibrosis (CF) is one of the most common, life-shortening autosomal recessive disorders with estimated incidences of approximately 1 in 3000 White live births, 1 in 17,000 Black live births, and 1 in 90,000 Oriental live births [1,2]. CF was recognized as a distinct clinical entity in 1938. It is a generalized disease of the exocrine glands characterized by abnormal sodium and chloride transport, leading to elevated electrolyte levels in sweat [3,4]. Dysfunction of the other exocrine glands occurs producing viscid secretions of low water content. This results in pancreatic insufficiency (PI), which results in malabsorption and failure to gain weight, as well as airway obstruction, which leads to increased susceptibility to recurrent bronchial infection, progressive lung damage, and eventual respiratory failure.

A Clinical Presentation

There are three categories of major clinical abnormalities in CF: (1) gastrointestinal tract involvement, characterized by PI leading to malabsorption and malnutrition; (2) respiratory tract involvement, characterized by recurrent infections and chronic obstructive pulmonary disease; and (3) salt loss in sweat that can lead to severe hyponatremic dehydration. The pancreatic disturbance begins prenatally and can cause intestinal obstruction in newborns with CF, a problem referred to as meconium ileus (MI). It has been estimated that 15−20% of CF patients have MI [5], 85−90% are pancreatic insufficient (PI), and 10−15% are pancreatic sufficient (PS) [6].

More recent studies have shown that PI develops during the first year of life such that about half the patients destined to have this problem show intestinal malabsorption by about 1 month of age, two-thirds by 6 months, and the remainder by 1 year [7]. Unlike PI, pulmonary status of patients with CF often appears normal at birth [8]; however, it inevitably shows obstruction and infection. The onset and rate of progression of CF lung disease are not well understood but appear to vary widely among individuals [8−11]. Other complications may occur as the disease progresses. For example, glucose intolerance and diabetes mellitus may develop [12,13]. The prevalence of CF-related diabetes (CFRD) is reported to be between 5% and 15% in children 6−17 years old and up to 35% in adults with CF [14−18]. Up to 11% of CF patients develop overt liver disease because of focal biliary cirrhosis [14]. Due to an absent vas deferens at birth (presumably resulting from ductal obstruction with dehydrated secretions), infertility in males with CF is virtually universal [19]. About 16% of patients reported in 2013 CF Foundation (CFF) Patient Registry had bone disease [14].

B Pathogenesis

On the basis of molecular genetics research [20], CF fundamentally can be attributed to mutations occurring in the long arm of chromosome 7. With cloning of the CF gene, it has been demonstrated that the most common mutation is a 3 base pair (bp) deletion, this results in the loss of a phenylalanine residue at amino acid position 508 of the predicted gene product, namely the cystic fibrosis transmembrane conductance regulator (CFTR) [21−23]. The 3 bp deletion mutant, commonly referred to as F508del, occurs in about 70% of the CF chromosomes [21] and more than 85% of CF patients in the United States have at least one F508del allele [24]. However, over 2000 other DNA mutations in the CFTR gene have been identified (http://www.genet.sickkids.on.ca/cftr/app) and more are still being found. Most mutations occur infrequently, and few (less than 10%) are common enough to be well characterized (http://www.cftr2.org) [25]. Among these gene

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00042-4

mutations, some are disease-causing, some are sequence variations that do not cause CF, some are associated with single or milder organ system involvement than typically seen in CF, and some have variable or unknown consequences. The severity of CF is determined by both copies of CFTR mutations [26,27], and further influenced by modifier genes [28,29], environment, and socioeconomic status of patients [30–33].

CFTR is a cAMP-regulated anion channel expressed primarily at the apical plasma membrane of secretory epithelia. The abnormal or absent CFTR protein is the underlying pathogenic factor in CF disease process due to its role in regulating ion transport across the apical membrane of epithelial cells, particularly chloride conductance, which is invariably defective in CF [2,4]. This defect leads to abnormally high chloride concentration in the sweat, which constitutes the classical diagnostic test for CF [34]. Since the discovery of CFTR gene in 1989 [20], research has focused on addressing the underlying genetic defect of CF. The potential strategies, including gene therapy targeting genetic mutations and the search for CFTR modulators targeting the defect protein, offer great promises for life-saving treatments for CF patients. In the past several years, landmark clinical trials have shown that correction of CFTR function leads to substantial clinical benefits for patients with CF [35,36]. Moving forward, basic and translational CF research remains essential to develop effective disease-modifying therapies and to make them available to all patients with CF.

C Diagnosis and Treatment

Individuals with suspected CF are identified for diagnostic evaluation after newborn screening (NBS), recognition of a positive family history, and/or following the development of the characteristic signs and symptoms such as steatorrhea or chronic cough. Diagnosis then may be made through various approaches, depending on age and phenotype, but ultimately the sweat chloride test is the key to diagnosis and should be used according to published diagnostic criteria [37].

CF NBS provides an opportunity for presymptomatic detection on a routine basis before irreversible pathology develops [8]. After benefits, particularly nutritional advantages [38–42], were demonstrated that outweigh the risks, the CDC recommended universal screening for CF [43]. Now, almost all the babies born in the United States and over 8 million newborns are screened annually for CF worldwide. The use of NBS for CF is based on initial detection of elevated immunoreactive trypsinogen (IRT) levels [44,45]. The discovery of the CFTR gene in 1989 [20] has promoted the development of new screening methods where the IRT test is coupled with a multipanel CFTR mutation analysis [46,47]. The standard NBS protocols begin with a first-tier phenotypic test that measures IRT in dried blood spots. Infants who have an elevated IRT are then referred for further testing, either a repeat IRT test at 2 weeks of age or DNA analysis for CFTR mutations. Infants with a second positive screening result are referred to sweat testing to establish the diagnosis of CF. It is important to understand that a positive IRT test alone is not equivalent to a diagnosis of CF. In fact, only about 1% of newborns with positive IRT have CF. In addition, not all CF cases are detected by screening for IRT; approximately 5% of CF patients show false-negative IRT in their dry-blood specimens obtained at birth [48]. There are various NBS protocols being implemented across the world. Variations in the effectiveness of individual programs warrant further quality improvement [49,50].

Without therapy, CF is usually fatal within the first decade of life. Current treatment is multifaceted and requires close monitoring by an expert multidisciplinary care team. This care should include regular evaluation, counseling, and intervention by expert physicians, nurses, dietitians, respiratory and/or physical therapists, and social workers. Genetic counselors, psychologists, and exercise physiologists are also important resources. Clinical management of CF involves treatment programs with three principal objectives: (1) improve nutritional status, (2) promote clearance of respiratory secretions, and (3) control bronchopulmonary infections. Care programs for CF patients in North America and many European countries are organized in specialized regional centers. These centers have placed particular emphasis on enhancing nutrition and using aggressive strategies to prevent progressive pulmonary disease [51]. Although there is currently no cure for CF, treatment programs have been generally effective, as evidenced by the increasing longevity of CF patients in the United States from less than 20 years to 40.6 years over the past three decades [14,52]. The primary causes of death in patients with CF are cardiorespiratory complications, accounting for about 80% of deaths. For this reason, most CF centers in the United States place a great deal of emphasis on respiratory management for patients with CF. In addition, with diagnosis through NBS, an increased emphasis has been placed on preventing malnutrition in the recent decade.

In the new era of nationwide CF NBS, many CFTR-associated abnormalities, in addition to the classic CF, have been identified, for example, CFTR-related disease, CFTR-related metabolic syndrome, CF screen positive, inconclusive diagnosis, and delayed CF [53]. With limited data on long-term outcomes, optimal clinical management for these patients is unclear. Clinical management has been inconsistent and difficult, despite published recommendations and guidelines [54–57], which are largely consensus-based and not evidence-based.

D Consequences of Malnutrition

Evidence has accumulated in recent years from longitudinal studies that the consequences of malnutrition in CF are more severe than previously appreciated from clinic-based cross-sectional observations. Long-term adverse consequences of malnutrition include: (1) permanently stunted growth [38–40]; (2) cognitive dysfunction [58,59]; and (3) greater susceptibility to lung disease [60–63]. More research is underway to address whether early nutritional intervention could alter long-term pulmonary disease progression.

II MALNUTRITION IN CF

CF is associated with an increased risk of protein-calorie malnutrition, as well as deficiencies in fat-soluble vitamins and other micronutrients. Malnutrition associated with CF is characterized by its early onset, and is often present at the time of CF diagnosis. At the mild end of the malnutrition spectrum, CF patients may have depleted stores or low circulating concentrations of a given nutrient, but no associated signs or symptoms. More pronounced nutritional deficiencies lead to metabolic abnormalities, structural changes, functional disturbances, growth failure, developmental delay, and a variety of other characteristics of malnutrition. Malnutrition is most likely to occur during periods of rapid growth when nutritional requirements are high, during pulmonary exacerbations, and with increased severity of lung disease.

Growth impairment, abnormalities in the biochemical markers of nutritional status, and clinical symptoms of malnutrition all have been reported in patients with CF. Historically, malnutrition in patients with CF was thought to represent either an inherent consequence of the disease process or a physiologic adaptation to advanced pulmonary disease. However, it is now recognized that there are multiple causes of malnutrition in CF and they can be attributed to three primary mechanisms [64–66]: increased energy and nutrient losses, increased energy expenditure, and decreased energy and nutrient intakes. Table 42.1 lists the major risk factors for malnutrition associated with CF.

TABLE 42.1 Factors Contributing to Malnutrition in CF

Disease Factors:
- Presence of PI
- Severity of PI (the degree of steatorrhea and azotorrhea)
- Partial intestinal resection secondary to bowel obstruction (caused by MI)
- Severity of respiratory disease
- Loss of bile salts associated with steatorrhea
- Cholestatic liver disease
- Diabetes mellitus

Nutritional Factors:
- Growth rate (of particular concern in young children and adolescents with CF)
- Energy and macronutrient intakes (e.g., the quantity and quality of food consumed)
- Micronutrient deficiencies (e.g., fat-soluble vitamins)
- Energy expenditure
- Eating behaviors

A Causes of Malnutrition

1 Increased Losses

Loss of nutrients from maldigestion and malabsorption as a result of PI is the primary factor contributing to energy and nutrient deficiencies in patients with CF [67]. The ductular cells of the pancreas respond to stimulation with secretin by producing a high-volume, bicarbonate-rich secretion. This secretion functions to neutralize gastric acid, thus enabling the pancreatic digestive enzymes to function at their optimum pH. The abnormal chloride transport caused by the defected CFTR protein leads to thickened secretions that obstruct the pancreatic ducts and prevent the secretion of enzymes and bicarbonate. In CF, PI is defined by the presence of measurable steatorrhea. This does not occur until 1–2% of pancreatic enzymatic capacity remains [68]. Therefore, CF patients with PI have severe, irreversible loss of pancreatic function. It is also important to understand that CF patients with pancreatic sufficiency (PS) do not have normal pancreatic function [69]. They have decreased volume of bicarbonate-rich secretion but continue to produce enough pancreatic enzymes to avoid steatorrhea.

Maldigestion and malabsorption caused by PI can be attributed to three major abnormalities: lack of digestive enzymes, inadequate bicarbonate secretion, and loss of bile salts and bile acids. Inadequate bicarbonate secretion results in impaired capacity to neutralize gastric acid in the duodenum, and a lower intestinal pH until well into the jejunum, which often reduces the effectiveness of pancreatic enzyme replacement therapy (PERT) [67–69] (see Section IV.A.2, Pancreatic Enzyme Replacement Therapy). Loss of bile salts and bile acids often exacerbate maldigestion and malabsorption. Bile acids are readily precipitated in an acidic milieu, and duodenal bile acid concentration may fall below the critical micellar concentration, thereby exacerbating fat maldigestion. Precipitated bile salts also appear to be lost from the enterohepatic circulation in greater quantities, thus reducing the total bile acid pool and altering the glycocholate: taurocholate ratio. Oral taurine supplements have been reported to benefit some CF patients [70].

Other factors also contribute to energy and nutrient losses in CF. Patients presenting with MI, in particular

those who have undergone intestinal resection, have further reduction in intestinal absorptive capabilities. Viscid, thick intestinal mucus, with altered physical properties, may affect the thickness of the intestinal unstirred layer, further limiting nutrient absorption. CFRD may increase caloric losses due to glycosuria if not adequately controlled. Advanced liver disease and biliary cirrhosis may result in reduced bile salt synthesis and secretion, which may lead to severe fat malabsorption.

2 Increased Requirement

Energy requirements in patients with CF are highly variable. Several studies have reported that patients with CF have an associated increased energy expenditure compared with non-CF patients [71–74]. A variety of explanations have been proposed to explain the increased energy expenditure observed in CF patients. These include chronic respiratory infection, increase in work of breathing, genetic and cellular defects, and changes in body composition.

Chronic respiratory infections, particularly with *Pseudomonas aeruginosa*, have been shown to be associated with 25–80% increase in metabolic rate and energy requirements [75]. The link between CF genotype and energy requirement was reported in a study by Tomezsco et al., who demonstrated that energy expenditure was increased by 23% in CF patients with homozygous F508del mutations as compared with non-CF controls [74]. Therefore, a patient with advanced lung disease might not be able to ingest sufficient calories to meet energy needs.

The hypothesis that a basic cellular defect may increase energy requirement was supported by in vitro studies showing that mitochondria from cultured fibroblasts obtained from CF patients had higher rates of oxygen consumption compared with control tissues [76,77]. When F508del was identified, it was proposed that the defective CFTR protein may affect cellular energy metabolism through its involvement in the regulation of ion transport across membranes since CFTR is a cAMP-regulated chloride channel [4].

3 Decreased Consumption

The appetite or caloric intake of CF patients may be limited due to a variety of disease complications. Acute pulmonary exacerbations are a common cause of anorexia, and respiratory infections often give rise to nausea and vomiting, which may further reduce caloric intake [63]. The biochemical causes of anorexia associated with acute infection are unclear, but elevated circulating levels of tumor necrosis factor may play a role [78].

In addition to pulmonary complications, a variety of gastrointestinal complications also contribute to anorexia and inadequate caloric intake [64]. Increased occurrence of gastroesophageal reflux disease (GERD) and esophagitis are observed in patients with CF. Distal intestinal obstruction syndrome (DIOS), a form of subacute or chronic partial bowel obstruction, usually occurs in older patients with PI. Large fecal masses palpable in the abdomen give rise to intermittent abdominal distention and cramping accompanied with reduced appetite. Constipation in the absence of DIOS is another cause of anorexia and abdominal discomfort in older patients with CF.

A number of dietary surveys indicate that CF patients often eat less than normal, particular during the period of 1970s and early 1980s, when CF patients were commonly prescribed with fat-restricted diets on the assumption that a reduction in dietary fat intake might improve bowel symptoms [79]. The observation of better growth and survival in CF patients who received unrestricted-fat, high-calorie diet in combination with PERT compared with those who received low-fat diet in the early 1980s has changed dietary practices in most CF centers [80,81]. Energy intakes of 110% or greater than the estimated energy requirement (EER) with 35–40% of energy from fat are now recommended for patients with CF [82,83]. However, CF patients often fail to consume such high quantities of calories and/or fat because of their disease manifestation. In several cross-sectional or short-term studies [84–88] and a small prospective 3-year study of 25 patients [89], energy and fat intakes of CF patients were reported to be much lower than these recommendations. A longitudinal study evaluating dietary intake patterns in children with CF from the time of diagnosis to age 10 years revealed mean energy intake was at ~110% of EER with fat consisting of ~37% of energy [39].

B Common Nutritional Deficiencies

1 Energy and Macronutrients

As discussed earlier, patients with CF are at high risk of energy deficiency due to their increased requirement and decreased consumption. Protein poses less of a nutritional problem than fat in the CF population. The major risk of protein deficiency in CF patients occurs during the first year of life, when the average requirement is at least three times as great as that in adulthood. Low serum markers of protein (e.g., albumin, prealbumin, and retinol binding protein) are commonly found in infants and young children with newly diagnosed CF. One-third to one-half of infants diagnosed through CF NBS were reported to be hypoalbuminemic [90–92]. Normalization of serum albumin level often occurs following comprehensive nutrition therapy [93].

The consequence of energy deficiency leads to impaired growth in children with CF. Weight retardation and linear growth failure are the most common observations documented in CF clinics [94,95], although its severity and prevalence vary greatly. Accurate estimates on the prevalence of malnutrition in the CF population

have been difficult to obtain in the past, due to lack of sufficient data. In recent years, comprehensive national databases, known as CF Patient Registries, have been compiled by the U.S. and Canadian CFFs, as well as the European CF Society, making it possible to determine population estimates on the prevalence of malnutrition associated with CF. Analysis on 13,000 pediatric CF patients documented in the 1993 U.S. CF Patient Registry revealed that the growth of CF children at all ages were mostly below normal [96]. Malnutrition was particularly prevalent in infants (47%) and adolescents (34%) as compared with children at other ages (22%), and in patients with newly diagnosed, untreated CF (44%). Underweight is also prevalent in adults with CF; approximately 35% of the 7200 adults with CF documented in the 1992–94 U.S. and Canadian CF Patient Registries were found to be underweight [97]. During the past decade, the prevalence of malnutrition has decreased steadily from ~25% in 1995 to ~15% in 2005 in pediatric CF patients [98].

2 Essential Fatty Acids

Essential fatty acid deficiency (EFAD) has been known to occur in CF patients [90,97,99,100]. During infancy, particularly before diagnosis, EFAD can occur with desquamating skin lesions, increased susceptibility to infection, poor wound healing, thrombocytopenia, and growth retardation. In patients who are adequately treated, clinical evidence of EFAD is rare, although biochemical abnormalities of essential fatty acid (EFA) status remain common [101–103]. Abnormal unsaturated fatty acids are more common in patients with PI than those with PS [104]. The major fatty acid abnormalities found in patients with CF are low levels of linoleic (18:2, *n*-6) and docosahexaenoic acids (22:6, *n*-3); alterations in arachidonic acid (20:4, *n*-6) level; and elevated levels of palmitoleic (16:1, *n*-7), oleic (18:1, *n*-9), and eicosatrienoic (20:3, *n*-9) acids. In EFAD, oleic acid is converted to eicosatrienoic acid, which is commonly referred to as the "pathologic triene" because its increase in EFAD, coupled with a decrease in arachidonic acid, leads to a high triene/tetraene ratio [93,105,106]. Multiple hypotheses have been proposed to explain the underlying mechanisms of abnormal EFA status associated with CF. Fat malabsorption secondary to PI is the most common explanation for EFA abnormalities. However, some investigators have postulated a primary metabolic defect in fatty acid metabolism [101–108].

Many studies have reported a clear association between better EFA status and better growth in children with CF. Plasma linoleic acid was shown to be correlated positively with growth in children whose CF was diagnosed before 3 months and followed up to 12 years of age [90]. Another study by van Egmond et al. showed better growth among CF infants who consumed a predigested formula that contained high linoleic acid (12% of energy) compared with those who consumed a comparable formula with lower linoleic acid (7% of energy), despite a lower total energy intake in the former group [109]. More recently, Shoff et al. demonstrated that, in children who experienced longer and more severe malnutrition due to delayed diagnosis, maintaining normal plasma linoleic acid (i.e., > 26% of total plasma fatty acids) in addition to sustaining a high-caloric intake (i.e., >120% of EER) is a critical determinant in promoting catch-up weight gain [110].

Despite the above evidence, EFA supplementation for CF patients remains controversial for several reasons. Firstly, not all patients respond to EFA supplementation; normalizing plasma linoleic acid is particularly difficult in patients with MI [66,74]. Secondly, *n*-6 fatty acids, including linoleic acid and its metabolite arachidonic acid, have been proposed to play a role in CF inflammation [111–115]. In the 2009 CFF infant care guidelines [116], clinical trials to "answer questions related to EFA supplementation in infants" are recommended as a priority of research to resolve this long, overdue controversy. Since then, a pilot study examining the effects of *n*-3 supplementation in children and adults showed that EPA and DHA supplementation for 3 months exhibited slow yet important clinical benefits regarding exacerbations and use of antibiotics. However, larger studies are required to ascertain the conclusions [117]. A recent review summarizing findings from four small studies also demonstrated insufficient evidence of the benefits of *n*-3 fatty acids supplementation [118].

3 Fat-Soluble Vitamins

Deficiencies of fat-soluble vitamins in the CF population have been demonstrated in many studies [89,91,114,115,119–126]. Vitamins A and E are of the greatest concern, particularly in patients with severe malabsorption or liver disease. However, recent studies show that deficiencies in vitamin D or vitamin K are also common, especially in CF patients with advanced cholestatic liver disease. Abnormalities in fat-soluble vitamins are particularly prevalent in newly diagnosed infants with CF. Studies on infants diagnosed through NBS showed that 20–40% had low serum retinol, 35% had low serum 25-hydoxyvitamin D, and 40–70% had low serum α-tocopherol [90,91,119].

Vitamin A deficiency was the first micronutrient deficit demonstrated in patients with CF. Clinical symptoms of vitamin A deficiency reported in CF patients include keratinizing metaplasia of the bronchial epithelium, xerophthalmia, and night blindness. Pancreatic lipase is required to digest retinyl esters prior to absorption. Other mechanisms for vitamin A deficiency in CF has been proposed, ranging from a defect in the mobilizing hepatic storage of vitamin A due to liver disease to low levels of retinol binding protein, which is responsible for transporting vitamin A in the

circulation [119,120]. More recently, elevated vitamin A intake and serum retinol have been of growing concern, especially among preadolescents and young adults. Excessive vitamin A intake may increase risks of bone complications. Although supplementation can prevent vitamin A deficiency in CF, caution should be exercised to ensure adequacy and avoid toxicity [121,122].

Vitamin E deficiency in CF is most commonly evidenced by low plasma levels of α-tocopherol and has been associated with hemolytic anemia [123]. Low α-tocopherol levels are prevalent in infants with CF identified with NBS programs [90,119]. Those with early, prolonged severe deficiency may also show cognitive dysfunction [58].

Recent evidence has also suggested vitamin D deficiency is prevalent in both children and adults with CF [125–127]. Suboptimal vitamin D status has been directly linked to poor bone mineralization in CF patients, although the cause of CF bone disease is multifactorial and not completely understood [125]. In the recent years, CFF developed evidence-based, age-specific, and stepwise approach recommendations for achieving and maintaining optimal vitamin D status [128].

Vitamin K deficiency has not been routinely demonstrated in patients with CF. However, vitamin K deficiency is likely to develop in CF patients with severe cholestatic liver disease, short-bowel syndrome, and lung disease requiring frequent antibiotic use [129–131]. Low levels of vitamin K are also seen in patients with CF not taking appropriate vitamin supplementation. Vitamin K status can be evaluated by prothrombin time or the more sensitive protein induced by vitamin K absence (PIVKA) measurement.

4 Minerals and Electrolytes

For patients with CF, sodium is of great concern because of its abnormally high content in the sweat. Therefore, sodium requirement may be considerably higher for CF patients than normal individuals. Salt depletion can be catastrophic, leading to severe hyponatremic dehydration and shock [132,133]. In addition, there has been concern that marginal or low body sodium may limit the growth of children with CF [134]. Young infants with CF are particularly at risk for hyponatremia, hypochloremic dehydration with metabolic alkalosis, irritability, and lethargy. Therefore, electrolyte status should be evaluated if there is any suspicion of electrolyte depletion, such as exposure to high environmental temperatures, over-bundling or excessive sweating. Serum sodium levels do not accurately reflect total body sodium; urinary sodium in relation to creatinine is a better indicator of sodium status in infants. Because of increased risk of hyponatremia, infants with CF should receive salt supplementation. Current guidelines recommend a daily dose of one-eighth teaspoon of table salt, which contains 12.5 mEq of sodium, for infants younger than 6 months; for infants age 6–12 months, a quarter teaspoon per day, but not to exceed 4 mEq/kg/day, was recommended [116]. In older children and adults with CF, although routine sodium supplements may not be necessary because the average American diet contains an overabundance of sodium, sodium supplements are definitely needed in conditions that may cause prolonged sweat loss.

Low calcium intake and suboptimal bone density accrual are of concerns even in the general pediatric population [135]. Children with CF have a higher risk of bone diseases because of poor growth and delayed puberty, malabsorption of nutrients needed for bone health (e.g., calcium, vitamins D and K), reduced physical activity, pulmonary inflammation with increased cytokines, and medication such as glucocorticoid therapy [125]. The relative contribution of these factors to development of bone disease in patients with CF remains to be elucidated. Little data are available regarding calcium supplementation in improving bone health in the CF population. A recent double-blind, cross-over, randomized trial with 15 CF children aged 7–13 years showed that supplementation with calcium (1000 mg), vitamin D_3 (2000 IU) or both for 6 months did not change serum calcium and 25-hydroxy-vitamin D concentrations and bone mineral gain, compared to the placebo (400 IU of vitamin D_3) group [136].

Stable isotope studies have reported increased fecal zinc losses and decreased zinc absorption in infants and children with CF [137,138]. Zinc deficiency affects growth and vitamin A status but is difficult to identify because serum zinc is not an adequate measure for zinc status. Therefore, current CFF guidelines recommend a trial of zinc supplementation, 1 mg/kg/day elemental zinc for 6 months, to CF children experiencing poor growth despite adequate caloric intake and pancreatic enzyme supplementation [82,116].

Anemia in CF has been reported with varying prevalence as high as 33%, with iron deficiency proposed to be the main cause [139]. Chronic lung inflammation may also alter iron metabolism. CF patients with advanced pulmonary disease have been shown to have low serum ferritin levels [139,140]. In the general pediatric population, the importance of diagnosis and prevention of iron deficiency has been emphasized recently, stemming from new evidence showing the adverse, long-term and irreversible effect on neurodevelopment and behavior caused by iron deficiency [141]. In children with CF, chronic lung inflammation poses additional risk for iron deficiency and anemia. In patients with CF, serum transferrin receptor is a more sensitive indicator of iron status than serum ferritin, because the latter is an acute phase reactant to inflammation, which may be artificially elevated with the presence of lung disease.

III NUTRITION ASSESSMENT

Frequent monitoring of the nutritional status for patients with CF is essential to ensure early detection of any deterioration and prompt initiation of nutrition intervention. Patients with CF are most vulnerable to experience malnutrition due to delayed diagnosis, during times of rapid growth (e.g., infancy and adolescence), and during pulmonary exacerbations. During these periods, close monitoring and intervention are critical to prevent nutritional decline. It should be emphasized that with comprehensive nutrition assessment and intervention, children with CF who are diagnosed early through NBS can achieve normal growth throughout childhood [38,39], and adults with CF can maintain normal weight status. In addition, optimizing growth and nutritional status is critical for CF patients, because malnutrition worsens lung disease, affects the quality of life, and reduces survival [94,142].

Assessment of nutritional status for patients with CF must include anthropometric, biochemical, clinical, and dietary assessments. The frequency at which the different indices of nutritional status monitoring should be measured is given in Table 42.2.

A Anthropometric Assessment

Anthropometric assessment, with an emphasis on physical growth in children and body weight in adults, is an important component of nutritional assessment in patients with CF. For children with CF, accurate and sequential measurements of head circumference (age 0−3 years), recumbent length (age 0−2 years), height (age 2−20 years), and weight (age 0−20 years) should be obtained at each clinic visit using standardized techniques. For adults with CF, body weight should be measured at each clinic visit. Other anthropometric assessments, such as skinfold measures (e.g., midarm circumference, triceps skinfold, etc.) provide additional information on body composition, that is, lean body mass and subcutaneous fat stores. However, skinfold measures are prone to measurement errors and reference standards are not available for all ages of children.

Growth measurements should be plotted on appropriate growth charts and converted to sex- and age-specific percentiles. For children with CF younger than 24 months, 2006 World Health Organization growth reference is recommended as a growth standard [143,144] to replace 2000 CDC growth reference, which is recommended for older children at age 24 months or above. Comparisons between the use of the CDC and WHO growth charts in CF revealed significant differences [145]. Concerns and confusions arise when switching growth references, as the transition may create disjunction by changing how a child's growth is assessed if the same cutoff values for malnutrition were applied. The current nutritional goal and malnutrition criteria in children younger than 24 months are set based on CDC growth charts, which need to be revised for the WHO charts.

Nutrition goals for weight and stature in patients with CF are summarized in Table 42.3. Patients with CF should aim at maintaining body mass index (BMI), ≥50th percentile for children age 2 years and older, ≥22 for female adults, and ≥23 for male adults, to support better lung function [82]. For children younger than 24 months, weight-for-length percentile at 50th percentile or above is recommended. However, this cutoff value is set for the CDC growth charts, which needs to be modified for the use of the WHO charts. With regard to linear growth, in addition to determining height-for-age percentile, it is important to evaluate whether the child's height is reaching his/her genetic potential. This can be estimated by using parental heights to calculate a target height range or an adjusted height percentile [82,146,147]. CF children whose heights are below their genetic potential are considered at risk and should be evaluated [82,83]. However, the target height method to estimate genetic potential suggested by CFF has flaws [147], and should be used with caution. In addition to weight, weight-for-stature, and length/height percentiles, weight gain and height velocity are more sensitive indicators of growth, and should be evaluated, especially when growth faltering is observed [82,116,148]. For young children with CF, appropriate weight gain needs to be maintained at or above 50th percentile expected for age.

B Biochemical Assessment

Monitoring biochemical indices of nutritional status is essential in patients with CF [82]. Current guidelines (Table 42.2) recommend routine, annual measurements of serum protein (albumin), vitamin A (retinol), vitamin D (25-hydroxycholecalciferol), vitamin E (α-tocopherol), and iron (hemoglobin, hematocrit).

Assessment of EFA status is not routinely performed but only as indicated. However, recent findings on the relationships between abnormal EFA status and growth in children with CF [90,91,110], particularly those with MI, warrant the consideration of routine monitoring of EFA status, at least annually, in patients with CF. Similarly, routine measurements of vitamin K, calcium, zinc, and sodium are not regarded as necessary in current guidelines [82,116], but may be needed in individual patients.

C Clinical Assessment

Clinical assessment of nutritional status in children with CF focuses on evaluation of the severity of maldigestion and malabsorption caused by PI. A total of 85−90% of

CF patients has PI. Pancreatic functional status not only has a direct influence on nutritional status but also is a strong predictor of long-term outcome [69,149]. Data from the 1990–95 U.S. CF Patient Registry demonstrated that patients with PS have an approximately 20-year longer lifespan than PI patients [69].

The clinical signs and symptoms of PI include abdominal discomfort (bloating, flatus, pain), steatorrhea (frequent, malodorous, greasy stools), and the presence of MI or DIOS. Objective tests for PI include: (1) duodenal measurement of pancreatic enzymes and bicarbonate; (2) 72-hour fecal fat balance study; and (3) fecal elastase-1 in spot stool samples. Among these, 72-hour fecal fat balance study has been the gold standard historically. A high-fat diet is ingested for 72 hours, and stool is collected and analyzed for fat excreted. For the most precise results, oral dye markers are used to indicate the period of high-fat ingestion, and the stool that follows the first marker, up to and including the second marker, represents the stool produced during the period of high-fat intake. In clinical practice, diet is often measured for 3 days and stool collected simultaneously. A coefficient of fat absorption, that is (fat intake − fecal fat loss)/fat intake × 100%, is calculated. In CF, PI is defined by a coefficient of fat absorption less than 93% [82].

Since the 72-hour fecal fat balance study is cumbersome and not well accepted by CF patients and care providers, measurement of fecal elastase-1 in a small stool sample has gained wide acceptance and is becoming the standard method of care in most CF centers [69]. Elastase is one of the 20+ enzymes secreted by the pancreas. It has the physical property of being stable as it transits the intestinal tract, unlike other enzymes that may be degraded by intraluminal proteases. As water is withdrawn from the intestinal contents in the colon, elastase concentrations increase, making it easy to measure in stool. This protein is stable through a wide range of pH and temperature, making it ideal to collect at home. Levels greater than 100–200 μg fecal elastase-1 per gram of stool generally indicate PS [69,150].

It is important to assess pancreatic functional status as soon as CF diagnosis is made. Approximately half of CF patients whose initial tests indicate PS become PI later [4]. Therefore, PS patients should be reevaluated at least annually to determine if they have changed to PI, especially if genotype studies reveal mutations that are generally associated with PI. For patients diagnosed with PI, PERT and vitamin supplementation should be started. It is important to understand that although PI can be treated with PERT, it cannot be completely corrected; many patients continue to have steatorrhea when they receive PERT [151]. In addition, response to PERT varies greatly among individual patients.

D Dietary Assessment

Assessments of energy requirement and dietary intakes are important ways of determining whether the patient is at negative energy balance. Evaluation of dietary intake is best performed by dietitians/nutritionists specializing in the care of patients with CF. For patients with good nutritional status, a 24-hour dietary recall may be used to assess dietary habits and the quality of dietary intake. However, for patients with suboptimal nutritional status, a

TABLE 42.4 Method for Estimating Energy Requirement for CF Patients

Step I: Estimate Basal Metabolic Rate (BMR) by Using the WHO Equations		
	Males	**Females**
0–3 years	60.9 × wt − 54	61.0 × wt − 51
3–10 years	22.7 × wt + 495	22.5 × wt + 499
10–18 years	17.5 × wt + 651	12.2 × wt + 476
18–30 years	15.3 × wt + 679	14.7 × wt + 496
>30 years	11.6 × wt + 879	8.7 × wt + 829
Step II: Estimate Energy Expenditure (EE) Using the Following Equation:		
	EE = BMR × (activity coefficient + disease coefficient)	
	Where activity coefficient = 1.3 (confined to bed)	
	1.5 (sedentary)	
	1.7 (active)	
	disease coefficient = 0 (normal lung function, i.e., $FEV_1 > 80\%$)	
	0.2 (moderate lung disease, i.e., FEV_1 40–79%)	
	0.3 (severe lung disease, i.e., $FEV_1 < 40\%$)	
Step III: Estimate Total Energy Requirement (ER), Taking into Account Pancreatic Functional Status		
	a. For PS patients, that is, coefficient of fat absorption (CFA) ≥ 93% ER = EE	
	b. For PI patients with a CFA < 93% ER = EE × (0.93/CFA)	
	c. For PI patients whose CFA has not been determined, use 0.85 as an approximate for CFA ER = EE × (0.93/0.85)	

Sources: D. Borowitz, R.D. Baker, V. Stallings, Consensus report on nutrition for pediatric patients with cystic fibrosis, J. Pediatr. Gastroenterol. Nutr. 35 (2002) 246–259; World Health Organization, Energy and protein requirements, WHO Tech. Rep. Ser. No. 724 (1985) 924.

three-day prospective food record is the best way to obtain quantitative estimates of energy and nutrient intakes. This assessment can then be used as the basis for initiating appropriate nutrition intervention.

Assessment of energy requirement for patients with CF is best determined by estimating the basal metabolic rate, the degree of malabsorption, and the severity of pulmonary disease. For patients older than 2 years of age, current CFF guidelines [83] recommend energy intakes at 110–200% of EER for the general population [145,146] to support weight maintenance in adults and weight gain at an age-appropriate rate in children. Alternatively, the 2002 CFF guidelines [82] provide a method to calculate energy requirement for individual patients based on their pancreatic functional status and the severity of lung disease, as outlined in Table 42.4.

IV NUTRITION MANAGEMENT

Nutrition management for patients with CF varies and depends on the stage of diagnosis (newly diagnosed CF vs routine management), patient's age (infancy, early childhood, adolescence, and adulthood), and disease severity. Nutrition management begins at the time of CF diagnosis. The first 6 months after the diagnosis of CF is a crucial period for establishing therapeutic interventions, dietary counseling, and nutritional education. Nutrition management for patients with stable CF focuses on maintaining optimal nutritional status and preventing malnutrition, and for patients experiencing malnutrition focuses on achieving catch-up growth (for children) and weight gain (for adults). In addition, PERT and vitamin supplementation are essential for all categories of nutrition management.

The multidisciplinary CF care team should monitor growth, provide anticipatory counseling, and plan intervention strategies for each individual CF patient. Achieving and maintaining normal growth and nutritional status require management of gastrointestinal and pulmonary symptoms, dietary intake and eating behaviors, and psychosocial and financial issues. Clinical care guidelines for nutritional management for patients with CF have been established by the U.S. CFF Foundation since 1992 [152], and were revised in 2002 [82] and 2008 [83] to incorporate more evidence-based recommendations. Guidelines for diagnosis care, gastrointestinal care, respiratory care, infection prevention and control care, other CF-related conditions care, as well as age-specific care are also available at https://www.cff.org. The European Cystic Fibrosis Society also updated its standard care guidelines in 2014 [148].

A Diagnosis and Treatment of Malabsorption

1 Diagnosis of PI

Exocrine pancreatic function should be assessed in the following situations: (1) at or shortly after diagnosis to provide objective evaluation of pancreatic status before enzyme therapy is initiated, and (2) to monitor PS patients for evidence of developing fat maldigestion, particularly

when frequent bulky bowel movements or unexplained weight loss occur. The preferred test for assessment of pancreatic functional status is fecal elastase-1, as aforementioned. However, fecal elastase-1 level is not diagnostic by itself but aids in defining PS ($>200\,\mu g/g$) or PI ($<100\,\mu g/g$). The level within the same patient may fluctuate during the first year of life [153]. Therefore, fecal elastase-1 should be remeasured at age 1 year to ensure the correct diagnosis.

2 Pancreatic Enzyme Replacement Therapy

There is a strong association between genotype and pancreatic phenotype [26,27,154]. PERT should be started if the patient is known to have two CFTR mutations associated with PI or objective evidence of PI [116]. PERT should not be started in infants with a CFTR mutation known to be associated with PS, unless there are unequivocal signs or symptoms of malabsorption [116].

In young infants diagnosed through NBS, PI is not present in some infants at the time of diagnosis but develops later in infancy or even in early childhood [7]. Therefore, it is important to repeat fecal elastase-1 measurement in infants who are initially PS, especially when gastrointestinal symptoms appear or poor weight gain occurs. CF children with laboratory evidence of PI should be started on PERT even in the absence of signs or symptoms of fat malabsorption.

Pancreatic enzymes are extracts of porcine origin containing amylase, proteases, and lipase. A large variety of enzyme products have been available previously. However, many were marketed without formal testing. In 2004, the FDA issued a notice requiring that manufacturers submit a new drug application for pancreatic enzyme products. As of 2010, there are three FDA-approved products. The actual activity of these enzymes varies considerably according to specific batches and the commercial manufacturer. Enzyme potency is based on the content of amylase, protease, and lipase in each capsule. However, many health care providers use lipase content to determine enzyme dosing to treat fat maldigestion. Commercial products are sold in capsules with varying lipase activity, ranging from 3000 to 36,000 lipase units/capsule.

The enteric-coated forms of pancreatic enzymes vary considerably in their biochemical coating, biophysical dissolution properties, and size of microspheres or microtablets [155,156]. There are few carefully performed clinical studies comparing the different formulations and little in vivo data are available that demonstrate the superiority of a single product. In fact, all currently available enzyme products fail to completely correct nutrient maldigestion in all patients with CF [157]. The reasons are multiple, and likely to vary from patient to patient, and in some cases may be due to factors unrelated to failed pancreatic digestion [158]. The enteric coating of enzyme microsphere or microtablets require a pH $>5.2-6.0$ for dissolution to occur in the proximal intestine, which may be acidic in the CF patient. Patients with CF and PI have gastric acid hypersecretion and a relative deficiency of bicarbonate secretion from the pancreaticobiliary tree. This may result in a more acidic proximal intestinal environment, which may be below the ideal optimal pH for maximal pancreatic enzyme activity and may hasten the inactivation of enzymes especially lipase within the small intestine. Histamine antagonists or proton pump inhibitors may be used to improve the intestinal milieu, but studies have revealed mixed results [159,160]. Even if nutrient digestion is achieved, malabsorption of nutrients may occur because of thick intestinal mucus, which may affect the unstirred water layer reducing absorption of fatty acids in the small intestinal epithelium [161]. Nevertheless, enzymes do improve nutrient digestion and absorption in CF patients, but the caregiver must be aware of the less than ideal efficacy of these products in individual patients.

a Dosing Guidelines

To date, no studies have been performed in infants to determine the optimal dose of PERT. Data are insufficient with regard to the association of enzyme dose to macronutrient content, coefficient of fat absorption, or growth [83]. Until reliable data are available, dosing is based on consensus recommendations established by the U.S. CFF and the FDA [82,83,162]. These include: 500−2500 units lipase per kg body weight per meal; or $<10{,}000$ units lipase per kg body weight per day; or <4000 units lipase per gram dietary fat per day. These guidelines were established when it was recognized that many CF centers were giving excessive doses of enzymes, which is strongly associated with a severe intestinal complication termed fibrosing colonopathy [162,163].

Response to PERT by individual patients will vary considerably, as will their required dosing schedule. Though dosing is best calculated using lipase units per gram fat ingested, it is perhaps more practical to use a dosing schedule with weight-adjusted guidelines [82,83,116]. Weight-adjusted guidelines, with a limit of 4000 units lipase/g fat or 2500 units lipase/kg/meal beyond 1 year of age, would avoid overdosing.

b Enzyme Administration

There are no convincing data concerning timing of enzyme dosing with meals, but for practical reasons, we recommend that enzymes be taken in 2−3 divided doses before and during meals [164]. Theoretically, this will result in more even mixing and gastric emptying of enzymes, though this has not been clinically proven. Enzymes are not required with simple carbohydrates

TABLE 42.5 Important Aspects of Early Care for Newly Diagnosed Infants and Young Children with CF

PERT (for PI)
High-calorie and high-fat diet (after human milk)
Fat-soluble vitamin supplementation (vitamins A, D, E, and K)
Salt supplements (essential to prevent fatalities)
Infection control (prevent all risky exposures)
Respiratory cultures (by vigorous oropharyngeal technique)
Antibiotic therapy as needed (goal: eradicate *Pseudomonas*)
Airway clearance teaching and recommendations
CF education with genetic counseling (CFTR genotype)
Lifestyle counseling (promote normal/quality life)

Source: Adapted from D. Borowitz, K.A. Robinson, M. Rosenfeld, S. D. Davis, K.A. Sabadosa, S.L. Spear, et al., Cystic fibrosis foundation evidence-based guidelines for management of infants with cystic fibrosis, J. Pediatr. 155 (2009) S73–S93.

(i.e., hard candy, popsicles, pop, jello) but are needed for foods containing fat, protein, and starch (rice, potatoes, etc.).

c Adjunctive Therapy

Histamine (H_2) antagonists and proton pump inhibitors inhibit gastric acid and in some cases may improve enzyme activity either by decreasing gastric acidity resulting in less destruction of unprotected conventional powder enzymes in the stomach, or by increasing pH in the upper intestine allowing for more rapid dissolution of the enteric coating dissolution and optimal conditions for enzymes to catalyze nutrients. As mentioned, efficacy of this treatment is not clear, as results in one study proved proton pump inhibitors to be helpful [159], while another found no benefit [160]. The CF caregiver should be cautioned that there are no safety data on the long-term use of these medications in children.

Newly Diagnosed Infants and Young Children up to 2 Years of Age

Guidelines for the care of infants diagnosed early through NBS were published in 2009 by Borowitz et al. [116]; key components of early care are summarized in Table 42.5. The core objectives of CF treatment after early diagnosis through NBS are to prevent malnutrition, control respiratory infections, and promote mucus clearance [116].

3 Initial Visits and Coordination with Primary Care Physician

The majority of young infants diagnosed through NBS appear to be totally healthy to the parents, and the diagnosis of CF is largely unexpected. Therefore, the psychosocial impact on the family must be carefully addressed at the initial visits [116]. Newly diagnosed infants with CF should be treated at an accredited CF center, ideally within 24–72 hours of diagnosis. At the first visit, adequate time for the family to receive comprehensive education and counseling is very important. Disbelief, anger, or anxiety about the new diagnosis is likely to be present, which affects the retention of information. Giving basic information in the clearest of terms and conveying the information in a sensitive, empathetic, and positive manner are key components of the visit. A variety of formats should be used to provide information, including verbal, written, and audiovisual methods.

Introduction of other members of the CF care team, namely the nurse, dietitian, respiratory therapist, and social worker, should occur with the first two visits [116]. This allows key components of nutrition and airway clearance to be taught, and facilitates the development of relationships with team members. A genetic counselor should meet with the family within 2 months of diagnosis to discuss in greater depth how mutations in the CFTR gene cause CF and the implications for other family members [116]. Equally important, the positive outlook for newly diagnosed infants should be reinforced and instill a sense of hope.

The pivotal role that both parents and primary care provider play as part of the CF team should be emphasized at the early visits [116]. Coordination with the primary care physician is essential, as families will be making numerous visits to their primary care provider and CF center during the first 2 years of life. Therefore, regular and open trilateral communications among the family, the primary care physician, and the CF center should be established. Communication between the primary care physician and the CF center is critical to ensure parents do not get conflicting messages, since many CF care goals are different from those of standard pediatric care (e.g., an emphasis on the need for the CF child to be chubby vs concerns about obesity in the general pediatric population).

4 Types of Feeding

Special attention to growth and nutrition early in life is essential because it is a time of extraordinary metabolic need; healthy infants double their birth weight by 4–6 months of age and triple it by 1 year. The first 6 months of life represent a unique window of opportunity to promote optimal growth, while poor growth during this critical period may be irreversible [39]. The U.S. CFF recommends that children reach a weight-for-length status of the 50th percentile by 2 years of age, with an emphasis of achieving this goal early in infancy [83,116]. However, optimal nutritional care to achieve this goal has not been defined.

a Human Milk Versus Formula

The basic principles of infant feeding for healthy term babies apply to feeding infants with CF. However, optimal feeding (i.e., breast milk, formula, or combination) to meet the increased nutritional requirement for infants with CF is unknown. The benefits of breastfeeding for healthy infants are widely recognized [165]. However, breast milk may be nutritional inadequate in calories, protein, EFA, and sodium to meet the increased requirements of CF infants, especially for those with MI or PI, who are at greater risk of poor growth and malnutrition [7,90,91,166–169]. On the other hand, breast milk's antimicrobial constituents are likely to offer protection against respiratory infections [170–173]. The issue of breastfeeding was less relevant before nationwide implementation of NBS, when CF infants were diagnosed at a median age of 8–9 months [174], an age when most infants would no longer be breastfed; now, the issue of breastfeeding is of prime importance.

Breastfeeding is historically discouraged for CF infants because of concerns about protein energy malnutrition, which is manifested by hypoproteinemia, hyponatremia, edema, and anemia [7,90,166–169]. Very few studies have examined whether exclusive breastfeeding promotes optimal growth and provides respiratory benefits for CF infants, and the findings are inconsistent due to various breastfeeding classifications, small sample size, and retrospective study designs [175–178]. The 2009 CFF infant care guidelines [116] continued its 2002 recommendation [82] to suggest breast milk as the initial type of feeding for CF infants, without specifying the exclusiveness or the duration of breastfeeding. As of 2013, approximately 60% of infants with CF were ever breastfed, and 15% were exclusively breastfed for at least 4 months [14]. A higher breastfeeding rate was observed in a recently launched multicenter observational study designed to evaluate the benefits and risks of breastfeeding in CF [179]. With that, more results will be generated to address issues related to breastfeeding in CF.

b Standard Formula Versus Special Formula

There is limited evidence to address whether formula-fed infants with CF and PI should consume special formula, for example, predigested formula containing protein hydrolysates and/or medium-chain triglycerides (MCTs). Among the three, very old studies conducted in the 1980s and 1990s, one reported similar nutritional status between CF infants fed hydrolyzed and standard formulas [180], another showed better anthropometric measures in infants fed hydrolysates [181], and the other study found improved fat and nitrogen absorption in infants fed semielemental formula when PERT was not given [182]. These conflicting results led the CFF to conclude insufficient evidence to recommend special formula for formula-fed infants with CF [116].

It is also unclear whether breast milk and standard formula should be routinely fortified to increase caloric and nutrient densities for feeding infants with CF who are growing adequately, for the purpose of sustaining normal growth or preventing growth faltering. This is another urgent nutritional issue recommended by the CFF for future research [116].

c Complimentary Foods

Infants with CF should be introduced to solid foods at the same age as healthy non-CF children, that is, 4–6 months of life, according to recommendations from the American Academy of Pediatrics. Nutrient and caloric-dense foods, such as meat, that will enhance weight gain and provide a good source of iron and zinc [141], are ideal as first foods for infants with CF. Breast milk or formula should continue through the first year of life, thereafter, whole cow's milk can be used in the thriving child.

As infants are introduced to table foods, it is important that families and primary care physicians understand that most children with CF need a balanced diet that is moderately high in fat to meet their nutritional requirement, which is different from the usual nutritional education given to families with healthy non-CF children for overweight and obesity prevention. For example, families should buy whole milk for the child with CF and lower fat milk for other children. During the second year of life, children establish self-feeding skills, food preferences, and dietary habits. Dietitians caring for children with CF should inquire about feeding behaviors to promote positive interactions and to prevent negative behaviors.

5 Enzyme Dose and Administration

PERT should be given with breast milk and formulas, including elemental and MCTs-containing formulas and all foods. An initial dose of 2000–5000 lipase units for each 120 mL feeding is recommended [116]. As the infant grows and the volume of intake increases, adjust the dose to up to 2500 lipase units per kg body weight per feeding, but not exceeding a maximal daily dose of 10,000 lipase units per kg body weight per day [116]. Enzyme dose in relation to caloric/fat intake and weight gain should be evaluated at each visit. The goal is to prescribe enzyme doses that are sufficient but not excessive to support optimal weight gain while minimizing the risk of fibrosing colonopathy. Nevertheless, caution to avoid fibrosing colonopathy may lead to excessively conservative enzyme dosing, as revealed from the CFF registry data that

TABLE 42.6 Recommendations for Daily Fat-Soluble Vitamin Supplementation[a]

	Vitamin A (IU)	Vitamin E (IU)	Vitamin D (IU)	Vitamin K (mg)
0–12 months	1500	40–50	400	0.3–0.5[a]
1–3 years	5000	80–150	400–800	0.3–0.5[a]
4–8 years	5000–10,000	100–200	400–800	0.3–0.5[a]
>8 years	10,000	200–400	400–800	0.3–0.5[a]

[a]*Currently, commercially available products do not have ideal doses for supplementation. Prothrombin time or, ideally, PIVKA-II levels should be checked in patients with liver disease, and vitamin K dose titrated as indicated.*

Robinson, M. Rosenfeld, S.D. Davis, K.A. Sabadosa, S.L. Spear, et al., Cystic fibrosis foundation evidence-based guidelines for management of infants with cystic fibrosis, J. Pediatr. 155 (2009) S73–S93.

average enzyme dose tended to be at the low end of weight-based dosing early in life.

In infants with CF, PERT should be offered before feeding, mixed with 2–3 mL (1/2 tsp) applesauce, and given by spoon [116]. Other strained fruit can be used if applesauce is not taken, but parents should be encouraged to use only one type of food to avoid problems with potential food refusal if many different types of food are used as the vehicle for enzyme delivery.

After 1 year of age, children can be offered enteric-coated products, mixed with one food. Swallowing of capsules is encouraged as soon as parents consider the child is ready. This varies considerably from patient to patient but occurs usually around 4–5 years of age. If children continue to experience difficulties swallowing capsules, parents should open the capsule and sprinkle the beads in the mouth which can be ingested by drinking a liquid. Children should be discouraged from chewing the capsules, as this will destroy the protective coating of enzymes and may cause irritation in mouth.

6 Energy Intake and Nutrient Supplementation

Sufficient calories are critical in infants with CF, and the best indicators that energy requirement is met are maintenance of normal growth or achievement of catch-up growth. In addition to energy intake, adequate intakes of EFA and micronutrients such as zinc and sodium are needed to promote normal growth.

All infants with CF should receive standard, age-appropriate nonfat-soluble vitamins plus fat-soluble vitamins A, D, E, and K as recommended by the CFF guidelines (Table 42.6). Because of increased risk of hyponatremia, sodium supplementation is especially important in infants with CF [116], particularly in those fed human milk, which contains a very low amount of sodium. Older infants receiving solid foods are likely to have low sodium intake, as baby foods contain no added salt. CF infants younger than 6 months should receive a daily dose of one-eighth teaspoon of table salt; this amount should be increased to a quarter of teaspoon for older infants aged 6–12 months [116].

B Routine Management for Patients Older than 2 Years of Age

1 Energy Intake and Nutrient Supplementation

To obtain adequate energy intake and compensate for fat malabsorption, CF patients typically require a greater fat intake (35–40% of calories) than what is normally recommended for the general population (25–35%). Fat restriction is not recommended, because fat is the most energy-dense macronutrient and provides EFA. MCT supplements may be utilized as a good source of fat because they require less lipase activity, less bile salt for solubilization, and can be transported as free fatty acids through the portal system.

In CF patients, vitamin supplementation is necessary to prevent the occurrence of deficiencies. A standard, age-appropriate multivitamin supplement should be given to all CF patients. Additional supplementation with fat-soluble vitamins is needed (Table 42.6).

CF patients are at risk of hyponatremia because of salt loss through the skin. Children and adults are advised to consume a high-salt diet, especially during summer months and for those who live in hot climates.

2 Age-Specific Recommendations

a Preschool Age (2–5 Years)

CFF published its first clinical practice guidelines for preschoolers with CF in 2016 to address the gap for care for this age group [183]. This period is crucial for a child's growth and development, and interventions during this time will optimize nutritional status and preserve lung health [183]. Routine nutritional monitoring and care recommended by the preschoolers guidelines are summarized in Table 42.2. For children at nutritional risk, that is, BMI < 50th percentile, or rate of weight gain <50th

percentile expected for age, or weight-for-age < 10th percentile, the guidelines recommended more intensive management and frequent follow-up, that is, 8 weeks or sooner, to ensure normal growth. Issues related to behavioral assessment and management of mealtime are also addressed.

Children in this age group have developed self-feeding skills, food preferences, and dietary habits. Food intake and physical activity vary from day to day. For these reasons, close monitoring of dietary habits, caloric intake, and growth velocity are important. Routinely adding calories to table foods, in the form of additional fat, may help with maintaining optimal growth at this stage. The importance of serving calorie-dense foods (such as whole milk rather than low-fat milk) and establishing positive mealtime interactions should be emphasized.

Studies showed that toddlers with CF have longer meal times than their peers without CF, yet still do not meet the CFF's dietary recommendations for increased energy intake [184]. As the duration of meal times increases, difficult behaviors also tend to occur more frequently [185]. Therefore, dietary counseling should include assessment of eating behaviors. One strategy to address behavioral problems is to limit mealtimes to 15 minutes for toddlers and use snack times as mini-meals. Another strategy is to teach parents alternative ways of responding to their child who eats slowly or negotiates what he or she will eat.

b School Age (6–10 Years)

Children in this age group are at risk for declining growth for various reasons. They typically participate in a variety of activities, leading to limited time for meals and snacks. They are also exposed to peer pressure and challenged to begin self-managing their disease. These factors may affect compliance with prescribed medications such as pancreatic enzymes and fat-soluble vitamins. In addition, acceptance and understanding by teachers and fellow students may be lacking, further stressing a child with CF. Encouraging children to help in meal planning and preparation maybe helpful in improving food intake.

It is important to begin monitoring bone health at this age [125]. Bone health can be evaluated by history (atraumatic bone fracture), physical examination (poor growth, back pain), and by radiologic and laboratory assessment. According to current guidelines [125], CF children age 8 and older who are at risk for poor bone health (i.e., poor growth, poor lung function, history of bone fracture, delayed puberty, or chronic use of glucocorticoids) should be screened by dual energy X-ray absorptiometry to assess their bone mass. In addition, serum calcium, phosphorus, and 25-hydroxy-vitamin D and parathyroid hormone should be measured annually [125].

c Adolescence (10–18 Years)

This stage represents another vulnerable period of developing malnutrition because of increased nutritional requirements associated with accelerated growth, endocrine development, and high levels of physical activity. In addition, pulmonary disease often becomes more severe in this period, increasing energy requirement. This is also the age when other complications, such as CFRD, begin to occur more frequently, which further increases the risk of poor growth and malnutrition.

Puberty is often delayed in adolescents with CF; it usually is related to growth failure and poor nutritional status, rather than to a primary endocrine disorder. Assessment of puberty should be performed annually at 9 years of age in girls and 10 in boys by a standardized self-assessment or physician examination [186,187]. In addition to plotting growth on the growth charts, evaluating height and weight velocity [186] in association with Tanner stages can be very useful in identifying delayed or attenuated pubertal growth.

Nutritional counseling should be directed toward the patient rather than the parents. Teenagers may be more receptive to efforts to improve muscular strength and body image as a justification for better nutrition compared to emphasis on weight gain and improved disease status.

d Adulthood

CF patients reaching adulthood are usually responsible for the entire management of their disease, as well as for the financial burden of a chronic illness [188,189]. While in college or working, adults with CF are constantly adapting to new schedules and stresses. The goal of nutrition management is to maintain optimal BMI and to prevent unintentional weight loss. Nutritional counseling must be practical and pragmatic to help adults with CF adjust to these changes. A minimum of one comprehensive evaluation per year is recommended [188]. However, more specific recommendations are needed for adult CF clinical care.

e Pregnancy and Lactation

Widespread experience in recent years has demonstrated that pregnancy and lactation can be accomplished successfully by some women with CF. Pregnant women with CF should follow the guidelines from the Dietary Reference Intakes [190] for nutrient intakes. Special attention should be given to appropriate weight gain, particularly during the last trimester of the pregnancy. In addition to the usual multivitamin supplementation for CF, a prenatal vitamin should be consumed daily. During lactation, marked increase in caloric intake is necessary to meet the high energy requirement during this period.

TABLE 42.7 Maximizing Calories for Healthy Patients with CF

Adding Calories to Foods	High-Calorie Foods and Snacks[a]
• Add fats such as butter, gravy, cheese, or dressings to starches, fruits, and vegetables • Use whipped cream on fruits and desserts • Makes "super" milk: ½ cup whole milk + ½ cup half and half • Flavor milk with syrups or powders (chocolate, strawberry, etc.) or add whole milk yogurt to milk • Add eggs to hamburger meat or casseroles (never serve raw eggs) • Use extra salad dressing; avoid low-calorie or reduced calorie dressings • Serve gravies and cheese sauces	• Full fat ice cream, puddings • Cookies and milk • Cheese or peanut butter crackers • Muffins or bagels with cream cheese or butter • Cheese breadsticks • Chips and dip • French fries • Whole milk yogurt • Egg salad, tuna salad, cheese, or avocado slices with crackers • Trail mixes, nuts, and granola (after the age of 2 years) • Cold cuts, pizza • Fresh vegetables with salad dressing or dip

[a]*Assess age-appropriateness, especially with respect to choking risk in young children, before recommending.*

C Nutrition Intervention for Poor Growth and Malnutrition

For CF patients who are experiencing poor growth and malnutrition, nutritional intervention beyond the level of routine management is required. Nutrition support can be delivered at various levels, beginning from behavioral intervention, dietary modification, oral supplementation, to enteral or parenteral supplementation. In addition, the presence of comorbid medical conditions that is likely to affect growth and nutritional status, such as GERD, DIOS, and CFRD, should be evaluated.

1 Behavioral Intervention

In an effort to increase dietary intakes, caregivers of young children with CF may be engaged in ineffective feeding practices such as coaxing, commanding, physical prompts, and parental feeding. Adolescents with CF may intentionally skip pancreatic enzymes in order to achieve a certain body image. An in-depth assessment of eating behavior, feeding patterns, and family interactions at mealtimes should be performed in CF patients at risk or experiencing malnutrition. If negative behaviors are present, behavioral intervention should be used in conjunction with dietary intervention to improve intake. For example, one behavioral strategy is to gradually increase calories by working on one meal at a time. Another strategy is to teach parents alternative ways of responding to their child who eats slowly or negotiates what he or she will eat. Referral for more in-depth behavioral therapy is also encouraged as needed.

2 Dietary Intervention

a Oral Supplements

For infants experiencing inadequate weight gain, increasing caloric density of the feedings is the first step. This can be achieved by fortifying breast milk or by concentrating formula. For infants who are taking solids, additional calories can be added to infant cereal with the addition of carbohydrate polymers (e.g., Polycose) and/or fats (e.g., vegetable oil, MCT oil, or Microlipids).

Dietary intervention should begin with dietary modification to increase caloric density of the diet, that is, addition of high-calorie foods to the family's regular diet without dramatically increasing the amount of food consumed. For example, margarine or butter may be added to many foods, and half and half can be used in place of skim milk or water when preparing canned soup. More examples of how to maximize the caloric density of the diet are given in Table 42.7. If dietary modification is ineffective, use of energy supplement may be introduced. However, it is important to assure that the energy supplement is not used as a substitute for normal food intake.

b Enteral Feedings

Enteral feeding can be initiated when oral supplementation does not improve growth and nutritional status significantly. The goals of enteral feeding should be explained to the patient and family, that is, as a supportive therapy to improve quality of life and outcome, and their acceptance and commitment to this intervention should be realistically assessed.

Enteral feeding can be delivered via nasogastric tubes, gastrostomy tubes, and jejunostomy tubes. The choice of enterostomy tube and technique for its placement should be based on the expertise of the CF center. Nasogastric tubes are appropriate for short-term nutritional support in highly motivated patients. Gastrostomy tubes are more appropriate for patients who need long-term enteral nutrition. Jejunostomy tubes may be indicated in patients with severe GERD; use of predigested or elemental formula may be needed with jejunostomy feeding.

Standard enteral feeding formulas (complete protein, long-chain fat) are typically well tolerated. Calorically dense formulas (1.5−2.0 kcal/mL) are usually required to provide adequate energy. Nocturnal infusion is encouraged to promote normal eating patterns during the day. Initially, 30−50% of EER may be provided overnight. Pancreatic enzymes should be given with enteral feeding. However, optimal dosing regimen is unclear with overnight feeding.

3 Evaluation of Comorbid Medical Conditions

a Severe Malabsorption

A large number of patients with CF continue to have malabsorption despite adequate dosing with potent pancreatic enzymes [156]. Subjective symptoms such as abdominal bloating or cramps, or bulky stools cannot reliably assess the severity of malabsorption [69]. Instead, objective assessment is advocated by a 72-hour fat collection (while eating a regular diet) and the prescribed dose of enzymes. If severe fat malabsorption is identified (fecal fat losses exceeding 20% of intake) and is clearly contributing to abdominal symptoms or malnutrition, the dose of enzymes could be increased up to the maximum recommended amount. Alternatively, inhibition of gastric acid secretion with a histamine antagonist or a proton pump inhibitor may raise intestinal pH and improve the efficacy of enzyme therapy. Several weeks after the adjustment to therapy has been made, the individual patient should be reassessed by a repeat 72-hour fecal fat collection.

b Gastroesophageal Reflux Disease

GERD is quite common in CF infants [191], particularly in those with respiratory disease. Drugs to suppress gastric acid may be indicated if reflux is severe. A predigested formula offers no advantage and should be only considered in individuals who have had significant bowel resection following complicated MI [180].

c Distal Intestinal Obstruction Syndrome

DIOS is unique to CF [192]. It is characterized by cramping abdominal pain, which may be periumbilical or in the right lower quadrant. A mass is usually palpable in the ileocecal area. It should be emphasized that simple constipation is a common problem in individuals with CF. Consequently, a careful history, abdominal examination and abdominal X-ray, is indicated when abdominal pain due to DIOS is suspected in order to distinguish it from constipation and other CF-associated complications such as intussusception and appendiceal abscess.

DIOS is treated with several different approaches. If the DIOS is severe, a balanced electrolyte solution (used for cleansing the bowel prior to colonoscopy) is very effective in relieving the subacute obstruction. Complete bowel obstruction is an absolute contraindication to the use of these solutions. Volumes of 4−8 L, delivered at 1 L/hour are usually required for a complete clean out in children >10 years of age. In younger children, the electrolyte solution should be administered at a rate of 10−40 mL/kg body weight/hour for 4−6 hours until the stools no longer have any solid material. *N*-acetylcysteine and, in severe cases, large volume enemas with hyperosmolar contrast agents are also used. More recently, a polyethylene glycol solution without electrolytes has been used by some practitioners to help with the management of DIOS and/or constipation in CF. Anecdotal reports suggest that this solution, a powder mixed with any choice of beverage, at doses of about 17−34 g once or twice per day is effective in children with CF. Most patients who have an episode of DIOS are prone to have recurrent episodes and it is logical for these patients to maintain a bowel regimen using polyethylene glycol, although there are no published studies [191].

d CF-Related Diabetes

Adolescents and adults with CF and PI are at increased risk of developing CFRD. In many instances, patients exhibit no clear-cut signs and symptoms of diabetes. Furthermore, determination of hemoglobin A1C is not a reliable test for the diagnosis of CFRD. The diagnosis should be considered in any patient who is exhibiting weight loss or poor weight gain. In 2010, the CFF recommended annual screening for CFRD by a modified oral glucose tolerance test after the age of 10 years [17,18]. In the patient who has CFRD, high energy meals and snacks are encouraged but energy needs and insulin requirements must be carefully balanced. Foods high in simple sugars may be limited according to insulin needs. Multidisciplinary care and the support of endocrinologists and certified diabetes educators are essential. In individuals who have impaired glucose tolerance, close monitoring by both the CF and endocrine teams are required, as these patients are at increased risk of developing CFRD.

Other complications secondary to CF are also common, including hepatobiliary manifestations, bone/joint

disease, pancreatitis, small intestinal bacteria overgrowth, gut dysbiosis, anxiety disorder/depression, etc. Ongoing and careful management of these complications is essential for high-quality care to improve morbidity and quality of life in CF.

D Patient and Parent Education

Education of patients and their caregivers is a vital and routine component of the multidisciplinary care of patients with CF [82,116,187]. A solid grounding in the special nutritional needs of a patient with CF should be established at diagnosis. This should include an explanation of the role of the pancreas and how enzyme replacement therapy helps to improve maldigestion. Parents should be given specific instructions on how to provide an appetizing, high energy, nutritionally balanced diet, particularly with a liberal use of fat to provide extra calories. It is important to communicate the expectation that most children with CF are able to grow and gain weight normally. Patients and their parents require education about the importance of fat-soluble vitamins. Details on when to administer enzymes and vitamins must be reviewed on several occasions. In the older children, concerns about adherence should be emphasized and assessed at each follow-up visit.

V CONCLUSIONS

The clear associations between nutritional status and clinical outcomes in CF mandate careful nutritional assessment, management, and monitoring of all patients with CF. In recent years, with new knowledge arising from NBS research, there has been a shift away from the idea that malnutrition is inevitable for most CF patients toward the more optimistic view that adequate nutrition and growth are possible if early diagnosis and aggressive nutritional monitoring and therapy are made for each individual patient. This task is best accomplished by involving a multidisciplinary team that includes dietitians in the care and management of CF patients. In this way, the goals of normal growth and prevention of malnutrition can be attained, which will improve the prognosis and quality of life for patients with CF.

Chapter 43

Current Understanding of Vitamin D Metabolism, Nutritional Status, and Role in Disease Prevention

Susan J. Whiting[1], **Mona S. Calvo**[2] **and Hassan Vatanparast**[1]

[1]*University of Saskatchewan, Saskatoon, SK, Canada,* [2]*Center for Food Safety and Applied Nutrition, Food and Drug Administration, Laurel, MD, United States*

I INTRODUCTION

Vitamin D is a nutrient that, until recently, was neglected by the nutrition community. Although recognized in the early 20th century as an essential nutrient, recommendations for intake were often qualified as being needed only in the absence of sunlight. In theory (and in ancient times when early humans all lived closer to the equator), all vitamin D needs could be met by exposure to sunlight that provided ultraviolet (UV) B radiation, but only recently have we come to understand how UVB acts and what other factors—particularly environmental—mitigate cutaneous vitamin D synthesis. Studying vitamin D requirements is difficult. Early dietary recommendations for vitamin D, such as the 1989 Recommended Dietary Allowance (RDA) [1], indicated a "relative paucity of recent controlled studies [and] ... lack of data on which to base requirements." It further stated that "clinical osteomalacia appears to be rare in the United States." What is known today, however, is that vitamin D deficiency and insufficiency are widespread [2], which was not identified when the Dietary Reference Intakes (DRIs) for vitamin D were first published in 1997 [3]. In 2011, new DRIs for vitamin D reflected the need for more dietary vitamin D [4]. While the 2011 DRI report did not set recommendations based on functions other than bone health, there remains a growing body of evidence for vitamin D's many roles in the body [5,6].

The role of vitamin D in preventing rickets was discovered early in the 19th century but it was not until the 1970s that the sequence of steps from skin precursors to active metabolite was understood. Despite the interest generated in solving the puzzle of how vitamin D increased intestinal calcium absorption, there were several reasons why progress toward a better understanding of vitamin D requirements failed to progress. There were technical challenges in analyzing vitamin D and its metabolites. Beginning in the 1980s, there was a greater focus on dietary calcium as the major "bone" nutrient, leaving vitamin D with only a minor role in osteoporosis research. And finally, the important contribution of sun exposure to vitamin D status was not fully realized until recently. Indeed, dietary intake recommendations for situations of complete year-round lack of skin synthesis give values that are 5−8 times higher than those recommended to maintain vitamin D status only through the winter. It has been shown that globally there is greater prevalence of chronic diseases such as cancer and immune disorders at extremes of latitudes where sun exposure for skin synthesis of vitamin D is limited [5].

Vitamin D affects people starting with fetal development and continuing to old age, functioning at both the genomic and nongenomic level in the regulation of key protein synthesis or in the intracellular metabolic pathways in virtually all tissues [5,6]. Growth, development, and maintenance of health are all affected, and in many regards, quality of life is as well. This chapter, while acknowledging vitamin D's contribution through the life span, focuses on vitamin D needs for maintenance of health, and on vitamin D's specific actions in selected clinical conditions. As research is ongoing, the reader can

Nutrition in the Prevention and Treatment of Disease. DOI: http://dx.doi.org/10.1016/B978-0-12-802928-2.00043-6

expect to learn enough about vitamin D's roles to be able to understand and apply the research as it unfolds.

II METABOLISM OF VITAMIN D

A Overview of Vitamin D Synthesis and Conversion to Its Active Metabolite

1 Vitamin D Is a Family of Compounds

To understand vitamin D is to appreciate the functions of the numerous metabolites that arise during its metabolism. Fig. 43.1 shows how vitamin D is provided, either through skin synthesis or from diet, and undergoes successive hydroxylations to form the active metabolite, 1,25-dihydroxyvitamin D. There are several natural occurring forms of vitamin D and many metabolites, and these are outlined in Table 43.1. The term "vitamin D" really represents all compounds having or potentially having the activity that we associate with the active metabolite of vitamin D; however, in nutrition we also refer to the precursor molecules provided in the diet or in supplements, which are cholecalciferol (for vitamin D_3) and ergocalciferol (for vitamin D_2), as "vitamin D." Generic use of the term "vitamin D" is a source of great confusion. Through this chapter, an attempt has been made to use the exact term for each metabolite in order to prevent confusion. Table 43.1 can be used as a guide for this purpose. When vitamin D_2 and D_3 can contribute to the same function, then "vitamin D" with no subscript is used.

2 Vitamin D_3 Synthesis in Skin

In the skin, there is 7-dehydrocholesterol (also called "provitamin D_3") in the epidermis and the dermis, which reacts, when UVB radiation in the wavelength range of 280–315 nm passes through these skin layers, to form previtamin D_3. Previtamin D_3 forms rapidly, however, skin pigmentation (melanin) competes with 7-dehydrocholesterol for the UVB photons, and therefore reduces the amount of UVB that can act on 7-dehydrocholesterol to form previtamin D_3. With prolonged exposure to UVB, inactive compounds are formed instead of previtamin D_3. Over a prolonged period of time, the previtamin D_3 that is formed

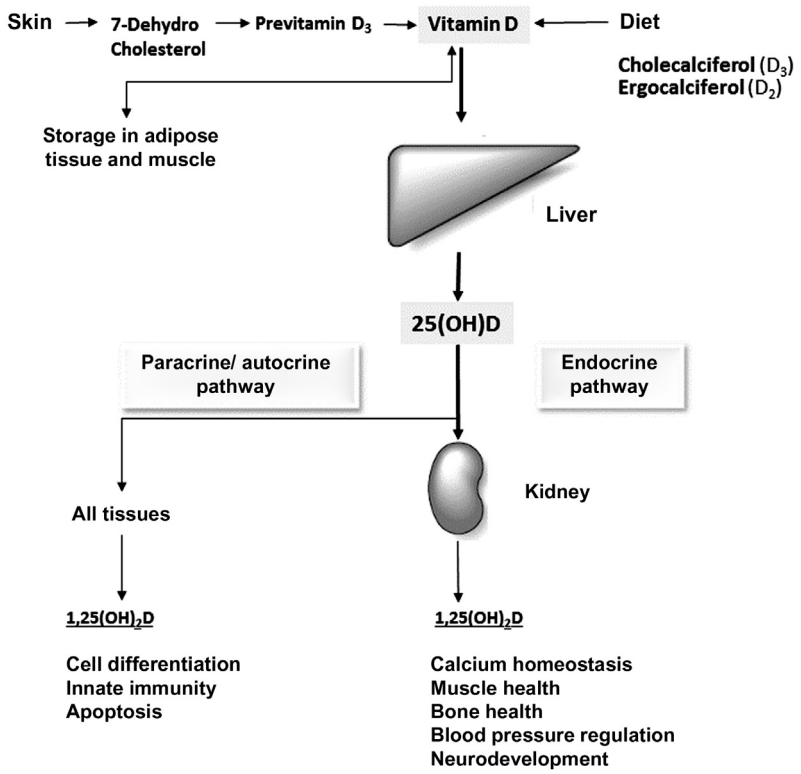

FIGURE 43.1 Overview of vitamin D metabolism, from synthesis (or provision in the diet) through to synthesis of active form. Once vitamin D_3 is made in skin, or provided from the diet (and some of this could be as vitamin D_2), it is converted in the liver to 25-hydroxyvitamin D [25(OH)D], which is the major circulating form of vitamin D. This 25(OH)D is now the substrate for production of the active form, 1,25-dihydroxyvitamin D, via two pathways. In the endocrine pathway, 1,25-dihydroxyvitamin D is made in the kidney under tight regulatory control; this 1,25-dihydroxyvitamin D circulates in the blood and acts to promote active calcium and phosphate absorption; working with PTH, the active form affects bone metabolism and kidney reabsorption of calcium. In the paracrine/autocrine pathway, 1,25-dihydroxyvitamin D is made and used locally by a variety of cells, including those of the immune system. *Modified from B.W. Hollis, C.L Wagner, Nutritional vitamin D status during pregnancy: reasons for concern, Can. Med. Assoc. J. 174 (2006) 1287–1290.*

TABLE 43.1 A Glossary of Vitamin D Compounds and Metabolites

Vitamin D Metabolite	Alternate Name(s)	Function	Clinical Utility of Measurement
"Vitamin D" (often used as synonym for vitamin D_3 or all dietary sources)	N/A	Term used to describe actions of the active metabolites of vitamins D_2 and D_3	N/A
7-Dehydrocholesterol	Provitamin D_3	Precursor to cholecalciferol found in skin; is acted upon by UVB	Not measured
Previtamin D_3	N/A	Intermediate in synthesis of cholecalciferol from 7-dehydrocholesterol	Not measured
Vitamin D_3	Cholecalciferol; calciol	Form of vitamin synthesized by animals in presence of UVB light	Provides information of recent sun exposure or ingestion of vitamin D_3
Vitamin D_2	Ergocalciferol	Form of vitamin synthesized by yeast and fungi in presence of UVB light	Provides information of ingestion of vitamin D_2
25-Hydroxyvitamin D_3 [25(OH)D_3]	25-Hydroxycholecalciferol; calcidiol, calcifediol	Circulating form of vitamin D_3, made from cholecalciferol	Measure of vitamin D_3 status
25-Hydroxyvitamin D_2 [25(OH)D_3]	25-Hydroxyergocalciferol	Circulating form of vitamin D_2, made from ergocalciferol	Measure of vitamin D_2 status
Total 25-hydroxyvitamin D [total 25(OH)D]	Total 25(OH)D	Represents the sum of 25(OH)D_2 + 25(OH)D_3	Measured using RIAs and other early assays and reflects all dietary and skin-derived sources
1,25-Dihydroxyvitamin D_3 [1,25-DHD]	1,25-Dihydroxycholecalciferol; calcitriol	Active metabolite of vitamin D_3	Measured to determine if active form can be made or to monitor treatment; not useful for vitamin D status
1,25-Dihydroxyvitamin D_2	1,25-Dihydroxyergocalciferol	Active metabolite of vitamin D_2	Measured to determine if active form can be made or to monitor treatment; not useful for vitamin D status
24,25-Dihydroxyvitamin D	24,25-Dihydroxycholecalciferol [or -ergocalciferol	Inactive; made instead of 1,25 metabolite if 1-hydroxylase is not stimulated	Not measured
1,24, 25-Trihydroxyvitamin D	Calcitroic acid	Inactive; made from 1,25 metabolite as mechanism for inactivation	Not measured
3-Epimers of vitamin D metabolites	3-Epi-25(OH)D_3	Unknown; found as a small percentage of total 25(OH)D in adults but in higher amounts in infants	Not routinely measured
	3-Epi-1,25$(OH)_2D_3$	Possibly has some activity	Not routinely measured

is changed due to thermal isomerization to vitamin D_3 (more appropriately called "cholecalciferol" or, less commonly, "calciol"). The reaction to form previtamin D_3 takes little time but the reaction converting previtamin D_3 to cholecalciferol, takes hours to occur [6] and is a rate-limiting step. Should more UVB photons reach the epidermis and dermis, previtamin D_3 is converted to inactive compounds with no vitamin D activity (tachysterol and luminsterol). Thus, excess exposure to UVB does not result in excess vitamin D production [6].

Besides the skin pigment melanin, other factors reduce skin synthesis of cholecalciferol. These include clothing (although some loosely woven clothing does permit UVB to pass through); window glass, sun screens formulated to

block UVB, particularly when the sun protection factor (SPF) is over 8 [6]; being indoors; tall buildings creating urban canyons; cloudy days; smog and light-blocking air pollution; and winter, when the sun does not rise far enough above the horizon to allow sufficient UVB irradiation to stimulate dermal vitamin D_3 synthesis. Thus, the term "vitamin D winter" refers to the time of year when UVB radiation is not sufficient for cholecalciferol synthesis in the skin.

Latitude is the major determining factor for intensity of UVB irradiation—whether in the southern or northern hemisphere. At the equator, vitamin D can be made year-round even in darker pigmented skin. Above latitude 37° there are 4 months of vitamin D winter; at latitude 42° there are 5 months, and close to the poles there would be no time during the year when vitamin D synthesis in the skin could occur [6,7]. Yet, not all analyses of vitamin D status and latitude show the expected relationship [8,9]. For example, there is now considerable vitamin D deficiency and insufficiency in people living near the equator, in countries of the Middle East, southern Europe [9], and in India [10]. This suggests that many factors are determining skin synthesis, so lack of UVB (e.g., "vitamin D winter") affects some countries, while clothing and customs such as time spent outdoors determine vitamin D in other countries. Age is another factor decreasing skin synthesis of cholecalciferol, as described below.

3 Conversion of Cholecalciferol and Ergocalciferol to 25-Hydroxyvitamin D

The cholecalciferol made from skin synthesis is released from the epidermis into the blood, where it is bound to vitamin D binding protein (DBP). Cholecalciferol and ergocalciferol (vitamin D_2) in the diet are absorbed and carried to the liver in chylomicrons. Intestinal absorption is not a limiting factor except when there is fat malabsorption (e.g., cystic fibrosis, Crohn's disease). Generally, fat-soluble vitamins are better absorbed with dietary fat. Added vitamin D_3 in orange juice is well absorbed despite just a small amount of fat in orange juice [11]; however, a study of a large (50,000 IU) dose showed 32% better absorption from a meal containing 30% fat compared to a fat-free meal [12]. Cholecalciferol and ergocalciferol circulate for only 1−2 days. This quick turnover is due to rapid hepatic conversion and uptake by fat and muscle cells [6,13].

There are two steps leading to the active form of vitamin D, which is 1,25-dihydroxyvitamin D (see Table 43.1). The first step is converting cholecalciferol or ergocalciferol to the major circulating form. This pathway involves four hepatic cytochrome P-450 enzymes (CYP2R1, CYP27A1, CYP3A4, CYP2J3) [6] that hydroxylate cholecalciferol or ergocalciferol at carbon 25. The resulting metabolites, 25-hydroxyvitamin D_3 and 25-hydroxyvitamin D_2 (together denoted as total 25(OH)D), are released into circulation. The amount of 25(OH)D that circulates is determined by the availability of its substrate, cholecalciferol or ergocalciferol [13]. With increasing levels of cholecalciferol made in skin or of dietary cholecalciferol and ergocalciferol, levels of 25(OH)D increase [6,14]. It is important to appreciate that 25(OH)D is the key metabolite indicating vitamin D status [6]. It is not the metabolically active form but it is the form that most accurately reflects deficiency or excess and is therefore used as a measure of vitamin D nutritional status [13].

Availability of serum 25(OH) is required for vitamin D activity. Fig. 43.2 illustrates the changes in 25(OH)D over a year, demonstrating how sun exposure impacts vitamin D status in light-skinned individuals living at about 50°N latitude [15]. One can see the impact of "vitamin D winter" in these subjects. This figure also demonstrates how an oral supplement of cholecalciferol can maintain the summer level of 25(OH)D through the winter months [15]. Studies indicate that while the molecule 25(OH)D has a half-life of 2−3 weeks [5], the amount in blood has an effective half-life of 2 months due to contribution from stores [16]. This means that in the absence of both

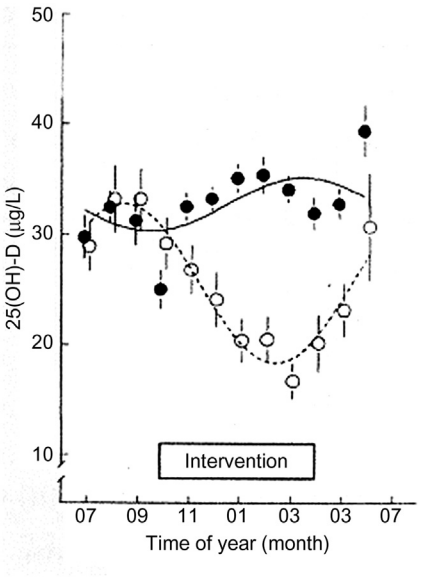

FIGURE 43.2 The data for this graph was derived from an RCT conducted in Germany (latitude 50°N). Open circles (○) represent mean levels of serum 25(OH)D of subjects throughout the year. Closed circles (●) are mean levels of serum 25(OH) in subjects who received the treatment regimen of 12.5 μg (500 IU) cholecalciferol and 500 mg calcium. Note that the units for 25(OH)D are expressed as μg/L (to convert to nmol/L, multiply by 2.5). *Reproduced with permission from C. Meier, H.W. Woitge, K. Witte, B. Lemmer, M.J. Seibel, Supplementation with oral vitamin D_3 and calcium during winter prevents seasonal bone loss: a randomized controlled open-label prospective trial, J. Bone Miner. Res. 19 (2004) 1221−1230.*

sun and adequate dietary source of cholecalciferol, serum levels of 25(OH)D will decline throughout the winter months.

Controversy surrounds the equivalency of the two precursors—cholecalciferol versus ergocalciferol—in the liver conversion to 25(OH)D [14,17]. When a single dose of either vitamin D_2 or vitamin D_3 was administered, $25(OH)D_2$ was shown to remain in blood for a much shorter time than a comparable dose of $25(OH)D_3$, declining after 1 week [18]. Nevertheless, when equal doses (1000 IU) of vitamin D_2 or vitamin D_3 were given daily to subjects, levels of 25(OH)D rose to the same extent, suggesting that physiologic amounts of either vitamin D form work similarly [19] when used on a daily basis as is typical of most dietary supplement use. What other studies find, however, is that providing vitamin D_2 results in production of $25(OH)D_2$ which is accompanied by a drop in $25(OH)D_3$ but little change in total 25(OH)D [14,17]. The health significance of this reduction in $25(OH)D_3$ with an increase in vitamin D_2 intake is unknown.

A study [13] looking at whether provision of the substrate for synthesis of 25(OH)D was rate-limiting, they reported a wide range of substrate levels in subjects given high doses of cholecalciferol or those living in a sunny near-equatorial region. As shown in Fig. 43.3, high doses of cholecalciferol from supplements (as much as 6400 IU) shown in panel A or sun exposure in Hawaii in panel B affected serum 25(OH)D levels similarly. The relationship is not linear, indicating a controlled, saturable reaction. Unless cholecalciferol is provided in sufficient amounts, the production of 25(OH)D is limited by its substrate.

4 Renal Conversion to the Active Metabolite: Endocrine Pathway of 1,25-Dihydroxyvitamin D Synthesis and Use

There are two pathways for conversion of 25-hydroxyvitamin D to the active form of vitamin D, which is 1,25-dihydroxyvitamin D (Fig. 43.1). The first to be described is the better known and understood pathway, now referred to as the endocrine pathway. In the endocrine pathway 1,25-dihydroxyvitamin D [$1,25(OH)_2D$] is synthesized in one tissue but acts elsewhere, thus fulfilling the definition of a "hormone."

In proximal renal epithelial cells, 1,25-dihydroxyvitamin D is made when the enzyme 1-α hydroxylase (also called CYP27B1) is stimulated by parathyroid hormone (PTH) (which had previously been stimulated by a low circulating plasma calcium level) or by a fall in intracellular phosphate levels [6,20]. This is a tightly controlled endocrine system and considered to be the major contributor to the circulating levels of the active metabolite of vitamin D. Plasma levels of 1,25-dihydroxyvitamin D rise only when needed, as a result of synthesis in the kidney. The "need" for vitamin D action relates to its primary role (endocrine function) of providing the building blocks of bone—calcium and phosphate. A need for calcium, this is expressed as hypocalcemia, acts as the trigger for synthesis and release of PTH. An increase in PTH has three actions relating to calcium metabolism: (1) increased resorption of bone in order to provide immediate calcium to the blood; (2) more efficient reabsorption of calcium in the renal tubule, in order to conserve blood calcium; and (3) increased activity of the 1-hydroxylase in the proximal renal tubule to increase

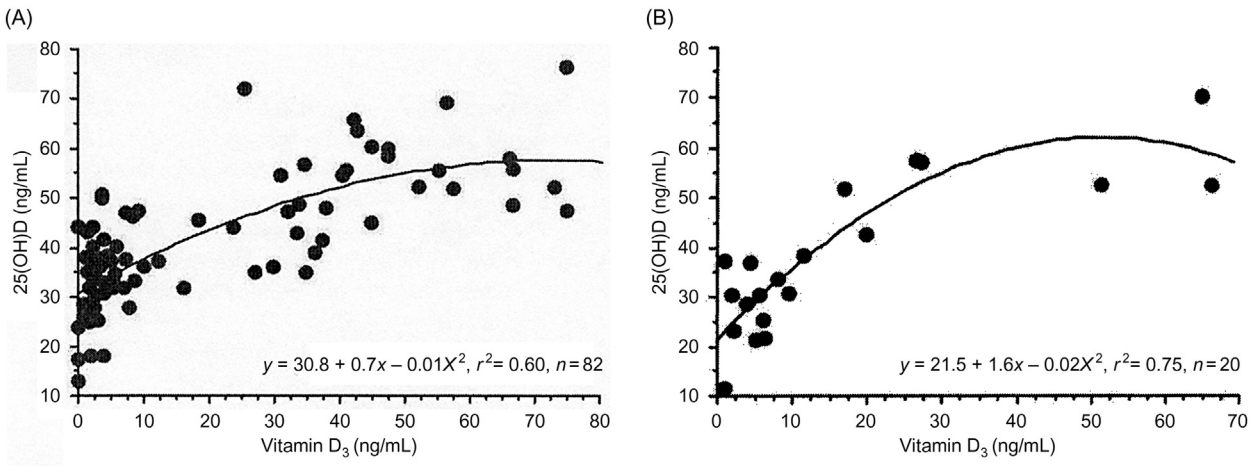

FIGURE 43.3 These graphs illustrate how either a high dose of cholecalciferol from a supplement of 150 μg (6000 IU) in panel A or sun exposure in Hawaii in panel B affect serum 25(OH)D. The authors of the study concluded that vitamin D status, as measured by serum 25(OH)D, is affected equally by diet or sun exposure. Further, unless cholecalciferol is provided in sufficient amounts, the production of 25(OH)D is limited by its substrate. *Reproduced with permission from B.W. Hollis, Circulating vitamin D3 and 25-hydroxyvitamin D in humans: an important tool to define adequate nutritional vitamin D status, J. Steroid. Biochem. Mol. Biol. 103 (2007) 631–634.*

levels of 1,25-dihydroxyvitamin D [21]. This third action, therefore, increases the concentration of 1,25-dihydroxyvitamin D in the blood that can travel to the small intestine and promote active absorption of calcium. The increase in plasma 1,25-dihydroxyvitamin D is also a way to provide this metabolite to other cells such as bone, parathyroid gland, and kidney, where it acts in concert with PTH to increase blood calcium levels. To complete the cycle, a rise in serum 1,25-dihydroxycholecalciferol acts to suppress PTH secretion. This type of regulation is a classical endocrine negative feedback mechanism.

Historically, the main action of circulating 1,25-dihydroxyvitamin D is to increase calcium (and phosphate) absorption [22]. This occurs in the duodenum, in enterocytes, where active calcium (and phosphate) absorption is promoted through genomic and nongenomic actions. The genomic mechanism of action of 1,25-dihydroxyvitamin D operates through receptors in the membrane of the cell nucleus, similar to that of other steroid hormones, while the nongenomic receptor is thought to operate through the cell's plasma membrane receptors. In either case, there is binding to a specific receptor called the vitamin D receptor (VDR) at the cell membrane of the enterocyte. In the nucleus, this complex, along with other coactivators, binds to a vitamin D response element (VDRE) to promote transcription of specific gene products. It has been long assumed that one protein product, a calcium binding protein called calbindin 9K, was required for translocation of calcium through the enterocyte during active transport of calcium (otherwise calcium absorption is passive, via paracellular channels) [5]. Studies with a knockout mouse having no gene for calbindin 9K showed that 1,25-dihydroxyvitamin D-mediated calcium absorption was normal in this mouse, thus leaving the exact gene products for active calcium translocation in doubt [23].

Without active absorption, the amount of calcium that can be absorbed is limited to about 15% of calcium intake which is paracellular (passive) absorption [24]. The effectiveness of passive absorption is dependent on the lumen concentration of calcium. When vitamin D status is improved, calcium absorption rises but eventually reaches a threshold level of about 30% in normal healthy adults who have no urgent need for calcium. In growth and pregnancy, calcium absorption can rise to levels of 80%, but only if vitamin D status is adequate; hormones, such as growth hormone and prolactin (respectively), are important for this high absorption value [3,5].

A second important action of circulating 1,25-dihydroxyvitamin D is to promote synthesis of mature osteoclasts [6]. Here, 1,25-dihydroxyvitamin D stimulates the osteoblasts to synthesize a specific receptor ligand, known as RANKL (receptor activator of the nuclear factor kappa-B ligand, abbreviated as NF-κB). These osteoblasts have the VDR, and the action of 1,25-dihydroxyvitamin D is genomic stimulating the RANKL protein synthesis. Once the RANKL is made, it exits the osteoblast and binds to a receptor (RANK) on preosteoclasts. This binding induces maturation of the cells into osteoclasts, which function to resorb bone. And the net result is release of calcium and phosphate into circulation. Thus, having been made in the kidney in response to a need for calcium or phosphate, 1,25-dihydroxyvitamin D's actions in the intestine and bone result in an increase of blood levels of both calcium and phosphorus.

5 Extra-Renal Conversion to the Active Metabolite: Paracrine/Autocrine Pathway of 1,25-Dihydroxyvitamin D Synthesis and Use

The other pathway for conversion of 25(OH)D to $1,25(OH)_2D$ is called the paracrine/autocrine pathway because these terms denote that the molecule is used locally in adjacent cells or used in the same cell in which it is made, respectively (Fig. 43.1). Less is known about this, but researchers found the 1-hydroxylase enzyme in many tissues other than the renal proximal tubule, and those working in cell culture systems were able to measure $1,25(OH)_2D$ production [25]. Further, the VDR has been identified in most tissues including brain, prostate, breast, gonads, colon, pancreas, heart, monocytes, and lymphocytes. Extra-renal $1,25(OH)_2D$ production is not regulated by serum calcium, phosphate, PTH, or other hormones such as fibroblast growth factor (FGF-23) released from bone [6]. Many actions have been proposed, but the modulation of immune function through actions on lymphocytes and macrophages is the most developed and seemingly has the greatest impact on chronic disease risk.

Cells of the immune system can produce $1,25(OH)_2D$ that acts in a paracrine manner to modulate the immune response [25–27]. For example, macrophages are an important part of the host defense against a variety of pathogenic organisms, including *Mycobacterium tuberculosis*, the etiologic agent of tuberculosis. Macrophages are activated to kill such pathogens because pattern-recognition receptors, such as toll-like receptor (TLR) 1 and 2, recognize molecular patterns associated with microorganisms that are not found in mammalian cells. In the case of tuberculosis, macrophages are activated via recognition of *M. tuberculosis* lipopeptides by a TLR2/1 dimer. This interaction triggers antibacterial mechanisms of the macrophage, including the production of the antibacterial peptide cathelicidin, which can kill susceptible pathogens [26]. Cathelicidin transcription is enhanced by $1,25(OH)_2D$ acting via the VDR to increase gene transcription. This TLR2/1 interaction also stimulates the expression of the 1-hydroxylase enzyme which catalyzes $1,25(OH)_2D$ synthesis, suggesting that vitamin D deficiency may impair protection against tuberculosis by

limiting $1,25(OH)_2D$ production by macrophages, although human intervention trials are needed to test this hypothesis [26]. In addition to vitamin D stimulation of antimicrobial peptides, it functions in the modulation of proinflammatory and antiinflammatory cytokines and chemokines secreted in response to bacterial endotoxins, and viral and parasitic agents [25].

Vitamin D also regulates aspects of adaptive immunity. Adaptive immunity refers to the acquired immune response that develops in response to infections and vaccinations. This process not only disables infectious agents but also provides "memory" that subsequently prevents a person from getting most infections a second time. T lymphocytes are an important component of adaptive immunity functioning as helper cells which promote antibody production by B cells. T lymphocytes (natural killer cells) also act as effector cells to kill virus-infected host cells or to promote macrophage-mediated responses, such as the one described in the previous paragraph against *M. tuberculosis*. Another function of 1,25-dihydroxyvitamin D is to act as a modulator of the adaptive immune system, thus having a role in infectious and autoimmune disease in addition to its well-characterized function in innate immune response [25,27].

6 Mechanism of Action of the Active Metabolite

The active form of vitamin D, 1,25-dihydroxyvitamin D ($1,25(OH)_2$ D), whether synthesized in the kidneys and released to the circulation or originating from extra-renal 1-alpha-hydroxylase activity is thought to operate through two distinctly different mechanisms: (1) the classical genomic action and (2) the rapid membrane initiated action or nongenomic action [28].

a Genomic Action

The classical genomic action of $1,25(OH)_2$ D involves the binding of this steroid hormone to its nuclear receptor which is a stereo-specific interaction. The vitamin D nuclear receptor is a member of the super family of steroid hormone nuclear receptors. Ligand-nuclear receptor binding initiates the cell's transcriptional machinery to regulate gene transcription. In the currently accepted model of $1,25(OH)_2D$ and VDR_{nuc} activation of gene transcription, when the ligand or 1,25(OH)D binds the nuclear receptor, it forms a heterodimer with the nuclear retinoid-X receptor. This heterodimer−DNA complex then interacts with the appropriate VDRE on the promoter genes of specific target cells which are up- or downregulated. The heterodimer−DNA complex then recruits necessary coactivator proteins to form a competent transcriptional complex capable of modulating mRNA production [28,29]. The discovery of the presence of the VDR_{nuc} in over 30 human tissues led to our new understanding of vitamin D's role in the regulation of B and T lymphocytes of the immune system, hair follicles, muscle, adipose tissue, bone marrow, and cancer cells through the mechanism of nuclear VDR regulation of gene transcription [29].

b Nongenomic Action

There are $1,25(OH)_2D$-mediated responses that were observed to occur within minutes to an hour; these actions were considered too rapid to be explained by the nuclear VDR regulating gene transcription mechanism. Such rapid responses included secretion of insulin by pancreatic beta-cells, rapid migration of endothelial cells, Ca^{2+} influx in skeletal muscle cells as modulated by phospholipase C, protein kinase C and tyrosine kinase, and activation of mitogen-activated kinase to identify only a few [28,29]. $1,25(OH)_2D$ can rapidly activate signal transduction pathways in addition to activation of the slower classical genomic mechanism of gene transcriptional regulation. Studies show that $1,25(OH)_2D$ can rapidly activate intracellular signaling molecules [30]. The plasma membrane receptor, termed membrane-associated rapid response steroid binding protein, does not behave as traditional membrane spanning receptors and can be found in the endoplasmic reticulum or relocated in the nucleus [30]. Specific VDR called VDR_m have been identified within the plasma membrane caveolae in a variety of different cell types including: intestine, kidney, lungs, leukemia, and osteoblast-like cells [29−31]. The nongenomic mechanisms may be critical for immune responses [30]; however, many important questions remain to be resolved concerning membrane-initiated vitamin D action.

B Inactivation and Excretion of Vitamin D

The hydroxylases in vitamin D metabolism are cytochrome P450 proteins. Some of these enzymes have been described above. There is the enzyme CYP24A1 also called 25-hydroxyvitamin D_3-24-hydroxylase which is responsible for catalyzing the conversion of 25(OH) D_3 and $1,25(OH)_2D_3$ into 24-hydroxylated products including $1,24,25(OH)_3D_3$ and 24,25 $(OH)_2D_3$, respectively (Fig. 43.4) [20,32]. This enzyme plays an important role in preventing unwanted buildup of 1,25-dihydroxyvitamin D by inactivating its precursor by forming the metabolite $1,24,25(OH)_3D_3$ that is also called calcitroic acid. Similar to other steroid hormones, most vitamin D metabolites are conjugated with gluconate or sulfate and excreted into the bile. Recent studies have shown a correlation between CYP24A1 and several diseases. Although the relationship between extensive

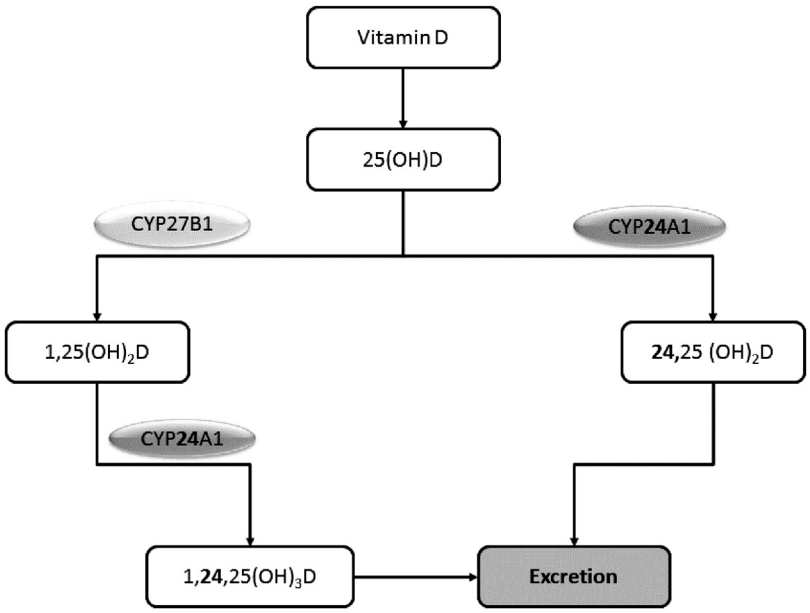

FIGURE 43.4 The pathway for inactivation of vitamin D involving conversion of either 25-hydroxyvitamin D [25(OH)D] or 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] by the enzyme CYP24. *From W.L. Miller, Genetic disorders of vitamin D biosynthesis and degradation, J. Steroid Biochem. Mol. Biol. 165 (2017) 101–108.*

accumulation of active vitamin D and idiopathic infantile hypercalcemia has been suspected for over 50 years, the actual cause of this vitamin D metabolism defect was not revealed until recently [32]. Now, the inactivating mutations of CYP24A1 are thought to be the cause of idiopathic infantile hypercalcemia. Further, the involvement of CYP24A1 in hypophosphatemia, chronic kidney diseases (CKDs), and hyperproliferative disorders (e.g., cancer, psoriasis) has encouraged scientists to develop CYP24A1 inhibitors and examine their effect in controlling vitamin D hypercatabolism [32].

III SOURCES OF VITAMIN D

A Food Sources of Cholecalciferol and Ergocalciferol

Vitamin D content in foods and supplements for either ergocalciferol or cholecalciferol are expressed as IU (international units) and in micrograms (μg), where 1 μg = 40 IU. Most food and supplement sources continue to use IU as the way to express content, so this convention is presented in this chapter. Data on food composition in Table 43.2 are divided into naturally occurring sources, fortified foods, and foods that have undergone bioaddition. There are only a few foods that naturally contain vitamin D as ergocalciferol or cholecalciferol [33] (Table 43.2), with fish having the greatest amount. In the wild, fish are part of a food chain that allows for concentration of vitamin D in the flesh of fatty fish (e.g., salmon, sardines, mackerel), while in lean fish, vitamin D is concentrated in liver (e.g., cod liver oil). With fish farming, levels of cholecalciferol in fish raised in aquaculture cannot be assumed to be equivalent to wild species. Further, it is now recognized that levels in fish are much more variable than previously recognized [34]; therefore, caution must be taken in using composition data. Other concerns about over-consumption of fish or fish oils include consumption of too much mercury and vitamin A. The muscle (meat) or liver of land animals that are exposed to sunlight or have vitamin D in their feed may be a natural source of vitamin D. Eggs are either a natural source of vitamin D, or can have additional vitamin D with bioaddition where the vitamin D is added to chicken feed [35]. Some foods such as meat and eggs also contain 25(OH)D which adds to the vitamin D content. "Potency adjusted" levels of 25(OH)D are the measured 25(OH)D levels multiplied by five [36,37].

Fortification provides close to three-quarters of the food-derived intake of vitamin D as measured in NHANES 2003–06 [38]. Most of the foods shown in Table 43.2 are fortified with vitamin D_3. In accord with a 2010 FDA regulation, soy products and other plant-based milks can be fortified with vitamin D_2 only [39]. Such foods can appeal to vegetarians who may prefer to consume a plant-based form of vitamin D. The use of a patented yeast which synthesizes vitamin D_2 after exposure to UVB light was recently approved in the United States and Europe for making bread and other baked goods. According to a recent study, Vitamin D_2 from light

TABLE 43.2 Selected Common Food Sources of Vitamin D in the United States

Food	Source of Vitamin D	Vitamin D_3 IU/serving	Potency Adjusted 25(OH)D IU/serving
Naturally Occurring			
Salmon, canned, 85 g (3 ounces)	Naturally occurring but variable	396–649	
Farmed salmon, 100 g[d]	Reduced due to use of plant protein-based foods	6.18 μg	
Sun dried shiitake mushrooms, 36 g (¼ cup cooked)	Naturally occurring; exposed to sun (UVB)	110 (vitamin D_2)	
Pork, cooked[b]	Naturally occurring but variable due to feed and/or sun exposure	31	50
Egg, 1 whole	Regular feed	40 (29–103[a])	88–106[a]
Fortified			
Fluid cow's milk, 250 mL (1 cup)	Fortification	100	
Orange juice with added calcium and vitamin D, 125 mL (1/2 cup)	Fortification of selected brands	50	
Plant-based milks such as soy or almond, 250 mL (1 cup)[a]	Fortification of selected brands	60–120 (vitamin D_2)	
Yogurt 170 g	Fortification of selected brands	60–200	
Cheese slice, 16 g	Fortification of selected brands	60	
Margarine, 10 g (2 teaspoons)	Fortification of selected brands	30–200	
Cereals, ready-to-eat, 1 serving (1/2 to ¾ cup)	Fortification of selected brands	40–100	
Bread, 100 g	Fortification of selected brands	90	
Bioaddition			
Portobello mushrooms, 85 g	Irradiated with UVB	400 as vitamin D_2	
Bread, 100 g	Use of irradiated yeast to make bread	400[c]	
Egg, whole[a]	Feed enhanced with vitamin D	280	180

irradiated yeast used to make bread, however, may not be available to humans [40]. Plant foods such as mushrooms which when briefly exposed to UVB produce significant amounts of vitamin D_2 and these foods have been shown to be bioavailable [41].

B Supplement Sources of Vitamin D

Supplements provide another source of intake. Vitamin D (i.e., cholecalciferol or ergocalciferol) is usually (but not always) found in multivitamin preparations at 400–1000 IU

TABLE 43.3 Vitamin D and Related Compounds Found in Some Commonly Used Vitamin D Medications in the United States

Brand Name or Type of Product	Related Compound	Dosage Forms	
Vitamin D (Supplemental)[a]			
Multivitamin	Cholecalciferol	Tablet	400−1000 IU
Calcium supplement with vitamin D	Cholecalciferol	Tablet	200−400 IU per 500−600 mg calcium
Vitamin D supplement	Cholecalciferol	Tablet, drops	400, 1000, 2000, 5000 IU
Vitamin D (Therapeutic)[b]			
Many brands	Ergocalciferol	Capsule	50,000 IU
Vitamin D in Other Medications			
Fosamax plus D	Cholecalciferol	Tablet	2800 IU weekly 5600 IU weekly
1,25-Dihydroxyvitamin D (Calcitriol)[b]			
Many brands	Calcitriol	Capsule Solution	0.25 and 0.5 μg 1 μg/mL

[a]*Available over-the-counter in North America.*
[b]*Requires a prescription from a physician in the United States.*

per tablet. In addition to multivitamins, there are single vitamin D supplements largely available as cholecalciferol in 400 IU, 1000 IU, 2000 IU, and 5000 IU dosages. Some calcium supplements contain various amounts of cholecalciferol or ergocalciferol, in the range 200−400 IU. These supplements are intended mainly for maintenance of status, and not for repletion of vitamin D deficiency. For that purpose, higher dosage forms are available through prescription, denoted in Table 43.3 as therapeutic preparations. Not shown are cod and other fish liver oil capsules; these are available over-the-counter but their use is discouraged due to high levels of preformed vitamin A (retinol) relative to levels of vitamin D [42]. Vitamin D metabolites (primarily the active form 1,25-dihydroxyvitamin D) are available to treat clinical conditions, and these are also listed in Table 43.3.

The biological equivalency of the two forms of vitamin D, ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) in humans, has been challenged [14,17]. Both forms of dietary vitamin D are converted to their corresponding 25(OH)D form equally well. There is more rapid disappearance of $25(OH)D_2$ than $25(OH)D_3$, thus the former form of vitamin D is less effective in maintaining plasma 25(OH)D levels. However, this property makes ergocalciferol a safer form of the vitamin to use in higher doses on a daily basis. Evidence of the safe use of vitamin D_2 in postmenopausal women has been reported [43]. Reports of toxicity of vitamin D_3 supplement use have been attributed to mistakes in the formulation and manufacturing of the dietary supplements that resulted in extreme intakes exceeding 50,000 IU daily [44]. To date, normal daily use of vitamin D_3 supplements within the DRI guidelines has not resulted in vitamin D intoxication.

C Dietary Intake of Vitamin D in the American Population

Vitamin D intakes of Americans became available with analysis of NHANES III data, and subsequent surveys have been used to estimate vitamin D intakes. Estimated daily mean intakes of vitamin D from food and supplements over age and gender groups from NHANES 2011−12 [45] are shown in Table 43.4. Data shown are mean intake from food, and mean intake from food and supplements. For all age/sex groups, intake from food ranged from 148 to 264 IU [45] and studies have shown that most of food-derived vitamin D in the United States is from fortified foods [38]. There were no apparent differences in intake among racial-ethnic groups. Supplement use contributed to vitamin D intake in those using them, adding on average more than 1000 IU for supplement users. The highest use was in women over the age of 60 years. When considering total intakes of non-supplement users, the mean intake of each age group did not meet the current DRI recommendation in any age group. As many individuals do not consume supplements, it is clear from these data [45] that the current vitamin D

TABLE 43.4 Estimated Mean Usual Daily Intake of Vitamin D from Food and from Food and Supplements, NHANES 2011–12

Sex	Age (Years)	Intake from Food (IU)	Intake from Food by Supplement Users (IU)	Intake from Supplements (IU)
Male and female	2–5	264	252	344
Male and female	6–11	240	240	424
Male and female	12–19	228	256	608
Male	20–39	208	304	824
Male	40–59	228	260	1412
Male	≥60	216	200	1292
Female	20–39	156	164	1080
Female	40–59	148	140	1392
Female	≥60	176	172	1980
All	≥2	200	232	1272

content of the U.S. food supply does not provide enough vitamin D for most Americans to meet the 2011 RDAs of 600 IU (800 IU for adults over 70 years) [4].

For those individuals with inadequate sun exposure, fortification is thought to be the most effective way to increase vitamin D intakes of the population. Many believe that mandatory fortification of commonly consumed food staples would ensure an even distribution of intakes compared to the current system of discretionary fortification of a variety of food categories. Table 43.5 shows the comparison of two countries, one with mandatory fortification (Canada) and one with only a small number of food products with discretionary fortification (United Kingdom). Both countries share similar latitudes, similar dietary habits and distribution of people of European and non-European ancestry. In Canada, milk and margarine are required by law to be fortified, and this has produced an intake of close to 200 IU for most age and sex groups [46]. In contrast, the United Kingdom had no mandatory fortification at the time of the National Diet and Nutrition Survey conducted 2008–12 [47]. Table 43.5 shows that the vitamin D intakes in the United Kingdom are half that of Canadians. The impact of mandatory fortification is also evident in the lower prevalence of Canadians with 25(OH)D levels in the "deficiency" range (9.1%) [48] compared to the United Kingdom where prevalence of vitamin D deficiency is 24% [47].

TABLE 43.5 Effect of Mandatory Food Fortification on Intakes from Food and Vitamin D Status: Canada Versus United Kingdom

Subject	United Kingdom		Canada	
Age group	No fortification		Mandatory fortification	
	Male	Female	Male	Female
Children	80 IU	76 IU	248 IU	
Adolescents	96 IU	76 IU	292 IU	216 IU
Adults	124 IU	104 IU	232 IU	204 IU
Older adults	156 IU	116 IU	268 IU	244 IU
Percent below 30 nmol/L				
Total population	24%		7.4%

D Sun Exposure as a Source of Vitamin D

Sunlight contributes UVB and UVA radiation, but only UVB permits cholecalciferol synthesis [49]. UVB includes the wavelength range of 280–315 nm, conversion of 7-dehydrocholsterol to provitamin D_3 is optimal at 290–315 nm [5]. Exposure to sunlight can be quantified in erythemal doses, that is, the appearance of reddening of the skin. A minimal erythemal dose (1 MED) causes reddening, and further exposure results in more severe sun burning. Tanning (the induction of the synthesis of the pigment melanin in the skin) also occurs but takes longer to manifest and occurs with UVA as well as UVB exposure [50].

Many environmental factors affect synthesis of cholecalciferol, as listed in Table 43.6. One that impacts a large portion of the global population is latitude. The United States provides a good example of the influence of latitude as it stretches from 20°N (Puerto Rico) to over 70°N (Alaska). It is important to recognize how latitude can impact vitamin D status. As illustrated in Fig. 43.2, there is a seasonal variation in circulating 25(OH)D at latitudes close to 50°N [15] where presumably casual exposure to sun in the late spring, summer, and early autumn has resulted in serum 25(OH)D that, on average, approaches 75 nmol/L. This is the level recommended by many researchers [6], as well as the Endocrine Society [51]. Fig. 43.2 illustrates the dramatic fall of serum 25(OH)D in winter to nearly half the concentration experienced in the spring and summer [15], presumably because dietary intake was not sufficient to provide enough vitamin D in the absence of UVB.

Studies have shown that one full body (i.e., almost completely naked) MED (1 MED) will synthesize as much as 20,000 IU of vitamin D_3 [49]. This intensity of sun exposure is not recommended due to concerns about skin phototoxicity. However, an exposure less than 1 MED will provide maximal cholecalciferol production [50]. Accordingly, one can calculate that an exposure of one-fourth of an MED to 25% of body surface is sufficient for vitamin D_3 production of 1000 IU [7]. To achieve 25% of body surface, one needs more than hands and face exposed, but also exposure of arms and legs; truncal exposure is also recommended [51]. Indeed, the "rule of nines" calculation for body surface area [52] indicates that to achieve exposure of 25% of body surface area, one would expose both lower arms (9%) and lower legs (18%). Exposure of the head could contribute to an additional 9% of surface area. The time to achieve this exposure will vary greatly by season, latitude, skin pigmentation, and use of sun-blocking lotions or cosmetics.

One can measure skin type and the resulting amount of melanin that is produced in response to UV exposure. The Fitzpatrick skin type (also called skin phototypes [50,52]) was originally developed in the United States in 1975 to facilitate UV dosage for psoriasis photochemotherapy in subjects with "white" skin, and characterized for skin types (I through IV); it was later expanded to categories V and VI, as shown in Table 43.7 [53]. These skin types vary in ability to burn and tan. The time to burn (i.e., 1 MED) reflects melanin production, and is an approximate indicator of the relative dose of UVB needed to synthesize equivalent amount of previtamin D_3 [54]. As shown in Table 43.7, skin type I needs only 40% of the time for 1 MED compared to skin type III, and skin type VI needs four times the exposure time of skin type III. The times given for ¼ MED are estimates based on exposure at 42°N (i.e., Boston), at noon, in summer, and

TABLE 43.6 Reasons for Low Sun (UVB) Exposure and Inability to Synthesize Cholecalciferol

Factor	Notes
Angle of sun in winter (November to March, inclusive at latitude 45°) not sufficient UVB	No synthesis
Being indoors and/or behind glass windows	No synthesis
Clothing, especially head-to-toe for cultural or environmental reasons	No synthesis if fabric blocks UVB. Some cloth is loosely woven and does permit UVB to penetrate
Darkly pigmented skin	More sun exposure time is needed than person with little pigment
Impairment of skin synthesis of vitamin D with age	More sun exposure time needed compared to younger person; amount made limited by substrate availability
Sunscreen use (SPF 8 or greater)	Sun protection factor (SPF) indicates amount of UV blocked: SPF blocks at 1/SPF. For example, SPF of 8 would allow 1/8 (~12%) of UV to penetrate

TABLE 43.7 Categorization of Skin Type Using a Traditional Dermatological System (Fitzpatrick Skin Type) and Association of These Categories with Vitamin D Synthetic Capacity of Skin

Fitzpatrick Skin Type	Skin Color	Common Geographic Origins	Skin Response to Sun Exposure[a]	Relative MED[b]	Approximate Time for ¼ MED[c]
I	White; (blue eyes, freckled, albino)	Northern European	Always burn, never tan	0.38	4 min
II	White (blond hair, blue or green eyes)	Northern European	Burn slightly, then tan slightly	0.75	6 min
III	White (brown eyes, darker complexion)	Southern European, Middle East	Rarely burn, tan moderately	1.0	7 min
IV	White ("Mediterranean")		Never burn, tan darkly	1.3	10 min
V	Brown	Asian, Native American, Pacific Islander	Never burn, tan darkly; Oriental or Hispanic skin	2.0	13 min
VI	Black	African	Never burn, tan darkly; Black skin	3.8	21 min

[a]*Characteristics of previously unexposed skin after 30 min direct exposure to sun.*
[b]*Relative MED dose of UVB exposure.*
[c]*Time estimated for sun exposure at 10:30 a.m. on June 21, to reach ¼ MED at 11.5°N, 29°N, and 42.5°N (values for 62.5°N would be double) from Webb and Engelsen reference [7].*
Sources: From B.A. Gilchrest, Sun protection and vitamin D: three dimensions of obfuscation, J. Steroid Biochem. Mol. Biol. 103 (2007) 655–663; M.F. Holick, M. Jenkins, The UV Advantage, Simon & Schuster, New York, NY, 2003; T.B. Fitzpatrick, The validity and practicality of sun-reactive skin types I through VI, Arch. Dermatol. 124 (1988) 869–871.

may be used to calculate the exposure time to reach a vitamin D dose of 1000 IU when 25% of body surface is exposed [7]. Other factors related to timing, such as age, have not been considered.

Thus, there is no single answer to how much sun exposure is needed to achieve and maintain an adequate vitamin D status. Some dermatologists have advocated for no sun exposure [50]; however, the World Health Organization Report [55] on solar UV radiation indicates that it is not appropriate to strive for zero sun exposure as this would create a huge burden of skeletal disease from vitamin D deficiency. Nonetheless, it is important to avoid excess exposure since this has been linked with skin cancers and skin photoaging [52]. A rational scheme to achieve skin synthesis of cholecalciferol without significant risk of overexposure has been published [7]. While this subject remains a source of considerable controversy, the public now has access to information that will allow weighing of personal risk and benefits of sun exposure. Sensible sun exposure is most important in growing children. Estimates of how much vitamin D_3 young Americans produce from their everyday outdoor UV exposure in the north (45°N) and south (35°N) for each season were reported [56]. The resulting estimates suggest that most American children are not getting enough sun exposure to meet either minimal ($\sim$600 IU/day) or optimal ($>$2000 IU/day) vitamin D requirements [56].

IV VITAMIN D NUTRITIONAL STATUS ASSESSMENT AND RELATION TO DISEASE RISK

A Indicators of Vitamin D Status

1 The Main Indicator of Vitamin D Status Is 25-Hydroxyvitamin D

Vitamin D status is evaluated by measuring the circulating levels of 25(OH)D, the level of which is related to the combined contributions of diet (including supplements) and skin synthesis. Measuring cholecalciferol and ergocalciferol is technically difficult and will only provide information on recent exposure (within the past 72 hours or less) [49]. In contrast, cholecalciferol and ergocalciferol are stored in fatty tissues (adipose, liver, muscle), and possibly can be made available for conversion to 25(OH)D when needed. However, these stores cannot maintain 25(OH)D levels through a long period of dietary or UVB deprivation [13]. There is some uncertainty as to whether storage of cholecalciferol in adipose is available to the body. Studies show that in obese individuals, serum levels of cholecalciferol, ergocalciferol, and 25(OH)D are lower than in nonobese individuals [57,58]. This may relate to cholecalciferol and ergocalciferol being sequestered in adipose without an ability to be released.

Measurement of 25(OH)D provides the best assessment of vitamin D "stores," that is, the form of vitamin D available to tissues for synthesis of 1,25-dihydroxyvitamin D by endocrine or paracrine/autocrine pathways (Fig. 43.1). This is because 25(OH)D, although not the active form of vitamin D, rises with intake and/or sun exposure, and declines with combined sun avoidance and low intake. The measurement units are nmol/L or ng/mL, and the conversion factor between these different units is the following: 1 ng/mL = 2.5 nmol/L. Measurement of 1,25-dihydroxyvitamin D, the active vitamin D metabolite, is not the preferred indicator (biomarker) of vitamin D status but rather a reflection, primarily, of the need for calcium and phosphate [5], as described earlier. Further, the amount of 1,25-dihydroxyvitamin D, in blood is influenced by renal function and other dietary and hormonal factors.

2 Classification of Vitamin D Status by Serum 25(OH)D

Until about 10 years ago [6] there was a lack of understanding that tissues needed a steady supply of 25(OH)D as a precursor for cellular synthesis of 1,25(OH)2D that functioned in the paracrine/autocrine pathways. Moreover, there was a lack of appreciation that vitamin D deficiency (low serum levels of 25(OH)D) may contribute to the risk of developing many chronic conditions beyond rickets and osteomalacia. For the longest time, the cut-off serum concentration determining vitamin D deficiency has been serum 25(OH)D below 25 or 30 nmol/L, as below this value, the patient has or will soon experience rickets (in children) or osteomalacia (in adults) [49]. New data over the past decade indicates other disease states may be affected but generally when 25(OH)D is much higher than that needed to prevent rickets and osteomalacia [51].

There is a clear disagreement as to what the normal range of 25(OH)D should be to reflect adequate vitamin D status. Table 43.8 outlines the various cut-off points that have been used in the two most recent guidelines for vitamin D [4,51], highlighting disagreement in the definition of "deficient" and "insufficient." In the 2011 DRI report on setting (for the first time) Estimated Average requirement (EAR), and RDA levels, as well as revising Tolerable Upper-Intake Level (UL) values for vitamin D [4], the level of 25(OH)D that represented adequacy for almost everyone (i.e., the RDA) was defined as a serum level of 25(OH)D at or above 50 nmol/L, as this level was deemed to provide for maximal calcium absorption, minimal risk of rickets in children, reduced fracture risk in adults, and minimal risk of osteomalacia in adults. The level of 30 nmol/L was set as the cutoff for deficiency. The level of 40 nmol/L was set as the EAR which should represent sufficiency for 50% of the population. In strong opposition to this cut-off value for sufficiency, the Endocrine Society has set sufficiency at 75 nmol/L based on suppression of PTH levels which reflects the amount required for calcium absorption and they defined "deficiency" at <50 nmol/L [51].

3 Issues Related to 25-Hydroxyvitamin D Measurement

There are many methods for determining circulating levels of 25(OH)D. A radioimmunoassay (RIA) and a competitive protein binding assay have been employed clinically, as well as an enzyme immunoassay [59].

TABLE 43.8 Classification of Vitamin D Status by Serum 25(OH)D[a] and Disease Risk

Serum 25(OH)D	Category
<20 nmol/L	Vitamin D deficiency
<30 nmol/L	At risk for rickets or osteomalacia
<50 nmol/L	Not at risk for clinical rickets or osteomalacia
30–75 nmol/L	Vitamin D insufficiency defined for at-risk populations with chronic conditions
≥75 nmol/L	Vitamin D adequacy for at-risk populations
125–150 nmol/L	Level set by IOM as UL
250 nmol/L	Level of 25(OH)D when 10,000 IU is ingested chronically, and level where no adverse effects are detected. Potential for adverse effects above this level

[a]*25-hydroxyvitamin D; to convert nmol/L to ng/mL, divide by 2.5.*
Sources: From Institute of Medicine, Dietary Reference Intakes for Calcium Phosphorus, Magnesium, Vitamin D and Fluoride, National Academy Press, Washington, DC, 2011; M.F. Holick, N.C. Binkley, H.A. Bischoff-Ferrari, C.M. Gordon, D.A. Hanley, R.P. Heaney, M.H. Murad, C.M. Weaver, Evaluation, treatment, and prevention of vitamin D deficiency: an Endocrine Society Clinical Practice Guideline, J. Clin. Endocrinol. Metab. 96 (2011) 1911–1930.

Combination Liquid Chromatography-Mass Spectrometry (LC-MS) is now being used for national survey data, and older data are being "adjusted" to this standard methodology to allow for comparison between surveys. The NHANES data shown below were analyzed using LC-MS as were data in Table 43.5. All of the widely used clinical laboratory methods perform reasonably well in identifying clinically important low serum 25(OH)D. It is important to mention that all clinical laboratories performing 25(OH)D testing should take part in external quality assessment programs; particularly because some of the commercially available assays may fail to recognize and accurately measure $25(OH)D_2$. Measurement of blood 25(OH)D is best performed on fasting serum sample as lipid-rich plasma can interfere with the assay so high-fat meals should be avoided at least 12 hours before the blood draw. Otherwise, blood may be taken at any time of day since there is no observed pronounced circadian variation in serum 25(OH)D. As previously indicated, results are reported as nmol/L or ng/mL. The conversion factor between these different units is the following: 1 ng/mL = 2.5 nmol/L.

A "new" metabolite of vitamin D was first detected in the blood of newborns and initially was measured as 25(OH)D [60]. This molecule, 3-epi-$25(OH)D_3$ arises in vivo from ingested cholecalciferol but is not a precursor of the active form (calcitriol) and thus does not have "vitamin D activity." In adults it represents about 5% of 25(OH)D levels [58]; however, in infants it can be much higher, and therefore overestimate vitamin D status [60].

When repleting deficient patients, one expects the serum 25(OH)D response to high dose supplementation with cholecalciferol or ergocalciferol to reach a plateau after 3 months of continuous treatment [15]. Therefore, if a patient's response to vitamin D supplements is to be monitored by taking repeated blood measures over time, samples should be checked no sooner than 3 months after treatment initiation. Monitoring of routine supplementation use is not necessary, but in situations where severe deficiency is being treated or there is reason to believe the patient may have impaired intestinal absorption, assessment of serum 25(OH)D would indicate the effectiveness of therapy.

4 Vitamin D Status of Americans: NHANES Data

The 2007–10 NHANES survey data provide current vitamin D status of Americans [58]. Mean levels of 25(OH)D are shown in Table 43.9. As well, the prevalence below

TABLE 43.9 Mean Serum Levels of 25(OH)D[a] and Prevalence of Vitamin D Deficiency (<30 nmol/L), of Not Meeting EAR (<40 nmol/L), of Insufficiency (< 50 nmol/L), of Less Than Optimal (<75 nmol/L), and of Exceeding UL (>125 nmol/L), NHANES 2007–10

Group	Age Group (Years)	nmol/L	% <30 nmol/L	% <40 nmol/L	% <50 nmol/L	% <75 nmol/L	% >125 nmol/L

[a] *25-hydroxyvitamin D. To convert nmol/L to ng/ml, divide by 2.5.*
[b] *Values are for ages 1–8 years.*
NHB, non-Hispanic Black; NHW, non-Hispanic White; EAR, Estimated Average Requirement; UL, Upper Level; M&F, male and female.
Source: From L.R. Schleicher, M.R. Sternberg, A.C. Looker, E.A. Yetley, D.A. Lacher, C.T. Sempos, C.L. Taylor, R.A. Durazo-Arvizu, K.L. Maw, M. Chaudhary-Webb, C.L. Johnson, C.M. Pfeiffer, National estimates of serum total 25-hydroxyvitamin D and metabolite concentrations measured by liquid chromatography–tandem mass spectrometry in the US population during 2007–2010, J. Nutr. 146 (2016) 1051–1061.

the various cutoffs for 25(OH)D levels are given: percent below 30 nmol/L defines risk of vitamin D deficiency; percent below 40 nmol/L is prevalence below EAR; percent below 50 nmol/L is prevalence of insufficiency according to Institute of Medicine (IOM) [4]; percent below 75 nmol/L is less than optimal ("deficiency" according to the Endocrine Society) [51]; and percent above 125 nmol/L is prevalence above the UL. In Table 43.9, for the total population at or over the age of 1 year, three-quarters were sufficient (i.e., >50 nmol/L), and a small percentage (~6%) was deficient (at-risk for rickets and osteoporosis). More importantly, these prevalences were not distributed equally across racial/ethnic groups. Non-Hispanic Blacks show high risk for deficiency which is reflected in prevalence of rickets in this group (see Section IV.B.1, Nutritional Rickets). Children ages 1−11 years showed the least insufficiency. There were few differences between the other age groups. Interestingly, older adults were no worse off than younger adults, as supplement use in older adults was higher [58].

As these NHANES data were collected in the northern states during sunny seasons and the southern states during winter months, the 25(OH)D data represent optimal levels of sun exposure opportunities for participants. Even so, winter season showed a 12 nmol/L lower 25(OH)D level; and latitude also a significant factor, with "northern" being 10 nmol/L lower than "southern." Other significant predictors of serum 25(OH)D concentration were: dietary intake of vitamin D (<200 IU vs ≥200 IU); supplement intake (<400 IU vs ≥400 IU); infection/inflammation (C-reactive protein <10 mg/L vs ≥10 mg/L); and body weight (higher vs lower BMI). Self-reported sun protection behavior did not show any significance.

5 Predicting 25(OH)D Levels

Serum 25(OH)D is influenced by exposure of skin to UVB and by dietary intakes of ergocalciferol or cholecalciferol. From its use in many research trials as well as in dosing studies [15], it can be estimated that 40 IU (1 μg) of cholecalciferol daily raises serum 25(OH)D by 2 nmol/L at basal levels, that is, in persons having serum 25(OH)D less than 50 nmol/L [61]. Once past this level, 40 IU (1 μg) will raise 25(OH)D by 1 nmol/L [62]. Sun exposure, as described earlier, will also impact on serum levels of 25(OH)D. Effects of dietary vitamin D and skin synthesis of cholecalciferol are additive; both contribute to serum total 25(OH)D [13]. Thus, it should be possible to predict vitamin D status in light-skinned individuals. For example, if a background of moderate sun exposure during the summer achieves a serum 25(OH)D of 50 nmol/L, then a further 1000 IU (25 μg) per day of dietary cholecalciferol would be needed to reach a serum 25 (OH)D level of 75 nmol/L.

Most of the studies determining dietary or solar contributions to circulating 25(OH)D have been conducted in light-skinned subjects. Our current understanding of dietary intakes needed to raise serum 25(OH)D is lacking for African Americans and others with darker skin, but evidence points to significant differences that should be taken into consideration when setting dietary requirements.

6 Other Biomarkers of Vitamin Deficiency

While it is well established that serum 25(OH)D is the best static indicator of vitamin D status, functional indicators provide information on how the deficiency/insufficiency is impacting on the health of the person. They also confirm that a deficiency exists, and may confer additional information about the need to monitor the efficacy of corrective interventions. The most common responsive functional indicator examined to date is the suppression of secondary hyperparathyroidism, based on the endocrine function of 1,25-dihydroxyvitamin D in providing enough calcium through active intestinal absorption to suppress PTH levels that were raised with hypocalcemia [63]. Performance indicators such as the "get up and go" test vary in proportion to serum 25(OH)D status; they reflect muscle strength and balance that are negatively affected in vitamin D insufficiency [64]. Pain is also associated with vitamin D deficiency, and minimal trauma fractures may also occur. These alone are not specific enough for diagnosis; however, they should be triggers to seek vitamin D testing.

B Clinical Conditions Associated With Vitamin D Deficiency and Insufficiency

1 Nutritional Rickets

Vitamin D deficiency results in rickets and osteomalacia, the former name used to describe the clinical signs observed in children, while the latter name being those signs in adults. Nutritional rickets is defined as "a disorder of defective chondrocyte as differentiation and mineralization of the growth plate and defective osteoid mineralization" [65]. It is caused by vitamin D deficiency and/or low calcium intake in children. Its diagnosis is made based on history, physical examination, and biochemical testing, to be confirmed by radiographs [65]. As outlined in Table 43.10, the physical signs of rickets in children present as severe bone, muscle, respiratory, and overall growth problems. Rickets is a disabling disease that usually begins in early childhood, before the age of 18 months [5]. Once the child can stand, gravity worsens the bone changes so that the classic picture of inward or outward bowed legs is observed. In addition to rickets occurring in very young children, a second peak can occur between 5 and 15 years of age [66]. Once the

epiphysis has closed, the condition is called osteomalacia. In adolescent cases of rickets characterized in Denmark [68], the authors identified 112 patients with nutritional rickets (due to low vitamin D) of whom 74% were immigrants to Denmark.

Reporting of rickets is not required in most countries, therefore prevalence is difficult to estimate. However, "reemergence" of nutritional rickets was noticed in the United States in the 1990s. Weisberg et al. summarized 22 case reports of rickets in the United States published from 1986 to 2003 [67]. These cases were predominately in African-American children ages 4–54 months, of whom 96% were breast-fed. In Canada, a survey of pediatricians over 2 years found that there had been 104 cases of infant rickets primarily those living in northern Canada, 94% of whom were breast-fed with no vitamin D supplementation [68]. Studies such as these have alerted authorities such as the IOM [4] and the American Academy of Pediatrics [69] to the need for vitamin D supplementation in breast-fed infants as well as in infants not consuming sufficient fortified formula to supply 400 IU per day [69]. In 2016, global consensus recommendations on preventing rickets were published [65] that also endorse vitamin D supplementation of breast-fed infants at the level of 400 IU per day. Alternatively, some researchers have found that supplementing mothers throughout pregnancy [70] or through lactation [71] can result in breast milk having adequate vitamin D activity (as cholecalciferol and 25(OH)D) to meet the needs of the infant. The amount needed by lactating mothers, however, to give the equivalency of 400 IU per day to the infant is not known but has been estimated to be as high as 6400 IU [71].

The musculoskeletal effects of rickets arise primarily because of a lack of calcium and phosphate for bone mineralization and muscle function. With chronic severe vitamin D deficiency, there is malabsorption of calcium and phosphate with a resultant hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism. These lead to impaired growth plate development and bone mineralization [5]. Not all cases of rickets arise from a primary deficiency of cholecalciferol (or ergocalciferol). Although rare, there are many other types of rickets, as shown in Table 43.11, many of these rarer types are inherited forms of rickets due to mutations in important receptors (e.g., VDR) or enzymes (e.g., 1-hydroxylase) involved in vitamin D metabolism or action. Some forms of rickets are not due to problems with vitamin D, for example, calcium deficiency rickets, which is common in African countries.

2 Osteomalacia

Osteomalacia is characterized by muscle atrophy (i.e., a waddling gait), by bone pain, and by fatigue; these signs are also seen in rickets [5]. There are drugs which cause osteomalacia. The most common drug-induced osteomalacia is due to anticonvulsant therapy, particularly phenytoin, barbiturate derivatives, and carbamazepine. Although the exact mechanisms require further study, it is thought that these drugs result in greater inactivation of 1,25-dihydroxyvitamin D, as well as reducing 25(OH)D, by inducing the renal enzyme 24-hydroxylase [32].

The diagnosis of osteomalacia is often missed, even when bone pain and muscle weakness are present [72]. An examination using iliac crest biopsies at autopsy from otherwise healthy male and female individuals (primarily accident victims) were quantified for indices of osteomalacia and related to serum 25(OH)D [73]. In subjects

TABLE 43.11 Types and Treatment of Rickets

Type of Rickets	Metabolic Abnormality Mechanism	Treatment
Vitamin D dependent	Insufficient cholecalciferol production from UVB exposure and lack of dietary cholecalciferol or ergocalciferol	Supplemental cholecalciferol or ergocalciferol or sun exposure (with appropriate UVB); aggressive therapy needed initially
Calcium-deficiency rickets	Low calcium intake	Provide adequate calcium and cholecalciferol or ergocalciferol
Fat malabsorption (e.g., cystic fibrosis)	Insufficient cholecalciferol production from UVB exposure and lack of dietary cholecalciferol or ergocalciferol	Subcutaneous or intramuscular injections of cholecalciferol recommended
Hereditary vitamin D-dependent rickets Type 1	Inactive or absent renal 1-hydroxylase enzyme	Provide 1,25-dihydroxyvitamin D (or 1-hydroxyvitamin D)
Hereditary vitamin D-dependent rickets Type 2	Mutations in VDR prevent normal actions of 1,25-dihydroxyvitamin D	Respond to high doses of either cholecalciferol or 1,25-dihydroxyvitamin D
Hereditary vitamin D-dependent rickets Type 3	Abnormal hormone response element binding protein	Respond to high doses of either cholecalciferol or 1,25-dihydroxyvitamin D
Hypophosphatemic rickets	Phosphatemia (acquired and inherited) and decreased 1-hydroxylase enzyme	Intravenous phosphate; remove tumor
Tumor-induced osteomalacia	Tumor secretes phosphate factor that causes phosphatemia (acquired and inherited) and decreased 1-hydroxylase enzyme

where 25(OH)D concentrations were below 75 nmol/L, over one-third experienced mineralization defects, that is, pathological increase in osteoid, while no defects were observed in individuals with serum 25(OH)D exceeding 75 nmol/L. Osteomalacia may be misdiagnosed as osteoporosis, but a rise in serum alkaline phosphatase is seen only in the former condition [72]. Osteomalacia in younger women when the pelvis is severely malformed can cause cranio-pelvic disproportion, obstructed labor, and need for Cesarean section in some parts of the world [74].

3 Osteoporosis

The "classic" vitamin D deficiency diseases are rickets and osteomalacia; however, it is now evident that some chronic diseases appear to have a sun-exposure etiology. In the early 2000s, it was recognized that other health outcomes were affected by vitamin D status [6]. A long list of diseases and health disorders has been under investigation ever since, including osteoporosis (Table 43.12). The mild, secondary hyperparathyroidism that occurs with vitamin D insufficiency (i.e., levels of 25(OH)D below 75 nmol/L) may cause increased bone turnover and bone loss—a clinical picture compatible with osteoporosis [75]. Vitamin D insufficiency is very commonly found in patients with osteoporosis and contributes to the clinical presentation of osteoporosis (low bone density, fractures, falls), as well as the variety of conditions that have been found to have a higher incidence when associated with insufficient vitamin D. Thus vitamin D insufficiency or deficiency should be considered in any patient with osteoporosis. Even after osteoporosis treatment has been initiated, a recent survey of patients attending osteoporosis clinics found approximately 50% of the patients had suboptimal serum 25(OH)D levels. Vitamin D insufficiency or deficiency should always be considered in patients with osteoporosis who do not appear to be responding to therapy (i.e., continuing to lose bone density, or continuing to suffer fragility fractures) [75].

Several pathological conditions contribute to secondary vitamin D deficiency that may lead to osteoporosis or osteomalacia. These include gastrointestinal disease, kidney disease, and drug-induced deficiency. Examples of the latter are shown in Table 43.13. Several common gastrointestinal disorders result in malabsorption [51], resulting in incomplete or absence of absorption of cholecalciferol/ergocalciferol. These include celiac disease, inflammatory bowel disease, gastrectomy, pancreatic insufficiency, and cystic fibrosis. As well, vitamin D deficiency can be precipitated from gastrointestinal

surgeries such as bariatric surgery (intestinal bypass) or small bowel resection (short gut syndrome).

Bone mineral density (BMD), believed to be the early indicator for risk of osteoporotic fracture, can be affected by vitamin D status. Randomized controlled trials (RCTs) in older adults have evaluated the effect of either vitamin D_3 or D_2 on BMD. A systematic review of the literature found that supplementation with 800 IU of vitamin D_3 daily, in combination with calcium reduced fracture risk [76]. A major limitation has been compliance rates for consuming the supplements of less than 80% and lack of assessment of vitamin D status (i.e., no 25(OH)D levels measured). Poor compliance with vitamin D supplementation was an issue noted more often in the large community-based trials [76]. Further, dose provided is an issue. When the daily vitamin D dose was only 10 μg (400 IU), there was no reduction in fracture risk [76,77]. This finding is not unexpected as that low amount of vitamin D_3 would only result in a small rise in serum 25(OH)D, approximately 7–10 nmol/L and deficient subjects (<30 nmol/L) receiving this small dose likely would not have serum 25(OH)D above 50 nmol/L.

A 2014 Cochrane review concluded that vitamin D alone was not sufficient but supplementation with both vitamin D and calcium reduced the risk of fragility fractures [78]. With respect to systematic reviews, the contribution of the Women's Health Initiative trial [79] is large, but this study gave only 400 IU to participants in addition to 1000 mg calcium, and allowed the placebo group to take supplements. In another systematic review, also published in 2014, the role of vitamin D was downplayed [80]; however, even after including studies where subjects were already sufficient (>50 nmol/L) there was a significant effect of vitamin D on femoral neck BMD. Including studies of vitamin D in participants already adequate for vitamin D with respect to bone health (>50 nmol/L) has caused confusion and as is discussed below, made the scientific community more cognizant of the difficulties in interpreting RCTs with vitamin D, as is discussed in Section VII.

TABLE 43.13 Medications Altering Vitamin D Status

Mechanism of Action	Condition for Use: Drug Family
Drugs reducing vitamin D absorption	Cholesterol-lowering agent: cholestyramine Weight loss drug orlistat and food additive olestra
Drugs reducing plasma vitamin D levels	Cholesterol lowering: statins
Drugs reducing 25(OH)D levels	Anticonvulsant medications: carbamazepine, phenobarbital, and phenytoin, gabapentin Antiretroviral agents: ritonavir and efavirenz, valproic acid Heartburn, peptic ulcer (histamine H2 receptor antagonist): cimetidine
Drugs impairing vitamin D metabolism	Oral corticosteroids: glucocorticoids Psoriasis: calcipotriol/calcipotriene

4 Muscular Health and Falls Risk

The risk of fracture in vitamin D deficiency is not only increased due to low bone density, but also to the greater risk of falls. Studies show that vitamin D reduces fracture risk in part by reducing risk of falls [81]. Here, vitamin D is acting to increase muscle strength and may thus improve balance and reduce falls. In a study of adults 65 years and older, neuromuscular performance tests such as chair stands and walking tests were performed and related to vitamin D status (Fig. 43.4). Performance improved as vitamin D status improved, up to a cutoff for serum 25(OH)D of 50−75 nmol/L. Vitamin D acts through both the endocrine and paracrine/autocrine systems to improve muscle health [81]. Atrophy of type II muscle fibers, those most responsible for muscle strength, is seen in vitamin D deficiency [81]. Even younger adults and athletes with low vitamin D status may show compromised muscle strength [82].

A study published in 2016 saw no benefit of vitamin D supplementation for falls risk, and may have detected adverse events associated with supplementation to adults 70 years and older [83]. For a year, two treatments were tested: a monthly dose of 60,000 IU of vitamin D_3 or a monthly dose of 24,000 IU vitamin D_3 together with 300 μg 25(OH)D (assumed to provide 15,000 IU), compared to a low dose group which was monthly 24,000 IU. At baseline only 58% of the subjects had serum 25(OH)D <50 nmol/L. Falls incidence was highest in both high treatment groups. These data suggest too much vitamin D may be harmful to muscle strength. A second explanation for the findings is that monthly dosing is not appropriate, especially when given in very high doses. Thus while there may be some contradictory findings for falls risk, earlier studies using daily dosing showed that preventing vitamin D insufficiency reduced risk of falls in older adults [84].

C Vitamin D Insufficiency as a Public Health Problem

Research is ongoing concerning how vitamin D status can impact on chronic disease. Both the endocrine and paracrine pathways are implicated as mechanisms for understanding how vitamin D is involved in chronic disease prevention. As shown in Fig. 43.1, the endocrine pathway, which maintains calcium and phosphate homeostasis, impact on bone, kidney, muscle, and cardiovascular health. The paracrine/autocrine pathways provide 1,25-dihydroxyvitamin D for cell functioning. Systems that are affected are those involving cell differentiation such as the immune system. These paracrine pathways may impact on a variety of diseases under investigation such as cancer, infectious, neurologic, and autoimmune diseases [81]. A summary of disease conditions under investigation as being influenced by vitamin D status are listed in Table 43.12. A brief summary of research to date is provided for some of these conditions.

1 Vitamin D and Cancer Prevention

The connection between vitamin D status and cancer becomes clearer if one looks to the disruption of normal cell activities which characterize cancers. Malignancies are characterized by disregulation in cell growth and differentiation. Observational studies of sun exposure or vitamin D status in relation to cancer risk early on showed protective relationships between sufficient vitamin D status and lower risk of cancer [81]. A Cochrane review of vitamin D supplementation for prevention of cancer in adults in 2014 found there was no strong evidence that vitamin D supplementation decreases or increases cancer occurrence in elderly community-dwelling women [85]. However, epidemiological studies of both colorectal and breast cancers show a consistent inverse association for

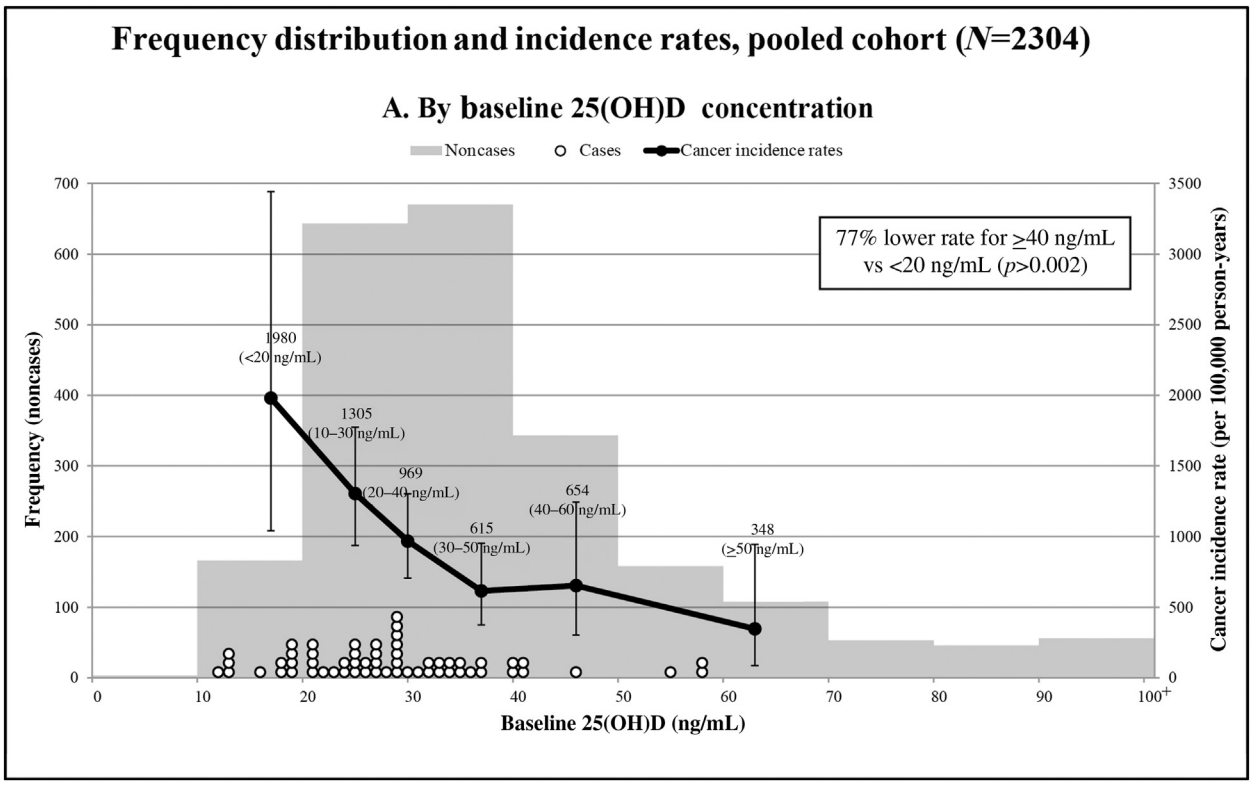

FIGURE 43.5 Frequency distribution and cancer incidence rates by 25(OH)D concentration of the pooled cohorts ($N = 2304$) followed for ~4 years. The bars represent the number of noncases and the white dots are the 25(OH)D concentration for each cancer case. *From S.L. McDonnell, C. Baggerly, C.B. French, L.L. Baggerly, C.F. Garland, E.D. Gorham, J.M. Lappe, R.P. Heaney, Serum 25-hydroxyvitamin D concentrations ≥ 40 ng/mL are associated with >65% lower cancer risk: Pooled Analysis of Randomized Trial and Prospective Cohort Study, PLoS One 11 (2016) e0152441.*

both incidence and mortality, but clinical trials have not borne out this relationship [86]. For colon and colorectal cancers, it is highly plausible vitamin D has an effect due to its roles in differentiation and gut barrier function [87]. A meta-analysis of 11 eligible studies of breast cancer and vitamin D found that a serum 25(OH)D level of 120 nmol/L was associated with a 50% lower risk of developing breast cancer [88].

Indeed, it may be that baseline levels of 25(OH)D determine how well vitamin D status is impacted in supplementation trials. Two cohorts of women 55 years and older, one being an RCT of vitamin D originally intended as an osteoporosis study, and the other a population-based prospective study, were combined to address this question [89]. Fig. 43.5 plots baseline 25(OH)D against the frequency of cancer over a 4-year period. When frequency was compared between cases <20 ng/mL (50 nmol/L) 25(OH)D and those occurring at or above 40 ng/mL (100 nmol/L), there was a 77% lower rate of all cancers, with the most common cancer being breast cancer. A similar relationship showing a 71% lower rate was seen when frequency was plotted against mean achieved 25(OH)D for all tests during the 4-year time period. Thus achieving a serum 25(OH)D of 100 nmol/L appears to be the key component to reducing incidence and may explain the lack of success in other trials.

There remains the debate as to whether vitamin D status should be improved by diet or sun exposure. In a study of persons with a diagnosis of nonmelanoma skin cancer, for whom sun exposure was the likely cause of this cancer, there were lower rates of second cancers (colon, gastric, and rectal cancers) [90]. These studies underscore the need for better understanding of the role of vitamin D, which for many people is through sun exposure. While sun exposure increases the risk of developing skin cancer [50], other evidence suggests it has the potential to reduce the risk of developing more severe forms of cancer [81].

2 Vitamin D and Immunity

Vitamin D's action in the immune system is well known, and as a consequence vitamin D has been studied with respect to its role in infectious disease as well as in autoimmune diseases [81]. Vitamin D plays a critical role in the innate immune system, which is initiated in

macrophages at first contact with an invading pathogen. Tuberculosis, influenza, and viral upper respiratory tract infections are under investigation. While consistent, strong evidence has not yet been found, there is convincing evidence that tuberculosis especially can be reduced, or severity of this condition reduced, with improvement in vitamin D status [91].

Poor vitamin D status has been shown to be associated with developing autoimmune diseases such as type 1 diabetes mellitus, multiple sclerosis, and inflammatory bowel disease [81]. Type 1 diabetes in children is related to serum 25(OH)D [92]. Even type 2 diabetes may be reduced with vitamin D supplementation [93]. Epidemiological studies have suggested that high circulating levels of vitamin D are associated with a lower risk of multiple sclerosis. Overall, studies support a protective effect of vitamin D, but there are some unanswered questions, including the mechanism of action and how genetic variations modify the effect of vitamin D status [94]. It merits mention that promising clinical evidence is emerging suggesting that vitamin D status influences the relapse rate and radiological lesions in patients with multiple sclerosis [95]. It remains unclear whether vitamin D can influence the course of multiple sclerosis progression, or influence the prevention of multiple sclerosis.

3 Vitamin D and Prevention of CKD and Cardiovascular Disease

The kidney is critically important for vitamin D metabolism, serum 25(OH)D concentrations are lower in patients with varying stages of renal function [96–98]. This relationship was characterized in the general U.S. population using NHANES III data, demonstrating significantly lower serum 25(OH)D only in those survey participants with low estimated glomerular filtration rates (eGFRs), that is, with values <29 mL/minute/1.73 m^2 [97]. These findings support the hypothesis that vitamin D status may be involved in the pathophysiology of progressive renal disease, which can ultimately lead to cardiovascular disease and increased mortality risk. There are a number of mechanisms through which vitamin D status may affect the progression of renal failure including: control of cell proliferation and differentiation, changes in the loss of podocytes, modulation of inflammation such as the suppression of proinflammatory cytokines, regulation of the renin-angiogenesis system to lower hypertension, decreased risk of anemia, and reduction of PTH levels [98]. Secondary hyperparathyroidism is a well-recognized hallmark of low circulating 25(OH)D even in individuals with normal renal function; however, low serum 25(OH)D in CKD has been shown to aggravate secondary hyperparathyroidism [98].

In the early 1970s, the active form of vitamin D_3, calcitriol, was used in the management of secondary renal hyperparathyroidism in CKD and hemolysis patients. Treatment with calcitriol waned with the publication of the 2009 Kidney Disease Improving Global Outcomes (KDIGO) guidelines, which recommended measurement of 25(OH)D and correction of vitamin D deficiency and insufficiency using 25OHD (calcifediol), cholecalciferol (D_3), or ergocalciferol (D_2) [99]. These treatment recommendations are the same as those for the general population [96] and studies have shown that the use of the precursors of the active form of vitamin D were safer and associated with survival benefits due to their pleiotropic effects on the cardiovascular system of the CKD patients [99]. The use of the active form of vitamin D sterols was controversial with some studies showing reduction in mortality in renal disease patients and no mortality benefits in other studies, particularly at higher doses [100,101].

Systematic reviews and meta-analyses in both dialysis and nondialysis CKD patients show nutritional vitamin D replacement using cholecalciferol or ergocalciferol increase serum 25(OH)D concentrations and effectively reduce PTH without adverse effects of hypercalcemia or hyperphosphatemia [102,103]. The majority of recent clinical trials of nutritional vitamin D in CKD patients have used cholecalciferol [104,105]; however, ergocalciferol's availability in higher doses through prescription have been shown to be safe and effective in lowering PTH in CKD stages III–V [106,107]. The Divine trial (Dialysis Infections and Vitamin D in New England), a prospective, multicenter, double-blind, randomized, placebo-controlled trial compared a high and standard dosing regimen of ergocalciferol with placebo in hemodialysis patients [106]. They reported safe and effective increases in 25(OH)D concentrations after short-term high doses (50,000 IU weekly or monthly) for 12 weeks without significant change in calcium, phosphate, or PTH concentrations over the study duration.

Calcifediol ($25(OH)D_3$) is the least studied of the three nutritional forms of vitamin D available for correction of vitamin D insufficiency/deficiency, and was recently introduced in a modified release formulation [90]. In a study in nondialyzed CKD patients that compared calcifediol treatment to placebo, the oral calcifediol was effective in increasing 25(OH)D in a dose-dependent manner [108]. It is important to observe the recent recommendations of the Italian Society of Nephrology's 2016 Guidelines specific to treatment with oral nutritional forms of vitamin D used to correct vitamin D deficiency in CKD patients. The society warns that: "Regardless of the preferred oral regime used in predialysis CKD patients, treatment with cholecalciferol, ergocalciferol and calcifediol should be discontinued in the presence of

25(OH)D levels [100 ng/mL] and/or with persistent hypercalcemia (> 10.5 mg/mL) in the absence of active vitamin D therapy" [99].

New evidence suggests that none of the three nutritional forms of vitamin D are as effective as exposure to adequate UVB or natural sunlight in CKD [109,110]. Krause and coworkers reported that patients who continued skin exposure to sun-simulating artificial lamps two or three times weekly before routine hemodialysis sessions maintained normal circulating $25(OH)D_3$ and $1,25(OH)_2D_3$ by stimulating the skin's natural ability to activate the conversion of the precursor to vitamin D_3. These authors recommend the use of intermittent suberythemal UVB exposure with a sun-simulation spectrum to treat and prevent vitamin D deficiency in chronic and end-stage kidney disease patients, a noninvasive treatment that could even be carried out during hemodialysis.

Kidney dysfunction is also associated with severe anemia due to low iron availability for hemoglobin synthesis, and with insulin resistance and glucose intolerance in the metabolic syndrome. CKD is associated with higher serum hepcidin (an iron storage protein), low serum 25(OH)D, and anemia, especially in African-American children [111,112]. Correction of vitamin D deficiency lowers hepcidin levels, allowing for improved iron availability, thus correcting the anemia.

Chonchol and Scragg [97] in their analyses of kidney function and vitamin D status in the NHANES III survey also demonstrated that serum 25(OH)D and levels of kidney function (eGFR) were both inversely associated with the homeostasis model assessment of insulin resistance (HOMA-IR), yet were independent of each other. Conversely, they found that survey participants with serum 25(OH)D levels in excess of 81 nmol/L had lower HOMA-IR. These findings suggest that low serum 25 (OH)D may be a risk factor in cardiovascular disease, since insulin resistance is an integral part of the putative path to cardiovascular disease development.

Strategies to raise serum 25(OH)D may decrease the risk of cardiovascular disease [113,114]. Evidence for a role of adequate vitamin D status in slowing the development of cardiovascular disease was demonstrated in a randomized, placebo-controlled, double-blind vitamin D supplementation trial where 2000 IU of cholecalciferol markedly improved the inflammatory cytokine profiles in patients with congestive heart failure [114]. In a recent review, the plausibility of vitamin D's involvement was highlighted [113]. There are vitamin D metabolizing enzymes in the heart and blood vessels, and in animal models of cardiovascular disease, vitamin D is antiatherosclerotic, antiinflammatory, and has direct cardioprotective actions. In epidemiologic studies in the general population, low serum 25(OH)D is associated with increased risk of cardiovascular disease and mortality. Currently, there are few and inconsistent data from RCTs concerning cardiovascular disease prevention and treatment; consequently, a recommendation cannot be made other than ensuring vitamin D adequacy in those at risk for cardiovascular disease [113,114].

4 Vitamin D and Neurological Conditions

As outlined in Table 43.12 there are many conditions for which vitamin D has been shown or has been implied to be important in their pathogenesis. Of interest are associations with conditions affecting the brain, such as dementia, Parkinson's disease, and autism. These diseases do not necessarily share similar pathways, and are only briefly described as less is known about each one. Evidence for a causal relationship between vitamin D deficiency and adverse cognitive or behavioral effects was first presented in 2008 [115]. There is biological plausibility in linking vitamin D to brain development and function but the effects appear to be "subtle."

Dementia, particularly Alzheimer's disease, has become an increasing health problem, in part due to longer life spans, but other causes may be implicated. In a population-based U.S. study, vitamin D deficiency was associated with increased risk of all-cause dementia and Alzheimer's disease. The risk of all-cause dementia and Alzheimer's disease markedly increased below a threshold of 50 nmol/L [116]. Parkinson's disease incidence has been related to outdoor exposure (UVB), giving rise to the hypothesis that vitamin D status may be a causal factor [117]. And finally, evidence is growing that autism is related to vitamin D. Patrick and Ames has shown that vitamin D (calcitriol) regulates serotonin synthesis and that this mechanism may be responsible for increased risk of autism in children whose mothers were vitamin D deficient [118].

D Treatment of Vitamin D Deficiency

When an individual is depleted of vitamin D, the amount of vitamin D needed for repletion is higher than that needed to maintain status; aggressive therapy is needed. Table 43.3 provides a list of commonly used vitamin D supplements, and new vitamin D-related medications are updated continuously at the Food and Drug Administration website [119]. As indicated in Table 43.11, many forms of rickets require high doses of vitamin D. This vitamin D can be provided daily or in intermittent doses, although there has been concern expressed about excessively high doses given monthly or yearly [120]. Hollis and Wagner [120] argue that vitamin D should be available on a daily basis to ensure stable circulating concentrations. When given in yearly doses, the level of 25(OH)D achieved is never known as monitoring, if it is

done, may not reveal the extent of transient toxicity. In general, it is not necessary to keep daily dosages below the tolerable UL for vitamin D, as this DRI is not intended as a barrier for treatment under a physician's care [121]. In situations where the diagnosis of rickets is determined to be a vitamin D-resistant form (Table 43.11), doses of the active metabolite 1,25-dihydroxyvitamin D or an analog with similar properties, is often administered.

V DIETARY REQUIREMENTS

A IOM Recommended Intake Values for Vitamin D, 2011

New reference values for vitamin D that apply to Canada and the United States were announced by the IOM in November 2010 and published in 2011 [4]. These revised DRIs generated much discussion, some of it in support [122], but many critical of the way in which the evidence for new roles of vitamin D were dismissed in the deliberations [123,124]. DRIs provide the reference values for assessment and planning functions in nutrition [121], that is, the EAR which is the median requirement, the RDA which is the amount that meets the needs of almost all (97.5%) healthy persons in the population, the Adequate Intake (AI) which is set for infants age 0–1 year, and the tolerable UL which is set at an intake level that poses no risk for adverse effects. Since first setting DRI recommendations in 1997, evidence has emerged suggesting a need to revise those initial DRI values [124]. The 2011 DRI committee used evidence-based reports and other data in its deliberations. The challenges that the committee identified in setting the new DRIs included: (1) an acknowledgment that vitamin D can be made through skin synthesis, so setting intake values must be made in the context of minimal sun exposure; (2) recognition that studies designed to provide evidence for dietary effects on bone gave both calcium and vitamin D, so isolating vitamin D's effects were a challenge; (3) complications in interpreting the impact of poor vitamin D status as bone health can be maintained with high intakes of calcium making the link between vitamin D and bone health very dependent on usual calcium intakes, which are generally low; and (4) the inability to distinguish the contribution to serum total 25(OH)D of sun-induced synthesis of vitamin D from ingested vitamin D, except in studies where 25(OH)D is measured in winter in subjects who are not exposed to other confounding factors such as trips to sunny destinations or use of tanning beds [4].

The values for each age/sex group for EAR, RDA, and AI are in Table 43.14. The level of 25(OH)D that was defined for adequacy for almost everyone including individuals with darkly pigmented skin (i.e., the RDA) was set at serum 25(OH)D at or above 50 nmol/L. This circulating level of 25(OH)D was deemed to provide for maximal calcium absorption, minimal risk of rickets in

TABLE 43.14 Dietary Recommendations for Vitamin D Intake Based on Healthy and At-Risk Status

Organization and Criterion	Age Group	Recommendation	Level of 25(OH)D Achieved	Notes
Healthy Population				
IOM, 2011	0–1 year	400 IU	50 nmol/L	RDA for healthy Canadians and Americans to achieve a 25(OH)D level of 50 nmol/L of 50 nmol/L. Infant level is an AI
	1–18 years	600 IU		
	19–70 years	600 IU		
	71+ years	800 IU		
At-Risk Population				
Endocrine Society, 2011	0–1 year	400–1000 IU	75 nmol/L	Recommended intake for at-risk patients in the United States to achieve a 25(OH)D level of 75 nmol/L. At-risk includes those who have a vitamin D deficiency, kidney failure, malabsorption syndrome, hyperparathyroidism, on medications that interfere with vitamin D, are African-American or Hispanic, are pregnant or lactating, are older adults with a history of falls or nontraumatic fractures, are obese, or have granuloma-forming disorders
	1–18 years	600–1000 IU		
	18+ years	1500–2000 IU

Gordon, D.A. Hanley, R.P. Heaney, M.H. Murad, C.M. Weaver, Evaluation, treatment, and prevention of vitamin D deficiency: an Endocrine Society Clinical Practice Guideline, J. Clin. Endocrinol. Metab. 96 (2011) 1911–1930.

children, reduced fracture risk in adults, and minimal risk of osteomalacia in adults [4]. Using data from studies conducted in winter time or at very high latitudes where sun exposure is assumed to be minimal, they used simulated dose–response prediction equations to find the intake of vitamin D that would achieve a mean 25(OH)D level of 50 nmol/L in almost everyone. This intake was found to be 600 IU, irrespective of age, gender, or race/ethnicity. There was recognition that older adults demonstrated a high degree of variability in attaining 25(OH)D in studies, thus their RDA was set at 800 IU. The level to achieve 40 nmol/L was estimated as 400 IU; this is the EAR. The vitamin D recommendation of 400 IU for infants, as an AI, is based on maintaining adequate serum 25(OH)D above 50 nmol/L. Recommended values during pregnancy and lactation are not different from other women in the same age group [4].

B Recommendations for At-Risk Groups

1 Endocrine Society, 2011

The IOM recommendations are for healthy individuals who are free of most chronic conditions and the target level of 25(OH)D used to determine the RDA was 50 nmol/L [4]. Subsequent to the IOM publication of the DRI for vitamin D and calcium, the Endocrine Society also published intake guidelines, but for individuals with chronic conditions known to influence vitamin D status [51]. The Endocrine Committee of experts defined vitamin D adequacy for those at risk as 75 nmol/L 25(OH)D [51]. The Endocrine Society focused on at-risk groups and stated that evidence is available to define "deficiency" as a level of 25(OH)D $<$50 nmol/L. Those individuals with a designation of "at-risk" include: rickets, osteomalacia, osteoporosis, CKD, malabsorption syndromes, medication use that interferes with vitamin D (e.g., see Table 43.13), and granuloma-forming disorders. In addition, there are life stage groups—pregnancy, lactation, older adults with fracture or fall history—and racial/ethnic groups—African-American and Hispanic children and adults—who are included in the "at-risk" designation. Finally, obesity puts people more at risk for vitamin D deficiency. The dietary recommendations for at-risk groups published by the Endocrine Society are found in Table 43.14. Intakes are provided as ranges as it is not known how much cholecalciferol or ergocalciferol is needed to raise serum 25(OH)D levels over 75 nmol/L.

2 Recommendations for Pregnancy and Lactation

By the third trimester of pregnancy there is an elevation of 1,25-dihydroxyvitamin D by the mother, corresponding to the time the fetus begins to calcify bones and the need for calcium is greatest [51]. Overall, pregnant women are at high risk for vitamin D deficiency, and complications such as preeclampsia and cesarean section are increased in those who are deficient [51]. In the 2011 IOM report, no special considerations were made for pregnancy; that is, women during these times would follow the recommendations for nonpregnant or nonlactating women. The IOM justification was that there were no data to suggest the needs of pregnant women were different, for example, fetal outcomes were compromised only when maternal 25(OH)D was below 40 nmol/L, a level that should be met if the woman followed RDA recommendations. The IOM indicated that during lactation, small increases in maternal 25(OH)D do not appear to impact breast milk content or infant 25(OH)D status [4]. However, the 2011 Endocrine Society Guidelines on vitamin D, pregnancy, and lactation are classified as times when screening for 25(OH)D should occur [51]. Recommendations during pregnancy by this group are the same as for at-risk adults of the corresponding age (Table 43.14).

There is emerging evidence that vitamin D recommendations should be made for pregnancy. Evidence is strong for vitamin D insufficiency being associated with first trimester pregnancy loss [125], gestational diabetes [126], preeclampsia [127], preterm birth [128], higher rates of primary Cesarean section [129], small for gestational age infants [130], and maternal postpartum depression [131]. With respect to lactation, it has been shown that when intakes of vitamin D by lactating mothers are optimal, that is, the mother's 25(OH)D levels are $>$75 nmol/L, breast milk levels reach "physiological" levels, supplying 400 IU of vitamin D per day to the infant [70,71]. The amount needed by lactating mothers to give the equivalency of 400 IU per day to the infant is not known but has been estimated to range between 2000 IU [70] and 6400 IU [71].

VI SAFETY OF VITAMIN D

A The Tolerable UL for Vitamin D

The daily tolerable UL was established to discourage potentially dangerous self-medication [121]. The two main indicators of excess vitamin D include hypercalcemia, which can lead to calcification of soft tissues such as arteries (arteriosclerosis) and kidney (nephrocalcinosis), and hypercalciuria, which reflects the presence of excess serum calcium and could be damaging on its own. Kidney stones are sometimes raised as a concern when vitamin D intakes are increased. When incidence of kidney stones is reported from RCTs of vitamin D, there is usually calcium supplementation along with vitamin D, so it has been difficult to distinguish the cause [85]. A study of over 2000 participants who had blood 25(OH)D measured

Metab. 96 (2011) 1911–1930.

and reported, prospectively, on health outcomes. No statistically significant association between serum 25(OH)D and kidney stones was found. Serum 25(OH)D ranged between 50 and 250 nmol/L [132].

A risk assessment for vitamin D showed that based on an analysis of all published reports related to excess vitamin D ingestion up to 2007, doses of supplemental vitamin D_3 ingested at levels below 10,000 IU/day were not associated with toxicity [133]. It is possible that intakes consistently above 50,000 IU/day could be linked to side effects including hypercalcemia [4].

UL values for infants 0–6 months and 6–12 months were set at 1000 and 1500 IU, respectively (Table 43.15). A no-observable-adverse-effect-level of 1800 IU was used to set these ULs as studies exist where high doses of vitamin D have produced hypercalcemia. An uncertainty factor (UF) of 1.8 was set for very young infants and a smaller UF for older infants indicting greater tolerance to vitamin D. For adults over 18 years, the committee concluded that 25(OH)D should not be above 125–150 nmol/L, and that using published data from a dosing study, determined that 4000 IU would not raise serum 25(OH)D above this threshold [4]. In that dosing study, Heaney et al. [16] gave cholecalciferol to subjects in doses up to 10,000 IU, and found no adverse effects in men treated for 5 months. The IOM indicated that attaining a 25(OH)D above 125 nmol/L had no potential benefit and possible (unknown) risk; therefore, the UL was set at 4000 IU which is an adjustment down from the 5000 IU that subjects ingested to reach 125 nmol/L with 5 months of dosing. For children, the committee chose to "scale down" the adult UL [4].

The Endocrine Society's recommendations for UL values are higher than those of the IOM levels. The Endocrine Society uses these higher amounts, shown in Table 43.14, as they represent intakes that would be used in treatment regimens for those at high risk of vitamin D deficiency or insufficiency [51]. Unless a person is under a physician's care, it would be prudent that the IOM values for ULs should be used as the highest safest intakes.

B Vitamin D Intoxication

Accidental poisoning or uninformed supplementation with vitamin D can occur, causing vitamin D intoxication [4,133]. Intakes reported in nine cases involved levels in the range of approximately 30,000–2,600,000 IU, and durations were between days and decades [133]. The signs and symptoms of vitamin D intoxication are associated with hypercalcemia and include constipation, lethargy, confusion, polyuria, and polydipsia [134]. Generally, toxicity occurred in cases where intake was over 50,000 IU per day, well above the current UL [4] or that set by the Endocrine Society [51]. Serum 25(OH)D associated with these high intakes ranged between 700 and 1600 nmol/L, well above the value of 250 nmol/L considered "high" [133]. The mechanism for toxicity with vitamin D is believed to involve increases in the concentrations of many vitamin D metabolites, including vitamin D itself as well as 25[OH]D; at high concentrations the DBP binding capacity is exceeded and there is release of "free" 1,25[OH]D which enters target cells to act unabated.

There is a genetic disorder called idiopathic infantile hypercalcemia in which symptoms of vitamin D toxicity occur at intakes much lower than those described above. Symptoms include severe hypercalcemia, failure to thrive, vomiting, dehydration, and nephrocalcinosis [135]. The cause of this is now understood to be mutations in CYP24A1, the enzyme responsible for inactivating vitamin D as shown in Fig. 43.4. Even at intakes as low as 500 IU, four patients developed hypercalcemia indicating that there are reasons to be cautious when first initiating treatment of infants with vitamin D. Hypercalciuria also occurs in these patients suggesting monitoring urine excretion should be one way to detect this genetic disorder.

TABLE 43.16 Factors Influencing Outcomes of RCTs Examining Vitamin D's Role in Chronic Disease

Reason	Comment
1. Inappropriate subject selection criteria	Subjects selected without regard to vitamin D status (deficient or insufficient)
2. Statistically underpowered	Small biological differences require large sample sizes; otherwise at risk of type 2 error
3. Uncontrolled additional exposure to vitamin D	Running a trial in a country with fortification with vitamin D (e.g., United States); running studies in summertime; allowing the use of other supplements (e.g., multivitamin)
4. Ineffective doses	Many early trials used 400 IU vitamin D or less
5. Poor treatment compliance	Subject compliance can be low in trials, and/or may not be tracked well
6. Improper dosing regimen (yearly or monthly)	High doses given intermittently do not act the same as a constant daily dosing; trials use these to streamline compliance to treatment
7. Insufficient treatment duration	Serum response to vitamin D treatment requires a minimum of 3 months exposure and likely longer for chronic disease endpoints

VII FUTURE CONSIDERATIONS

As indicated in this chapter, there are many diseases found to be associated with vitamin D status, yet concrete evidence is lacking for many of them. As a result, there are differing opinions about what target serum concentration of total 25(OH)D to use as a cutoff. One reason for such confusion over vitamin D requirements is due to the lack of understanding of how to gather evidence confirming the role of vitamin D in chronic disease risk. Most studies have been cross-sectional, thus supplying only "associations" rather than cause and effect. Some large prospective studies have been done, yet there are many confounders. It is clear that the major problems lie with the design of the RCTs, the so-called gold standard for evidence-based dietary recommendations. Many vitamin D experts are calling for better designed RCTs, citing the numerous ways in which past RCTs have erred [136,137]. Table 43.16 outlines many of the ways in which RCTs involving vitamin D have led to misinterpretation of results. When insufficient doses of vitamin D are given to groups of subjects who are already adequate, it is not surprising there would be null findings. Even the large-scale trials that have not yet reported findings by the time this chapter was written may have design flaws that will contribute to the confusion, making interpretation of requirements for vitamin D inconclusive.

VIII CONCLUSION

Vitamin D inadequacy is a significant public health concern in the United States, as well as other countries around the world, whether it is defined by the IOM as 25 (OH)D $<$50 nmol/L, or by the Endocrine Society at 25 (OH)D $<$75 nmol/L. Many Americans are in high-risk groups, or get little sun exposure, so having an affordable source of food that is relatively low in vitamin D exacerbates this problem. Action is needed to ensure adequate dietary intakes from food and dietary supplements and/or appropriate sun exposure. Vitamin D deficiency leads to not only rickets and osteomalacia, which are likely to go undiagnosed in the population, and to osteoporosis, but also to neuromuscular disabilities, neurological conditions, kidney failure, increased risk of cancer development, poor immunity, and to other problems still under investigation. Better understanding of vitamin D metabolism and status will lead to its effective use in prevention and treatment of a variety of chronic diseases.

Chapter 44

Osteoporosis: The Early Years

Connie M. Weaver and Kathleen M. Hill Gallant
Purdue University, West Lafayette, IN, United States

I INTRODUCTION

The risk of developing osteoporosis is largely determined by the mass and size of bone acquired by adulthood known as peak bone mass [1]. The greater the skeletal mass at its peak and the stronger the geometry, the greater the amount of loss that can occur before entering the fracture risk zone. An interplay between heritable factors and environmental factors determines peak bone mass (Fig. 44.1). It is estimated that genetics contributes 60−80% and lifestyle factors contribute the remaining 20−40% [2,3]. Genes that control growth and development are thought to also largely determine bone acquisition [2].

Nutrition and physical activity are the primary lifestyle determinants of bone acquisition, and increasing evidence suggests that the interactions between these two are stronger determinants than either alone. Nutrition plays an important role in preventing osteoporosis through building optimal peak bone mass within one's genetic potential. This chapter reviews the influence of diet and nutrients on bone health and the basis of requirements for nutrients that are based on skeletal health. Nutrition likely can also play a role in fracture risk during childhood. Skeletal fragility in childhood occurs when bone mineral density (BMD), as assessed by dual-energy X-ray absorptiometry (DXA), expressed as a *Z*-score is less than −2.0 [4]. Skeletal fragility can arise from a lag between peak height velocity and bone mineralization during the pubertal growth spurt or as a consequence of eating disorders or disease. Less is known about the role of diet in the context of pediatric disorders, and research is needed to address these gaps.

This chapter focuses on the development of peak bone mass and the role of nutrition in bone acquisition. The reader should consult the companion chapter by Robert Marcus (Chapter 45: Osteoporosis in Adults) for a discussion of osteoporosis and bone qualities.

II ACQUIRING PEAK BONE MASS AND BONE STRENGTH

Understanding the timing for an effective nutritional intervention can be as important as the nature of the intervention. Textbooks commonly cite that bone mass is acquired throughout the third decade of life and frequently quote a longitudinal study that averaged annual bone gains over a decade, ignoring the fact that the rate of accrual decreased over time and became trivial by age 30 years [5]. In a metabolic balance study, women older than age 21 years were not in positive calcium retention on intakes of 1300 mg calcium per day [6]. Increase in BMD with age depends on the skeletal site. For total body BMD, 95% of adult peak bone mass was achieved by age 16.2 years and 99% was achieved by age 22.1 years [7]. Peak BMD in white women occurred at age 23 years for the spine, 18.5 years for the femoral neck, 14.2 years for the greater trochanter, and 15.8 years for Ward's triangle [8] (Fig. 44.2). Clearly, to markedly influence peak bone mass, lifestyle practices are more important prior to the end of puberty than postadolescence.

When there are transient periods during which diet is inadequate, some catch-up growth is possible [9]. In a calcium-supplemented controlled trial from early puberty until development of peak bone mass in girls habitually consuming on average 830 mg calcium per day, calcium supplementation increased accrual of BMD of total body (Fig. 44.3) and radius through puberty compared to the placebo group [10]. However, by age 18 years, the advantage was reduced. There was an interaction with size such that girls who were taller by age 18 years did not fully catch up. The extent of catch-up growth undoubtedly

depends on the degree of inadequacy of the diet, the timing and duration of the period of inadequacy, and the degree of repletion. Regardless, the period of inadequacy is itself a period of vulnerability—that is, in this example, a higher risk of fracture.

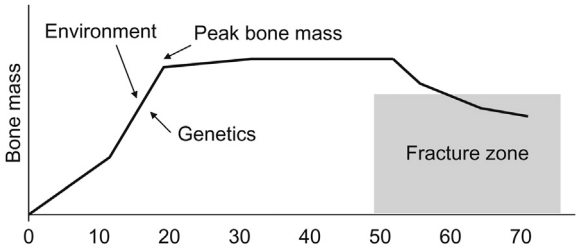

FIGURE 44.1 Bone mass throughout the life span. The influence of genetics and the environment is greatest during growth.

The impact of genetics on development of peak bone mass is evident in Fig. 44.3. The light gray lines show tracking of total body BMD of 15 representative individuals. Those who began the trial with lower BMD remained lower throughout development of peak bone mass. Modifications through lifestyle choices occur within one's genetic potential.

Bone geometry plays an additional role beyond bone mass in resistance to fracture. Bone geometry includes dimensions of bone such as length and cross-sectional area. The relationship of bone geometry to fracture risk in childhood and measurement by peripheral quantitative computed tomography has been described by Kalkwarf [11]. The effect of diet on bone geometry is a rather recent field of study because of the relative newness of this technique. The exercise intervention trials that have used this outcome measure have illustrated additional information gained about bone strength.

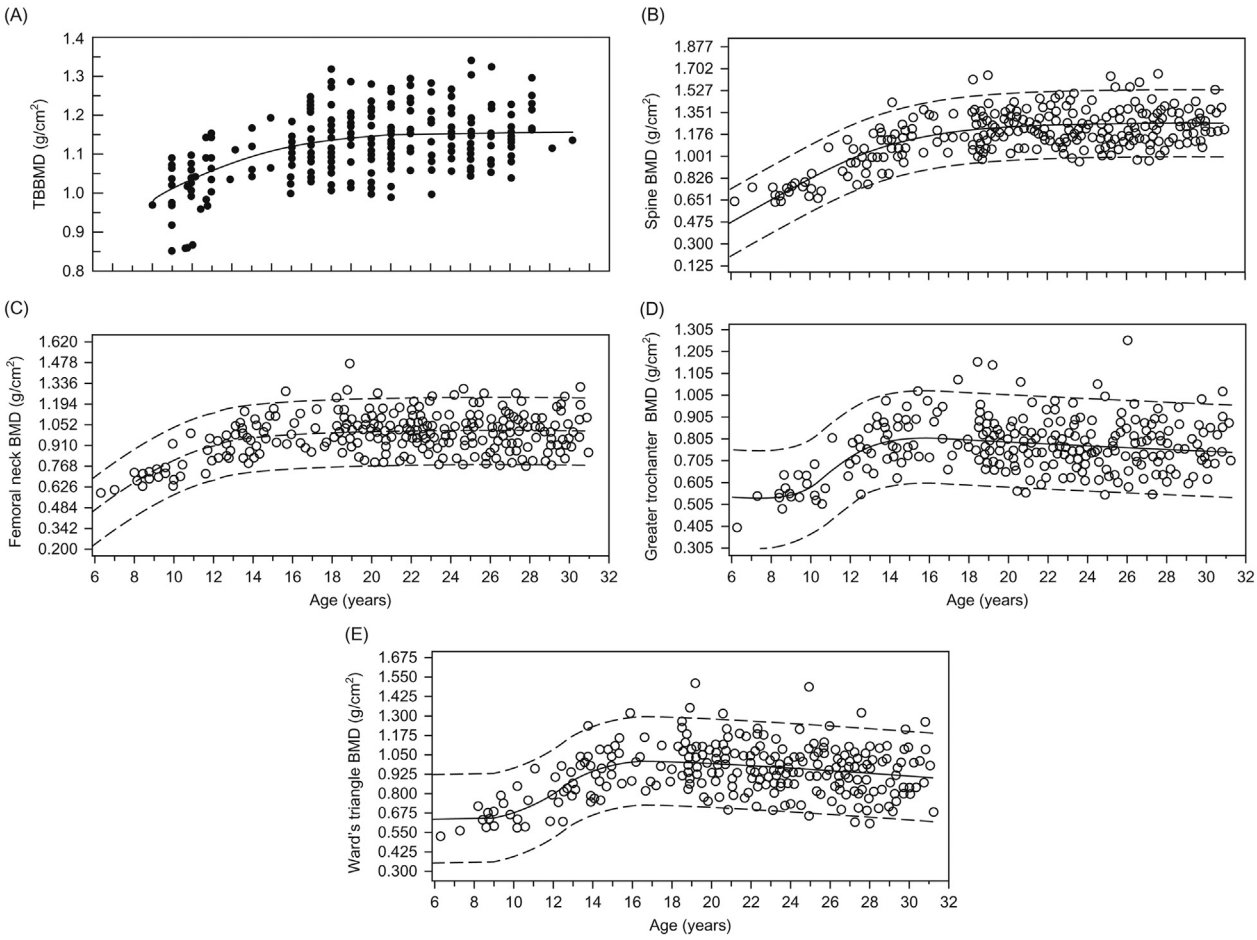

FIGURE 44.2 BMD accumulation with age in females. Gains in BMD vary with skeletal site. Almost 95% of adult peak total body BMD occurred by age 15.2 years (A), and the highest BMD of the spine occurs by age 23 years (B), by age 18.5 years for the femoral neck (C), by age 14.2 years for the greater trochanter (D), and by age 15.8 years for Ward's triangle (E). *Reproduced from D. Teegarden, W.R. Proulx, B.R. Martin, J. Zhao, G.P. McCabe, R.M. Lyle, Peak bone mass in young women, J. Bone Miner. Res. 10 (5) (1995), 711–715 [7]; Y.-C. Lin, R.M. Lyle, C.M. Weaver, L.D. McCabe, G.P. McCabe, C.C. Johnston, Peak spine and femoral neck bone mass in young women, Bone 32 (5) (2003), 546–553 [8].*

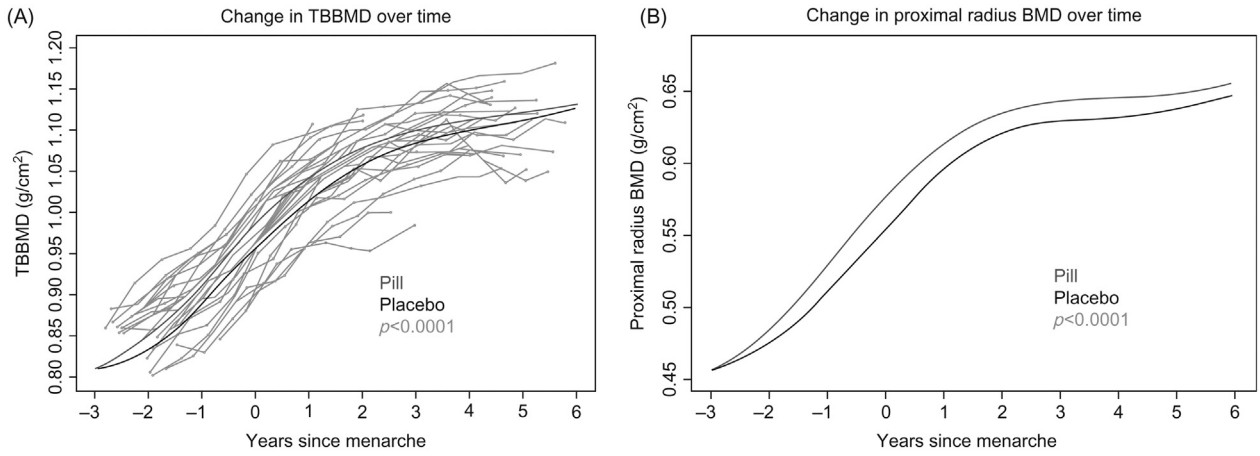

FIGURE 44.3 Total body BMD (A) and proximal radius (B) was significantly higher in prepubertal girls randomized to 1 g calcium supplement daily compared to those assigned to placebo from age 10 to 18 years [10].

III SKELETAL FRAGILITY IN CHILDREN

Fractures in children are associated with low bone mass and density for age [12]. If low bone mass in childhood leads to lower peak bone mass in adulthood, the risk of fracture increases later in life. Relative skeletal fragility can occur naturally with growth spurts. Beyond genetically programmed qualities, bone mass and density throughout life are influenced primarily by nutrition, physical activity, and hormones. Furthermore, eating disorders, smoking, alcohol abuse, and various drugs also influence bone mass. To a large extent, these factors work independently in that one cannot compensate for inadequacy of another. However, dietary calcium and physical activity have important interactions. Finally, some disorders are associated with low BMD.

A Relatively Low BMD During Puberty

Puberty is a period of rapid skeletal growth that is genetically programmed and hormonally driven. The rate of total body bone mass accrual throughout adolescence was determined by Bailey et al. in a longitudinal study of white boys and girls [13]. From this study, we know that approximately 25% of adult peak bone mass is acquired over approximately 2 years—on average this occurs from age 12 to 14 years in girls and age 13 to 15 years in boys. Peak bone mineral content (BMC) velocity is higher and occurs later for boys than for girls. The timing of bone mineral acquisition is more closely linked to pubertal development than to chronological age [2,13].

During puberty, bones first elongate and then mineralization, or bone consolidation, ensues. At the age of peak height velocity, adolescents have acquired 90% of their adult height (or bone size) but only 60% of adult total body BMC. Thus, early puberty is a period of relatively low BMD and, therefore, susceptibility to fracture is not unlike that of age-related bone loss [14–16]. The higher incidence of fracture during this time of life corresponding to the lower BMD in the study by Bailey et al. [13] is shown in Fig. 44.4. Approximately 51% of boys and 40% of girls experience fractures by age 18 years [16].

The dramatic increase in rates of childhood fracture in the United States in just three decades is apparent in Fig. 44.5. Fracture incidence increased 32% in males, with the greatest increase at age 11–14 years, and 56% in girls, with the greatest increase at age 8–11 years. Increased rates of childhood fracture may relate to reduced consumption of milk, change in physical activity or recreational activities, and/or increased body weight during this time period. The prevalence of excessive adiposity in children and adolescents has nearly tripled while the incidence of fracture has increased [19]. In adults, increased weight has been associated with increased bone mass [20], but overweight children and adolescents have higher rates of fracture [12,21,22]. The increased incidence in fracture with excessive body weight in children has been hypothesized to occur because of greater force being placed on bones such as the radius during falls, lower bone mass and bone strength with increasing body fat when adjusted for total body weight, and impaired mobility [21,23–28]. The interaction between calcium intake and body mass index (BMI) is described later. Changes in bone geometry that accompany increases in bone size throughout childhood include increases in cortical thickness and bone diameter [29]. Bone diameter and cortical thickness are less in children with excess body fat [28]. This emphasizes the need to maintain ideal body weight in children.

B Disorders Associated With Low Bone Mass

A number of disorders have been associated with low bone mass in children (Table 44.1). Skeletal health should be evaluated with diagnosis of these disorders. If skeletal fragility develops, bone fractures can occur with minimal or no trauma, a condition known as osteoporosis. The ability to reverse bone deficits with early diagnosis and treatment remains uncertain.

Amenorrhea most often results from excessive exercise or energy intakes too low to sustain physiologic levels of estrogen. Anorexia nervosa is an eating disorder characterized by intense fear of gaining weight or becoming fat. In this condition, body weight is less than 86% of normal for height and age. Reduction in bone gains or acceleration of bone loss resulting in low BMD for age can occur with anorexia nervosa [30]. Osteoporosis that develops as a result of anorexia nervosa is more severe than with other causes of estrogen deficiency. Girls with anorexia nervosa had lower fat and energy intakes than did girls without anorexia nervosa [30]. Severity of low bone mass (i.e., osteopenia) is worse if the eating disorder is initiated in adolescence than in adulthood and worse for a longer duration [32].

Little is known about specific diet therapies and improved bone health in the other disorders. Nutrient recommendations or dietary guidelines have not been established for any of these disorders for lowering risk of low bone mass. It is logical that recovery of low body weight would be helpful to bone. Some interesting associations suggest that future research may show a benefit for nutritional therapies. For example, vitamin K deficiency is prevalent among children with cystic fibrosis [31].

IV NUTRITION AND DEVELOPMENT OF PEAK BONE MASS

The role of diet in development of peak bone mass is thought to have a great impact on risk of osteoporosis [1].

The formative years set the foundation for the skeletal reserves and for lifelong eating and exercise habits. In fact, osteoporosis has been called a pediatric disease. This chapter approaches the role of diet under two themes: diet patterns and individual nutrients. So much of the research base has focused on individual nutrients that supplementation with calcium and vitamin D has become a first-line strategy of prevention and therapy. Although calcium and vitamin D are the two nutrients important to bone most likely to be deficient, this reductionist approach to research and medical nutrition therapy aimed at building strong bones is woefully inadequate. Dietitians can play a critical role in assessing the overall diet and making recommendations that will have greater impact on body weight and health than simply recommending supplements. To understand the quality of the evidence behind public health recommendations related to bone health, a discussion of the limitations of our research designs and measures is warranted.

A Limitation in Methodology

Whether interpreting the effects of diet patterns or individual nutrients on bone, the limitations of investigation of nutritional effects on bone should be appreciated. Difficulty in assessing diet and individual nutrient consumption is not unique to studies of bone and is discussed elsewhere in this book. To quantitatively determine the effect of intake of a nutrient or diet pattern is best accomplished through controlled feeding studies. However, to control diets for sufficiently long periods for bone properties to change is not practical except in animal studies. Although changes in bone properties occur faster in pediatric studies than in studies of adults, it still requires a year or several years to evaluate the magnitude of the effect of interventions on bone. During the first 6 or more months following onset of an intervention, changes in bone reflect the bone remodeling transient [32]. This is a period of adaptation through changes in bone formation rate or bone resorption rate if the intervention is effective. Longer periods are required to determine the effect of the intervention on steady-state bone balance. In children, changes in bone are relatively rapid during periods of active growth. Often, the major challenge is to distinguish between the effects of intervention and growth [33].

The traditional outcome measures for assessing nutritional effects on bone properties—that is, BMC and BMD—may be altered by 2% or less per year as a result of a nutritional intervention. This magnitude of change is difficult to detect by DXA in short-term studies. However, this level of impact over many years can have a profound effect on risk of fracture. Other changes in bone that can indicate strength, such as bone geometry that can be assessed by three-dimensional imaging, also require substantial intervention periods and, to date, do not offer improved precision over DXA. It is preferable to use BMC rather than BMD as the primary outcome measure to assess efficacy of interventions in children. Effective dietary interventions could augment bone size rather than merely affect the mass of bone per unit volume. Thus, because BMD is calculated to adjust for size, it can miss most of the actual change in bone mass during growth. However, DXA only captures two-dimensional space, and consequently it is somewhat affected by size [34] and can correlate with changes in BMC. Interventions during growth that influence bone mass and bone size have a dramatic influence on bone strength [11]. A number of investigators have attempted to correct DXA measures for bone size, such as calculating bone mineral apparent density, BMC for height, and BMC for bone area, but there is no consensus regarding the best approach [35, 36]. Currently, it is recommended to use BMC as the primary outcome, and it is also helpful to measure bone area and other indicators of bone size. Anthropometric measures can be good predictors of BMC in children [37].

Several shorter term approaches for assessing perturbations in bone are available. Serum and urine biochemical markers of bone turnover can determine qualitative changes in bone turnover, but within-subject variation is high [38]. Furthermore, biochemical markers of bone turnover do not measure bone mineral but, rather,

measure fragments of collagen in connective tissue that leak into circulation when bone remodels. Thus, the units cannot be converted into units of bone.

Other short-term methods for analyzing perturbations in bone most often measure calcium as a surrogate for bone. Calcium is a good surrogate for bone because it is present in a fixed proportion of bone mineral. By multiplying BMC determined from DXA by the fraction 0.31, one can derive calcium content in grams. Calcium levels in the blood are not a good indicator of calcium/bone status because they are tightly controlled within a narrow range. Short-term changes in bone balance can be estimated from calcium balance studies. During growth, bone balance is positive. The use of calcium balance studies to determine requirements and response to an intervention has been described [39]. In children, adaptation to a new calcium intake requires approximately 1 week before balance is determined. Calcium isotopic tracers can be used to measure all components of calcium metabolism [39–41]. Combining calcium balance studies and use of oral and intravenous tracers of calcium can provide the data for compartmental modeling whereby determination rates of transport of calcium in and out of pools and the mass of each pool are possible.

B Strength of the Evidence for Diet and Peak Bone Mass

A recent National Osteoporosis Foundation (NOF) position paper reported a systematic review of predictors of peak bone mass [1]. The consensus grades of evidence for factors related to diet are given in Table 44.2.

TABLE 44.2 Evidence Grading for Nutrition and Development of Peak Bone Mass

Nutrition Factor	Grade
Macronutrients	
• Fat	D
• Protein	C
Micronutrients	
• Calcium	A
• Vitamin D	B
• Micronutrients other than calcium and vitamin D	D
Food Patterns	
• Dairy	B
• Fiber	C
• Fruits and vegetables	C
• Detriment of cola and caffeinated beverages	C
Use of alcohol	D

Lewis, et al., The National Osteoporosis Foundation's position statement on peak bone mass development and lifestyle factors: a systematic review and implementation recommendations, Osteoporos. Int. 27 (4) (2016) 1281–1386 [1].

C Dietary Patterns and Bone Health

When formulating recommendations for food patterns for different subgroups, the Dietary Guidelines Advisory Committee for Americans (DGAC) considered bone health [42]. The food patterns were designed to meet nutrient recommendations including bone-related nutrients. Calcium and vitamin D were identified as shortfall nutrients of public health concern. The evidence for a relationship between milk and milk products and bone health was also reviewed in determining quantities to recommend for optimal health. In addition to getting adequate nutrients and milk products, the committee considered dietary habits detrimental to health, especially with regard to energy excess but also for bone health. Dietary patterns as they influence acid–base balance may also play a role in bone health. The 2015 DGAC concluded that there is limited evidence for a dietary pattern that is higher in dairy products, fruits, vegetables, grains, and nuts, and lower in meats and saturated fat are beneficial for bone health outcomes in adults (which included decreased risk of osteoporosis and fracture). However, the DGAC could not draw the same conclusion in children and adolescents due to the paucity of data on dietary patterns and bone health in this age group [42].

1 Milk and Milk Products

The NOF position paper rated evidence for the relation of dairy intake to development of peak bone mass as a B grade [1]. Few randomized controlled trials (RCTs) have been done in children with bone outcome measures. The largest and most effective was in Chinese girls with low calcium intakes compared to Western countries [43].

The *Dietary Guidelines for Americans* includes 2 cups of milk or milk product daily for children aged 2–8 years and 3 cups after age 8 years [42]. The amount of milk was set to help meet requirements for several nutrients, including calcium, magnesium, potassium, riboflavin, and vitamin D. Milk products provide approximately 50–79% of the calcium in the diets for children in the food patterns for age and gender recommended by the 2010 DGAC [44]. The milk group also provides more than 10% of the nutrients in the pattern for riboflavin, vitamin B_{12}, vitamin A, thiamin, phosphorus, magnesium, zinc, potassium, protein, and carbohydrate. If milk products are excluded from the patterns, intake for calcium falls below 64% for all children and below 33% for young children; it also falls below 88% for magnesium—as low as 33% for some age groups [44]. Alternatives to milk products given in

the DGAC report were low-lactose milk products [44]. Although some fortified foods, such as calcium-fortified soy milk, have nutrient profiles similar to that of milk, it is difficult to meet calcium and potassium requirements without milk. Milk product consumption has been associated with overall diet quality. Adequacy of milk intake has been associated with adequacy of calcium, potassium, magnesium, zinc, iron, riboflavin, vitamin A, folate, and vitamin D for children [45].

Many calcium-fortified foods are on the market that could theoretically be used to provide the requirements for this nutrient. Gao et al. [46] evaluated the ability of dairy-free diets to meet calcium intake while meeting other nutrient requirements using diets in U.S. children aged 9–18 years for those participants in NHANES 2001–02 who reported no intake of dairy. Calcium requirements were not met without use of calcium-fortified foods, and only one child accomplished this. Average calcium intake without dairy products was 498 mg/day for girls and 480 mg/day for boys compared to 866 and 1070 mg/day, respectively, with dairy products. At calcium intakes of approximately 400 mg/day, calcium retention was only 131 mg/day compared to almost three times that much if the adequate intake for calcium is met [47]. In a longitudinal study of 151 white girls, dairy product/calcium intake at age 9 years was associated with total body BMD gain from age 9 to 11 years [48]. Milk avoiders have increased risk for prepubertal bone fractures [49]. Retrospective studies have shown that the incidence of postmenopausal fracture is inversely related to drinking milk in childhood [50,51]. In the nationally representative NHANES database, the incidence of hip fracture was twice as high for those who consumed one glass of milk or less per week compared to those who consumed at least one serving per day during childhood [50].

Milk consumption in children has declined over time. In the Bogalusa Heart Study, during the two decades from 1972 to 1994, average milk consumption by 10-year olds declined by an average of 64 g [52]. Fluid milk consumption was negatively correlated with soft drink consumption, which had a detrimental effect on bone gain in girls [53]. The displacement of milk with soft drinks removes a rich package of nutrients from the diet. On average, males of all ages consume more dairy than females. In an analysis of NHANES data from 2001 to 2008, females had the highest average dairy consumption at ages 4–8 years old, of around 2 cups/day, that steadily declined with greater age; whereas males had a peak mean consumption of approximately 2.5 cups/day of dairy at ages 14–18 years, that then steadily declined after that point with increasing age [54].

2 Plants Versus Animal-Based Diets

The mix of animal- and plant-derived foods in the diet of an individual influences two postulated determinants of bone health—acid–base balance and amount of protein. Although dietary protein is a nutrient, because the type of protein influences acid–base balance, dietary protein is discussed in this section on dietary patterns. Intake of fruits and vegetables also influences the acid–base balance.

The role of the type and amount of proteins in bone health has been studied for several decades, but little work has been done in children. Alkaline dietary salts contain the cations K^+, Ca^{2+}, and Mg^{2+}, which act as buffers for organic acids produced during metabolism and hepatic oxidation of S-containing amino acids that would otherwise lower blood pH. Increased metabolic acidosis has been associated with increased bone resorption in cell culture systems [55] and increased urinary calcium excretion in humans [56]. Bone is thought to serve as a reservoir of buffering capacity due to the carbonate and hydroxyapatite salts. Typical acid loads produced on a Western diet are on the order of 1 mEq of acid/kg/day. Investigators have attempted to estimate the renal acid load of diets as a measure of acid–base load by taking into account the mineral and protein composition of foods [57]. Thus, diets high in fruits and vegetables that contain potassium and produce an alkaline ash and those richer in plant proteins than animal proteins, which contribute more S-containing amino acids, have been promoted for better bone health through improving acid–base balance. A high ratio of dietary animal to vegetable protein intake has been associated with increased rates of bone loss and increased risk of fracture [58].

The hypothesis that increasing dietary protein or animal versus plant proteins or even acid–base balance influences bone has been challenged. Bonjour [59] argues that bone is unlikely to be the main source of buffering acid loads because bone mineral is not in direct contact with systemic circulation. Rather, buffering of acid loads is accomplished through elimination of carbon dioxide by the lungs and hydrogen ions by the kidney. The increased urinary calcium with increased protein intake generally, or S-containing amino acids specifically, is offset by, and in fact is due to, increased calcium absorption with no increase in bone resorption or net differences in calcium retention [60,61]. Increased dietary potassium does reduce urinary calcium excretion, but this did not appear to affect calcium balance because calcium absorption was also reduced as dietary potassium increased [62]. Intake of fruits, vegetables, and herbs does inhibit bone resorption, but this effect is independent of their alkali or potassium contributions [63].

There is evidence that adequate dietary protein promotes bone accrual in children. In an 18-month RCT in which 12-year-old girls consumed a pint of milk a day, an increase in total body BMD was associated with an increase in serum insulin-like growth factor-1 (IGF-1) [64]. The relation between protein intake and bone gains in lumbar spine and femoral neck in 193 subjects aged 9–19 years was positive, particularly in prepubertal children [65]. An interesting hypothesis has been put forth that aromatic amino acid intake may induce an increase in calcium absorption and

serum IGF-1 compared with branched-chain amino acids through activation of calcium sensor receptors in the gut to increase gastric acid production [66].

A study that related biomarkers of diet over 4 years to bone strength in children indicated that both anabolic and catabolic actions influenced bone strength [67]. Urinary nitrogen reflecting protein intake was positively associated with BMD and measures of bone size. Conversely, potential renal acid load (PRAL) was negatively associated with BMC and cortical area. Dietary protein contributes to PRAL.

3 Salt

Dietary salt is the largest dietary predictor of urinary calcium excretion [68]. However, the response of adolescents to dietary salt is racially dependent. In controlled feeding studies using a crossover design with high (4 g, 172 mmol) and low (1.3 g, 5.7 mmol) sodium diets, white adolescent girls excreted more sodium on a high-salt diet than did black girls of matched weight and sexual maturity [69]. Because calcium is excreted with sodium through the shared transport proteins in the kidney, high-salt diets resulted in more calcium excretion and lower calcium retention in white girls than in black girls in the same study [70]. Thus, a high intake of dietary salt is detrimental to growing bone, but the consequences to bone are greater for white than black individuals.

D Individual Nutrients and Bone Health

Calcium is by far the most studied single nutrient related to bone health. Vitamin D is the focus of much current research. These two nutrients are the most likely ones of those important to bone health to be deficient. It should be understood that because bone is a living tissue, all essential nutrients are required for bone growth.

1 Calcium

a Current Recommended Requirements and Their Basis

Current recommended dietary allowances (RDAs) and upper levels (ULs) for calcium, vitamin D, phosphorus, and magnesium are given in Table 44.3 [71].

Calcium requirements can be determined by using the factorial approach (replacement of losses through urine, stools, and skin adjusted for absorption) or by estimating the intake for maximal calcium retention. The 2010 panel used the factorial approach [71] and the 1997 panel used the intake for maximal retention approach where possible [72], but recommended intakes for most age groups by both panels were the same.

Determining calcium intakes for maximal calcium retention requires studies on a range of calcium intakes. The RCTs described next studied only two levels of calcium intake—that of the self-selected diet or one's dietary intake plus the calcium intervention source. One can assess whether calcium supplementation is effective with this study design, but it is not possible to determine an optimal intake. It would be desirable to estimate bone accretion over a range of calcium intakes in different age groups, but this would require large, expensive studies. Instead, data on calcium retention at different calcium intakes are available from short-term controlled-feeding studies in which composites of diet and complete urine and stool collections are analyzed for calcium so that

TABLE 44.3 Dietary Reference Intakes for Bone-Related Nutrients in Children and Adolescents

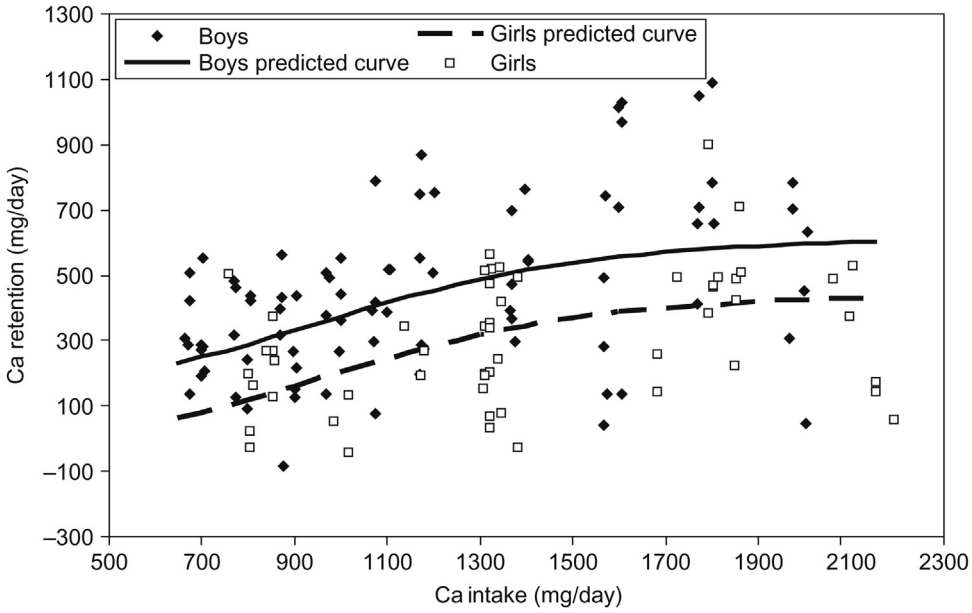

FIGURE 44.6 Calcium retention as a function of calcium intake in adolescent boys (upper curve) and girls (lower curve) [74].

calcium retention or balance (intake—loss from urine, stools, and sometimes sweat) can be calculated. As calcium intakes increase, calcium retention increases until a plateau intake is reached at which further calcium intakes are excreted. A comparison of calcium retention as a function of intake between boys and girls is shown in Fig. 44.6 [73]. Although boys retained more calcium at a given level of calcium intake than did girls, the calcium intake at which retention was not further significantly increased did not differ by gender. Similarly, black girls had higher calcium retention across a range of calcium intakes without different slopes [74]. Thus, boys are more efficient than girls in using calcium, and blacks are more efficient than whites, which results in higher bone mass as adults; however, the need for calcium to produce skeletons of greater bone mass is not detectably different over short periods. Asian girls are also more efficient than white girls in retaining calcium across a range of calcium intakes [75].

b Calcium and BMI

There is an interaction between calcium intake and BMI on calcium retention. Fig. 44.7 illustrates this relationship for white 12-year-old girls [76]. As BMI increases, skeletal calcium accretion increases, but only if calcium intakes are adequate to provide the necessary structural materials. Without adequate dietary calcium, insufficient calcium is retained to build enough skeletal mass appropriate for body weight, which may explain the doubling of fractures shown in Fig. 44.5.

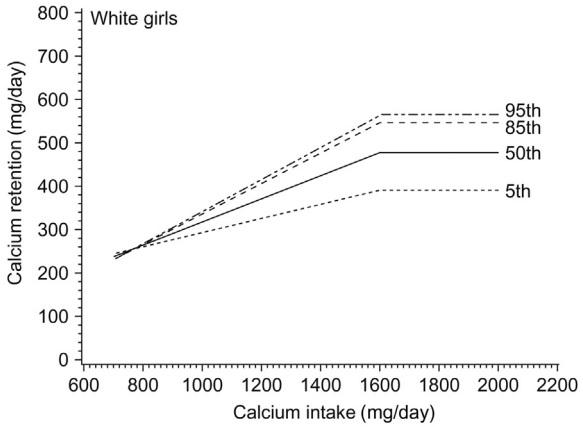

FIGURE 44.7 Influence of BMI (as percentiles of BMI-for-age) on calcium retention curve in white 12-year-old girls [77].

c Evidence for Relationship to Bone

The NOF position paper rated evidence for calcium and development of peak bone mass as grade A [1]. This was the only dietary factor that merited an A grade. This is because there is a large body of evidence from RCTs of calcium intake in children that have reported positive effects on one or more skeletal sites (Table 44.4). Intervention studies have used calcium salts, calcium-fortified foods, and milk with a variety of bone outcomes. Cheese was more effective than calcium carbonate at increasing tibial cortical thickness [89].

Retaining a high-calcium intake during growth for optimizing peak bone mass is prudent. The limitations of

our methodologies contribute to lack of clarity, but several observations support the importance of adequate dietary calcium and bone development during childhood. Retrospective studies showing a benefit of childhood consumption of milk reducing fracture incidence later in life offer one example. Also, adequate dietary calcium can have a positive interaction with exercise in young children and adolescents. In one study, the presence of both mechanical loading and adequate calcium was required for increased BMD [93]. In other studies, calcium alone increased bone size, an index of greater bone strength [47,88]. Neither the effects of dietary calcium on bone quality nor potential interactions with physical activity were usually considered in the BMD-based RCTs evaluated in the meta-analysis of Winzenberg et al. [94].

One hypothesis to explain the influence of dietary calcium on bone proposed that calcium alters the timing of menarche [95]. Evidence for this possibility came from the RCT of Bonjour et al. [97]. The initial trial was a 1-year intervention of calcium-fortified foods in 7.9-year-old girls that showed a positive effect of calcium on mean BMD changes in six skeletal sites. This cohort was followed through age 16.4 years, which allowed determination of the age of menarche and subsequent changes in bone. Interestingly, girls assigned to the calcium intervention for 1 year began menarche earlier than girls assigned to the placebo group [95]. The extra time of exposure to estrogen resulted in more bone gain in subsequent years even though the calcium intervention was discontinued.

d Dietary Calcium

Calcium intake in most diets is predominantly from dairy products [42]. The particular dairy product distribution varies somewhat with race and ethnicity [96]. The discrepancy between calcium intakes and recommendations becomes a large gap after age 11 years. This is a common problem. Looker [98] compiled calcium recommendations and intakes across the life span for 20 countries. The percentage of adolescents meeting country-specific recommendations was approximately 60% for males and approximately 50% for females. Most children older than age 8 years in the United States have calcium intakes below recommended levels. Only 15% of girls and 23% of boys aged 9–13 years and 13% of girls and 42% of boys aged 14–18 years have calcium intakes above the recommended intakes, according to NHANES data from 2003 to 2006 [99]. However, this is slightly increased in NHANES data from 2001 to 2002, particularly for girls aged 9–13 years and boys aged 14–18 years, which during those years only 6% and 31% met recommended intakes, respectively [100].

It is important to reach children early to establish and maintain dietary habits that will ensure lifelong adequate calcium intakes. There is a fair degree of consistency of calcium intake over time. In a 15-year longitudinal study begun as adolescents, tracking of calcium intake resulted in correlations of $r = 0.43$ for males and $r = 0.38$ for females [101]. Calcium intake is also a marker for intake of other nutrients [42]. This is not true for individuals who consume calcium in the form of supplements.

Calcium absorption from dairy products does not depend on fat content or flavoring. In fact, children who drink flavored milk have higher calcium intakes than non-milk drinkers and have similar total intakes of added sugars in diet and similar BMI as children who drink exclusively white milk [102]. A comparison of calcium bioavailability and the number of servings of various foods required to replace 1 cup of milk or yogurt on the basis of absorbed calcium is given in Table 44.5.

For children 4- to 8-years old, the equivalent of 2.6 cups of milk would be required to meet the RDA, and for children older than 9 years, it would be 4.3 cups. Other foods typically provide the equivalent of at least two-thirds of a cup of milk, so milk is not expected to provide all of the calcium requirements.

e Safety of High Intakes

The UL for calcium is 2500–3000 mg/day [71]. The primary concern for excessive calcium intake from supplements in adults is kidney stones. Interactions with trace mineral absorption are also a concern. Dose–response safety data are not available for children 1- to 18-years old.

2 *Vitamin D*

a Recommendations, Dietary Sources and Intakes, and Status

The RDAs of children for vitamin D are given in Table 44.3. The American Academy of Pediatrics supports these recommendations, but it recommends supplemental vitamin D of 5 μg/day to infants not ingesting fortified formula [104]. The amount of new evidence bearing on inputs for optimal health and safety has been remarkable. However, the strength of the new evidence is largely in adults, and we have much to learn about children. NHANES data from 2001 to 2008 show that 75% of children aged 4- to 18-years old have total vitamin D intakes below the Estimated Average Requirement (EAR) [54], indicating that intakes are falling short of recommendations on a population level.

Vitamin D across the life span and dietary sources of vitamin D are described in Chapter 43, Current Understanding of Vitamin D Metabolism, Nutritional Status, and Role in Disease Prevention. Dietary sources of vitamin D are limited and mostly consumed as fortified foods, especially milk. A summary of studies on vitamin D status in children and adolescents worldwide was compiled by El-Hajj Fuleihan [105]. The range in mean serum 25-hydroxyvitamin D levels (the best status indicator for vitamin D) was large: 13–142 nmol/L. For children at

risk for vitamin D deficiency, recommended intakes are 600–1000 IU/day.

b Evidence for a Relationship to Bone

Vitamin D deficiency in young children has long been associated with rickets. An intake of 2.5 μg (100 IU)/day is thought to be adequate to prevent rickets [105,106]. This disorder is described in Chapter 43, Current Understanding of Vitamin D Metabolism, Nutritional Status, and Role in Disease Prevention.

The vitamin D–parathyroid hormone (PTH) homeostatic regulatory axis helps regulate serum calcium levels in response to dietary calcium. Under conditions of low calcium intake, serum calcium levels fall, PTH is released, and vitamin D is converted to its active form, 1,25-dihydroxyvitamin D. Serum calcium levels rise as intestinal calcium absorption is upregulated; renal reabsorption of calcium increases, which conserves urinary excretion of calcium; and bone resorption increases. Interestingly, improving vitamin D status with supplementation of 1000 IU (25 μg) vitamin D_3 per day for 4 weeks resulted in a significant decrease in fractional calcium absorption in adolescents [107]. Apparently, vitamin D status was adequate at 4.5 nmol serum 25(OH)D and/or calcium intake of approximately 1000 mg/day was sufficiently high without supplementation to optimize fractional calcium absorption. Similarly, a 12-week dose–response RCT of vitamin D_3 supplementation, ranging from 400 to 4000 IU/day in children in early puberty, found no effect of supplementation at any level on fractional calcium absorption [108]. This was despite significant increases in serum 25(OH)D over the 12-week study. However, mean baseline 25(OH)D levels were sufficient at 70 nmol/L. Response to vitamin D levels used in the RCTs would only have the potential to be effective if doses were adequate and beginning vitamin D status of the subjects was sufficiently inadequate.

The NOF position paper rated the level of evidence as grade B for vitamin D and development of peak bone mass [1]. The seven RCTs relating vitamin D supplementation and bone (Table 44.6) are quite varied among the

studies. As with calcium absorption, vitamin D and calcium intakes would be interdependent.

One RCT of two doses of vitamin D equivalent to 200 and 2000 IU/day in 10- to 17-year-old Lebanese girls was able to improve vitamin D status on the higher dose and improve total hip BMC and area but not other bone measures [109]. Dietary calcium intakes were low in that study. Lean mass was increased with vitamin D supplementation. Subjects in both the Cheng et al. [89] study and the Viljakainen et al. [110] study had adequate calcium together with vitamin D.

c Safety of High Doses

Dose–response studies of longer duration than have been reported are needed to truly determine ULs of safety studies in which risk intoxication is unmentioned. The current ULs are given in Table 44.3.

Safety is assessed by observing no change in serum or urinary calcium levels. The 5-μg dose of vitamin D was ineffective in the Cheng et al. [89] study but effective for the femur in the study by Viljakainen et al. [110], but only when a compliance-based analysis was used. That study showed a dose–response change in vitamin D. Single oral doses of vitamin D have been given with no change in mean serum or urinary Ca:Cr ratios [110].

In the study by El-Hajj Fuleihan et al. [109], adolescents given 14,000 IU (350 μg/week) of vitamin D_3 for 1 year showed no change in mean serum calcium level. This is equivalent on a daily dose to the UL. We do not know the safety of much higher doses in children.

3 Other Nutrients

Although many other nutrients are necessary for growing bone, there is little evidence that current intakes compromise development of peak bone mass for most individuals. Two minerals besides calcium that comprise a substantial protein of bone mineral are phosphorus and magnesium. Bone mineral is calcium phosphate, but 60% of the magnesium in the body resides in bone. RDAs and ULs for these nutrients for children are given in Table 44.3. The dietary Ca:P ratio affects bone mineralization and turnover through intestinal calcium and phosphorus transports [115]. Phosphorus is clearly essential for bone acquisition, but deficiency has not been a concern for children. Excessive intakes of phosphorus in soft drinks have been a concern. However, as discussed previously, the negative association of soft drink consumption and bone in girls is likely due to displacement of milk as a beverage.

Magnesium deficiency disrupts bone accretion. Rats fed 50% of their requirement for magnesium have structural changes that lead to reduced bone volume [116]. Obtaining recommended intakes of magnesium is not of concern for children. Iron deficiency also has a detrimental effect on bone morphology in growing animals that is exacerbated by calcium deficiency [117].

V CONCLUSION

Making wise nutritional choices during growth is a window of opportunity to build optimal peak bone mass to reduce risk of fracture later in life. If the opportunity is neglected, the consequence can be fracture. During infancy, it is not difficult to meet requirements through breast-feeding or infant formulas. The other accelerated growth period, puberty, is much more difficult. Diets vary widely in nutrient sufficiency; peers may have more influence than caregivers. Fracture incidence in childhood is highest during the pubertal growth spurt when bones elongate before they consolidate and BMD is lower. The incidence of pubertal fractures is increasing, possibly related to the increase in obesity coupled with a decline in consumption of milk as the beverage of choice. Diet patterns may be as important in building strong bones as adequacy of individual nutrients. The *Dietary Guidelines* offer a good plan. Supplements may be useful for some individuals and in some conditions.

Chapter 45

Osteoporosis in Adults

Robert Marcus
Stanford University, Stanford, CA, United States

I INTRODUCTION

Osteoporosis is a global skeletal disorder of decreased bone strength in which the only important consequence is an increased risk for fracture with minimal trauma. The term *porosis* means "spongelike," which aptly describes the appearance of that portion of the skeleton, the trabecular skeleton, which is most afflicted with this disease (Fig. 45.1). Bone strength is a complex function integrating bone mineral density (BMD) and bone quality. BMD is the concept most familiar to the public, to patients, and to physicians, but it is only one determinant of bone strength, all other contributions that are not captured by BMD measurement come under the rubric of "bone quality." The term *quality* should more properly be considered as the plural *qualities* because it encompasses a wide variety of characteristics that are enumerated later in this chapter. Osteoporotic, or fragility, fractures traditionally have been grouped according to their location, either in the spine (vertebral) or nonspine, the latter including those of the distal radius (Colles' fractures) and the proximal femur (hip fracture). It is important to understand that because of its global nature, osteoporosis imposes an increased risk for virtually all fractures in affected individuals.

Already more common than any other generalized skeletal condition, osteoporosis continues to increase in prevalence. Based on data from the National Health and Nutrition Examination Survey III (NHANES) and from the 2000 National Census, the National Osteoporosis Foundation estimated that, in 2002, 20% of postmenopausal white women in the United States had osteoporosis, and an additional 52% had low bone density at the hip [1]. In the whole population, approximately 8 million have osteoporosis, of whom approximately 1.5 million will fracture each year. One out of every two white women will experience an osteoporotic fracture at some point in her lifetime [1−3].

Although men have a lower prevalence of osteoporosis than women, perhaps 25% as great, fragility fractures certainly occur in men, and some of these, particularly at the hip, carry a less favorable prognosis in men than for women. The most common osteoporotic fractures occur as compression deformities of the thoracic or lumbar spine. Although two-thirds of these do not acutely produce symptoms, they must not be viewed in any sense as benign events. Even mild compression fractures aggravate by four- or fivefold the short-term risk for subsequent fractures. Approximately one-third of vertebral fractures produce symptoms when they occur and are referred to as "clinical" vertebral fractures. These are more likely to be of moderate or severe degree in deformity and are the fractures most likely to result in long-term pain, deformity, and disability. In the Study of Osteoporotic Fractures (SOF), a long-term observational study of thousands of older women, clinical vertebral fractures were associated with an eightfold excess of mortality similar to that observed with hip fracture [4]. The incidence of vertebral fractures in women begins to rise early in the sixth decade, corresponding in time to the menopausal loss of endogenous estrogen. The incidence continues to increase in succeeding decades (Fig. 45.2) [3].

At nonvertebral sites, forearm fractures, particularly at the distal radius, also increase during the sixth decade but stabilize thereafter, at which time the incidence of hip fracture begins exponentially to increase [3]. Both forearm and hip fractures result directly from a fall. Whether an individual fractures the arm or the hip reflects the manner of falling. Younger women with normal locomotion generally fall while walking and break a fall by arm extension. Older and more frail women often fall while transferring from a seated to a standing position. If they

fail to elevate their centers of gravity sufficiently to support an upright posture, they fall backwards or to the side, directly impacting the femoral greater trochanter and possibly leading to hip fracture [5,6].

This chapter focuses on the characteristics of a healthy skeleton, the underlying pathophysiology of osteoporosis, the characteristics of osteoporotic bone, approaches to conserving bone throughout adult life, and therapeutic approaches to treating skeletal fragility. A comprehensive discussion of the various pharmacologic agents available for patient management lies outside the scope of this chapter, and the critical role of bone acquisition during years of growth through adolescence appears in the companion chapter in this volume on childhood bone development (Chapter 44: Osteoporosis: The Early Years) which the reader is strongly urged to consult.

II THE SKELETON

Bone is a complex cellular tissue that contains, by weight, approximately 30% organic constituents and 70% mineral. The most abundant protein in the organic compartment is type I collagen, a fibrillar structure consisting of three interweaving strands—normally two strands of alpha-1 collagen and one strand of alpha-2 collagen. Collagen represents 98% of the organic phase of bone, and various noncollagen proteins account for the remainder [7].

The mineral phase of bone is approximately 95% hydroxyapatite, a highly organized crystal of calcium and phosphorus. Other minerals normally found in bone mineral include sodium (indeed, approximately 30% of total body sodium can be stored in bone crystal), magnesium, and fluoride. Incorporation of fluoride and strontium into bone crystal is of particular relevance because these compounds have seen use as therapy for osteoporosis.

A Bone Cells

The processes of bone formation and breakdown (resorption) require cellular activity. Three major cell types reside in bone and conduct these processes: osteoblasts, osteocytes, and osteoclasts.

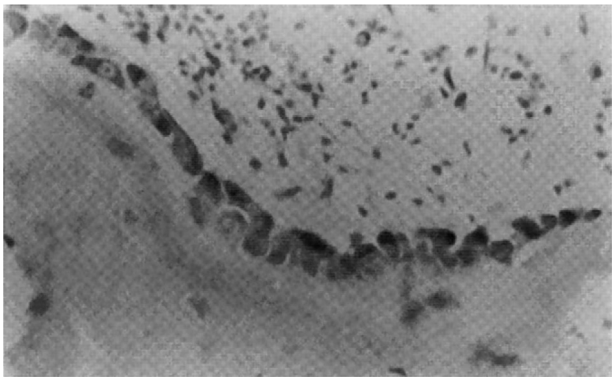

FIGURE 45.3 Low-power view of osteoblasts lining the bone surface. *From C.A. Lee, T.A. Einhorn, The bone organ system, form and function, in: R. Marcus, D. Feldman, J. Kelsey, Osteoporosis, Academic Press, San Diego, CA, 2001, 3–20 [7], with permission.*

Osteoblasts are the primary bone-forming cells. They derive from stem cells in the bone marrow stroma. These stem cells are pluripotential, having the capacity to develop along multiple lineages, including fibroblasts, hematopoietic cells, myocytes, adipocytes, chondrocytes, and osteoblasts. During linear growth, osteoblasts invade a temporary cartilaginous template to form primary lamellar bone. During remodeling (see later discussion), a wave of osteoblast precursors migrates to the base of a resorption cavity, acquires the characteristics of mature osteoblasts, and lays down new bone (Fig. 45.3).

Osteocytes are osteoblasts that have become embedded within their own secreted matrix. Each osteocyte sits in its individual hole, or *lacuna*, connected to one another throughout the bone matrix by a highly developed network of channels, or *canaliculi*. Osteocytes appear to be the monitors and responders to a bone's mechanical environment (Fig. 45.4).

Osteoclasts are multinucleated giant cells of macrophage lineage. They undertake the enzymatic destruction of bone during the resorption phase of remodeling (see later discussion). During this process, osteoclasts form a seal at the bone surface with the aid of anchoring proteins called integrins whose receptors exist in the bone matrix. This seal creates a sequestered region underneath the osteoclast into which hydrogen ion is secreted using a carbonic anhydrase-dependent pump and resulting in a highly acidic local environment. In addition, the osteoclast secretes a variety of hydrolytic enzymes, such as cathepsins, which hydrolyze bone matrix (Fig. 45.5).

A fourth cell is also observed in bone. So-called *lining cells* are seen as a syncytial layer of dormant cells that covers bone surfaces. This group of cells is thought to serve a surveillance function that responds to microscopic damage by locally stimulating new remodeling activity. Lining cells also originate from osteoblasts and, although dormant, retain the capacity in certain circumstances to convert into functional osteoblasts and lay down new bone. This appears to be one mechanism through which administration of parathyroid hormone (PTH) achieves a rapid increase in bone formation (see section VB on Pharmacologic therapeutics).

Eighty percent of the adult skeleton consists of compact bone. This is referred to as the *cortical* or *appendicular* skeleton and comprises mostly the long bones as well as the outer shells of the central, or *axial*, skeleton, which includes the spine, sternum, pelvis, and the ends (metaphyses) of long bones. The axial skeleton has a heavy complement (perhaps 40% by weight or 80% by surface area) of a honeycomb-like series of vertical and horizontal bars, or *trabeculae*, and is therefore frequently called

trabecular bone (in orthopedics this may also be called *cancellous* bone). In adults, the trabecular bone of the spine and pelvis constitutes the primary residence of red bone marrow. Because the cells responsible for conducting the processes underlying adult bone loss originate in the bone marrow, and because these processes occur on the surfaces of bone, it should be no surprise that trabecular bone, with its rich complement of bone marrow and extensive surface area, should be the bone compartment that experiences the earliest and most rapid loss of bone with aging.

At any time during adult life, the amount of bone contained within the skeleton consists of that bone which was present at the end of growth, the so-called "peak bone mass," minus that which has been lost. One frequently encounters patients who report being told, following a bone density test, that they have "lost 30% of their skeleton." The problem with such conclusions is that one simply cannot determine from a single BMD measurement whether a deficit in bone mineral reflects bone loss or failure to achieve the peak bone mass that might have been predicted for that individual. In fact, the majority of young adults with low bone mass have not lost bone at all but, rather, have age-related deficits related to poor acquisition of peak bone mass. (See chapter 44 by Weaver on childhood bone acquisition in this volume.)

B Physiologic Roles of the Skeleton

During vertebrate evolution, the skeleton acquired two fundamental but not necessarily compatible functions. By virtue of its dense mineralization, bone provides the structural rigidity necessary to withstand the effect of gravity and support terrestrial locomotion. By adapting to region-specific differences in its mechanical environment, denser, stronger bone exists where it is needed without requiring a universal increase in skeletal weight to the point that mobility is jeopardized.

Bone also constitutes the *primary* repository in the body for calcium. Indeed, 99.5% of body calcium is contained within bone and can be mobilized to support the extracellular calcium concentration at times of need. For the great majority of vertebrates, the calcium environment is extremely high, reflecting its very high concentration in ocean water ($\sim$400 mg/L). Facing the threat of calcium toxicity, ocean fish must be able to eliminate excess calcium from their bodies, which they accomplish through a calcium-dependent ATPase system in the gills. Progression of vertebrates onto land, with freshwater far more dilute in calcium, required mechanisms to promote calcium extraction from the environment and to conserve it within the body. PTH, the peptide secretory product of the parathyroid glands (first appearing in amphibians), serves this role. In response to minute-to-minute relatively mild reductions in extracellular calcium concentration, such as during the hours following a meal, PTH stimulates the kidney to conserve calcium by regulating renal tubular reabsorption efficiency. When calcium deficits become sustained or severe, such as in the face of chronically inadequate dietary calcium, PTH stimulates the renal production of $1,25(OH)_2$ vitamin D (calcitriol), the potent hormonal form of the parent vitamin, which in turn enhances intestinal calcium absorption. In this setting, PTH also stimulates bone remodeling by initiating the formation of new remodeling units and resulting in delivery of calcium from the skeleton to the extracellular environment. Together, these actions restore plasma calcium concentrations to their normal level [8]. It must be understood that PTH action on the skeleton does not selectively remove calcium from the skeleton but is accomplished by an increase in bone remodeling (see later discussion) so that the release of mineral to the plasma compartment is accompanied by a net loss of bone.

C Remodeling: The Key to Understanding Age-Related Bone Loss

Many mammals, primates, and humans maintain skeletal integrity through a continuous process of breakdown and renewal known as *remodeling*. This process occurs lifelong, although during childhood and adolescence it is overshadowed by the events of linear growth (modeling). Once growth centers have fused and skeletal maturation is complete, remodeling becomes the dominant—and indeed, with rare exception, the only—mechanism through which bone is added to or removed from the skeleton. Each remodeling event is carried out by discrete bone multicellular units and consists of an initial phase of bone resorption that is coupled to a longer phase of bone formation (Fig. 45.6). These are initiated when cells of macrophage lineage come from the bone marrow to points on the bone surface and fuse into multinucleated osteoclasts that dig into and remove bone. The cavity thus created reaches a depth of 60 μm within 6−8 weeks. In this manner, both mineral and matrix constituents are returned to the circulating extracellular fluid. Released from the resorbed matrix is a rich assortment of cytokines and growth factors that then attract into the base of the cavity a wave of osteoblast precursor cells from the marrow stroma. These transform into functional osteoblasts and begin to lay down new bone matrix. Once the new bone reaches a thickness of approximately 20 μm, it begins to accumulate mineral. By the end of approximately 6 months, bone formation is complete and the bone is restored almost to its basal state. However, like many biological processes, bone remodeling is not 100% efficient; that is, the amount of new bone formed does not

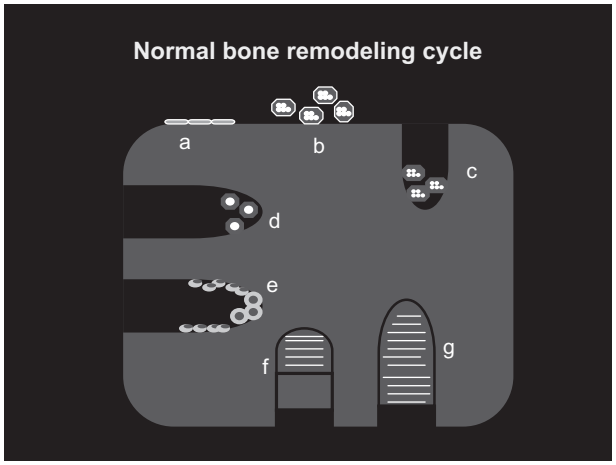

FIGURE 45.6 The bone remodeling cycle. This drawing represents a region of trabecular bone. All remodeling events occur on the bone surface. (a) 90% of bone surface is generally covered by thin layer of dormant lining cells. (b) Coalescence of osteoclast precursors at a site on the bone surface with creation of multinucleated osteoclasts. (c) Osteoclasts remove a divot of bone, reaching 60 μm in depth by 6–8 weeks. (d) Soluble factors released by osteoclastic resorption recruit a new wave of cell proliferation (preosteoblasts) into the base of the resorption cavity. (e) Preosteoblasts acquire the osteoblast phenotype. (f) Osteoblasts secrete new bone matrix, which begins to acquire mineral after a thickness of approximately 20 μm is achieved. (g) New mineralized bone almost fully replaces resorbed bone by approximately 6 months. Small deficits are left, reflecting remodeling inefficiency and accounting for the process of age-related bone loss. *Copyright Robert Marcus.*

completely make up for the older bone removed, so a small bone deficit remains as a consequence of each remodeling event, called the "remodeling imbalance." The cumulative effect of the hundreds of thousands of remodeling units in play at any one time is the readily observable phenomenon of age-related bone loss. Consequently, anything that promotes an overall increase in whole body bone remodeling aggravates the rate of bone loss and, by contrast, interventions that slow remodeling constrain bone loss. This forms the basis for using drugs that slow remodeling as a mainstay of osteoporosis treatment, as discussed later in this chapter.

Another word should be said concerning matrix mineralization during the bone formation phase of remodeling. Mineral is rapidly laid down for the initial several weeks but thereafter changes to a slow, linear rate. Mineral is never fully saturated in the bone, so it continues to accumulate as long as that particular unit of bone survives. The only thing to terminate this process would be the initiation of a new wave of osteoclastic resorption to clear out this region of older bone. Thus, if overall remodeling slows, bone survives longer and becomes more densely mineralized. The consequences of this finding are also discussed later.

If, as described, bone remodeling leads to loss (and presumably weakening) of bone, one may ask why it has evolved and what its purpose may be. It appears that the cardinal role of remodeling is to serve a scavenger function, through which fatigued or damaged bone is cleared away and replaced (albeit at the long-term price of gradual bone loss). In addition, remodeling is the means by which PTH restores normocalcemia in response to hypocalcemia.

D Intercellular Communication Among Bone Cells: Triggers and Constraints on Remodeling

Because initiation of each remodeling event begins with delivery of osteoclasts or their precursors to the bone surface, it is important to have passing familiarity with the signals that control this initial event [9,10]. The key cell for controlling osteoclast production is the osteoblast. This bone-forming cell elaborates two distinct proteins, a stimulator and a repressor, that regulate osteoclast production. The osteoclast stimulator was initially called "osteoclast differentiation factor," but now that its primary target is known, it has been given the less transparent name of RANK-ligand. RANK is an abbreviation for the "receptor that activates NF-kappa β" (a gene present in osteoclasts and other cells of macrophage origin). Under stimulation by agents known to increase bone remodeling (e.g., PTH and L-thyroxine), the osteoblast synthesizes and extrudes RANK-ligand that binds to RANK located on osteoclast precursors, leading to production of new osteoclasts. The repressor molecule, also produced by osteoblasts, is a protein called osteoprotegerin (OPG). Production of this protein increases when the osteoblast binds agents that inhibit remodeling, such as estrogen. OPG exhibits high affinity for RANK-ligand and therefore acts as a false receptor, neutralizing the effect of any RANK-ligand with which it comes into contact.

The RANK–RANK-ligand–OPG complex acts in a push–pull manner to regulate osteoclast production and hence controls the rate of bone remodeling. When stimuli favor greater remodeling, RANK-ligand production increases, OPG decreases, and RANK is activated. When remodeling is suppressed, RANK-ligand decreases, OPG increases, and RANK is constrained. Interference with RANK-ligand function is the basis of a recently developed therapy for osteoporosis (see Section V.B.1.f: Denosumab).

III ADULT BONE MAINTENANCE

For many years, scientific inquiry into the basis of adult bone loss and development of osteoporosis was highly

parochial. Nutrition scientists focused on the diet, exercise physiologists and mechanical engineers focused on physical activity and the mechanical environment, and physicians whose responsibility was to care for patients with osteoporosis focused largely on menopausal estrogen loss. It is now abundantly clear that acquisition and maintenance of a healthy skeleton is far more complex than can be explained by any of these individual spheres. One needs to view the skeleton as subject to diverse influences throughout life so that bone status at any particular time is the result of a stochastic process by which each individual insult or event over a lifetime has made its independent contribution.

A Major Influences on Age-Related Bone Loss

Successful bone maintenance requires continued attention to the same "hygienic" factors that influenced bone acquisition: physical activity, diet, and reproductive status. Bone maintenance requires sufficiency in all areas, and the others do not compensate deficiency in one. For example, amenorrheic athletes lose bone despite frequent high-intensity physical activity and supplemental calcium intake [11,12]. Successful bone maintenance is also jeopardized by known toxic exposures such as smoking, alcohol excess, immobility, systemic illnesses, and many medications.

1 Habitual Physical Activity

The skeleton's mechanical function was referred to previously. To accomplish this role in a manner that optimizes bone strength while at the same time not unduly increasing its weight, bones accommodate the loads imposed on them by undergoing alterations in mass, in external geometry, and in internal microarchitecture. The first enunciation of this principle is credited to the German scientist Julius Wolff as "Wolff's law" [13]. As a consequence of such adaptation, steady-state bone mass reflects its mechanical environment, a concept that applies when comparing bone mass among individuals, different bones within an individual, and even different regions within a single bone. A substantial body of research has addressed this concept. These studies are of two general types: (1) comparisons of bone mass of athletes to that of sedentary controls and (2) descriptions of associations between level of physical activity and bone mass within a general population. The first type of study generally considers only very active or sedentary individuals, and hence extreme differences in activity are represented. In the latter case, a broader range of physical activity is examined.

Considerable evidence indicates that elite athletes and chronic exercisers have higher BMD than age-matched, nonexercising subjects—a finding, not surprisingly, that applies primarily to sites that undergo loading during the exercise (reviewed in Ref. [14]). Activities associated with high load magnitude at low number of repetitions (cycles) are associated with substantial increases in bone mass. For example, world-class and recreational weight lifters have 10−35% greater lumbar spine BMD than sedentary age-matched controls. Comparing dominant to nondominant limbs in athletes whose sport involves unilateral loading represents a special case. For example, increased BMD in the playing compared to the nonplaying arm of tennis players has been repeatedly observed. By contrast, swimming, a buoyant activity not associated with counteracting the effect of gravity, does not appear to increase BMD. In one study of elite university athletes, swimmers actually had lower bone mass than gymnasts or nonathletic controls, despite increased muscle bulk and regular weight training [15]. Young athletes who spend more than 20 hours each week in a buoyant environment for many years may simply not experience sufficient gravitational stress to promote fully the expected degree of bone acquisition.

These comparisons of athletes and control subjects must be interpreted with caution. Because no measurements of bone mass are made prior to initiating the exercise program, a causal relationship between exercise and bone cannot be proven. It may be that individuals with higher bone density are more apt to succeed in athletics, and therefore they enter the "athlete" and chronic exercising groups. Conversely, elite swimmers may have excelled in buoyant activity because of a lighter skeleton. In many studies, important characteristics of the matched controls have been overlooked. Factors such as menstrual status, nutrient intake, and use of tobacco or alcohol may have confounded the results. Finally, skeletal status is most frequently expressed as the areal BMD (g/cm^2), a term that overestimates BMD in persons with large bones and underestimates it in smaller people. Thus, if exercisers and controls are not well matched for height, conclusions based on BMD may be spurious.

With respect to the impact of habitual physical activity within the general population, many studies now point to a significant skeletal effect of physical activity on the acquisition of bone during the second and third decades. The situation is less clear for moderately active adults, in whom no consistent relationship between current activity level and bone mass has been established. In our own work, strong relationships between estimates of daily energy expenditure and BMD were completely negated by normalizing the data for body weight or lean mass [14]. Several reports document positive relationships between lifelong physical activity and bone status.

Thus, cross-sectional studies generally support the notion that elite athletes and chronic exercisers have

increased BMD, the magnitude of this difference likely depending on the type and intensity of exercise, age, sex, and hormonal status. However, data concerning moderate physical activity remain uncertain.

One approach to eliminating the selection bias of cross-sectional studies is a randomized controlled trial in which exercise is the intervention. A number of properly controlled studies of this sort have been reported. Although most indicate a positive effect of imposed exercise on BMD, the magnitude of response has been very disappointing to those who anticipated the large differences observed in cross-sectional studies. Rarely do the increases in BMD exceed 2% after 1 or 2 years of rigorous training, regardless of the type of exercise used (endurance vs resistance training) [16–19].

Understanding the meager response to exercise interventions is related to the fact that skeletal response to mechanical loads is curvilinear in nature. Complete immobilization, as seen with high-level spinal cord injury, leads rapidly to devastating bone loss, with deficits approaching 30–40% over several months. By contrast, imposition of even substantial training regimens on normally ambulatory people or animals increases bone mass by only a few percent over a similar period. This is illustrated in Fig. 45.7, in which the effect of walking on bone mass is schematized. As an individual goes from immobility to full ambulation, duration of time spent walking becomes progressively less efficient for increasing bone mass. A person who habitually walks 6 hours each day might require another 4–6 hours just to add a few more percent BMD. On the other hand, adding a more rigorous stimulus, such as high-impact loading, for even a few cycles would increase the response slope.

The worst thing that can happen to the skeleton is to be immobilized. For maintaining bone mass during adult life, a certain degree of daily weight bearing is required, and the vast majority of even sedentary individuals achieve this. Small increments in BMD can be achieved by increasing one's daily exercise schedule, but, as a consequence of Wolff's law, these will remain only so long as the added activity continues. For most individuals, particularly if they are elderly or frail, walking provides the soundest and most prudent physical activity for skeletal maintenance.

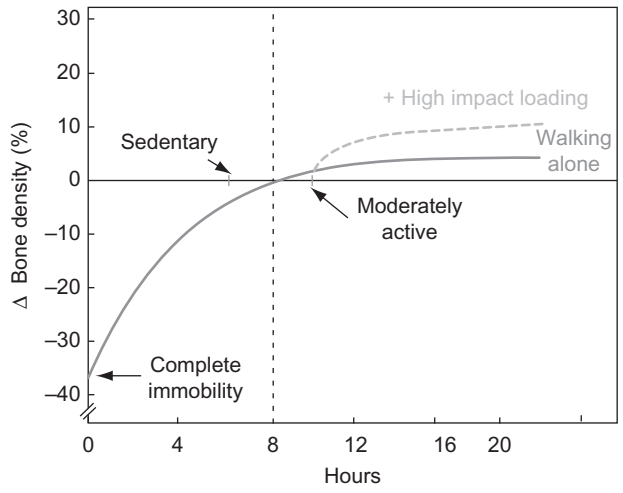

FIGURE 45.7 The curvilinear nature of skeletal response to mechanical loading. *Copyright Robert Marcus.*

2 Nutrition

a Energy

Reflecting the major influence of weight-bearing activity on bone, bone mass is strongly related to body weight, so it should be no surprise that severe deficits in bone occur in states of profound malnutrition. Although frank starvation is extremely rare in developed societies, bone deficits are frequently encountered in medical conditions associated with extremely low body mass, such as anorexia nervosa, as well as various forms of intestinal malabsorption and cachexia. It may be difficult to assign responsibility for bone deficits in such patients to any specific nutrient because patients generally show profound reductions in the consumption of many nutrients. In teenagers with anorexia nervosa, skeletal deficits appear very early, and their magnitude is exacerbated because bone is lost at a time when other girls of similar age are gaining bone at an accelerated rate. Bachrach et al. [20] observed that whole body bone mass correlates linearly with body mass in normal teens, and that the bone mass of girls with anorexia nervosa lies exactly on this curve. In other words, skeletal deficits in young girls with anorexia nervosa primarily reflect their body mass. When these girls were observed over time, weight rehabilitation (a gain of at least 5 kg) was associated with a gain in bone mass.

The next section deals specifically with a group of skeletally important nutrients and nutrient groups. The reader might find it helpful once having read this material to consult the recently developed U.S. Government website ChooseMyPlate (www.choosemyplate.gov) in which food patterns were designed to meet the bone nutrient requirements.

b Calcium

The concept that osteoporosis is a disease of calcium deficiency was proposed more than a century ago, although a central role for calcium intake did not emerge into the scientific mainstream for many years. This largely reflected the overpowering influence of Professor Fuller Albright, who conceived of osteoporosis as a deficiency of bone matrix due to osteoblast failure, usually as a consequence of menopausal loss of estrogen [21]. Intensification of interest in calcium occurred with the publication of three

independent reports. The first, by Matkovic et al. [22], demonstrated a difference in hip fracture incidence in two different regions of Croatia that were demographically very similar except for a substantial difference in the calcium content of local water supplies. Second was the publication of NHANES II, which showed that habitual calcium intakes of American girls and women failed to meet recommended dietary allowances (RDAs) as early as age 11 years [23]. Third was a landmark paper by Chapuy et al. [24] that clearly demonstrated the ability of supplemental calcium and vitamin D to reduce the incidence of hip fracture in a highly vulnerable population.

When one considers that the skeleton is the repository for more than 99% of total body calcium, it is inconceivable that individuals whose intakes are below the amount necessary to maintain whole body calcium balance could be in negative balance without losing bone. Calcium may be considered a "threshold nutrient," which means that below a critical value some physiological function (e.g., calcium balance) is dependent on intake, but at intakes above that value no further impact accrues. Because the mineral demands for growth, early adult, and older adult maintenance differ substantially, the "threshold" value and therefore the intake requirements also differ by age [25,26]. Table 45.1 shows that recommendations for calcium intake have increased substantially over time from previous RDAs [27] and are closely allied to those derived from the literature of formal calcium balance studies [28].

In 2011, the Institute of Medicine (IOM) published updated values for dietary reference intakes for calcium and vitamin D following a comprehensive review of the literature and scientific testimony. The full report is available online (see Tables 45.1 and 45.2). In general, the IOM recommendations are reasonably close to earlier elaborations. One emphasis of the IOM statement was that intakes above those shown as upper level increased the risk of adverse experiences, such as kidney stones.

Although a consensus conference on optimal calcium intake concluded that current habitual calcium intakes by both men and women are inadequate for optimal bone health [25], and several clinical trials demonstrated the ability of calcium supplementation to constrain the rate of bone loss and even reduce fractures [24,29–35], there remains in the medical and research communities some resistance to reaching consensus regarding the role of calcium inadequacy in the pathogenesis of osteoporosis. In part, this reflects considerable uncertainty in estimating the amount of calcium that people habitually consume. For example, dietary histories and food frequency questionnaires carry substantial imprecision. Also, it must be remembered that calcium is not absorbed in a vacuum but, rather, in the course of eating or drinking other foods, and its availability from foods is highly influenced by other nutrients. For example, although the calcium content of spinach is quite good, it is rendered essentially nonabsorbable by the presence of oxalate and perhaps other anions to which it binds [36]. Further consideration of the roles of phosphorus, sodium, and protein appears later.

For adults, calcium intakes in the range of 1000–1500 mg/day are recommended. Note that individuals in early to middle adult life, such as 20–50 years of age, have calcium intakes within reasonable proximity to recommended values and, by virtue of being young enough to undertake regular weight-bearing activity and to maintain normal reproductive function, generally have only modest stress on skeletal balance, as shown by very low rates of bone loss. After menopause (average age, 51 years), and certainly at more advanced ages, declines in endogenous reproductive hormones and in the insulin-like growth factor I axis, coupled with overall trends toward less physical activity, make it less likely that dietary

TABLE 45.1 Various Estimates of the Calcium Requirement (mg/day) in Women

deficiency will be buffered and more likely that age-related bone loss will be aggravated.

c Phosphorus

Various domestic animals respond to excessive dietary phosphorus by increasing the endogenous concentration of PTH, resulting in negative calcium balance and bone loss. In such animals, optimal dietary ratios of calcium to phosphorus approach 1.0. This has led to a popular theory that because calcium:phosphorus ratios in human diets typically are well below 1.0, phosphorus overconsumption initiates a similar process in humans.

Firm evidence to support a role for phosphorus excess in human osteoporosis has not been forthcoming. In contrast, some evidence indicates that intestinal calcium absorption and balance are fairly impervious to very wide variations in daily phosphorus consumption [37,38]. Separate mention should be made concerning the role of phosphorus-containing soft drinks. Cola drinks contain phosphoric acid as their source of effervescence, and one reads frequently in the lay press that the high content of phosphorus in colas is an important contributor to developing osteoporosis. However, although excessive soft drink consumption may well contribute to poor bone status, this is so because these beverages have been substituted for milk, thus exchanging a calcium-rich drink for one that contains essentially no calcium [39].

d Protein

For many years, a concept has circulated as a subtext in osteoporosis research that consumption of excess protein, particularly from animal sources, is an important contributor to the development of osteoporosis. This is considered the consequence of the fact that protein catabolism generates ammonium ion from ammonia and sulfate from sulfur-containing amino acids. When protein intake increases, citrate and carbonate ions are released from bone to neutralize these acids, and, because urinary calcium is closely linked to renal acid excretion, urinary calcium rises. However, plant proteins contain amounts of sulfur similar to those in eggs, milk, and meats, and therefore increased intake of protein from either animal or plant sources similarly increases urinary calcium. Furthermore, the impact of protein on calcium balance depends to a major degree on other nutrients contained in the consumed food. For example, milk calcium compensates for urinary calcium losses generated by milk protein, potassium in such plants as legumes and grains decreases calcium excretion, and the high phosphorus content of meat offsets the calciuric effect of the protein [40].

Nutritional status assessments of patients with osteoporosis do not support a view that these patients have enjoyed a life of luxurious protein consumption. Barger-Lux et al. [41] reported that women with low calcium intakes generally consumed insufficient amounts of multiple nutrients, including protein. Sellmeyer et al. [42] reported higher protein intakes to be associated with greater age-related bone loss in the SOF cohort. However, a substantial body of evidence does not sustain this view. Protein consumption was reported to be an important positive predictor of bone mass in elderly women [43]. In the Framingham cohort, Hannan et al. [44] reported bone loss over time to be inversely related to protein intake, with rates of loss in the highest quartile of protein consumption less than one-third of those in the lowest quartile. Kerstetter et al. [45] conducted a series of controlled balance studies that showed that although calciuria increased with increased protein intake, this did not come from bone but was rather a reflection of improved intestinal calcium absorption. In a randomized controlled trial, Dawson-Hughes and Harris [46] showed that the improvement in BMD in subjects supplemented with calcium and vitamin D was confined mainly to individuals whose protein intake was in the highest tertile. Delmi et al. [47] found that supplemental protein improved recovery from hip fracture, accelerated hospital discharge, and also slowed bone loss in the contralateral hip. Heaney [48]

concluded that the weight of evidence shows high protein intake to be osteoprotective, but only if calcium intake is adequate, whereas the protective effect of calcium occurs only when protein intake is relatively high.

e Sodium

Urinary excretion of calcium and that of sodium are highly linked, and increased sodium intake is known to promote calcium excretion. A similar effect occurs with most diuretic agents (with the single exception of thiazides, which uncouple the handling of these two cations). Thus, it is not unreasonable to expect that increased dietary sodium might be conducive to negative calcium balance and aggravate bone loss. In a 2-year prospective trial, Devine et al. [49] examined the influence of urinary sodium excretion and dietary calcium intake on bone density of postmenopausal women. Urinary sodium excretion (a robust indication of intake) correlated negatively with changes in BMD, and the data suggested that halving sodium intake had the same effect on BMD as increasing daily calcium intake by 891 mg [49].

f Vitamin D

The importance of vitamin D to skeletal maintenance is thoroughly discussed elsewhere in this volume. When severe, vitamin D deficiency is associated with significant undermineralization of bone matrix, a condition known as osteomalacia [50]. At milder levels of vitamin D inadequacy, impaired calcium absorption promotes compensatory secretion of PTH, which increases bone remodeling and aggravates bone loss. Maintaining vitamin D adequacy is an important and widespread issue for the general population and for the vast majority of patients with osteoporosis. It appears that optimal vitamin D status is achieved at 25-hydroxyvitamin D concentrations of approximately 30 ng/mL (80 nmol/L). To achieve this goal, previously recommended vitamin D consumption of 400–800 units/day is not adequate, and doses of 1000–2000 units/day are preferable.

3 Reproductive Hormonal Status

Decades of studies in animals and humans support the concept that achieving and maintaining normal gonadal function is a critical determinant of bone health during pubertal bone acquisition and throughout adult life in both women and men. Indeed, the impact of menopausal loss of endogenous estrogen on skeletal balance can be so profound that many investigators have focused solely on the contribution of estrogen withdrawal to osteoporosis without regard for the other contributions described previously. We now understand that permanent loss of estrogen at menopause is not the only circumstance in which gonadal status has a skeletal impact. During earlier adult life, transient episodes of oligo- or amenorrhea may also be associated with at least transient bone loss [51].

The mechanisms by which estrogen withdrawal affects the skeleton involve multiple organs. The direct skeletal effect of the most potent circulating estrogen, 17-β estradiol, is to suppress the rate of bone remodeling. This is achieved by downregulating the formation of osteoclasts. In some rodents, this effect has been related to the suppression of an osteoclast-stimulating cytokine, interleukin-6 [52,53]. In other animal models and in humans, strong evidence has been presented for the participation of other cytokines, including interleukins and transforming growth factor-β [54]. In addition, estrogen withdrawal reduces osteoblast production of OPG, the decoy receptor for RANK-ligand discussed previously [55]. These cytokine effects are reversed when estrogen is replaced. The use of estrogen as pharmacologic therapy for the prevention and treatment of osteoporosis is described later.

IV DIAGNOSIS OF OSTEOPOROSIS

Because traditional radiographic techniques cannot distinguish osteoporosis until it is severe, diagnosis was, until recently, clinical, requiring a history of one or more low-trauma fractures. Although highly specific, such a grossly insensitive diagnostic criterion offered no assistance to physicians who hope to identify and treat affected individuals who have been fortunate not yet to have sustained a fracture. The focus in this section is the measurement of BMD. However, one must be cognizant of a wide variety of risk factors other than bone density that may profoundly influence an individual's risk for fracture. A partial list of these factors is presented in Table 45.3.

The introduction of accurate noninvasive bone mass measurements afforded the opportunity to estimate a person's fracture risk and to make an early diagnosis of osteoporosis. Large prospective studies have shown that a reduction in BMD of 1 standard deviation (SD) from the mean value for an age-specific population confers a two- or threefold increase in long-term fracture risk [56–59]. In a manner similar to that by which serum cholesterol concentration predicts risk for heart attack or blood pressure predicts risk for stroke, BMD measurements can successfully identify subjects at risk of fracture and can help physicians select those individuals who will derive greatest benefit for initiation of therapy. Indeed, the gradient of risk associated with a 1 SD difference in BMD is even greater than those for cholesterol and heart attack.

Several factors limit the ability of BMD measurements to predict an individual's fracture risk with great accuracy. The normative data against which BMD comparisons are most often made have been determined for Caucasian men and women and do not necessarily apply to other ethnic groups. This problem is gradually being overcome as ethnic-specific BMD data have begun to penetrate the literature. BMD is clearly related to body

TABLE 45.3 Partial List of Risk Factors for Osteoporosis and Related Fractures

Major Factors
• Personal history of fracture as an adult
• History of fragility fracture in a first-degree relative
• Low body weight (less than approximately 127 lb)
• Current smoking
• Use of oral corticosteroid therapy for more than 3 months
Additional Risk Factors
• Impaired vision
• Estrogen deficiency at an early age (<45 years)
• Thyroid hormone excess
• Intestinal malabsorption
• Some varieties of hypercalciuria
Selected Medications (cyclosporin and related agents, thiazolidinediones, possibly selective serotonin inhibitors)
• Dementia
• Poor health/frailty
• Recent falls
• Low calcium intake (lifelong)
• Immobilization or low physical activity
• Alcohol in amounts >2 drinks per day

weight, but routine clinical bone mass assessments are not weight-adjusted. Various features of bone geometry that affect bone strength and fracture risk are not considered in the clinical interpretation of bone mass measurements. These include bone size, the distribution of bone mass around its bending axis (moments of inertia), and some derivative functions such as the hip axis length [59]. Moreover, bone mass measurements cannot distinguish individuals with low mass and intact microarchitecture from those with equal mass who have trabecular disruption and cortical porosity. They also cannot distinguish other aspects of bone quality.

In 1994, a group of senior investigators in this field offered a working definition of osteoporosis based exclusively on bone mass [60]. The reasoning behind this proposal, made on behalf of the World Health Organization, was that the clinical significance of osteoporosis lies exclusively in the occurrence of fracture, that bone mass predicts long-term fracture risk, and that selection of rigorous diagnostic criteria would minimize the number of patients who are incorrectly diagnosed. The authors suggested a cutoff BMD value of 2.5 SD below the average for healthy young adult women. Using this value, approximately 30% of postmenopausal women would be designated as osteoporotic, which gives a realistic projection of lifetime fracture rates. In addition, Kanis et al. [60] proposed that BMD values of 1 or 2 SD below the young adult mean be designated as "osteopenic." Such values identify individuals at modestly increased risk for fracture but for whom a diagnosis of osteoporosis would not be justified because it would mislabel far more individuals than would actually be expected ever to fracture.

This approach has proven useful for clinical management, but it has limitations. Its application to young people prior to their acquisition of peak bone mass would, of course, be inappropriate. The BMD measurement is subject to several confounding factors, including bone size and geometry. Because BMD correlations among skeletal sites are not strong, designating a person "normal" based on a single site, such as the lumbar spine, necessarily overlooks individuals with low bone density elsewhere, such as the hip. It seems reasonable to suppose that adjustment of bone density readings for such factors as body size, bone geometry, and ethnic background might improve the accuracy of this technique. Finally, studies indicate that although individuals with low BMD are at greater relative risk to fracture, many fractures in the population are experienced by individuals with normal bone mass [61–63]. Knowledge of a low bone density at a particular point in time offers no information regarding the adequacy of peak bone mass attained, the amount of bone that may have been lost, or the quality of bone that remains.

The World Health Organization completed an initiative to give individuals an estimate of their absolute 10-year fracture risk. It is based on the concept that BMD plus clinical risk factors predict fracture risk better than BMD or clinical risk factors alone. When BMD is not available, fracture risk can be calculated with only the clinical risk factors. This published initiative, called FRAX, is readily available for routine use via an online calculator (www.shef.ac.uk/FRAX). It is also included in current Dual-Energy X-ray Absorptiometry software and available as a smartphone application. Separate calculation tools are provided at this website for individuals living in many other countries worldwide. In many countries, osteoporosis treatment guides include intervention thresholds based on FRAX fracture risk calculations.

A Beyond BMD: The Question of Bone Quality

As stated in the introduction to this chapter, osteoporosis is a condition of decreased bone strength, where strength is a composite function of BMD and bone quality.

Several diverse qualitative characteristics have been described that directly influence bone strength. The more important factors—bone geometry, microarchitectural integrity, mineralization state, and remodeling rate—are briefly considered here. For more detailed information, the reader may consult Seeman and Delmas [64]. The first factor is overall bone geometry. A bone of greater diameter is better able than a smaller bone to withstand either a compressive or a bending force. One reason that men are relatively less susceptible to forearm fractures than are women is the fact that long bones of men are wider. A second feature, particularly in trabecular bone, is microarchitectural integrity. Normal trabecular bone is a honeycomb of highly connected vertical and horizontal trabeculae (Fig. 45.1A), and the holes, or spaces between the trabeculae, are fairly uniform. By contrast, osteoporotic trabecular bone gives the appearance of Swiss cheese (Fig. 45.1B). The holes are not uniform because excessive bone resorption has perforated the trabeculae, leaving confluent, sometimes extremely large holes that represent the permanent loss of entire trabecular units. A third important qualitative factor is the state of bone remodeling. It will be remembered that each remodeling event begins with the removal by osteoclasts of a divot of bone from trabecular surface. At any one time, then, there are hundreds of thousands of resorption holes, or *lacunae*, on bone surfaces. These holes are an inherent point of weakness to the bone, permitting very modest mechanical loads to overload the structure and fracture it. In mechanical engineering parlance, such points of weakness are called "stress concentrators." Mechanical stresses that are generated across an area of bone divert from their normal path of stress transmission to focus on the area of weakening, thereby overloading it. Thus, individuals with higher levels of bone remodeling activity will have more stress-concentrating lacunae on their bone surfaces, giving them a greater chance for fracture than somebody in a low remodeling state. Finally, the degree of bone mineralization is also an important feature of bone quality. Roughly speaking, except in extreme cases, the more mineralized the bone matrix, the greater its mechanical strength. Because a portion of bone continues to accumulate mineral as long as it exists, individuals with lower remodeling rates will have bone that is older, and therefore more mineralized and stronger, than individuals whose bone is remodeled more rapidly.

One message from this inquiry into bone quality is that a BMD measurement simply does not describe a sufficient amount of information about the nature of the skeleton ever to be a gold standard for the presence of osteoporosis. Unfortunately, currently, no suitable noninvasive measurements are available for routine assessment of bone quality in patients outside a research environment. Therefore, one is forced to rely on BMD measures to some degree. That being said, one also should not depend on changes in BMD over time as a true index of whether patients have improved or deteriorated in response to therapeutic interventions. One important indication of overall bone quality is whether a given person has already sustained a low-trauma fracture. Evidence has been published that individuals with such fractures have more serious disruption of qualitative measures seen on bone biopsies than individuals who have not fractured [65]. Therefore, the presence of a vertebral compression fracture on a radiograph of the spine may reasonably permit the physician to conclude that the patient has poor bone quality.

V OSTEOPOROSIS PREVENTION AND TREATMENT

A Hygienic Management

The term *hygienic* is used here in the sense of being nonpharmacologic. It refers to the appropriate attention to lifestyle factors that either protect or damage bone. These principles have universal application regardless of whether one wishes to forestall bone loss and development of osteoporosis or treat established disease.

1 Physical Activity

As described previously, the skeleton adapts to its mechanical environment so that the steady-state amount of bone reflects daily exposure to mechanical forces. Although the skeletal response to vigorous exercise, such as weight lifting (resistance activity) or running (endurance activity), may be greater than that observed with walking, the majority of middle-aged and older individuals are more likely to persist long term with a program of walking. A progressive schedule of walking 30 minutes or more several days each week provides a mechanical load to the legs and axial skeleton and should form the basis of skeletal maintenance for ambulatory persons in their middle and advanced years. Younger individuals should certainly be encouraged to pursue more vigorous activities, but it must be remembered that the effects of high-load environments persist only so long as the high loading schedule continues. If a person stops training, the bone perceives a reduction in mechanical environment and adaptive responses will lead to loss of bone until a new steady state is reached.

2 Dietary Factors

With respect to overall dietary intakes, substantial weight loss during adult life is a risk factor for fractures. Weight-loss programs are associated with measurable decreases in BMD, and the impact of so-called yo-yo weight

fluctuations, although unclear, carries some skeletal risk. As discussed previously, the nutrients of most relevance to skeletal maintenance are calcium and vitamin D. A daily calcium intake of 1200−1500 mg should be the goal for most healthy adults. Consuming a quart of nonfat milk each day could approach this, but it is very unlikely that most adults, even dairy enthusiasts, will consistently accomplish that. Each quart of milk contains approximately 1100 mg calcium, although this may vary somewhat depending on its fat content. Because calcium is contained within the aqueous phase of milk, an equal volume of low-fat or skim milk has more water, and hence more calcium, than whole milk. In addition, some brands of reduced-fat milk are enriched by the addition of milk solids, which further increases calcium content.

Many segments of the population experience loss of lactase, the enzyme necessary for the hydrolysis of the major milk sugar lactose. Many afflicted individuals experience bloating, cramps, or other symptoms of intestinal distress if they consume lactose-containing dairy products. Several strategies can be recommended for such individuals. Lactose-free milk is readily available in markets. Lactose in this product has been prehydrolyzed to its constituent sugars, glucose and galactose, by incubation with commercial lactase. This milk has a slightly sweet taste due to the taste of its hexose sugars. For those who do not care for this taste, lactase tablets can be taken immediately prior to drinking milk. Yogurt and other products in which lactose is hydrolyzed provide an excellent substitute for milk. Many cheeses are rich in calcium (not cottage cheese, however) but have the complicating feature of high sodium content. The calcium:sodium ratio of most liquid dairy products is approximately 1.0, but the ratio is well below 1 for hard cheeses. Given the relationship between sodium intake and calciuria [49], depending on cheese calcium consumption may not be effective.

Other reasonably good food sources of calcium include small fish (anchovies, herrings, and sardines), nuts, and some green vegetables (broccoli). However, it is quite difficult to attain calcium adequacy with these foods alone without also consuming dairy products. For example, it may require 6 cups of broccoli to provide as much calcium as would be consumed in a single 8-ounce glass of milk.

For many individuals, a calcium supplement offers the most convenient approach to reaching target levels of calcium intake. Many calcium salts are available on an over-the-counter basis. Calcium carbonate has the advantage of having the highest percentage by weight in calcium (40% of calcium carbonate is calcium) so that the fewest number of pills need to be taken. Calcium citrate is a reliable calcium supplement. It has been alleged that individuals who have achlorhydria or are taking medications that reduce gastric acid secretion better absorb the citrate salt than the carbonate. However, it has been shown that when calcium carbonate is taken with food, there is sufficient acidity in the food to permit normal calcium absorption [66]. Therefore, my general recommendation for individuals who will likely not consume more than 1000 mg calcium per day through food alone is to take a 500 mg calcium supplement as calcium carbonate each morning with breakfast. For individuals with osteoporosis who are receiving pharmacological treatment, I increase that recommendation to 1000 mg calcium/day.

In 2008, Bolland et al. [67] reported on a calcium intervention trial in older women, in which consumption of calcium as supplement, but not as food, was associated with an increased risk for cardiovascular complications, including myocardial infarction. Subsequently, the same group published a meta-analysis from which they concluded that "calcium supplements without vitamin D are associated with an increased risk of myocardial infarction" [68]. This publication created a storm of controversy. Although the meta-analysis was constructed from multiple clinical trials, the most cases came from the single trial reported by Bolland and colleagues [67]. Myocardial infarction was not an end point of that trial, and cases were not adjudicated. The 2-year pill compliance rate was only 55% and was lower yet in the group receiving calcium. Although the conclusions were based on an intervention in older women, a number of the studies included in the meta-analysis included both men and women, and none independently showed even a trend toward a cardiovascular adverse effect. All these factors could introduce bias into group comparisons. Moreover, some independent studies failing to support the views of Bolland et al. were not represented in the meta-analysis [68]. In particular, a well-designed and executed clinical trial in which cardiovascular end points were prespecified showed no impact of calcium supplementation on either atherosclerotic vascular mortality or first hospitalization, either during the 5-year clinical trial or during a 4.5-year follow-up period [69]. Given the importance of this topic, a committee from the American Society for Bone and Mineral Research evaluated the available data and concluded that "the weight of evidence is insufficient to conclude that calcium supplements cause adverse cardiovascular events; however, the debate continues."

B Pharmacologic Therapy

The variety of approved drugs for the prevention and treatment of osteoporosis has expanded enormously during approximately the past decade (Table 45.4). These are grouped into two general categories—antiresorptive (sometimes called anticatabolic) and bone-forming (or anabolic). The first category contains the great majority of registered products. Although the fundamentals of their

TABLE 45.4 Approved Medications for the Prevention and Treatment of Osteoporosis

Antiresorptive
• Calcium/vitamin D
• Estrogens
• Bisphosphonates
• Alendronate
• Risedronate
• Ibandronate
• Zoledronatic acid
• Calcitonin
• Strontium ranelate (not approved in United States)
Bone-forming
• Teriparatide
• PTH (1–84) (not approved in United States)

mechanism of action differ from one product to the next, they all act ultimately to inhibit either the development of osteoclasts from their precursors or the activity of mature osteoclasts. Such actions confer skeletal protection in two ways, both of which are predictable consequences of slowing the remodeling rate by 30–70%, as per the previous discussion of bone quality. First, and perhaps most important, at least during the first year or so of therapy, reducing the creation of new resorption lacunae results in a major reduction in the prevalence of stress concentrators on bone surfaces. Second, because any given point on the bone surface will survive longer when the remodeling rate is low, the bone continues to gain mineral for a longer period of time and ultimately becomes relatively hypermineralized.

By contrast, only one bone-forming agent—the 1–34 fragment of human PTH (teriparatide; see later discussion)—is approved, as of this writing, in the United States for the treatment of osteoporosis. Its actions involve the direct stimulation of bone-forming osteoblasts.

Selection of appropriate therapies for individual patients is beyond the scope of this chapter. The following material briefly describes each of these approved products.

1 Antiresorptive Agents

a Calcium and Vitamin D

Strictly speaking, calcium and vitamin D have an antiresorptive activity on bone. By slightly elevating blood calcium concentrations, endogenous PTH secretion is reduced and overall bone remodeling decreases. The role of calcium and vitamin D in skeletal maintenance was described previously. Calcium administration to osteoporotic women with previous vertebral fractures has been shown to decrease the risk for subsequent fracture [33] and, when combined with a modest amount of vitamin D, has been shown to reduce the incidence of hip fracture in elderly women [24]. Suffice it to say that calcium and vitamin D adequacy are essential components of all successful therapies, and the general approach described previously must be pursued if any pharmacologic regimen is to succeed. Indeed, therapeutic failures are frequently attributable to inadequate vitamin D status. Note that all major osteoporosis trials were designed to show an effect of drug on bone turnover, BMD, and fracture incidence superior to that of the control regimens, which invariably consisted of calcium and vitamin D.

b Estrogen

The use of estrogen to treat postmenopausal osteoporosis has been popular for at least 50 years. The era of the 1970s and 1980s saw the publication of many small clinical trials demonstrating the effects of various estrogen and estrogen/progestin combinations in early and postmenopausal women to improve calcium balance, to suppress markers of bone turnover, to increase BMD, and in small series to protect against vertebral compression fractures [70]. Because the available studies did not demonstrate a compelling case that estrogen administration to women with established osteoporosis led to a significant reduction in fracture incidence, U.S. Food and Drug Administration (FDA) approval of estrogen was specified for prevention of osteoporosis, not for treatment. With publication of results from the Women's Health Initiative, we now have conclusive evidence for the nonvertebral fracture efficacy of estrogen, even in women who were not osteoporotic or at high risk for fracture [71]. Unfortunately, the Women's Health Initiative also established that estrogen, particularly when given in combination with progestin, increased the development of breast cancer, myocardial infarction, and other cardiovascular events and potentially contributed to cognitive decline. Thus, although estrogens remain highly effective when treating women with hot flashes, current opinion holds that they should be used at the lowest possible dose and for the shortest possible duration and are not recommended as long-term therapy for prevention or treatment of osteoporosis.

c Selective Estradiol Receptor Modulators

These compounds are neither hormones nor estrogens but, rather, molecules that interact with the estradiol receptor in multiple tissues of the body. For a comprehensive description of selective estradiol receptor modulator

(SERM) physiology, the reader is referred to the review of Siris and Muchmore [72]. Briefly summarized, unlike estrogens, SERMs interact with the estradiol receptor and activate estrogen-regulated genes in a manner that is tissue specific. For example, like estrogen, tamoxifen stimulates uterine hyperplasia and suppresses bone remodeling, but unlike estrogen, it inhibits estrogen actions at the breast. On the other hand, raloxifene has no effect on the endometrium, acts like estrogen on bone, and antagonizes estrogen action at the breast. Although several such molecules were introduced into clinical medicine before their mechanisms of action were clarified (e.g., tamoxifen), recent years have seen the development of numerous molecules in this class for the intended purpose of treating osteoporosis. As of this writing, only two SERMs, raloxifene (Evista, Eli Lilly & Co.) and bazedoxifine, in combination with a low dose of conjugated estrogens (Duavee, Pfizer Inc.) are FDA approved for preventing osteoporosis. Raloxifene has been shown to prevent the development of frank osteoporosis in women with low bone mass and also to offer substantial long-term protection against vertebral fracture in women with established osteoporosis [73], thus it is approved also for treatment of established osteoporosis. At the approved dose of 60 mg daily, raloxifene offers significant protection against the development of estrogen receptor-positive breast cancer, for which it also has received FDA approval.

d Bisphosphonates

Bisphosphonates are analogs of the naturally occurring phosphate ester pyrophosphate, in which a carbon atom has replaced the central oxygen bridge. This substitution renders the compounds nonsusceptible to hydrolysis by alkaline phosphatase, a ubiquitous enzyme that hydrolyzes pyrophosphate. Bisphosphonates are poorly absorbed from the gut, but once absorbed they are taken up by bone. The presence of two phosphate groups permits the molecule to bind avidly to hydroxyapatite so that the half-life of bisphosphonates in the skeleton may be a matter of many years. In theory, osteoclasts imbibe the bisphosphonate during the course of bone resorption, resulting in osteoclast death and a decrease in resorption. Differences in one of the two side chains underlie differences in action among agents of this class. The first generation of bisphosphonates acted to inhibit intermediary metabolism. More recent compounds that have amino groups on the side chain act in a manner similar to the statin class of antilipid drugs—that is, inhibiting the mevalonate synthesis pathway, but at a level (farnesyl diphosphate synthetase) that is further downstream, leading to interference with prenylation of plasma membrane lipids [74]. First developed and introduced for the treatment of Paget's disease of bone in the 1960s, several bisphosphonates have shown significant improvement in BMD and reductions in fracture. Three oral bisphosphonates are currently approved for prevention and treatment of osteoporosis: alendronate (Fosamax) [75], risedronate (Actonel) [76,77], and ibandronate (Boniva) [78]. The last may also be administered by intravenous infusion. Another very potent bisphosphonate, zoledronic acid, has received FDA approval for treatment of osteoporosis. This agent is administered only once each year by intravenous infusion.

In recent years, it has become apparent that some patients receiving long-term potent bisphosphonates may experience potentially serious complications of treatment, including osteonecrosis of the jaw (ONJ) and nonclassical or "atypical" hip fractures [79]. Although the precise mechanisms by which such complications may be induced remain unsettled, it appears likely that they reflect in some manner the degree to which bone remodeling has been suppressed. For example, because of its role in chewing, the mandible receives some of the heaviest mechanical loads of any bone in the body. To maintain mandibular health and prevent fatigue damage, it is necessary to have a robust and responsive remodeling system. In the presence of potent antiresorptive therapy, remodeling might not be adequate to prevent tissue breakdown and subsequent necrosis. Similarly, a number of case reports and patient series have described the occurrence of fractures in the subtrochanteric region of the femur in patients exposed to long-term bisphosphonates. These transverse fractures show a characteristic radiographic appearance, with thickening of the bony cortex and "beaking" of the fracture fragment. In a very large population-based study, it was determined that although there is a small added risk for such atypical fractures, the overall benefit:risk ratio for bisphosphonates remained substantially positive in that the overall fracture incidence in bisphosphonate-treated patients was considerably lower than that of nontreated patients [80]. Nonetheless, a trend in treatment strategy has attended the emergence of ONJ and atypical fractures, in that many experts now recommend bisphosphonate therapy be stopped following 5 consecutive years of treatment, with subsequent monitoring of BMD so that treatment can be restarted if and when bone loss recurs. The degree to which undertaking such a "drug holiday" may promote further bone loss and fractures remains under study.

e Calcitonin

This 32-amino acid peptide is a natural hormone throughout the vertebrate phylum. Its primary physiological role appears to be to reduce the rate of bone remodeling by inhibiting the action of mature osteoclasts. Calcitonin obtained from salmon is considerably more potent than

the human hormone and has been approved for treatment of osteoporosis [81]. Although calcitonin can be given by subcutaneous injection, most patients take the drug as a nasal spray (Miacalcin). In approved doses, calcitonin is a relatively weak antiresorptive drug with efficacy characteristics that are far less pronounced than those of the other approved antiresorptive agents.

f Denosumab

In Section II.D, Intercellular Communication Among Bone Cells: Triggers and Constraints on Remodeling, I described the role of the RANK−RANK-ligand (RANKL) system for regulating bone turnover. In 2010, the FDA approved denosumab, a human monoclonal antibody that specifically binds to RANKL, prevents the activation of RANK on the surface of osteoclasts and their precursors, and thereby inhibits osteoclast formation and function, substantially decreasing the rate of bone remodeling [82]. In its pivotal clinical trial, denosumab reduced the occurrence of all categories of fragility fracture: vertebral, hip, and nonvertebral. Based on its mechanism of action, denosumab is considered a potent antiresorptive drug. Marketed under the trade name Prolia (Amgen), it is approved for treatment of men and postmenopausal women with osteoporosis at high risk of fracture. The drug is administered by vein every 6 months and is generally well tolerated. Some concern has been expressed regarding the tendency for patients to experience lower blood calcium concentrations when treated with denosumab, and hypocalcemia is considered a contraindication for its use. In addition, in clinical trials, serious infections leading to hospitalization were more frequent in the denosumab group than with placebo. These include bacterial endocarditis, skin infections, and infections in the abdomen and urinary tract. ONJ has been reported in a few patients receiving denosumab.

g Strontium Ranelate

Strontium has received approval in Europe and Asia for treatment of osteoporosis. It becomes incorporated directly into the bone mineral, which creates an artifactual increase in BMD. However, strontium does appear to be an effective antiresorptive compound and has been shown to reduce fracture risk. Because no studies of this compound have been conducted in the United States, it does not appear that strontium can ever receive FDA approval and so it is unlikely to be introduced into the U.S. market.

2 Bone Formation Therapy

a Teriparatide (Forteo and Forsteo in Europe)

Teriparatide is the generic term for the 1−34 fragment of human PTH. It is approved as a single daily subcutaneous injection for up to 2 years at a dose of 20 μg/day. Teriparatide is the first bone anabolic agent approved for treatment of osteoporosis. (The full-length PTH (1−84) molecule has not received approval in the United States but is marketed in Europe. Its actions are qualitatively similar to those of teriparatide.) Teriparatide directly stimulates osteoblasts to form new bone and results in considerably greater increases in BMD than are observed with antiresorptive drugs. In addition, teriparatide uniquely repairs the disrupted microarchitecture of trabecular bone to a normal pattern and also increases the thickness of cortical bone. These effects result in substantial reduction in both vertebral and nonvertebral fracture [83]. Teriparatide given very long term at high dose to Fischer 344 rats led to a high rate of osteosarcoma. Other animal models have shown no such effect, and although a relationship to human carcinogenesis seems very unlikely, one cannot be certain that no relationship exists. Because duration of therapy was a critical element for carcinogenesis in rats, teriparatide use is currently restricted to 2 years. Teriparatide is marketed by Eli Lilly & Co. as Forteo (and as Forsteo in Europe) for the treatment of men and postmenopausal women with osteoporosis whose physicians consider them at high risk for fracture. As of this writing, teriparatide has been generally available for more than 13 years, and no carcinogenesis signal has yet appeared. As opposed to several of the antiresorptive agents, it is not a drug for prevention of osteoporosis.

VI CONCLUSION

Efforts are underway to bring forth additional compounds of both the antiresorptive and bone-formation classes. Other developmental targets currently focus on bone-forming agents, and new PTH analogs and modes of delivery for teriparatide are in human trials, as is suppression of a bone formation-inhibiting molecule, sclerostin. Still largely in animal studies, strategies to activate a newly discovered anabolic pathway in bone, the Wnt pathway, have begun.

Thus, the future of pharmacologic therapy for osteoporosis seems reasonably bright. However, the overall outlook for this disease remains clouded. With aging of the population, trends toward increasingly sedentary life, and substandard intakes of critical nutrients, the worldwide burden of osteoporotic fractures is likely to increase dramatically. Even now, it is difficult in the United States to get appropriate diagnosis and treatment for afflicted patients, even those with multiple fractures. With growing competition from other aspects of health care and with continued threats of onerous governmental and health insurance constraints on reimbursement for osteoporosis diagnosis and treatment, it is not at all certain that an explosive increase in fragility fractures and their consequences will be avoided.

[a] *As retinol activity equivalents (RAEs): 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.*

[b] *As α-tocopherol: α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the* 2R-*stereoisomeric forms of α-tocopherol (*RRR-, RSR-, RRS-, *and* RSS-α-tocopherol*) that occur in fortified foods and supplements. It does not include the* 2S-*stereoisomeric forms of α-tocopherol (*SRR-, SSR-, SRS-, *and* SSS-α-tocopherol*), also found in fortified foods and supplements.*

[c] *As niacin equivalents (NE): 1 mg of niacin = 60 mg of tryptophan.*

[d] *As dietary folate equivalents (DFE): 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.*

Note: An Estimated Average Requirement (EAR) is the average daily nutrient intake level estimated to meet the requirements of half of the healthy individuals in a group. EARs have not been established for vitamin K, pantothenic acid, biotin, choline, chromium, fluoride, manganese, or other nutrients not yet evaluated via the DRI process.

Sources: From Dietary Reference Intakes for Calcium, Phosphorous, Magnesium, Vitamin D, and Fluoride (1997); Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B_6, Folate, Vitamin B_{12}, Pantothenic Acid, Biotin, and Choline (1998); Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids (2000); Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc (2001); Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids (2002–2005); and Dietary Reference Intakes for Calcium and Vitamin D (2011). These reports may be accessed via www.nap.edu.

[a]As retinol activity equivalents (RAEs): 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.

[b]As cholecalciferol: 1 μg cholecalciferol = 40 IU vitamin D.

[c]Under the assumption of minimal sunlight.

[d]As α-tocopherol: α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of α-tocopherol (RRR-, RSR-, RRS-, and RSS-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of α-tocopherol (SRR-, SSR-, SRS-, and SSS-α-tocopherol), also found in fortified foods and supplements.

[e]As niacin equivalents (NE): 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).

[f]As dietary folate equivalents (DFE): 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

[g]Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h]Because 10–30% of older people may malabsorb food-bound B_{12}, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B_{12} or a supplement containing B_{12}.

[i]In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j]It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.

Note: This table (taken from the DRI reports, see www.nap.edu) presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level; sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a group. It is calculated from an Estimated Average Requirement (EAR). If sufficient scientific evidence is not available to establish an EAR, and thus calculate an RDA, an AI is usually developed. For healthy breastfed infants, an AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all healthy individuals in the groups, but lack of data or uncertainty in the data prevents from being able to specify with confidence the percentage of individuals covered by this intake.

[a] *As preformed vitamin A only.*
[b] *As α-tocopherol; applies to any form of supplemental α-tocopherol.*
[c] *The ULs for vitamin E, niacin, and folate apply to synthetic forms obtained from supplements, fortified foods, or a combination of the two.*
[d] *β-Carotene supplements are advised only to serve as a provitamin A source for individuals at risk of vitamin A deficiency.*
[e] *ND, not determinable due to lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.*

Note: A Tolerable Upper Intake Level (UL) is the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects to almost all individuals in the general population. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to a lack of suitable data, ULs could not be established for vitamin K, thiamin, riboflavin, vitamin B_{12}, pantothenic acid, biotin, and carotenoids. In the absence of a UL, extra caution may be warranted in consuming levels above recommended intakes. Members of the general population should be advised not to routinely exceed the UL. The UL is not meant to apply to individuals who are treated with the nutrient under medical supervision or to individuals with predisposing conditions that modify their sensitivity to the nutrient.

[a] *As retinol activity equivalents (RAEs): 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.*

[b] *As cholecalciferol: 1 μg cholecalciferol = 40 IU vitamin D.*

[c] *Under the assumption of minimal sunlight.*

[d] *As α-tocopherol: α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of α-tocopherol (RRR-, RSR-, RRS-, and RSS-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of α-tocopherol (SRR-, SSR-, SRS-, and SSS-α-tocopherol), also found in fortified foods and supplements.*

[e] *As niacin equivalents (NE): 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).*

[f] *As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.*

[g] *Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.*

[h] *Because 10–30% of older people may malabsorb food-bound B_{12}, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B_{12} or a supplement containing B_{12}.*

[i] *In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.*

[j] *It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.*

Note: This table (taken from the DRI reports, see www.nap.edu) presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level; sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a group. It is calculated from an Estimated Average Requirement (EAR). If sufficient scientific evidence is not available to establish an EAR, and thus calculate an RDA, an AI is usually developed. For healthy breastfed infants, an AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all healthy individuals in the groups, but lack of data or uncertainty in the data prevents from being able to specify with confidence the percentage of individuals covered by this intake.

Note: This table (taken from the DRI reports, see www.nap.edu) presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level; sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a group. It is calculated from an Estimated Average Requirement (EAR). If sufficient scientific evidence is not available to establish an EAR, and thus calculate an RDA, an AI is usually developed. For healthy breastfed infants, an AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all healthy individuals in the groups, but lack of data or uncertainty in the data prevents from being able to specify with confidence the percentage of individuals covered by this intake.

[a] *As preformed vitamin A only.*
[b] *As α-tocopherol: applies to any form of supplemental α-tocopherol.*
[c] *The ULs for vitamin E, niacin, and folate apply to synthetic forms obtained from supplements, fortified foods, or a combination of the two.*
[d] *β-Carotene supplements are advised only to serve as a provitamin A source for individuals at risk of vitamin A deficiency.*
[e] *ND, not determinable due to lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.*

Note: A Tolerable Upper Intake Level (UL) is the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects to almost all individuals in the general population. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to a lack of suitable data, ULs could not be established for vitamin K, thiamin, riboflavin, vitamin B_{12}, pantothenic acid, biotin, and carotenoids. In the absence of a UL, extra caution may be warranted in consuming levels above recommended intakes. Members of the general population should be advised not to routinely exceed the UL. The UL is not meant to apply to individuals who are treated with the nutrient under medical supervision or to individuals with predisposing conditions that modify their sensitivity to the nutrient.
