Preface

Critical care medicine is a dynamic and exciting arena where complex pathophysiologic states require extensive knowledge and up-to-date clinical information. An extensive knowledge of basic pathophysiology, as well as awareness of the appropriate diagnostic tests and treatments that are used to optimize care in the critically ill is essential. Since our first edition 7 years ago, new information crucial to the care and understanding of the critically ill patient has rapidly accumulated. Because this knowledge base crosses many different disciplines, a comprehensive multidisciplinary approach presenting the information is essential, similar to the multidisciplinary approach that is used to care for the critically ill patient. We have strived to provide this content in an easily digestible format that uses a variety of teaching tools to facilitate understanding of the presented concepts and to enhance information retention.

To meet the demand to provide comprehensive and diverse education in order to understand the pathogenesis and optimum care of a variety of critical illnesses, we have substantially revised the prior topics in the first edition with updated information. We have also markedly expanded the number of topics covered to include acute lung injury and the acute respiratory distress syndrome, an expanded discussion of the physiology and operation of mechanical ventilation, obstetrical care in the ICU, neurosurgical emergencies, acute coronary syndromes, cardiac arrhythmias, role of whole body rehabilitation in the ICU, ethical conduct of human research in the ICU, and nursing care of the ICU patient. Nurses, physical and respiratory therapists, nutritionists, and pharmacists have contributed to the efforts of surgeons, anesthesiologists, radiologists, cardiologists, pulmonary and critical care physicians, and other healthcare professionals to provide the complete and up-to-date information that is presented in this second edition. This text should be useful not only for the internist, anesthesiologist, or surgeon who practices in the ICU, but also for the nurses, therapists, and other ancillary professionals who care for the ICU patient.

This second edition is also designed to make the dynamic environment of the critical care unit understandable and the approach to the patient both logical and successful. The book continues to build on the three main components presented in the first edition: (1) the description of the procedural tasks commonly performed for the critically ill patient, (2) explanations of the most common pathophysiologic states encountered, and (3) descriptions of specific disease entities with details regarding their differential diagnosis, diagnostic strategy, and therapeutic plan.

This book also uses several educational approaches that we have found useful in our own teaching sessions and prior textbooks. Clinical cases introduce chapters and highlight chapter segments to emphasize clinical relevancy. As an additional study aid, margin notes highlight important teaching points and facilitate easy review of the chapter content. To consolidate the principles outlined in each chapter, review questions with full-text explanations are provided at the end of each chapter. In this second edition, we have added in-text referencing for sentinel papers and also provided a suggested reading list at the end of each chapter. All these elements help reinforce the most important messages for the reader and provide ready sources of information for further self-education.

This textbook is the effort of many individuals across many disciplines who practice at Temple University School of Medicine and Temple University Hospital. Nonetheless, only evidence-based literature is used to provide the basic concepts and therapeutic and diagnostic strategies presented; the content does not represent the convention of care endorsed by any single institution.

We hope that you find the information helpful in your understanding of critical illnesses and the current evidence-based approaches to the care of the ICU patient.

GERARD J. CRINER, MD

Acknowledgments

Writing textbooks is not easy; in critical care medicine, especially, it requires the efforts of many individuals. The editor-in-chief wholeheartedly appreciates the efforts of all the contributors of this textbook and the many others who made publication of this textbook a reality. These individuals especially include the co-editors, Drs. Gilbert D'Alonzo and Rodger Barnette, who helped enormously with editorial assistance. Additionally, the editorial staff at Springer were extremely helpful with their support and editorial assistance throughout the project.

Last but not least, I acknowledge the everlasting support of my wife, Helga, and my children, Kate, Kristin, Karla, Andrew, and Rachel. Their patience and help provide the necessary nurturing personal environment required to successfully accomplish professional endeavors.

GERARD J. CRINER, MD

PART I

Critical Care Procedures Diagnostic Testing and ICU Policies

CHAPTER 1

DILIPKUMAR K. PATEL, KAMARDEEN O. ALAO, NEIL W. BRISTER, AND RODGER E. BARNETTE

Airway Management

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter you should be able to:

- Perform a focused exam to assess the need for oxygen therapy and ventilatory support.
- Understand the function of support devices that serve to improve oxygenation or ventilation.
- Identify urgent situations that require immediate establishment of an effective airway.
- Utilize an anatomic classification system of the upper airway that identifies potentially difficult endotracheal intubations.
- Understand the equipment and resources needed to safely establish an airway.
- Identify unique situations that require skilled personnel to safely establish an airway.
- Understand criteria for extubation and tracheotomy.

EVALUATION FOR INTUBATION

The key elements of respiratory function are oxygen delivery, gas exchange, and the work of breathing.

Airway management and mechanical ventilatory support are crucial components of state-of-the-art respiratory care in intensive care unit (ICU) patients.[1] Providing adequate oxygen levels to critical organ systems, such as the cardiovascular and central nervous system, while reducing the work of breathing is foundational to the practice of critical care medicine. Establishing, securing, and managing an airway is thus central to safe and effective patient care.[2,3] Before addressing the need for endotracheal intubation and mechanical ventilatory support, it is necessary to review some key concepts of respiratory function; these include oxygen (O_2) delivery to metabolically active tissues, removal of carbon dioxide (CO_2), work of breathing, and adequacy of ventilation.

Oxygen Delivery and Exchange

The most important agent that can be administered to a patient is supplemental oxygen. Oxygen is essential for the metabolism and function of all cells in the body. Clinical evidence of oxygen deprivation is a late sign of hypoxemia. Whatever the cause, oxygen deprivation results in rapid depletion of ATP and altered metabolic functions at a cellular level that ultimately result in respiratory and metabolic acidosis. Persistent hypoxemia has profound influence on cerebral function and can progress to cerebral anoxic injuries.

Broad categories of impaired oxygen delivery and exchange include the following:

- Low inspired fraction of oxygen: high altitude – normal $P(A\text{-}a)O_2$.
- Hypoventilation: drug overdose, Guillain-Barre syndrome, Flail chest.
- Diffusion impairment: chronic obstructive pulmonary disease (COPD), asthma, parenchymal lung disease, restrictive lung diseases, acute lung injury (ALI)/ARDS, pneumonia, pulmonary embolism.
- *V*/*Q* mismatch (areas of the lungs ventilated but not perfused): airway disease, vascular disease, pulmonary embolism.
- Pulmonary shunt (areas of the lungs perfused but not ventilated): acute lung disease/ARDS, parenchymal lung disease, cardiogenic pulmonary edema, pulmonary infarction.

Clinical Manifestations of Respiratory Insufficiency

Signs and symptoms of oxygen deprivation are evident in the evaluation of neurologic, respiratory, and cardiovascular systems. Family members may notice subtle changes before healthcare providers.

Oxygen deprivation results in neurological, respiratory, and cardiovascular system changes to compensate for the hypoxic condition. A rapid neurological evaluation will note signs of anxiety, lethargy, hallucinations, or frank unresponsiveness. Other signs or symptoms may include confusion or clouded thinking, interrupted speech, progressive fatigue, and decreased mental status. Bouts of confusion and combative behavior may be late signs of deteriorating oxygen delivery to the brain. Family members may detect subtle signs of hypoxia before healthcare providers.

Respiratory symptoms may include the new onset of dyspnea, tachypnea, or diaphoresis. A complete evaluation of the respiratory system involves observing the patient's respiratory pattern. Behavioral adjustments made in an attempt to improve breathing may include sitting upright or leaning slightly forward with the elbows placed on a table or some other fixed surface, nasal flaring, and the use of abdominal musculature during exhalation or the accessory muscles of respiration during inspiration. Cyanotic changes are seen late and signify imminent respiratory failure.

Cyanotic changes are late signs of imminent respiratory failure.

Finally, a patient's expected cardiovascular response to oxygen deprivation is tachycardia, hypertension, and arrhythmias. However, a nonspecific response to hypoxia may be observed in patients with heart failure, diabetes, or those receiving beta-blocking medications. This response may include bradycardia, unexplained hypotension, or asystole. Persistent hypoxemia in high-risk patients may precipitate myocardial ischemia and/or infarction.

Evaluation of Breathing and Ventilation

Normal respiratory rate is between 16 and 20 breaths/min; normal minute ventilation is 90–100 mL/kg. An increasing respiratory rate or changes in tidal volume outside normal values result in increased work of breathing. Increased work of breathing is an attempt to meet increased oxygen needs and/or excretion of excess carbon dioxide; it is energy consuming and can contribute to respiratory collapse. Progressive changes in a patient's respiratory pattern may indicate pending respiratory failure.

Normal respiratory rate is 16–20 breaths/min. Increasing respiratory rate or abnormal tidal volumes increases the work of breathing.

Nonpulmonary causes of increased work of breathing include but are not limited to sepsis, cardiogenic shock, and anemia. In sepsis, the percentage of cardiac output, which supports the respiratory musculature, may increase from a baseline of 5% to as high as 25%. Although not a primary malfunction of the respiratory system, the increased work of breathing can contribute to patient morbidity and mortality.

Important considerations in evaluating respiratory distress are the degree of distress and any coexisting diseases that may influence the patient's condition. It may be necessary to urgently establish an airway before determining the exact pulmonary or nonpulmonary cause of altered respiratory mechanics (Table 1-1). Progressive ventilatory failure or increasing hypoxemia that is not responsive to supplemental oxygen or noninvasive methods of assisted ventilation is a primary indication for endotracheal intubation. In most circumstances, clinical assessment of general patient status, persistent oxygen desaturation, and changes in ventilatory pattern secondary to increased work of breathing are helpful in making the decision to intubate. Continuous end-tidal capnography may be a useful ventilatory monitor, but pulse oximetry is most commonly used in clinical settings. Arterial blood gases (ABGs) generally are not required to determine the need for emergent intubation, however, if available, may permit correlation with the patient's clinical status.

The degree of respiratory distress and the patient's general medical condition will impact the need for mechanical ventilatory support.

Apnea and cardiovascular collapse require immediate intubation, resuscitation, and mechanical ventilation. However, in less desperate circumstances, there may be sufficient time to more completely evaluate the degree of respiratory distress and coexisting disease processes prior to making the decision to intubate. In addition to reviewing the recent history and any changes in physical examination, the results of clinically relevant laboratory values or radiologic studies should be reviewed or ordered. These studies include complete blood count, blood chemistry, prothrombin time, ABG levels, chest radiograph, chest CT, spiral CT, or arteriogram.

A prolonged elevated minute ventilation changes respiratory mechanics and increases the work of breathing; such effort may not be sustainable without assistance.

Interpretation of ABG

Pulse oximetry is the key noninvasive modality used to measure the patient's arterial oxygenation status. Normally, oxygen saturation should be ≥95%. A saturation of 90% indicates a PaO_2 of 60 mmHg, which borders on insufficient oxygen availability to meet cellular demands. An ABG is an invasive test used to identify the severity of respiratory and metabolic parameters contributing to pulmonary failure (please refer to Chap. 15). A $PaO_2 \leq 55$ mmHg

Pulse oximetry is a quick and noninvasive method used to assess oxygen saturation.

TABLE 1-1

CAUSES OF AIRWAY OBSTRUCTION

UPPER AIRWAY	LOWER AIRWAY
Laryngospasm: secretions/blood	Bronchospasm: asthma, CHF
Tumor	Foreign body aspiration
Foreign body aspiration	Inspissated secretions/mucous plugging
Large tongue, obstruction: obesity	Pulmonary embolus: blood, air, fat, or amniotic fluid
Soft tissue obstruction: sleep apnea	Pulmonary edema
External compression: neck hematoma, neck trauma, tumor, stab wound, carotid surgery; abscess	Endobronchial intubation
Vocal cord swelling/polyps/paralysis	Kinked endotracheal tube
Tracheal stenosis	Aspiration
Bilateral recurrent laryngeal nerve injury	Tumor
Endotracheal tube obstruction	Bronchial blood clots

or an $SaO_2 \leq 2$ defines the lower acceptable limits of persistent hypoxemia. If the $P(A\text{-}a)O_2$ is normal (0–10 mmHg), hypoventilation explains the presence and degree of hypoxemia; the most likely causes of acute respiratory failure are central nervous system or chest wall abnormalities. If the $P(A\text{-}a)O_2$ is increased, hypoventilation does not completely explain the presence of hypoxemia, and another condition such as COPD, severe asthma, and/or early-stage ALI must be present. If hypoxemia exists without hypoventilation, an elevated $P(A\text{-}a)O_2$ confirms a *V*/*Q* abnormality.

Normal $PaCO_2$ value is 40 mmHg. Any significant deviation from that baseline value requires investigation. An increased respiratory rate should result in lower $PaCO_2$ values. Elevated $PaCO_2$ in the context of tachypnea may indicate inadequate ventilation, respiratory fatigue, and pending respiratory failure. Patients with severe COPD and CO_2 retention may breathe comfortably with values of $PaCO_2 \geq 50$ mmHg and $PaO_2 \leq 55$ mmHg. However, a patient with new-onset congestive heart failure (CHF) may have an increased risk for respiratory failure with the same set of parameters. Consequently, a comprehensive assessment of the situation is crucial to determining the urgency of the need for mechanical ventilation (Table 1-2). It is also important to realize that although it is appropriate to place pulmonary disorders into individual categories for teaching purposes, a patient may have simultaneous disease processes that lead to respiratory failure and the need for intubation and ventilatory support. Assessment of the metabolic component of the ABG should be clinically correlated with current patient condition and treated appropriately. Not all radiographic exams or laboratory tests will be available at the time a critical decision must be made.

Oxygen Therapy in Respiratory Distress

Management of acute respiratory failure is dependent on the clinical presentation of the patient. The primary goal is to ameliorate life-threatening hypoxemia by increasing both FiO_2 (fractional inspired oxygen concentration) and minute ventilation, thus ensuring adequate oxygen delivery to tissues. The secondary goals are management of acid/base disorders and the rapid diagnosis and treatment of the underlying disease processes.

The initial choice regarding concentration and flow rate of supplemental O_2 is based on the severity of the hypoxemia. Oxygen delivery apparatus, such as nasal cannula, face masks, nonrebreather, and partial nonrebreather masks are used to deliver O_2 to nonintubated patients. The FiO_2 delivered through nasal prongs or nasal cannula can be adjusted by flow rate to a maximum alveolar delivery concentration of 40–50%. Simple facemasks with O_2 flow rates of ≥10 L/min may allow alveolar O_2 concentrations of 60%. A nonrebreather mask with O_2 flow of 10–15 L/min may permit a slightly greater alveolar O_2 concentration. The performance of these masks improves with a tight fit between the mask and the patient. If endotracheal intubation is needed and time permits, preoxygenation with 100% oxygen for 3–5 min, using a mask that creates an extremely tight seal with the patient, will allow for denitrogenation of the functional residual capacity (FRC) and increase the reserve of oxygen.

TABLE 1-2

DISEASE PROCESSES THAT MAY REQUIRE INTUBATION

Trauma
Major thoracic or abdominal surgery
Postoperative: residual anesthetic, fluid overload, bleeding, airway surgery
Acute mental status change
Upper airway obstruction
Pneumonia
Pneumothorax
Pulmonary embolus: air, blood, fat, amniotic fluid
Severe asthma (status asthmaticus)
Flail chest
Chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF)
Unstable hemodynamics, e.g., evolving myocardial infarction
Shock: hemorrhagic, cardiogenic, neurogenic, or septic
Ischemic bowel
Acute renal failure with fluid retention

Maintaining Patent Airway

A patent airway provides a path for the delivery of oxygen and the exhalation of CO_2. An unobstructed airway is present when air movement can be readily detected at the nose or mouth. The tongue is the most frequent cause of partial or complete airway obstruction in obtunded patients. Lack of air flow or noisy breathing or snoring, indicate the need to intercede and improve air flow. This can be accomplished by repositioning the head and shoulders, extension of the neck, provided neck injury is not suspected, and moving the chin forward. This is known as a jaw-thrust or chin-lift maneuver and is often the most effective way to improve airway patency. Other interventions would include the use of a nasal or oral airway or a laryngeal mask airway (LMA). An oral airway splints the tongue anteriorly and prevents it from falling into the posterior pharynx thus relieving airway obstruction. Oral airways are not well tolerated in awake patients, so they are best used when the patient has been sedated or is unresponsive. A nasal airway (also known as a nasal trumpet because of its flared end) is better tolerated by an awake patient and will help relieve soft tissue airway obstruction in the naso-oropharynx.

An airway mask breathing unit (AMBU) is a type of bag-valve-mask. It is a device which can be connected to a high-flow oxygen source and is used to provide ventilation via a mask that fits securely over the nose and mouth. The bag, which is compressed manually, is self-filling. Assisted ventilation requires synchronization with the patient's breathing pattern. Assisted ventilation also helps relieve the work of breathing until the patient improves or a more secure airway can be established.

There are limited methods for the provision of noninvasive ventilatory support. These include continuous positive airway pressure (CPAP) and noninvasive positive pressure ventilation (NPPV) (see Chaps. 44 and 45). Some patients tolerate noninvasive methods of ventilation during a period of respiratory distress. Other patients become claustrophobic with tightly fitted masks and do not tolerate this method of treatment even for short periods of time. If the patient clinically appears to deteriorate, then immediate intubation and mechanical ventilation may be warranted.

If an FiO_2 greater than 70% is required for more than several hours, particularly in an unstable patient, endotracheal intubation should be considered.

Maintenance of adequate circulation is a crucial factor in acute respiratory failure. Optimizing cardiac function with inotropes, vasodilators, or vasopressors may improve oxygenation and/or ventilation and possibly eliminate the need for mechanical ventilation. Cardiac and hemodynamic status will also help determine the type of sedative-hypnotics and dosage most appropriate to facilitate intubation. Mechanical ventilation and positive end expiratory pressure (PEEP) increase intrathoracic pressure and may reduce cardiac output and blood pressure (BP).

In summation, the initial evaluation of respiratory distress includes identifying disease processes and assessing the ABCs as in any emergent situation: Airway (oxygenation delivery and exchange), breathing (work of breathing and ventilation), and circulation. A recent ABG further helps assess the patient's oxygenation and acid/base status. The patient's symptomatic and behavioral changes, physical exam, and other clinical criteria guide in the decision to proceed with intubation (Table 1-3).

A quick assessment to evaluate the need for intubation includes observing the ABCs of an emergent situation: aberrations in airway, breathing, and circulation may mandate ventilatory support.

PATIENT EVALUATION PRIOR TO INTUBATION

Certain medical information should be assessed and readily available before intubation and includes the following:

Medical Allergies/Alerts

Most drug allergies are not related to the sedative-hypnotics and muscle relaxants used during endotracheal intubation. Be aware that medical-alert bracelets may identify a history of malignant hyperthermia or difficult airway control. A history of pseudocholinesterase deficiency or

TABLE 1-3

CRITERIA FOR INTUBATION OR ASSISTED VENTILATION

EXAMINATION/TEST	NORMAL	ASSISTED VENTILATION
Mental status	Oriented	Confusion/obtunded
Accessory muscle use	Minimal	Considerable activity
Nail beds/skin color	Pink	Cyanosis
Respiratory rate (bpm)	12–20	>30
SaO_2 (%)	>95%	<88%
PaO_2 (mmHg)	75–100 (room air)	<70 (facemask)
$PaCO_2$ (mmHg)	35–45	>45–55[a]
A-a gradient (mmHg)	10–25	>100
VE (mL/kg)	90	150–200
NIF (cm H_2O)[b]	<(–25)	>(–25)
Vital capacity (mL/kg)	65–75	<15

[a]Check for metabolic alkalosis
[b]Negative inspiratory pressure

malignant hyperthermia limits the use of succinylcholine as a muscle relaxant. There are also rare reported cases of allergy or porphyria associated with the use of sodium thiopental.

Aspiration Risks

Full stomach precautions are required for trauma, small bowel obstruction, gastroesophageal reflux disease, upper GI bleed, hiatal hernia, pregnancy, obesity, diabetes, recent food ingestion, and altered mental status. In an emergency intubation, it is reasonable to assume that the patient has increased aspiration risk. In ICU patients, enteral feeds should be stopped and if a nasogastric or orogastric tube is present, it should be suctioned prior to endotracheal intubation; some practitioners believe that the nasogastric or orogastric tube should be removed following suctioning, but this practice is not universally agreed upon.

Neurologic Status

The patient's mental status governs the technique and approach used to place an endotracheal tube (ETT). The obtunded patient will need little to no sedation or only topical oral anesthesia. The combative patient may require higher doses of sedative-hypnotics to safely establish an airway. Intubation may be associated with temporary increases in intracranial pressure (ICP) which can be of concern in patients with intracranial disease processes. The most dramatic increases in ICP are seen in the setting of hypoxia and hypercarbia; thus, the most skilled practitioner should intubate and initiate controlled ventilation rapidly. If hemodynamic status permits, it is appropriate to use standard induction doses of sedative-hypnotics and succinylcholine or another rapidly acting muscle relaxant.

Musculoskeletal Status

Musculoskeletal status influences the choice of medications as well as the technique used for intubation. Neuromuscular diseases impact the type and dosage of neuromuscular blocking agents. Neck injury, arthritis, cervical stenosis, and/or a thick muscular neck raise concerns about the ease of intubation and may lead to the decision to intubate using a fiberoptic bronchoscope or one of the devices listed later in this chapter. Life-threatening hyperkalemia has been reported in patients with muscle weakness, paralysis, or prolonged bed rest following the administration of succinylcholine.

Coagulation Status

Patients with severe liver disease, coagulopathy, or those receiving warfarin or other anticoagulants are at increased risk for bleeding from nasotracheal intubation. Trauma to the nasal passages can cause bleeding that may interfere with visualization of the glottis and successful intubation.

Previous Intubations or Tracheostomy

A history of tracheostomy or prolonged intubation can result in tracheal narrowing and thus limit the diameter of the endotracheal tube (ETT) that will pass into the trachea. For this reason several different sizes of ETT should be available.

Obesity and Generalized Body Edema

Obesity and generalized body edema can make control of the airway difficult. Obese patients often have redundant upper airway tissue, which may manifest as repetitive night-time obstruction in the form of sleep apnea. Multiple unsuccessful attempts at intubation may lead to significant injury, edema, or bleeding, making subsequent attempts more difficult and increasing the risk to the patient. The senior physician should be fully knowledgeable in regard to the American Society of Anesthesiologists' (ASA) difficult airway algorithm and be prepared to move on to the next step(s) if necessary. Intubation is not a benign procedure and carries with it certain inherent risks, even when performed by a skilled practitioner. Any information that suggests possible complications or difficulty in placing an ETT directly impacts the method and technique utilized. Obtaining this information can be done in a relatively short period of time while the patient and equipment are being prepared.

Any information that suggests possible complications or difficulty in placing an ETT directly impacts the method and technique utilized.

PRACTICAL APPROACH TO INTUBATION

General Approach

Checklist Prior to Intubation

- Call for additional help and assistance
- Supplemental O_2, AMBU bag
- Position the patient
- Continue monitoring
- Check intubating equipment and ETT
- Suction
- IV access
- Prepare for resuscitation

Call for assistance as soon as possible when endotracheal intubation of a patient is imminent. Such person include an ICU nurse, nursing assistant, respiratory therapist, or another physician. The presence and help of well-trained assistants in positioning patients, applying cricoid pressure, handing off equipment, monitoring, and administering IV medications increases the safety and success of intubation. Proper communication and coordination of roles and responsibilities among healthcare providers is vitally important in successful airway management.

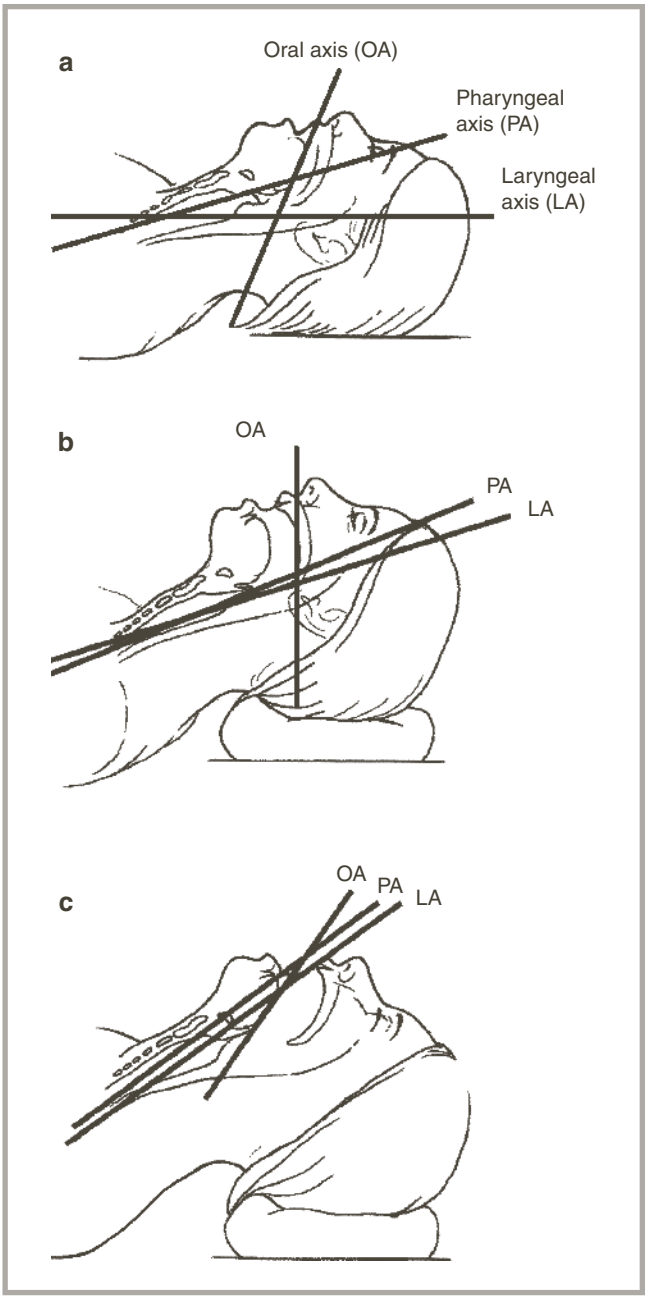
The ability to perform intubation quickly, efficiently, and safely is dependent on having the appropriate equipment and personnel. Supplemental oxygen is mandatory.

The patient should be moved to the head of the bed and simultaneously with this move blankets or pillows should be used to obtain an optimal patient position for intubation. While preparing to emergently intubate a patient, one assesses airway anatomy as rapidly as possible. The upper airway includes the nose, mouth, oropharynx, mandibular space, and neck. Evaluation of nasal anatomy is not routine, but is pertinent in the presence of head and/or neck injury. Restricted mouth opening may affect the ability to place a laryngoscope and view the glottis via direct laryngoscopy. Figure 1-1 illustrates that three different axes require alignment to provide maximal visualization of the glottic opening by direct laryngoscopy. These axes are the oral axis, the pharyngeal axis, and the laryngeal axis. Proper positioning of the head, neck, and shoulders can facilitate optimal alignment of these axes and increase the likelihood of successful intubation (Fig. 1-1).

Optimizing patient position facilitates endotracheal intubation.

FIGURE 1-1

Schematic representation of the oral axis (*OA*), pharyngeal axis (*PA*), and laryngeal axis (*LA*) in three different head positions. In position (**a**), the head is resting on a pillow with the head slightly flexed to align the PA and LA; however, the OA is not aligned. In position (**b**), the head is in neutral position with divergence of each axis. Position (**c**) is optimal for laryngoscopy, with the head on a pillow and neck extended (sniff position), thus aligning the OA, PA, and LA. (**a–c**) (Reprinted with permission from Mallampati et al.[5])



Monitors

Noninvasive BP, EKG, and pulse oximetry are essential monitors during endotracheal intubation. The patient's BP should be cycled every 2–3 min until hemodynamic stability is confirmed. Pulse oximetry should be audible and alarms activated. A stethoscope for auscultation of breath sounds should be readily available. Portable or disposable capnography will detect end tidal CO_2 (et CO_2) and assist in confirming correct placement of the ETT in the trachea.

Oxygen Delivery System

Usually, the patient receives supplemental oxygen via nasal cannula, facemask, or some type of noninvasive ventilatory support. An AMBU bag can provide a high percentage of oxygen and allows the practitioner to assist or fully support ventilation should apnea occur. Other types of breathing circuits or ventilatory support devices may be used; however, the AMBU

bag meets the needs of most adult patients and is widely available. The AMBU bag should be connected to a high-flow oxygen source (wall or cylinder).

Intravenous Access

A secure and well-functioning peripheral intravenous (IV) line allows for administration of IV fluids and medications to facilitate intubation. IV access is also important for the management of hemodynamic instability, which may occur after intubation. Preexisting peripheral cutaneous intravenous central catheter (PICC line), central line or dialysis catheters may be used in emergent settings. Some of these catheters will contain heparin solutions.

Suction System

Visualization of the airway may be obscured by secretions or blood. A large diameter suction catheter must be immediately available to clear secretions or debris from the airway during laryngoscopy; this will both enhance visualization and minimize aspiration risk.

Airway Support Devices

Oral airways, nasal trumpets, laryngeal mask airways (LMAs), and ETT exchangers of different sizes and types are some of the commonly used airway support devices. Although these items are not always necessary, having them readily available is considered the best practice.

Endotracheal Tubes of Several Sizes

ETT size is primarily determined by patient age. In most adult individuals, a 7 or 8-mm ETT is chosen. With adolescents and children, however, a smaller tube is required. Consideration should be given to using the largest acceptable ETT as this may enhance the ability to perform bronchoscopy at a later time. However, the highest priority is to establish an airway and this may be more readily accomplished with a smaller ETT.

Laryngoscopes

Distinct anatomic differences exist among patients. Therefore, several types and sizes of laryngoscopy blades should be available (Fig. 1-2).

Medications

The medications most commonly administered during endotracheal intubation are narcotics, sedative-hypnotics, and muscle relaxants; these may be used alone or in combination, taking into consideration their indications, hemodynamic profiles, and side effects. Details regarding these agents can be found in Chapters 57 and 58.

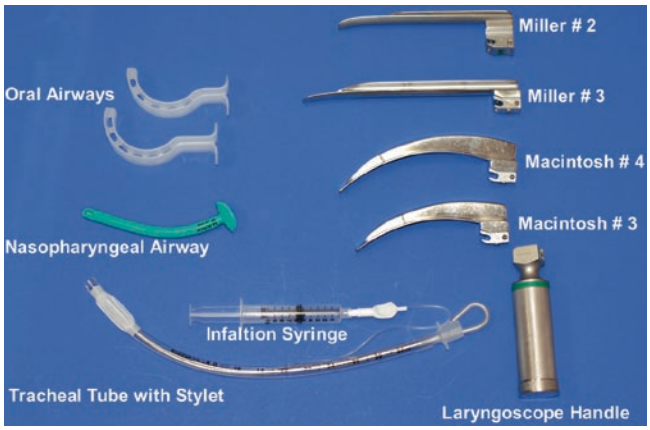


FIGURE 1-2

Standard equipment used for direct laryngoscopy and endotracheal intubation. Oral and nasal airways, and various size laryngoscope blades and handle are shown. A # 8.0 endotracheal tube (ETT) is shown with stylet and inflation syringe.

Additional Devices for Difficult Airway Management

These devices are used when conventional techniques are unlikely to result in the safe establishment of an airway. These devices include but are not limited to: Fiberoptic bronchoscopes, the Bullard Laryngoscope, and the GlideScope®. A description of these devices, and others, as well as the indications for their use is discussed in a later section of this chapter.

ACT OF INTUBATION

Having decided to proceed with intubation, most practitioners classify airway management into three basic categories based on airway assessment: easy, somewhat difficult, and extremely difficult. The American Society of Anesthesiologists[4] has developed a pathway for the establishment of an airway in each of these situations (Fig. 1-3).

Restriction of mouth opening affects the ability to place a laryngoscope and view oropharyngeal and glottic structures. Anesthesiologists utilize a classification system known as the Mallampati scale[5] that defines the relationship of the tongue to the oropharynx (Fig. 1-4). If, when the patient opens the mouth and extends the tongue, the soft palate and uvula are visualized and the structures of the posterior pharynx are easily identified, it is considered a Mallampati Class I. In Class IV, the tongue occupies most of the oral cavity and none of the aforementioned structures can be visualized. Class I suggests that endotracheal intubation via direct laryngoscopy is likely to be easily performed, whereas class four suggests that significant difficulties will be encountered.

Assessing the anatomy of the upper airway, the Mallampati score, and the range of motion of the neck help identify patients with a difficult airway.

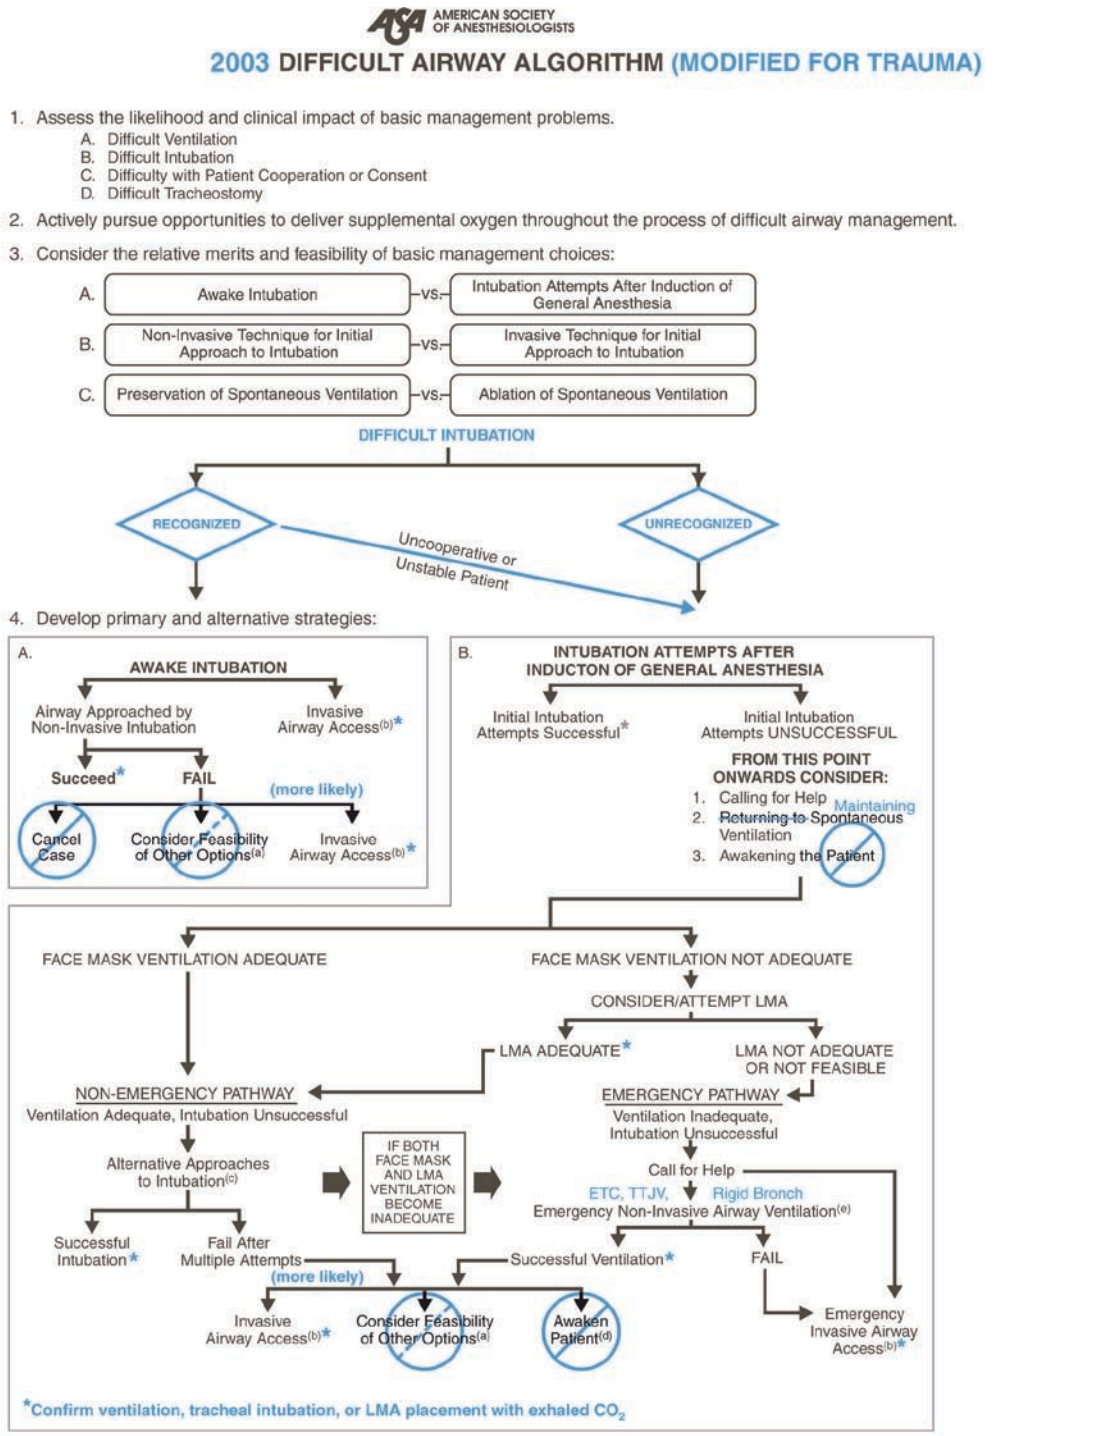
With the head extended, the distance from the thyroid cartilage to the tip of the chin (mental prominence) is known as the thyromental distance; this space can be measured in fingerbreadths or centimeters (normally three fingerbreadths or greater than 6 cm) (Fig. 1-5). The larynx and the tongue fit into a portion of this anatomic space. Pierre–Robin syndrome, which is characterized by micrognathia and macroglossia, is associated with extreme crowding of the mandibular space. Patients with this syndrome are extremely difficult to intubate using standard methods. A more common example of anatomical crowding within this space is in obese patients and patients with obstructive sleep apnea. In these settings, the mandibular space may be normal, but there is crowding due to the excessive soft tissue in the mandibular space and posterior pharynx.

Finally, head, neck, and mouth mobility is important for optimal positioning and the success of the procedure. A limited range of motion of the mouth and/or the neck may limit visualization of the glottic structures. The extent to which visualization of the glottis occurs has been classified into 4 grades based on the anatomic structures visualized. Grade I is visualization of the epiglottis, arytenoid cartilage, and glottis (see Fig. 1-6).

The height of the hospital bed should be adjusted to a level comfortable for the practitioner. This individual must be able to easily adjust the patient's head position, gain access to the oropharynx, and be in a position to view the glottic opening via direct laryngoscopy. Ideally, the patient is supine; however, patients with significant respiratory dysfunction may be positioned head-up or in a sitting position. If extremely short of breath and cognizant of his or her surroundings, the patient may become agitated if placed in a supine position. Therefore, preoxygenation and ventilation are controlled with the patient upright. Sedation and/or muscle relaxant is then administered, the patient is moved rapidly to the supine position, and the trachea is intubated. The optimal position for intubation is the sniffing position (Fig. 1-1). In an adult male, an 8.0 mm ETT is preferable in the ICU setting. Smaller-diameter tubes result in an increased resistance to gas flow and during weaning may increase the work of breathing.

Orotracheal intubation via direct laryngoscopy is the most commonly used technique for establishing a secure airway.

Once the ETT is placed and the cuff of the ETT inflated, it is necessary to confirm appropriate placement by listening to the chest for equal breath sounds and monitoring $etCO_2$ litmus analyzers or $etCO_2$ detectors. Continuous end-tidal CO_2 return is the best indicator of proper ETT placement. It is important to auscultate the abdomen to ensure that the ETT is not in the stomach. Breath sounds in both the abdomen and the chest most likely indicate esophageal intubation; continuous end-tidal CO_2 is absent in this setting. Phonation also indicates incorrect placement of the ETT. Other methods used to identify appropriate placement include observation of chest wall motion and humidification in the ETT with expiration. Esophageal intubation should be acted upon promptly.



a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway. Judgment required. Rarely appropriate for trauma patients.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation (FOB), intubation stylet or tube changer (airway exchange catheter, (AEC) light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery. Rarely applicable in the trauma patient.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope (Rigid Bronch), esophageal-tracheal combitube ventilation (ETC), or transtracheal jet ventilation (TTJV

f. Extubation strategies include: evaluation of the airway with FOB and extubation over an airway exchange catheter (AEC).

FIGURE 1-3

American Society of Anesthesiologists (ASA) difficult airway algorithm 2003 modified for trauma (from Wilson.[4] Reprinted with permission from the American Society of Anesthesiologists. A copy of the full text can be obtained from ASA, 520 N. Northwest Highway, Park Ridge, IL 60068-2573).

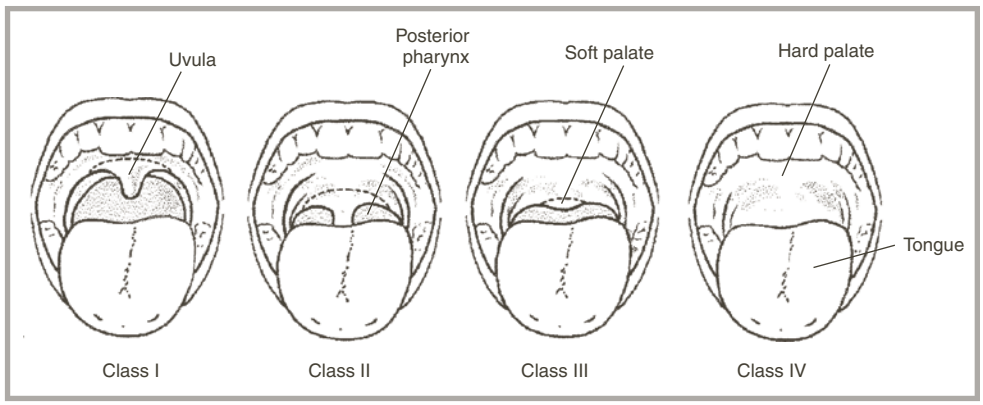


FIGURE 1-4

Maximal opening of oral cavity (left to right, class I–class IV) provides visualization of structures in the oropharynx. In class I, structures are easily identified, and in class IV, the tongue obstructs the view of the posterior pharynx (modified from Mallampati et al,[5] with permission).

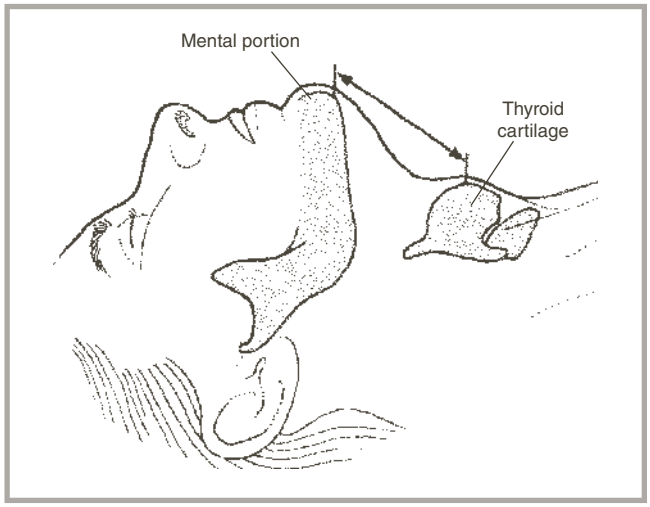

FIGURE 1-5

The distance from the mental portion of the mandible to the thyroid cartilage notch is known as the thyromental distance.

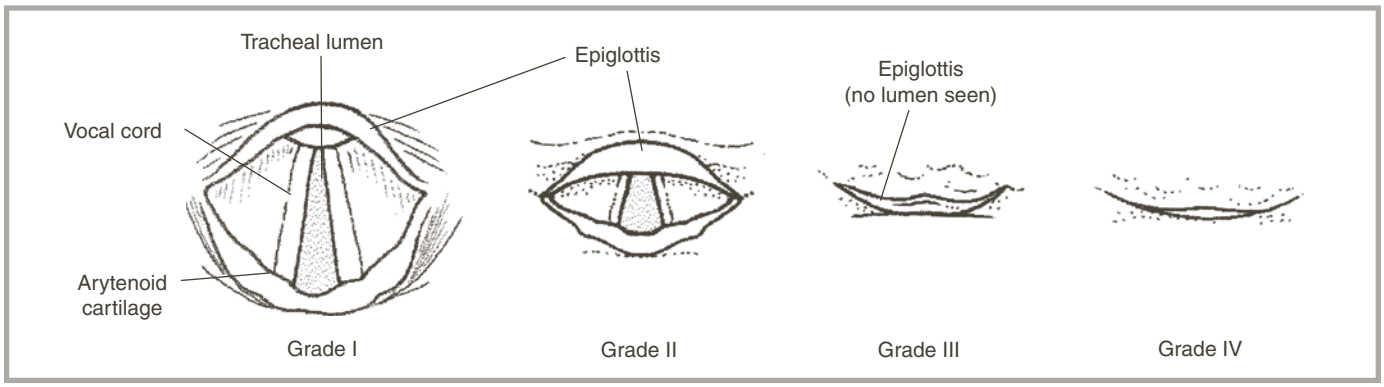

FIGURE 1-6

Grade I: optimal view of vocal cords during laryngoscopy. With a grade III view only the epiglottis can be clearly identified and the tracheal lumen cannot be visualized (Modified from Mallampati et al,[5] with permission).

With complete cardiovascular collapse, there is insufficient perfusion to the lungs. Even if the ETT is correctly positioned, there will be no $etCO_2$ as a result of the lack of pulmonary blood flow. The alveoli are ventilated but not perfused. This is the circumstance in which the ETT is positioned correctly within the trachea, yet no $etCO_2$ is detected.

There are commonly three types of critically ill patients who require intubation: unconscious, awake or combative, and semiconscious. Regardless of the level of consciousness each patient's airway is evaluated for potential difficultly in establishing an airway. Patients

with cardiopulmonary arrest are typically unconscious, flaccid, and usually do not require drug therapy to facilitate airway management. The awake or combative patient may require sedation and muscle relaxants to facilitate tracheal intubation. The use of sedative-hypnotic agents and muscle relaxants may be contraindicated if the airway examination indicates that endotracheal intubation will be difficult. Semiconscious patients with preserved airway reflexes may only require topical anesthesia (i.e., lidocaine spray, jelly or ointment). Application of topical anesthetics to the oropharynx and hypopharynx is intended to obliterate sensation and the gag reflex during laryngoscopy and intubation. This type of patient may require small doses of short-acting sedative medications to induce a brief state of unconsciousness or to control hypertension while placing the ETT. Neuromuscular blocking agents are not commonly administered in this circumstance. The disadvantage with most sedatives is that the patient may become apneic.

The technique of topical anesthesia should be considered in any awake patient with a high likelihood of being difficult to intubate. The awake patient will maintain spontaneous respiration if there is a failure to appropriately position the ETT in the trachea. Direct laryngoscopy is performed in the conventional manner and additional topical anesthesia is applied to the epiglottis and vocal cords if necessary prior to intubation.

After sedative-hypnotics have been administered, anesthesiologists typically withhold muscle relaxants until they confirm their ability to ventilate the patient. With a tight mask fit, ventilation is confirmed by normal chest expansion and expiratory humidity within the clear face mask. Inability to ventilate the patient at this juncture raises significant concerns regarding how to secure the airway. The addition of neuromuscular blocking agents at this point may worsen the situation and expose the patient to greater risk. The method of intubation is dependent upon the airway evaluation, the patient's level of consciousness, operator skill, available equipment, and assistance at bedside.

Following intubation, the ETT position is confirmed, the cuff is inflated, the tube is secured to the patient, adequate tidal volumes and oxygenation are established, and the patient is placed on mechanical ventilatory support. Endotracheal tubes (ETTs) with high-volume, low-pressure cuffs are now used routinely; however, care should be taken to prevent both over and underinflation of the cuff. There are a number of ways to secure the ETT. Regardless of the method used (benzoin, tape, umbilical tape, or ETT holders), the tube must be carefully positioned and secured, as it is now a lifeline for the patient. A chest X-ray will confirm the ETT position. The ETT is considered to be in an optimal position when the tip is 2–3 cm above the carina, or slightly below the level of the clavicular heads, with the patient's head midline and in a neutral position. Flexion of the head can move the distal end of the ETT toward the carina; extension can move it toward the vocal cords. It is for this reason that uncontrolled positioning of a patient's head during transport may result in dislodgement of the ETT from the trachea.

Although respiratory distress may overburden the cardiovascular system before intubation, hemodynamic instability may occur after intubation as a result of several factors.

Severe respiratory distress overburdens the cardiovascular system. Heart rate (HR) and BP are frequently elevated secondary to sympathetic nervous system stimulation from anxiety, hypercarbia, hypoxia, and increased work of breathing. Vagal stimulation may occur with direct laryngoscopy, causing a precipitous drop in HR and then BP; laryngoscopy can also markedly increase HR and BP. When dramatic changes in hemodynamics occur, the procedure may need to be interrupted to treat these responses. After intubation, a decrease in BP and HR are often seen due to decreased sympathetic stimulation as hypoxia and hypercarbia are corrected; positive pressure ventilation may also contribute to these changes.

Rapid Sequence Induction and Intubation

When a full stomach is suspected, a rapid sequence induction and intubation is used to minimize the risk of aspiration.

One associated technique used in emergency intubations is known as rapid sequence induction and intubation with criciod pressure. This technique, compressing the cricoid cartilage (located below the thyroid cartilage) posteriorly against the esophagus (also known as the Sellick maneuver) may prevent gastric contents from reaching the posterior pharynx, thus minimizing the risk of aspiration. The technique requires preoxygenation, rapid induction of deep sedation, and the simultaneous use of muscle relaxants without first confirming the ability to mask ventilate; this is the standard technique routinely used to minimize the risk of

aspiration. Adequate bedside suctioning equipment must be present. The effectiveness of this technique for preventing aspiration has recently been questioned; however, it is still a common practice.[6]

Modified Rapid Sequence Induction

This is a rapid sequence induction as described above; however, mask ventilation is continued as medications are administered and cricoid pressure is applied. This technique is commonly used in situations where the patient could not be adequately preoxygenated prior to intubation, or when it is important to maintain a low pCO_2, as in neurologic emergencies.

Nasotracheal Intubation

With a nasotracheal intubation, the ETT is introduced into the pharynx via the nose and then into the trachea. This procedure is usually performed under direct laryngoscopy with a Magill forceps, which is used to guide the ETT into the trachea. It is important to use the Magill forceps to direct the ETT tip while advancing the tube into the nose; pulling the ETT with the forceps may damage the cuff.

A variation of this technique is to insert the ETT through the nose into the pharynx and then into the trachea without visual confirmation. This is known as a blind nasal intubation. Successful intubation is dependent upon the adjustment of the patient's head position, changing tube direction by rotating the ETT, and advancement of the tube while listening for transmitted breath sounds through the ETT. Vasoconstrictors, lubricants, and topical anesthetics are used to prepare the nares for nasal intubation. The diameter of the ETT may be limited by the size of the nasal passages; an ETT that has a smaller diameter and an increased length will likely be required if this route is chosen. The risk of bleeding is notably higher with the nasal route and sinusitis can develop with prolonged intubation. Consequently, this technique is falling out of favor if a prolonged intubation is anticipated.

Prolonged nasotrachael intubation is commonly associated with the development of sinusitis.

Difficult Intubation

If the initial attempt at intubation fails, then alternative solutions need to be identified. If the patient can be easily ventilated by mask, there is time to carefully consider the next steps. These steps can be as simple as changing patient head or neck position or suctioning to improve visualization during the second attempt under direct laryngoscopy. Changing the type of laryngoscope blade or its size may provide better exposure of the anatomic structures of the airway. Smaller ETTs may facilitate passage through a stenotic section of the trachea. Another issue may be patient movement or combativeness, which prevents successful intubation. Additional sedation may be needed in this situation. Muscle relaxants may be added to facilitate tracheal intubation, although it is important to keep in mind that the resultant loss of muscle tone and apnea may worsen the situation. Finally, a different practitioner may be successful. In many of these situations, altering the approach with one or more of these maneuvers may result in successful intubation.

If the initial attempt at intubation fails, then alternative solutions need to be identified. If the patient can be easily ventilated by mask there is time to carefully consider the next steps.

Repeated manipulation and attempts to intubate often results in bleeding and swelling of the airway, making oxygenation and ventilation increasingly difficult or impossible. The American Society of Anesthesiologists developed the difficult airway algorithm[4] to "reduce the likelihood of adverse outcomes" (see Fig. 1-3). The principal adverse outcomes associated with the difficult airway include (but are not limited to) death, brain injury, myocardial injury, and airway trauma. A major goal of the algorithm is to maintain a patent airway at all times. The algorithm is focused in three areas: difficult intubation, difficult ventilation, and difficulty with both ventilation and intubation. The goal of airway management strategies is to avoid the "cannot ventilate, cannot intubate" situation and to deliver supplemental oxygen throughout the process of airway management. Primary and alternative strategies deal with each difficult situation.

The ASA algorithm describes the clinical management of the recognized and unrecognized difficult airway.

SUPPORT DEVICES

To Improve Oxygenation or Ventilation

Laryngeal Mask Airway

Support devices are available that may improve oxygenation or ventilation if endotracheal intubation is not possible.

The LMA (Fig. 1-7) can be used to establish an airway in many situations where intubation is difficult or in the operating room where the use of an LMA has become common for relatively short cases that do not require muscle relaxants. The LMA is a tube with a mask-like structure that is blindly placed into the oropharynx and seated over the laryngeal outlet after inflation of the cuff ventilation is established. Positive pressure ventilation via an LMA is not recommended in a critical care setting as gastroesophageal insufflation and loss of tidal volume will inevitably occur. The LMA sits over the glottis and thus there is not the same expectation of airway protection as with endotracheal intubation.

The LMA is poorly tolerated by a conscious patient because of the stimulation of the airway reflexes and should be avoided.[7,8] Sedation is required when inserting this device, as well as during its use. An LMA should be avoided in patients with gastroesophgeal reflux disease (GERD) or when an aspiration risk is present. A specific type of LMA (fast-track LMA®) (Fig. 1-8) allows for ventilation and acts as a guide to direct a specially designed ETT into the trachea.

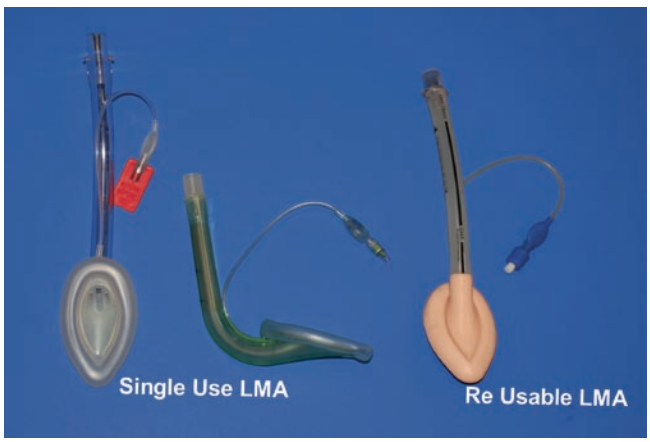

FIGURE 1-7

Laryngeal mask airways (LMAs). Various size and types of LMAs used to ventilate patients either following difficult intubation or during general anesthesia procedures.

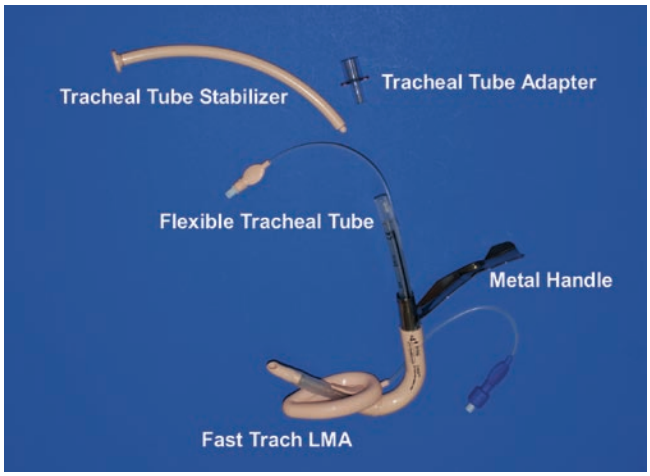

FIGURE 1-8

Fast Trach® LMA. Specially designed LMA allows positioning in the oral-pharyngeal cavity and confirmation of ventilation via the LMA. Flexible tracheal tube advanced into the tracheal with tracheal tube stabilizer.

Combitube

The combitube is used in emergency situations, usually in out-of-hospital settings. It is a double-lumen tube blindly placed into the oral cavity and advanced into either the esophagus or trachea. Inflation of the two balloons and ventilation of each port allows for identification of the port that communicates with the trachea.

For Management of the Difficult Airway

Fiberoptic Bronchoscope

Fiberoptic intubation may be used to establish an airway in controlled settings.

The fiberoptic bronchoscope is a thin, flexible device that allows visualization of airway anatomy via a bundle of light-transmitting fibers. The device requires a light source and has a port that allows for suctioning of secretions or insufflation of oxygen. The operator must have a good working knowledge of airway anatomy and skill in manipulating the bronchoscope. Fiberoptic scopes are available in various sizes. The larger scopes provide greater suctioning ability and increased rigidity, which facilitates threading the ETT over the bronchoscope and into the trachea.

If airway management is likely to be difficult secondary to anatomic issues, edema, tumor, or tissue injury, fiberoptic intubation should be considered. Awake fiberoptic intubation requires time, so the degree of respiratory distress affects the decision to use this technique. Topical anesthesia is needed for both the oropharyngeal and nasopharyngeal routes; a topical vasoconstricting agent is also applied if the nasal route is chosen. Many practitioners will place a nasal trumpet, coated with a topical anesthetic gel, prior to introducing the ETT into the nares. This helps deliver the topical anesthetic and allows assessment of the patency of the nasal passage. With the oral approach, a specially designed oral airway (Ovassapian Airway) guides the fiberoptic scope around the tongue and into the posterior pharynx.

In emergent situations, if an LMA has been used to establish an airway, a fiberoptic bronchoscope can be advanced through the LMA to visualize vocal cord, tracheal, and carinal anatomy. It may be possible to advance a small ETT over the bronchoscope and through the LMA lumen into the trachea. The intubating LMA is a device that is specifically designed to allow the passage of an ETT through the LMA and into the trachea.[9,10]

Bullard Laryngoscope

The Bullard laryngoscope (Fig. 1-9) is a rigid fiberoptic laryngoscope designed to facilitate laryngoscopy and tracheal intubation in patients in whom oral, pharyngeal, and laryngeal axial alignment is difficult or impossible.[11] It has also been found to be useful in patients with limited mouth opening. It has an attached stylet on which an appropriately sized ETT is mounted for oral intubation of the trachea. With the neck in a neutral position, the blade portion is passed into the mouth and guided along the surface of the tongue until the tip rests in the epiglottic valeculla. It is essential to maintain the blade in a midline position. Following placement, elevate the handle straight up; this will cause the tip of the blade to retract the epiglottis and permit a view of the glottic opening. With the glottic opening in view, the ETT is released from the stylet and advanced into the trachea.

FIGURE 1-9

Bullard laryngoscope showing introducing stylet for ETT, battery handle, light source and eye piece for viewing laryngeal structure.

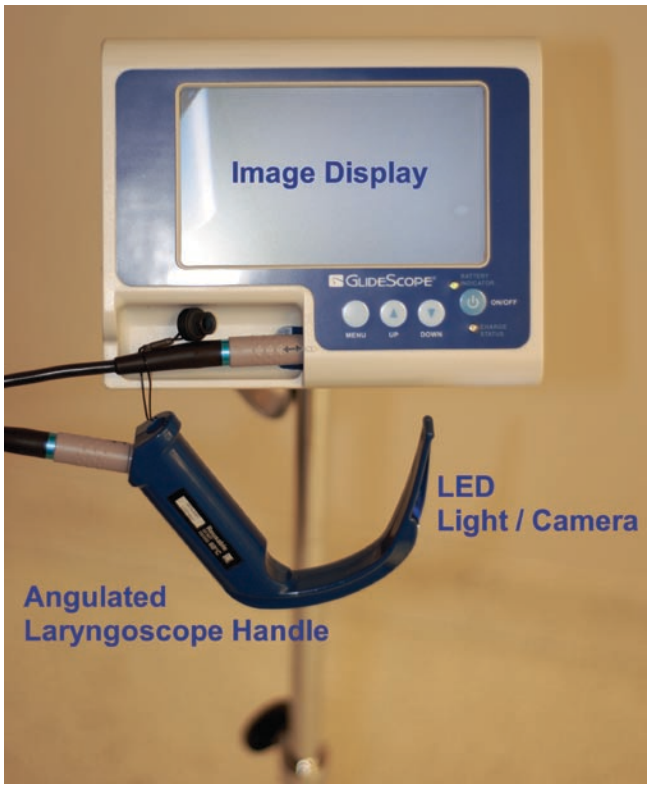

FIGURE 1-10

GlideScope® is a video laryngoscope system with angulated laryngoscope handle containing both light source and camera for viewing laryngeal structure on the image display screen.

Glidescope® Video Laryngoscope

This is a video laryngoscope (Fig. 1-10) that incorporates a digital camera into the blade and when properly positioned displays a view of the glottic opening on the associated monitor. Because it does not require direct line-of-sight, it is particularly useful for the patient with an anterior larynx. With the glottic opening in view on the video screen, the stylated ETT is advanced along the lateral edge of the laryngoscope blade. When the tip of the ETT comes into view on the screen, it is directed toward the glottic opening and advanced into the tracheal.[12,13] This device may be used for airway management in locations other than the operating room.

Other Techniques

Other techniques for establishing an airway include use of the illuminating intubating stylet (Lightwand) and retrograde intubation. The Lightwand uses transillumination of the midline neck to guide tracheal intubation without direct visual confirmation of airway anatomy. Retrograde techniques involve threading a wire or catheter through a puncture site in the cricothyroid membrane and then up the trachea and out through the mouth. This wire then serves as a guide for a stiff catheter, over which the ETT is threaded and advanced into the trachea. There are commercially available retrograde intubation kits that include all necessary equipment. In an ICU setting, operator experience may be a limiting factor for this technique.

Retrograde intubation, or the use of a lightwand, requires an experienced and skilled practitioner.

When intubation is not possible and ventilation becomes difficult or impossible, a surgical airway must be rapidly established. If surgical personnel are unavailable, cricothyroidotomy with a large-bore IV catheter followed by transtracheal jet ventilation can temporize the situation. Commercial cricothyroidotomy sets are available that provide a more substantial temporary airway that can be converted to a formal tracheotomy at a later time.

Table 1-4 lists some of the complications associated with the act of intubation, laryngoscopy, or tracheostomy. It is clear that intubation should be performed only if indicated. It is generally understood that the longer the artificial airway is maintained, the higher the likelihood of complications associated with its use.

TABLE 1-4

COMPLICATIONS OF INTUBATION

Laryngospasm/bronchospasm
Lip, tongue, or mucosal lacerations
Tooth damage
Neck extension results in nerve damage or exacerbation of nerve injury
Hypertension, tachycardia, bradycardia
Esophageal intubation
Kinked ETT, tube malfunction
Endobronchial intubation
Aspiration
Mucosal inflammation and ulceration
Glottic, subglottic, tracheal edema and stenosis
Vocal cord paralysis, granuloma, or hoareness
Excessive/inspissated secretions
Pneumonia/tracheobronchitis
Nasal bleeding from nasal intubation
Tracheal tear or retropharyngeal dissection
Tracheomalacia
Inominate artery perforation

PHARMACOLOGIC AIDS FOR INTUBATION

Numerous pharmacologic agents are available to aid the process of establishing an airway. Choice of agent is influenced by the patients' physiologic status and the pharmacodynamic and pharmacokinetic effects of the agents under consideration.

Numerous agents are available to induce a rapid state of unconsciousness and ensure a cooperative patient during intubation. These agents include: benzodiazepines, narcotics, propofol, barbiturates, etomidate, and ketamine. Choice of specific induction agents is influenced by the patients' cardiovascular and neurological status at the time of intubation and the experience of the operator. Neuromuscular blocking agents facilitate tracheal intubation, but provide absolutely no sedative or hypnotic effects.

The medications chosen for facilitating intubation are potent sedative-hypnotics that have a rapid onset time; many also have a short redistribution half-life. Anesthesiologists typically administer these types of pharmacologic agents following preoxygenation with 100% O_2. This may be accomplished with several minutes of breathing 100% O_2 or 5 deep breaths if the patient is cooperative. The reserve of oxygen in the FRC of the lung delays desaturation if airway control is unexpectedly difficult. During the period of unconsciousness, and prior to intubation, the ability to mask ventilate the patient should be confirmed.

The uncooperative patient with a difficult airway presents the most problematic situation. Use of sedative-hypnotics and neuromuscular blocking agents eliminates spontaneous movement, but does not guarantee the ability to ventilate the patient. It is important to reassess the patient following intubation to ensure that neurologic injury has not occurred during the procedure. Sedation can then be reinstituted for patient comfort and to allow synchronization with ventilatory settings. Additional information regarding sedative-hypnotics and neuromuscular blocking agents is provided in Chaps. 57 and 58, respectively.

SPECIAL SITUATIONS

Special situations, such as epiglottis, facial or airway trauma, or the presence of a mediastinal mass significantly affect the manner in which an airway is established.

Certain conditions may influence the method of intubation. These conditions include, but are not limited to, a full stomach, increased ICP, myocardial ischemia, neck injury, mediastinal mass, and facial trauma.

Full Stomach, Nausea, or Vomiting

A patient with a "full stomach" has a higher risk of aspirating stomach contents into the lungs during intubation. It is important to minimize this potential complication with the use of clear antacids (Bicitra), an awake-intubation, or a rapid sequence induction (previously described). Histamine receptor type 2 blocking agents and proton pump inhibitors may limit the risk of pneumonitis should aspiration occur; however, their onset of action is too slow to be efficacious in urgent situations. Many patients requiring intubation in the ICU have received enteral

nutrition and thus are at a risk for aspiration. Other risk factors include pregnancy, obesity, gastroparesis, bowel obstruction, emergency surgery, recent trauma, or an upper GI bleed.

Increased Intracranial Pressure

Increased ICP may be secondary to head trauma, brain tumor, subarachnoid hemorrhage, or other conditions. Any of the induction agents listed above (with the exception of ketamine) may be used; hypercarbia and hypoxia are to be avoided. Noting pupil size before and after intubation provides an initial neurologic assessment.

Myocardial Ischemia

Cardiovascular status impacts the choice of medications used to induce a state of unconsciousness. Most induction agents are myocardial depressants; subsequent hypotension and tachycardia are common. Both myocardial ischemia and cardiomyopathy may be associated with a decreased cardiac output and slow circulation time that leads to a delayed onset of action of these agents. Reducing the dose and administering over a longer time period may be prudent. Laryngoscopy and sympathetic response may induce or exacerbate significant arrhythmias.

Neck Injury

Patients who require a restrictive neck brace have limited neck motion. This may limit optimal positioning and subsequent glottic visualization.[14] If intubation under direct laryngoscopy is attempted an assistant should maintain in-line stabilization of the head and neck. Other techniques described earlier in this chapter may be appropriate.

Mediastinal Mass

An anterior mediastinal mass can compress the trachea, mainstem bronchi, or major vascular structures. A patent airway may be maintained by the patient's muscle tone, spontaneous ventilation, and/or position.[15] Changes in any one of these may result in airway collapse or profound hypotension. Radiologic studies should be obtained or reviewed if time allows.

Oropharyngeal and Facial Trauma

Blind nasal intubation is contraindicated due to the possibility of an undiagnosed basal skull fracture and subsequent injury from the ETT.[16] The ability to open the mouth may be significantly compromised in the presence of mandibular fractures. Forcing the mouth open after muscle relaxation may result in hematoma formation or bleeding into the oral cavity. If facial injuries are substantive, a surgical airway may be required.

Self-Extubation

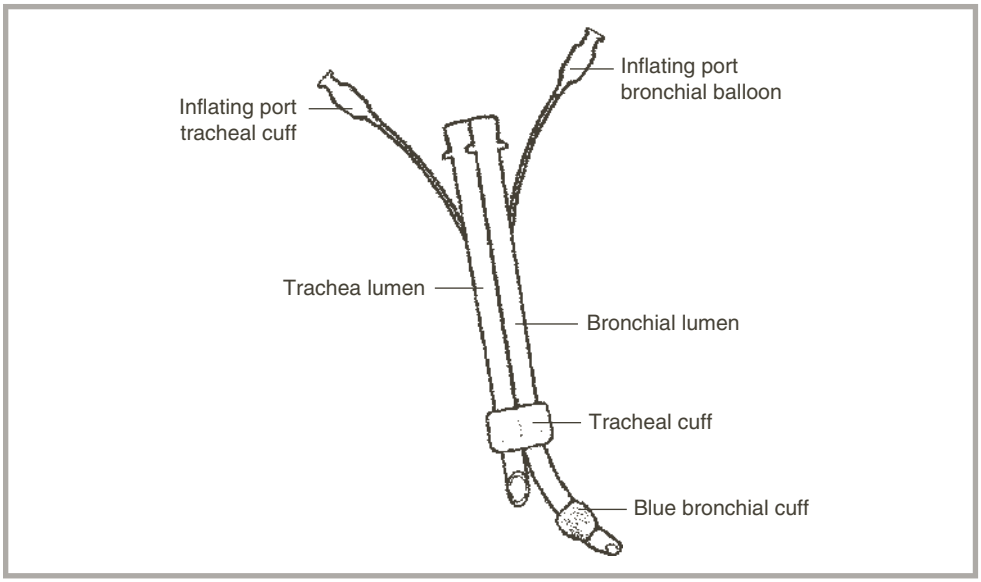
Patients who extubate themselves may not require immediate reintubation. Patients who are alert and self-extubate are more likely to remain extubated than patients who have been unintentionally extubated.[17] The patient's oxygenation and ventilatory pattern should determine if an airway needs to be reestablished. After self-extubation or unintentional extubation, the possibility of aspiration should be considered. Reintubation may be difficult due to secretions and airway edema.

One-Lung Ventilation

Indications for one-lung ventilation using a double-lumen endotracheal tube (DLT) in the operating room are classified as absolute and relative. Absolute indications include isolation of a healthy lung to prevent contamination from infection or bleeding, controlled

FIGURE 1-11

The double-lumen tube (DLT) can be right-or left-sided. Because of the likelihood of obstructing the right upper lobe bronchial orifice when using the right-sided DLT, the left-sided DLT is used most frequently in both the intensive care unit (ICU) and operating room setting.



distribution of ventilation to one lung only, or unilateral lung lavage. Relative indications are related to the need to improve surgical exposure. With the increasing use of video-assisted thoracoscopy, the need to have a non-moving collapsed lung is increasingly important. The DLT has a large external diameter, and experience is required for proper positioning. The distal bronchial lumen is curved to allow placement into a mainstem bronchus. Proper placement is routinely confirmed with fiberoptic bronchoscopy. Even a minor change in patient position may result in displacement of the DLT from its proper position; thus, in the ICU setting, it is prudent to sedate these patients and administer neuromuscular blocking agents.

Independent lung ventilation may be indicated for unilateral infection, bronchopleural fistulas, or a ruptured pulmonary artery. There are instances in which the compliance of each lung is so substantially different as to require independent ventilation; a DLT can provide this type of support (Fig. 1-11). The narrow lumens may preclude effective suctioning and fiberoptic evaluation.

Withholding Intubation

It is not always appropriate to establish an airway in patients with respiratory distress; this is true when a "do not resuscitate" (DNR) order has been issued. If therapeutic measures are considered medically futile, then it is reasonable to withhold such therapy (see Chap. 37 for a broader discussion of these issues).

WHEN TO EXTUBATE

The underlying process that induced respiratory distress must be improved before considering extubation.

Numerous criteria for extubation have been proposed; none are perfectly predictive of the patient's ability to maintain spontaneous ventilation. There continues to be considerable discussion regarding weaning parameters and protocols within the medical community (see Chap. 47 for a broader discussion of this topic).

WHEN TO PROCEED WITH TRACHEOTOMY

Timing of tracheotomy is based on the patient's condition, the anticipated need for mechanical ventilation, and the demonstrated progress, or lack thereof, while intubated.

The timing of converting to tracheotomy is based on clinical judgment and the duration of endotracheal intubation. The literature supports proceeding with tracheotomy within a 2–6 week period.[18,19] The decision to proceed with tracheotomy should be tailored to the patient's

medical requirements.[18,20] Patients who require tracheotomy usually have pulmonary disease in addition to other major organ system dysfunctions. Tracheotomy may need to be delayed in patients with a recent median sternotomy. There is often concern in this setting regarding the potential for serious wound infections of the chest secondary to the surgical trauma of the tracheotomy and the introduction of airway secretions into shared tissue planes.

It is well recognized that some stroke patients have limited ability to protect the airway due to loss of airway reflexes. In bone marrow transplant patients, neutropenia may be significant and cause early pneumonia. Early tracheostomy may be helpful in these patient groups.[21] Other advantages of tracheotomy include accelerating the process of weaning and thus reducing the duration of ventilation, length of hospitalization, and costs. On the other hand, tracheotomy may provide no benefit to patients with respect to survival and duration of mechanical ventilation and may increase airway injury. Tracheotomy does require proper care such as maintaining patency by frequently changing the inner cannula and limiting cuff pressures to reduce tracheomalacia and tracheal stenosis.[22] A rare but serious risk of tracheostomy is inominate artery perforation caused by erosion of the tracheal wall by a chronically over inflated tracheal cuff.

Patients are often more comfortable and as noted above frequently wean from ventilatory support faster following tracheotomy; presumably because dead space and resistance to gas flow are reduced. Pulmonary toilet and suctioning of secretions are improved. Therefore, although it is a surgical procedure and in most cases requires exposure to anesthetic agents, the advantages of the procedure usually outweigh the risks.

Tracheostomy is performed when the overall benefits outweigh the risks of the procedure.

MANAGING THE CHRONICALLY INSTRUMENTED AIRWAY

Endotracheal Tube Designs

Several types of ETTs are available for airway management. Most common in the ICU setting are tubes composed of polyvinyl chloride (PVC). In some instances, an armored or anode tube may be used to prevent kinking and subsequent obstruction. High-volume, low-pressure cuffed ETTs are now used routinely. Excessive cuff pressures may lead to mucosal ischemia and tracheomalacia. The goal is to inflate the cuff with the minimum amount of air needed to provide an effective seal for mechanical ventilation. A cuff pressure of 25 mmHg is the suggested upper pressure limit. An inappropriately sized ETT will require excessive cuff pressures to maintain a seal; changing to a larger diameter ETT may correct this situation.

Finally, there is an ETT on the market that allows continuous suctioning of pooled oral secretions from an orifice located just above the ETT cuff; the goal of this design is to decrease the incidence of ventilator-associated pneumonia (VAP).[23] A silver-coated ETT was studied in a recent, large, multicenter-center trial and documented a reduced incidence of VAP; the FDA recently approved this product.[24]

MAINTENANCE OF ENDOTRACHEAL TUBES

Once positioned within the trachea, the ETT must be properly maintained if it is to continue to function as an effective airway. Inspissated secretions, mucous plugs, or blood clots can partially or completely block the lumen, thus limiting effective ventilation and increasing peak airway pressure. The ETT can be displaced into the right mainstem bronchus with neck flexion or out of the trachea with neck extension. The ETT cuff may be underinflated allowing an air leak and aspiration of oral secretions, or overinflated, leading to mucosal ischemia.

Maintenance of indwelling ETTs is mandatory to ensure patency and proper position.

Several steps can be taken to minimize potential problems:

- Suctioning: Suctioning helps minimize the potential for mucous plugs within the ETT.
- Pressures: Cuff pressures should be less than 25 mmHg to minimize ischemic injury. If a seal cannot be obtained with a pressure less that 25 mmHg, consideration should be given to changing to a larger diameter ETT.

- Tape Changes: Frequently, the tape used to secure the ETT produces excoriation of the skin of the face and neck. If the patient remains intubated for a prolonged period, there may be less injury with cloth tape or IV tubing. Additionally, the lips are at risk for pressure injury if the ETT tube is continually taped in the same position. Commercially designed tube holders have similar complications associated with their use. Frequent inspection is important and may prevent these complications.
- Nasotracheal Tubes: Nasotracheal tubes eliminate some of the patient discomfort associated with oral ETTs. However, nosocomial sinusitis is a complication that affects 25–50% of the nasally intubated patient population 7 days postintubation.

Tracheal irritation begins as soon as the ETT is placed.

A significant potential complication of prolonged intubation is the development of postintubation laryngotracheal stenosis.[22] Tracheal irritation begins shortly after the ETT is placed. Risk factors associated with laryngotracheal stenosis include direct pressure necrosis from high cuff pressures, prolonged intubation, trauma during intubation, intubation technique used for the placement of ETT, the severity of respiratory failure, infection, and poor tissue perfusion.

Endotracheal Tube Changes

ETT changes should be done only when necessary and only under the supervision of experienced practitioners.

ETT exchanges should be done only when necessary and only under the supervision of experienced practitioners. Changing an ETT may be required secondary to a cuff leak, inspissated secretions leading to obstruction of the lumen, or the need to change to a different type or size ETT. Frequently, these patients have been intubated for a prolonged period and upper airway edema may be present. Direct laryngoscopy should be performed to evaluate the oropharynx and glottic opening. If minimal edema is present and the vocal cords easily visualized, then the ETT can be exchanged under direct vision. However, if there is significant edema it may be prudent to exchange the ETT using a tube exchange catheter. This hollow semi-rigid plastic catheter (Cook® catheter), acts as a guide and allows for the insufflation of oxygen. The in situ ETT can be removed and a new one placed using a technique similar to the Seldinger's technique for vascular access. Consideration should be given to performing this type of ETT exchange under direct laryngoscopy, which displaces upper airway tissue (see the ASA algorithm for ETT exchange in ICU patients with difficult airways (Fig. 1-12) [4].

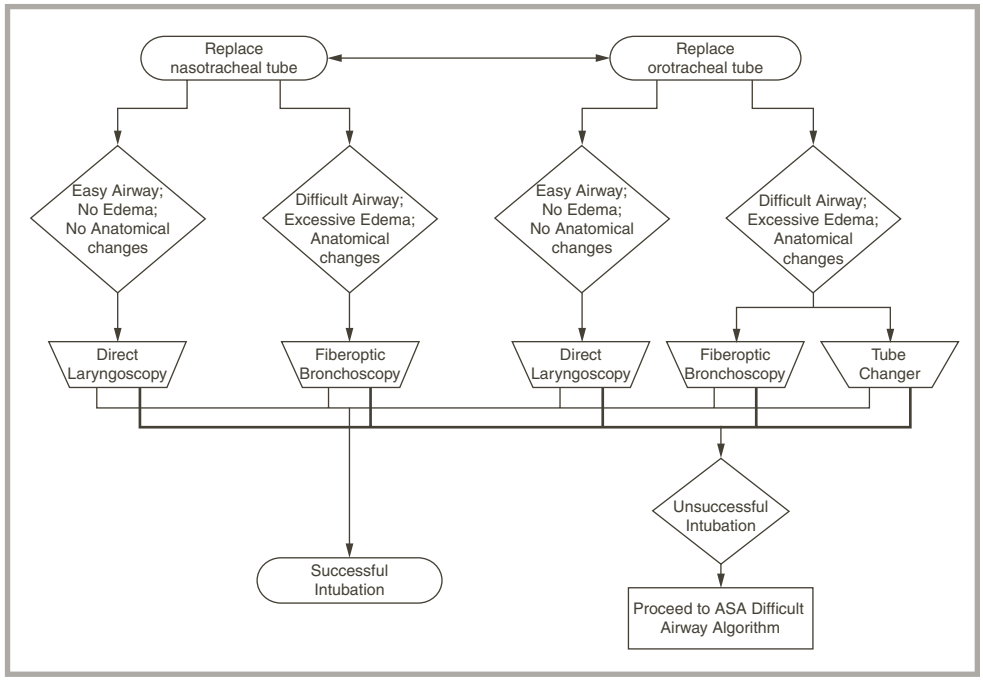


FIGURE 1-12

Algorithm specifically focused toward changing naso or oral tracheal tubes in the critically ill patients (from Wilson.[4] Reprinted with permission of the American Society of Anesthesiologists. A copy of the full text can be obtained from ASA, 520 N. Northwest Highway, Park Ridge, IL 60068-2573).

SUMMARY

Modern state-of-the-art critical care medicine would not exist without the ability to safely manage patients' airways and provide mechanical ventilatory support. There are multiple techniques available for establishing and maintaining an artificial airway; the choice of a specific technique and device is contingent on the patient's anatomy, disease processes, and the practitioner's experience.

The ASA algorithm on management of the difficult airway is a valuable resource, and physicians practicing in an ICU setting should be familiar with it and the ventilatory support devices it references.

After the establishment of an airway, it is incumbent on the intensivist to understand the benefits, limitations, potential risks, and complications associated with the different types of endotracheal and tracheotomy tubes.

REVIEW QUESTIONS

1. **Signs of hypoxia in a medical or surgical patient can include which of the following:**
   - **A.** Changes in the patient's mental status
   - **B.** Patient changing from the supine position to a sitting position
   - **C.** Tachycardia or bradycardia
   - **D.** Hypertension or hypotension
   - **E.** Cyanosis

2. **A medical patient whose arterial PCO_2 is 55 mmHg requires which of the following:**
   - **A.** Immediate endotracheal intubation
   - **B.** Assessment of their medical history
   - **C.** Repeat arterial blood gas measurements
   - **D.** Assessment of physical exam and vital signs
   - **E.** Supplemental oxygen

3. **Evaluation of the airway before an urgent intubation should include which of the following:**
   - **A.** Assessment of the maximal opening of mouth and visualization of structures in the oropharynx
   - **B.** Amount of edema or fat tissue in the neck region of the patient
   - **C.** Conditions such as hiatal hernia, pregnancy, obesity, or recent food ingestion that may contribute to aspiration of stomach contents
   - **D.** History of previous vascular surgery
   - **E.** Knowledge of patient's pulmonary artery pressures

4. **Equipment that is absolutely necessary for intubation of a patient in the critical care setting includes which of these:**
   - **A.** Ventilator
   - **B.** AMBU bag (airway mask breathing unit)
   - **C.** Nasal cannula or face mask oxygen source
   - **D.** Suctioning equipment
   - **E.** Bronchodilator agents

5. **Effects of laryngoscopy can include which of the following:**
   - **A.** Increase in HR
   - **B.** Decrease in HR
   - **C.** Asystole
   - **D.** Ventricular arrhythmias
   - **E.** Increase or decrease in BP

ANSWERS

1. The answer is A, B, C, D, E. Signs of hypoxia can masquerade as any of these changes. The initial signs of hypoxia (tachycardia and hypertension) may not be appreciated or attenuated by other medications such as beta-blockers or analgesia and sedative medications. Changing from the supine to sitting position is a compensatory behavior in an attempt to improve oxygen exchange.
2. The answer is B, D. Assessment of the patient's history focuses on COPD, the associated retention of CO_2, and concomitant metabolic alkalosis. Previous sedative or narcotic medications may result in an acute increase in PCO_2. Supplemental oxygen theoretically may inhibit respiratory drive.
3. The answer is A, B, C. Answers A and B are concerned with the anatomic structures that may change the level of difficulty associated with laryngoscopy and correct placement of an ETT. Conditions that increase the likelihood of regurgitation and aspiration should also be assessed.
4. The answer is B, D. An AMBU bag is necessary for maximal preoxygenation of the patient as well as permitting hand-ventilation of the patient before intubation. Hand-ventilation may be required by the patient's medical condition or medications used before intubation. Suction equipment is always necessary and should be immediately available next to the patient's head when manipulation of the airway is anticipated.
5. The answer is A, B, C, D, E. Induction of anesthesia, use of muscle relaxation, and endotracheal intubation can induce significant sympathetic stimulation. Intubation is also associated with vagal stimulation. Most sedative-hypnotic agents used for induction can cause vasodilatation.

CHAPTER 2

IRENE PERMUT AND WISSAM CHATILA

Oxygenation Without Intubation

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Identify different devices for supplying oxygen therapy.
- Describe the mode of function of different oxygen-supplying devices.
- Select specific devices to deliver oxygen in different patient populations.
- Adjust the oxygen delivery devices to ensure adequate oxygen supplementation.

Oxygen therapy, a lifeline for many critically ill patients, can be delivered in nonintubated patients via several devices. Unlike patients with chronic hypoxemia, the long-term comfort and cosmetics of the patient are not a concern of intensivists; instead, the goal is to ensure adequate oxygen delivery to prevent hypoxemia. Although hypoxemia is often corrected with oxygen therapy, care should be taken to understand the pathophysiology leading to hypoxemia. The appropriate management of hypoxemia should include treatment of the underlying pathology to prevent any complication and progression of the disease. For example, many patients with postoperative atelectasis develop hypoxemia responsive to oxygen therapy. Treatment of postoperative hypoxemia with oxygen supplementation alone, without initiating lung reexpansion measures to treat atelectasis, is insufficient.[1] This chapter covers noninvasive modes of supplying oxygen and does not discuss other means of correcting hypoxemia.

SUPPLYING SUPPLEMENTAL OXYGEN

The goal of oxygen supplementation is to ensure adequate oxygenation regardless of the mode of delivery.

There are three main components of oxygen supplementation: (1) the control component, which includes regulators (reducing valves that buffer high pressures from bulk oxygen systems to a lower pressure patient point of access) and flowmeters (which control and indicate flow) (Fig. 2-1), (2) the blending of air and oxygen, and (3) the administration of oxygen through devices that include cannulas and masks.[2] Respiratory care therapists are usually responsible to ensure proper functioning of the first two components, but physicians who order oxygen supplementation tend to specify the mode of oxygen delivery; therefore, physicians should familiarize themselves with indications of available devices for oxygen administration.

The oxygen delivery devices can be divided into two major groups: low-flow and high-flow oxygen systems.[3] Nasal cannulas, simple masks, and reservoir masks are examples of low-flow systems that are used when consistency of the fraction of inspired oxygen (FiO_2) delivery is not crucial. Low-flow systems provide supplemental oxygen at a rate that is less than the peak inspiratory flow rate. In contrast, high-flow oxygen systems deliver oxygen at a rate that is above the peak inspiratory flow rate. Therefore, they are capable of delivering up to 40 L/min of conditioned gas and providing a precise and consistent FiO_2 regardless of the patient's breathing pattern. Venturi masks and oxygen tents are examples of high-flow systems. Accordingly, when prescribing oxygen, the desired range of FiO_2 and the patient's ventilatory pattern need to be considered to ensure effective oxygen supplementation. Both low-flow and high-flow systems can deliver a wide range of FiO_2; the terms "low" and "high" do not reflect the delivered FiO_2 but describe the flow of gas delivered through the system. A detailed description of each device follows in the next section (Table 2-1).

Do not confuse low-flow devices with low concentration of oxygen supplementation.

DEVICES THAT PROVIDE SUPPLEMENTAL OXYGEN

Nasal Cannula

The nasal cannula, the most common oxygen delivery system, is used both for hospital inpatients and for outpatients (Fig. 2-2). It consists of two small prongs inserted about 1 cm into each nare through which flows 100% oxygen, with the oxygen flow adjusted by the flowmeter. Although nasal cannulas are well tolerated in the majority of patients, there is a great

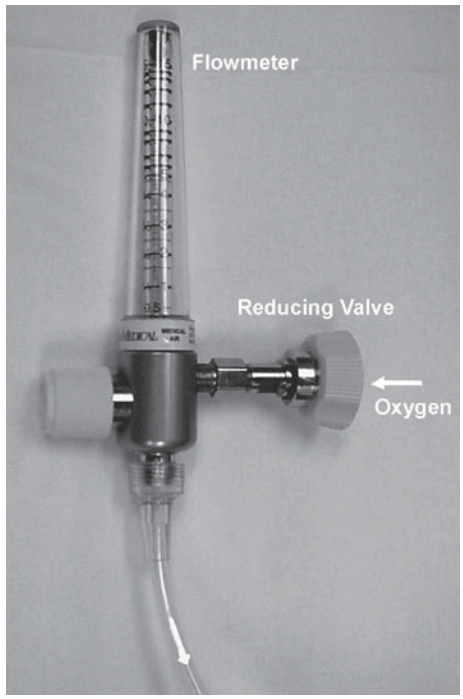

FIGURE 2-1

A flowmeter that regulates the flow of oxygen from a central source while simultaneously displaying the oxygen flow rate.

TABLE 2-1

OXYGEN CONCENTRATIONS FOR LOW- AND HIGH-FLOW DELIVERY SYSTEMS

DEVICE	OXYGEN FLOW RATE (L/MIN)	FIO_2
Nasal cannula	1	0.21–0.24
	2	0.23–0.28
	3	0.27–0.34
	4	0.31–0.38
	5–6	0.32–0.44
	6–8	Up to 0.50
Simple masks	5–6	0.30–0.45
	6–10	0.35–0.55
Venturi masks[a]	4	0.28
	6	0.28

[a]The final FiO_2 varies according to the oxygen flow and the total gas delivered, which is a function of the diluter jet and flow settings

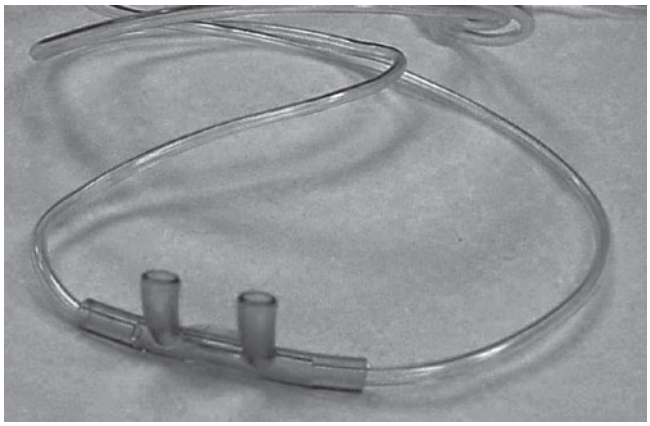

FIGURE 2-2

A nasal cannula used to deliver supplemental oxygen.

variability in the final FiO_2 because of admixture with entrained ambient air. The amount of oxygen delivered to the patient depends upon the amount of oxygen supplied as well as the minute ventilation of the patient. Thus, this system is valuable for patients who require up to 40% of uncontrolled oxygen, or those who do not tolerate facemasks. The use of a nasal cannula is not effective in patients who have significant nasal obstruction and are mouth breathers. Flows greater than 6 L/min are discouraged because of drying of the nasal mucosa, crusting of secretions, epistaxis, and septal perforation. However, recently nasal cannulas have been used also in several high-flow delivery systems that could provide adequately humidified oxygen at flow rates up to 40 L/min (see below).

Simple Mask

Similar to the nasal cannula, the simple mask does not allow precise control of delivered oxygen concentration because of dilution with ambient air that is drawn in and inspired from the exhalation ports (Fig. 2-3). However, the mask can deliver higher FiO_2 (to 55%) with higher flows (7–10 L/min) and produces a good seal around the patient's nose and mouth. Another advantage of the mask compared to the nasal cannula is improved humidification

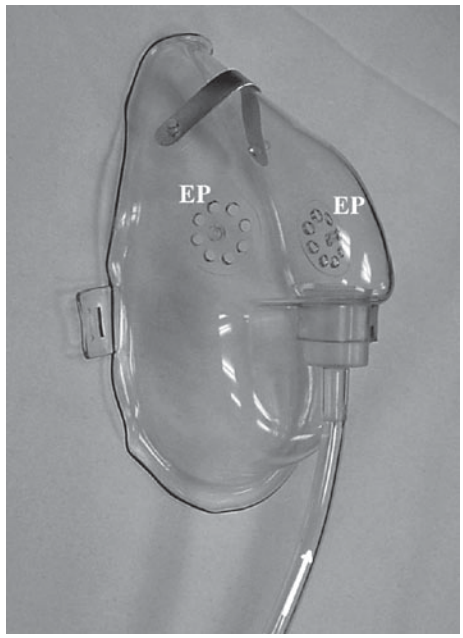

FIGURE 2-3

A simple facemask for oxygen delivery that has portholes for expiration (*EP*).

and fewer drying side effects. On the other hand, care should be taken not to order low flows (<5 L/min) when using the simple mask because of the potential for rebreathing exhaled carbon dioxide when the mask dead space is not continuously flushed by flowing oxygen.

Partial-Rebreathing Mask

Except for a reservoir bag, the partial-rebreathing mask is comparable to the simple mask (Fig. 2-4). The oxygen source directly feeds into the reservoir bag. As the patient exhales, the first third of the exhaled tidal volume returns into the reservoir and the rest dissipates through exhalation ports. The first third of the exhaled tidal volume comes mostly from the anatomic dead space, and therefore has high oxygen and low carbon dioxide concentration.

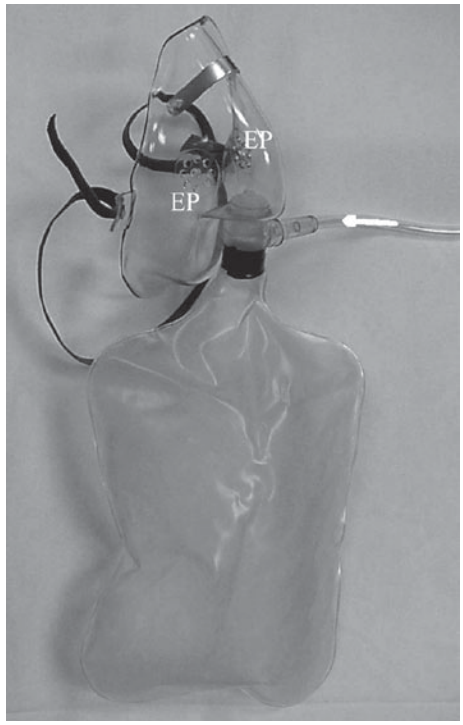

FIGURE 2-4

A partial-rebreathing facemask that delivers high levels of oxygen. The inflatable bag acts as an oxygen reservoir from which the patient can rebreathe high concentrations of supplemental oxygen. The patient expires through expiration ports (*EP*), as illustrated.

When the patient inhales, gas is drawn from the bag, which contains oxygen-rich exhaled gas and supplied oxygen, as well as from the exhalation ports. The partial-rebreathing mask has the potential to deliver up to 60% inspired oxygen concentration as long as a high oxygen flow rate is maintained and the reservoir bag does not collapse. Partial-rebreathing masks are variable performance devices, and therefore, the amount of oxygen delivered is partially dependent on the breathing pattern of the patient.

Nonrebreathing Mask

Two valves, added on the inhalation and exhalation ports, distinguish the nonrebreathing mask from the partial-rebreathing mask (Fig. 2-5). These two one-way valves allow the patient to inhale oxygen from the reservoir, but prevent the backflow of expired volume into the bag during exhalation and thereby avoid entraining ambient air through the exhalation ports during inspiration. The nonrebreathing mask can deliver close to 100% oxygen when adequate flow is maintained and the mask has a good seal on the patient's face. Manufacturers of nonrebreathing masks avoid placing valves on the two exhalation ports as a precautionary measure in the event of inspiratory valve malfunction, which would interrupt the flow of oxygen (note one exhalation port is covered in Fig. 2-5). To avert potential valve problems, some intensivists make up reservoir masks by adding large deadspaces to simple masks (Fig. 2-6). These reservoir masks, known as tusk masks, still require high flows of oxygen to flush all exhaled air from the mask dead space and minimize the entrainment of the ambient air during inspiration.

The nonrebreathing mask can deliver up to 100% FiO_2.

FIGURE 2-5

A nonrebreathing facemask. A one-way valve at the inhalation port (*IV*) prevents expired gases from refilling the oxygen reservoir bag. The presence of a one-way exhalation valve (*EV*) prevents room air from being inspired during inhalation.

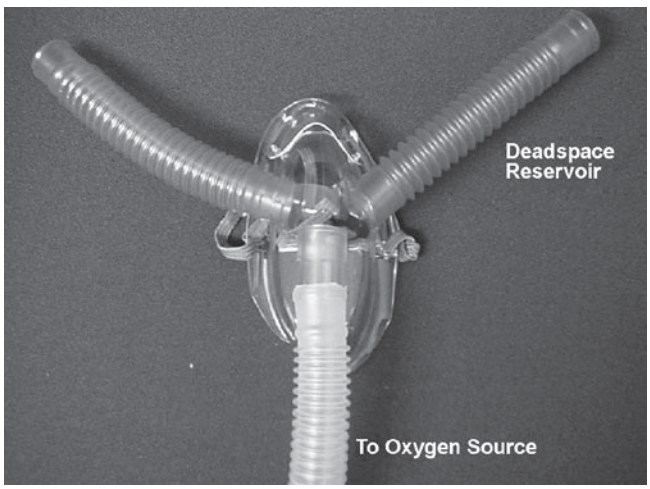

FIGURE 2-6

Modification of a facemask with 6-in. tubing substituted for EVs to prevent entrainment of room air during inspiration. The mask is also known as a "tusk mask."

Venturi Mask

In nonintubated patients, the venturi mask is the only mask that delivers controlled high-flow oxygen concentration.

The venturi mask is an example of a high-flow oxygen delivery system. Oxygen is forced through a short constriction (the venturi valve) which results in increased gas flow based on the Bernoulli principle; the high-velocity flows of oxygen going through the narrow orifice generate a subatmospheric pressure around the stream of oxygen, which in turn entrains a specific proportion of room air (Fig. 2-7). After the gas leaves the valve, there is an increased area causing the pressure to drop and the flow to increase and the air is entrained from either side of the valve. Changes in the patient's minute ventilation do not effect the concentration of delivered oxygen because the mask delivers a constant mixture of supplied oxygen and surrounding air at a flow rate higher than the patient's inspiratory flow. Therefore, the accuracy of delivered oxygen is within 2% of the set FiO_2. Patients with chronic respiratory insufficiency who are at a risk of developing worsening hypercapnia while on oxygen supplementation are good candidates for this mask.

Nasal High-Flow Oxygen Therapy

Traditional nasal cannulas are unable to safely and comfortably deliver oxygen at flow rates above 6 L/min. This is due to a lack of adequate humidification, which is necessary for ciliary function, to prevent thickening of secretions and to decrease heat loss. Another important

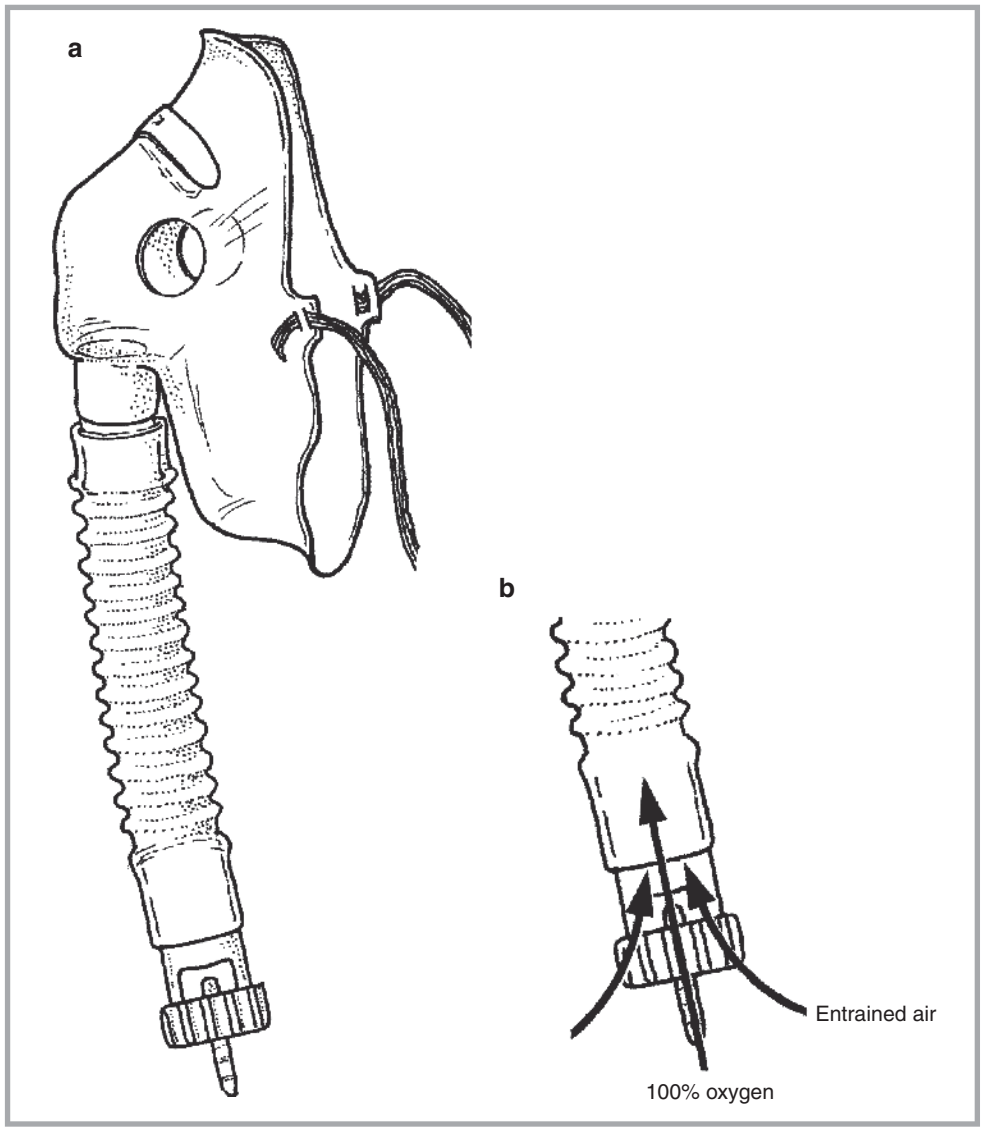

FIGURE 2-7

(**a**) A disposable venturi mask that allows more precise control of delivered oxygen. Gas passes through a small opening exit with a high velocity generating subatmospheric pressure that also entrains room air from the side ports. (**b**) Different diluter jets specify the amount of delivered oxygen and entrained room air mixtures that are used to vary the inspired oxygen concentration.

consideration for high-flow oxygen delivery systems is the energy required to heat the inspired gas from ambient to body temperature. The need for the delivered gas to be heated increases as the flow of delivered oxygen increases. There are now several high-flow nasal cannula oxygen delivery systems[4] that can provide adequately humidified oxygen at flow rates ranging between 15 and 40 L/min (Vapotherm® and AquinOX®). Because these systems operate at high flows, the oxygen delivery is constant regardless of the patient's minute ventilation. Concerns pertaining to patient exposure to *Ralstonia* species isolated from the heated humidification system of Vapotherm® led to its withdrawal from the market,[5] but it was recently reintroduced.

AMBU (Airway Mask Breathing Unit) Bag and Mask

Bag and mask ventilation is usually reserved for patients with decompensated respiratory failure, or after cardiopulmonary arrest, while preparing the equipment required for intubation. The majority of patients can be adequately supported with bag-mask ventilation as long as a tight seal between the patient's face and mask is maintained. A variety of masks are available, but a clear mask should always be used to observe for vomiting and potential aspiration.

Oxygen-Conserving Devices

Oxygen-conserving devices are used mostly in outpatients; these systems are not available in many hospitals and are not suited for the management of acute hypoxemia. There are two main mechanisms for oxygen conservation. One mechanism is based on collecting 100% oxygen during exhalation in a reservoir. The reservoir is either mechanical, such as the nasal reservoir cannula or a pendant reservoir cannula that then empties on inspiration (Fig. 2-8), or anatomic via a small catheter inserted into the trachea (Fig. 2-9). The transtracheal oxygen system uses the proximal trachea as an expanded anatomic reservoir; oxygen flowing into the trachea washes out the anatomic dead space, thereby also reducing the work of breathing. Transtracheal catheters may be effective at treating patients with severe hypoxemia that is refractory to treatment with oxygen via nasal cannula. In addition, they may be concealed with clothing, and may therefore improve compliance, comfort, and functional capacity in comparison to other oxygen-conserving devices. On the other hand, transtracheal catheters require higher maintenance to prevent infection at the site and obstruction of the catheter by dried secretions or life-threatening mucous balls.

The second mechanism for oxygen conservation is based on the pulsation of oxygen during the first quarter to one-half of each inspiration. During inspiration, the final portion of inspired air never reaches the alveoli and therefore does not participate in gas exchange.

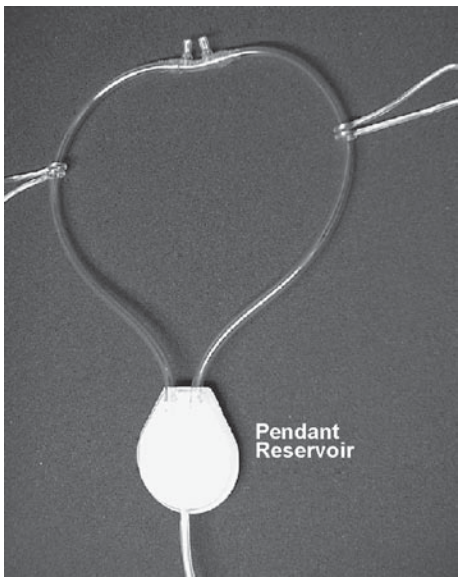

FIGURE 2-8

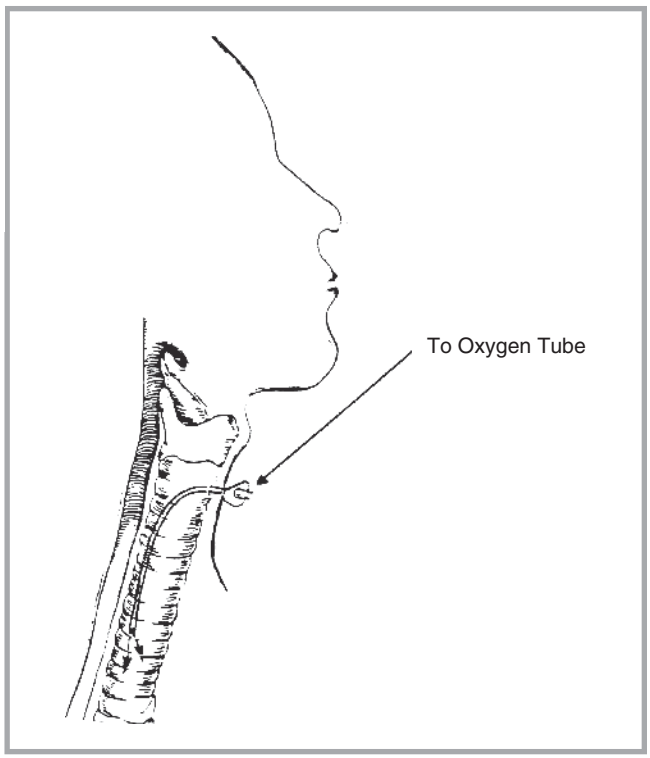
Nasal cannula capable of delivering high filled oxygen with the use of an oxygen reservoir. The pendant reservoir device serves as a repository of enriched oxygen from which the patient can breathe with each inhalation. The nasal cannula and tubing are larger than conventional nasal cannula to allow a higher flow of inspired gas.

FIGURE 2-9

Proper placement of a transtracheal catheter for oxygen administration. The transtracheal oxygen delivery system uses the proximal trachea as an anatomic reservoir.



Therefore, efficient oxygen delivery should occur during the initial portion of inhalation. With oxygen pulsation devices, as in the pendant reservoir cannula, nasal prongs are used to deliver the oxygen.

Heliox

Helium is 86% less dense (0.179 g/L) than room air (1.293 g/L). The lower density of helium improves the chances of obtaining laminar flow through the airways. Laminar flow through an airway occurs at low flow rates, whereas turbulent flow occurs at high flow rates. The likelihood of laminar gas flow through an airway is determined by the Reynolds number (Re), which represents the relationship between the airway radius and velocity, gas density, and gas viscosity.[6]

$$\mathrm{Re} = \frac{(\text{airway radius})(\text{velocity})(\text{density of gas})}{\text{gas viscosity}}$$

The lower density of helium lowers the Reynolds number and thus promotes laminar flow through the airways. Heliox decreases the work of breathing in patients with increased airways resistance and improves ventilation. Importantly, heliox does not treat the underlying disease, but can be used as a temporizing measure until other therapies take effect. Indications for heliox include upper airway obstruction, with some suggestions that it might be of benefit in status asthmaticus and chronic obstructive pulmonary disease (COPD) exacerbation.[7] Helium and oxygen mixtures typically come in ratios of 80:20, 70:30, and 60:40 (helium:oxygen). Therefore, this therapy will not be beneficial if an FiO_2 of greater than 40% is necessary.

CONTINUOUS POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) is not considered as a mode of noninvasive ventilation.

CPAP is often confused with noninvasive ventilation (bilevel positive airway pressure [BiPAP®] or pressure support ventilation). Although both modes of ventilatory support can be delivered via nasal or oronasal masks, they have different functions.[8]

CPAP works by generating a continuous airflow that maintains a continuous positive pressure to the respiratory system during inspiration and expiration. Unlike BiPAP®, CPAP does not provide increased pressure during inhalation and therefore does not provide true ventilatory support. However, CPAP may be helpful in improving oxygenation through three mechanisms. First, CPAP serves to prevent airway collapse. Second, by expanding end-expiratory lung volume, CPAP increases functional residual capacity, thus reducing the degree of intrapulmonary shunt caused by both atelectasis and fluid. In addition, through complex heart–lung interactions, the applied positive pressure may have favorable hemodynamic effects in patients with compromised cardiac function. CPAP improves left ventricular performance by reducing left ventricular preload and afterload. Obviously, CPAP can be applied in intubated patients in the form of positive end-expiratory pressure (PEEP), but when used in spontaneously breathing nonintubated patients it serves as a pneumatic splint of the airway, which makes it a very effective method to treat obstructive sleep apnea. In the hospital, the role of CPAP is limited to patients with known obstructive sleep apnea and selected patients with decompensated heart failure (hemodynamically stable and cooperative) to prevent intubation by improving oxygenation and decreasing the work of breathing. Despite the above mechanisms of action, oxygen is frequently bled into the apparatus, that is, added to its tubing, to treat hypoxemia.

Although CPAP has been shown to reduce the work of breathing in patients with chronic obstructive lung disease, many physicians elect to use noninvasive ventilation such as BiPAP® support. BiPAP® provides the added advantage of delivering inspiratory support as well as PEEP. While BiPAP® can provide ventilatory support to a spontaneously breathing patient, there is also the ability to set a back-up ventilatory rate to ensure continued respiratory effort. However, one should keep in mind that in both CPAP and BiPAP® the final oxygen concentration will be uncontrolled because of patient's breathing pattern, mask fit, and, most important, the machine setting. The efficacy of CPAP and BiPAP® in improving oxygenation is partially dependent on patient selection. Acute or chronic respiratory failure, acute pulmonary edema, and sleep-related breathing disorders are all clinical settings when it is appropriate to consider the use of CPAP or BiPAP® (Chap. 46). However, intubation and mechanical ventilation should be pursued if the patient has failed CPAP or BiPAP®, is hemodynamically unstable, or is at high risk of aspiration.

Recently, another mode of noninvasive ventilation has been introduced to treat patients with complex form of sleep disordered breathing. These devices (BiPAP®AVAPS™, and VPAP adapt SV®) adapt to changing breathing patterns of patients with mixed types of apneas and deliver variable pressure support. They perform breath-to-breath analysis, constantly adjusting the delivered bilevel pressures (IPAP and EPAP), in order to deliver a steady minute ventilation. These devices are mostly used in the outpatient setting and have not been evaluated in hospitalized patients requiring treatment for central or mixed sleep apnea syndromes.

MONITORING

Transcutaneous pulse oximetry is effective to monitor adequate oxygenation but can be inadequate in certain subgroups of patients.

Hospitalized patients requiring oxygen supplementation should be monitored with transcutaneous pulse oximetry to ensure adequate oxygen delivery and oxygenation. However, oxygen saturation is not the only parameter that needs to be closely observed in critically ill patients with impending respiratory failure.[9] Other clinical parameters (unstable vital signs, physical findings such as altered mental status that suggest organ dysfunction) that characterize severe illness dictate the frequency and the intensity of monitoring. A subgroup of patients with chronic hypoventilation, for example obesity hypoventilation and some patients with COPD, may experience worsening respiratory acidosis with supplemental oxygen. These patients are better monitored with arterial blood gases to better assess the level of carbon dioxide retention. It is also important to be aware of other limitations of the transcutaneous pulse oximetry measurements.[10] Patients suffering from various hemoglobinopathies and poisonings, such as carbon monoxide inhalation or cyanide toxicity, can have normal transcutaneous oxygen saturation values but still be severely hypoxemic.

SUMMARY

A wide variety of devices are available to deliver oxygen therapy for inpatients. Although the nasal cannula route is most widely used, critically ill patients often require other devices to meet their oxygen needs. Breathing pattern, underlying mechanism of hypoxemia, and tolerability should all be considered when choosing an oxygen delivery device, keeping in mind that the primary goal of management is adequate oxygenation.

REVIEW QUESTIONS

1. **Which of the following oxygen devices delivers precise FiO_2?**
   - **A.** Partial-rebreathing mask
   - **B.** Venturi mask
   - **C.** AMBU bag and mask
   - **D.** CPAP

2. **A patient with COPD on home oxygen, set at 2 L/min and delivered via a nasal cannula, was admitted to the intensive care unit for the monitoring of the upper gastrointestinal bleeding. The patient is comfortable with an oxygen saturation of 95% while on oxygen at 2 L/min via nasal cannula. While the patient is monitored with continuous pulse oximetry, it is recommended to do the following:**
   - **A.** Increase the FiO2 to 4 L/min using the nasal cannula
   - **B.** Change the nasal cannula to a venturi mask to deliver 30% FiO2
   - **C.** Continue the current oxygen setting
   - **D.** Continue oxygen at 2 L/min but change from nasal cannula to a partial-rebreathing mask

3. **A 70-year-old-man, with a past medical history of severe chronic obstructive lung disease on chronic oxygen therapy at 2 L/min via nasal cannula, presents to the emergency room in respiratory distress, diaphoretic, and agitated. He gives a history of progressive dyspnea associated with a worsening productive cough, fevers, and chills. On arrival to the emergency room, his vital signs were blood pressure 150/90 mmHg, pulse rate 130 beats/min, temperature 38.5°C, and respiratory rate 33 breaths/min; his oxygen saturation measured by transcutaneous pulse oximetry was 80%. He was placed on oxygen supplementation at a FiO_2 of 30% delivered with a simple facemask, and he was treated with repeated doses of nebulized bronchodilators. While waiting for the rest of his workup, the patient's transcutaneous pulse oximetry was reading 90% but his breathing was becoming more labored and he was difficult to arouse. What is the most appropriate step in the management of this patient?**
   - **A.** Discontinue the simple mask and place him back on nasal cannula at 3 L/min of oxygen flow
   - **B.** Keep the simple mask and increase the FiO_2 to 50%
   - **C.** Change the simple mask to a nonrebreathing mask to try to deliver a FiO_2 of 100%
   - **D.** Start AMBU bag-mask ventilation and prepare to intubate the patient

ANSWERS

1. The answer is B. The most precise delivery devices are the high-flow air-entrainment devices such as the Venturi mask. The rest are dependent on mask seal and patient ventilatory pattern.
2. The answer is C. Because the patient is hemodynamically stable and there is no evidence of hypoxemia, there is no need to change the oxygen delivery system or FiO_2.
3. The answer is D. The patient is in acute respiratory failure showing deterioration of his clinical status despite aggressive conventional therapy; therefore, he needs to be intubated for ventilatory assistance and protection of his airway. Remember that the primary goal to therapy is to ensure adequate oxygenation. Although the change in his mental status may be related to CO_2 retention, if FiO_2 is lowered he will become more hypoxemic.

CHAPTER 3

JOSEPH CROCETTI, MONTSERRAT DIAZ-ABAD, AND SAMUEL L. KRACHMAN

Blood Gas Sampling

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Know the indications for obtaining an arterial blood gas.
- Understand the techniques used to measure an arterial blood gas.
- Have an understanding of the acid–base status and buffering system of the body.
- Identify sources of error in arterial blood gas measurements.
- Know how to identify the presence of a simple and mixed acid–base disorder.
- Know the causes of a simple acid–base disorder.
- Understand the measurements of arterial oxygenation.
- Know the components that can affect mixed venous oxygenation.

Critically ill patients require intensive monitoring to rapidly detect acute life-threatening changes, to institute therapies, and to determine the response to therapeutic interventions. Blood gas sampling is an important source of insight into a patient's metabolic status, oxygenation, and overall ventilatory function (Table 3-1). This chapter reviews both arterial and mixed venous blood gas analysis; clinical decision making based on this data often leads to changes in patient care, which may have a significant effect on survival.

INDICATIONS FOR ARTERIAL BLOOD GAS ANALYSIS

Acid–base status is determined by measuring arterial pH and $PaCO_2$.

Arterial blood gas sampling provides the assessment of two important measures in the care of a critically ill patient: the systemic acid–base status and the total body oxygenation.[1] The systemic acid–base status is determined by measuring the arterial pH and partial pressure of

TABLE 3-1

INDICATIONS FOR BLOOD GAS SAMPLING

Arterial blood gas
Assess acid–base status
Assess systemic arterial oxygenation

Mixed venous blood gas
Identify alteration in oxygen delivery or consumption
Determine response to therapeutic intervention
Determination of systemic acid–base status
Determination of systemic arterial oxygenation
Assess response to therapeutic intervention

carbon dioxide ($PaCO_2$) and calculating the serum bicarbonate [HCO_3^-], using specific electrodes in a blood gas analyzer.[2,3] Arterial partial pressure of oxygen (PaO_2) is also determined using a blood gas analyzer, whereas the arterial oxygen saturation (SaO_2) is measured with a co-oximeter. Although this chapter discusses acid–base status and arterial oxygenation separately, the reader must be aware that these two entities are closely associated under physiologic conditions. For example, decreases in oxygenation can lead to tissue hypoxia, which will affect overall acid–base status. Conversely, acid–base disorders can shift the oxyhemoglobin dissociation curve and thus affect regional and/or systemic oxygenation.

Arterial PaO_2 is determined using a blood gas analyzer.

ACID–BASE STATUS

Measurement of Acid–Base Status

The $HCO_3^- – CO_2$ system is the principal buffer utilized by the body to maintain the arterial pH within the normal physiologic range.[4] The arterial blood pH and $PaCO_2$ are directly measured from the arterial blood gas using a blood gas analyzer. [HCO_3^-] is not directly measured, but is calculated from the blood gas analyzer utilizing the relationship between pH, $PaCO_2$, and [HCO_3^-], as expressed in the Henderson–Hasselbalch equation:

The $HCO_3^- – CO_2$ system is the principal buffer utilized by the body.

$$pH = 6.1 + \log(HCO^3/(0.03 \times PaCO_2)) \quad (3\text{-}1)$$

Another approach in evaluating the acid–base status of the patient utilizes the measured serum [HCO_3^-] rather than the calculated [HCO_3^-]. The total serum CO_2 can be measured from a venous blood sample. Because serum [HCO_3^-] constitutes approximately 95% of the total CO_2, the two measures are often used interchangeably. However, the measured total CO_2 is 1–3 mmol/L higher than the [HCO_3^-] value calculated from an arterial sample. Therefore, to minimize errors, assessment of acid–base disorders is made with the calculated [HCO_3^-] value obtained from an arterial blood sample.

The acidity of body fluids is measured in terms of the hydrogen ion concentration [H^+]. The important relationship between the [H^+] and the $HCO_3^- CO_2$ buffer system can also be expressed in a modified form of the Henderson–Hasselbalch equation as:

$$[H+] = 24 \times paCO_2 / HCO_3^- \quad (3\text{-}2)$$

The serum [H^+] is about three million times less than the serum sodium concentration, yet because of its small size, it is highly reactive and thus tight regulation is appropriate. The pH is defined as the negative log of [H^+]:

$$pH = -\log[H^+] \quad (3\text{-}3)$$

and is normally maintained between 7.35 and 7.45. pH and [H^+] are inversely related, and thus estimation of [H^+] can be made from pH. Between pH 7.2 and 7.5, for each 0.1 U change in pH, there is a 10 mmol/L change in [H^+] in the opposite direction. This correlation is lost at a pH above 7.5 or below 7.2.

pH is normally maintained between 7.35 and 7.45.

Acid production in the body occurs in two major ways. The first pathway involves CO_2, which is produced during oxidative metabolism and then hydrated by the cytoplasmic enzyme carbonic anhydrase to produce carbonic acid (H_2CO_3). This volatile acid is disposed of by the elimination of CO_2 via the lungs. The second pathway involves nonvolatile metabolic acids that are produced by aerobic and anaerobic metabolism and includes sulfuric, phosphoric, and lactic acids. Because these nonvolatile acids are not in equilibrium, they must be metabolized and excreted by the kidneys if a physiologic acid–base status is to be maintained.

Buffer Systems

Changes in acidity can be stabilized by the body's buffers.

Both the lungs and kidneys play a major role in regulating acid–base status.

Derangement in the body's pH can have severe effects on cellular and physiologic function and thus tight regulation of acid–base status is imperative. Changes in acidity can be stabilized but not totally corrected by the body's buffers, which are molecules that accept or donate hydrogen ions. As already mentioned, the major buffer in the body is HCO_3^-; less important roles are played by phosphates, protein, and hemoglobin. Both the lungs and kidneys play a crucial role in the regulation of the body's acid–base status, and there is tightly linked interdependency between the respiratory and metabolic systems.

There are, however, two standard metabolic measurements that are independent of the respiratory system, the standard HCO_3^- and the base excess. The standard HCO_3^- is the plasma HCO_3^- concentration present in a blood sample that is fully saturated with oxygen and equilibrated in vitro at 38°C with a $PaCO_2$ equal to 40 mmHg. The normal standard HCO_3^- is 24 nM/L. Standardization of the blood oxygen content is important because the level of oxygenation will alter hemoglobin buffering capacity. When hemoglobin releases oxygen, it becomes less acidic and accepts more protons, thus increasing its buffering capacity; the opposite occurs after oxygen is taken up by hemoglobin.

The base excess is the amount of acid or alkali that must be added to a liter of fully oxygenated blood exposed in vitro to a $PaCO_2$ of 40 mmHg at 38°C to obtain a normal pH. When alkali is needed to achieve a normal pH, the sample being evaluated is said to have a base deficit. When acid is needed to achieve a normal pH, a base excess is present. Although these parameters are independently calculated, neither the standard HCO_3^- nor the base excess has been shown to offer any advantage over plasma bicarbonate level in the determination of a metabolic acid–base disturbance.

Sources of Error

Body temperature can affect arterial blood gas.

Although the blood gas analyzer is considered the gold-standard for the evaluation of acid–base status and oxygenation, errors can occur (Table 3-2). A patient's body temperature can affect arterial blood gas analysis, yet arterial blood gas samples are routinely analyzed with the electrodes heated to a constant temperature of 37°C. Temperature correction refers to the adjustment of the values measured at 37°C to that of the patient's actual temperature. For instance, if a patient's temperature is below 37°C, the temperature-corrected $PaCO_2$ and PaO_2 are lower because the solubility of CO_2 and O_2 is decreased at lower temperatures. The temperature-corrected pH is higher than the 37°C value because water is less dissociated into $[H^+]$ and $[OH^-]$ at lower temperatures. The clinical significance of changes caused by temperature is uncertain, however, and it is recommended that clinical decisions be based on measurements obtained at 37°C.[5]

An air bubble in the arterial blood gas can affect PaO_2 and $PaCO_2$.

Air bubbles in the arterial blood gas sample will affect the PaO_2 and $PaCO_2$. CO_2 diffuses from the blood into the bubbles, which decreases the $PaCO_2$ and increases the pH. The effect of air bubbles on PaO_2 measurement in the blood depends on the concentration gradient between blood PaO_2 and the oxygen tension of room air (PaO_2 of 159 mmHg at sea level). If

TABLE 3-2

SOURCES OF ERROR IN ARTERIAL BLOOD GAS MEASUREMENTS

Changes in body temperature	Time left in syringe
Air bubbles	Elevated WBC count
Heparin	Elevated platelet count

the blood concentration is higher than that of the ambient atmosphere (and therefore of the air bubble), the PaO_2 measured in the blood will be falsely lowered; the opposite will occur if the gradient is reversed.

Heparinization of the blood sample limits the deposition of protein on the electrodes. However, excess heparin can affect blood gas analysis by lowering the $PaCO_2$ and calculated HCO_3^- due to a dilutional effect.[6] Although heparin is an acid, the pH is usually not affected because of the buffering effects of the blood. The PaO_2 can also be falsely elevated.[6]

The time during which the arterial blood gas sample remains in the syringe will also affect the results. Ongoing metabolism by white blood cells and platelets will decrease the PaO_2 and increase $PaCO_2$, resulting in a decrease in pH. Thus, it is important to place the arterial blood gas sample on ice to slow metabolism. At room temperature, the rate of change caused by metabolism is about 0.1 mmHg/min for $PaCO_2$ and 0.001 U/min for pH. The PaO_2 will fall more rapidly in an arterial sample when the blood is fully saturated, as opposed to a venous sample. Because the rate of change for these parameters is proportional to the leukocyte and platelet count, marked changes can be seen in patients with substantive leukocytosis, leukemia, or thrombocytosis. For instance, a condition characterized as "leukocyte larceny" has been reported in which the high WBC seen in acute leukemia severely decreases the measured arterial blood gas PaO_2, while the oxygen saturation observed on the pulse oximeter is normal.

"Leukocyte larceny" can affect the measured PaO_2 in patients with leukemia.

SIMPLE ACID–BASE DISORDERS

The term acidemia refers to an increase in $[H^+]$ and a decrease in the pH of the arterial blood, whereas acidosis refers to a process that causes acid to accumulate in the body. The term alkalemia refers to a decrease in the $[H^+]$ and increase in the pH of the arterial blood, whereas alkalosis refers to a process in which alkali accumulates in the body.

Metabolic Acidosis

A metabolic acidosis occurs when there is either an increase in acid accumulation or a decrease in extracellular bicarbonate, with a resulting decrease in both serum pH and $[HCO_3^-]$.[7,8] As a compensatory response, there is an increase in alveolar ventilation leading to a decrease in $PaCO_2$. Maximal respiratory compensation results in a $PaCO_2$ of 10 mmHg. The expected compensatory $PaCO_2$ can be calculated using the Winter's equation:

A compensatory response to a simple metabolic acidosis is a decrease in $PaCO_2$.

$$PaCO_2 = 1.5[HCO_3^-] + 8 \pm 2. \quad (3\text{-}4)$$

Thus, with a simple metabolic acidosis, the patient's minute ventilation will increase and $PaCO_2$ will decrease to a value calculated from the Winter's formula (Table 3-3). If the calculated and observed $PaCO_2$ are different, then a mixed acid–base disorder is present (see following).

TABLE 3-3

ACID–BASE CALCULATIONS: SECONDARY COMPENSATION

Metabolic acidosis	$PaCO_2 = 1.5 \times [HCO_3^-] + (8 \pm 2)$
Metabolic alkalosis	$PaCO_2 = 0.7 \times \Delta[HCO_3^-]$
Respiratory acidosis	
Acute	Decrease in $pH = 0.008 \times \Delta PaCO_2$
	Increase in $HCO_3^- = 0.1 \times \Delta PaCO_2$
Chronic	Decrease in $pH = 0.003 \times \Delta PaCO_2$
	Increase in $HCO_3^- = 0.3 \times \Delta PaCO_2$
Respiratory alkalosis	
Acute	Increase in $pH = 0.008 \times \Delta PaCO_2$
	Decrease in $HCO_3^- = 0.2 \times \Delta PaCO_2$
Chronic	Increase in $pH = 0.003 \times \Delta PaCO_2$
	Decrease in $HCO_3^- = 0.4 \times \Delta PaCO_2$

Metabolic acidosis can be categorized on the basis of whether there is an anion gap:

$$\text{Anion gap} = [\text{Na}] - (\text{Cl} + \text{HCO}_3^-) = 12 \pm 4 \text{ mEq/L} \quad (3\text{-}5)$$

The anion gap is based on the principle of electroneutrality, in which the total serum cations equal the total serum anions. Because the normal reference range for the anion gap is 12 ± 4 mEq/L, it more accurately reflects the amount of unmeasured anions in the plasma, the majority of which are plasma proteins. Common anions and cations are listed in Table 3-4.

Albumin is the major anion in the blood.

Despite the wide use of the anion gap, it has limitations that must be appreciated before it can be applied clinically. Albumin is the major anion in the blood, and thus changes in the serum albumin will have a major effect on the anion gap. For every 1 g/dL decrease in albumin, there is a 2–3-mEq/L decrease in the anion gap. Thus, in patients who are severely hypoalbuminemic, the normal anion gap may be as low as 4–5 mEq/L. Other common causes of a decreased anion gap are paraproteinemias, hyponatremia, lithium toxicity, profound hyperkalemia, hypercalcemia, hypermagnesemia, or halide poisoning (Table 3-5). Recognition of factors that reduce the anion gap is important because patients with a "normal anion gap" may actually have a low anion gap with a concomitant severe metabolic acidosis. Finally, the blood pH can alter the anion gap by affecting the anionic charge of serum proteins and by altering the quantity of organic acids; this can lead to a 1–3-mEq/L decrease in the anion gap in acidemic states and a 3–5-mEq/L increase in alkalemic states.

With an anion-gap acidosis, there is 1 mEq/L decrease in HCO_3^- for every 1 mEq/L increase in the anion gap.

In a pure anion gap metabolic acidosis, for every 1 mEq/L increase in the anion gap, there is a reciprocal decrease of 1 mEq/L in the serum HCO_3^-. For instance, if a patient has a calculated anion gap of 20 mEq/L, this is 8 mg/L above the normal value of 12 mEq/L. This difference (calculated anion gap – normal anion gap) is referred to as the "delta gap." A reciprocal decrease in the serum [HCO_3^-] should occur (24–8), resulting in a [HCO_3^-] of 16. If the actual HCO_3^- differed from 16 mEq/L, it would suggest the presence of a mixed acid–base disorder. Another way to do this is to simply add the delta gap to the measured HCO_3^-. If the sum is less than 24 mEq/L, it suggests the presence of an associated nongap metabolic acidosis. If the sum is greater than 24 mEq/L, it suggests a coexisting metabolic alkalosis. This approach is very useful in excluding the presence of a mixed acid–base disorder. The causes of an anion gap acidosis are listed in Table 3-6. Treatment should be directed at the underlying cause. In patients with poisoning due to methanol and ethylene glycol, a useful tool is the osmolar gap[9]:

$$\text{Osmolar gap} = \text{Measured osmolality} - (1.86 \times [\text{Na}^+]) + \text{glucose}/18 + \text{BUN}/2.8 + \text{ethanol}/4.6 \quad (3\text{-}6)$$

where glucose, blood urea nitrogen (BUN), and ethanol are given in mg/dL. With a normal osmolar gap being <10 mOsm/L, methanol and ethylene glycol poisoning are associated with both an elevated anion and osmolar gap. Treatment has been directed at the inhibition

      - Dilutional acidosis

of alcohol dehydrogenase to prevent the formation of the toxic metabolites that are responsible for the morbidity associated with ingestion. Traditionally, ethanol infusions have been used to compete with toxins for the enzyme. However, more recently, fomepizole (4-methylpyrozole) has been shown to be highly effective at inhibiting alcohol dehydrogenase without the side effects that can occur with ethanol infusion.[10,11]

Nonanion-gap acidosis can be categorized into those disorders with a normal or elevated serum potassium level and those with hypokalemia (Table 3-6). A nongap acidosis can result from (1) the loss of [HCO_3^-] from the body, (2) the inability to replace the [HCO_3^-] used during the day to neutralize acids produced by the body, (3) the administration of an acid, or (4) the administration of fluid that does not contain [HCO_3^-], also known as a dilutional acidosis. The urine anion gap can often be useful in differentiating the cause of a nongapped acidosis. Defined as:

The urine anion gap can help define the cause of a nongap acidosis.

$$[Na^+] + [K^+] - [Cl] = \text{urine anion gap} \quad (3\text{-}7)$$

the urinary gap is normally negative as a result of the excretion of ammonium into the urine. If the urine anion gap is positive, it reflects an impairment in ammonium excretion, as is seen in patients with renal tubular acidosis (RTA).[12,13] The urinary pH can then be helpful in differentiating the type of RTA that is responsible for the nongap acidosis. If the pH is high (>6.0), a distal RTA is present. If the urinary pH is low, and remains low even with HCO_3^- infusion, a proximal RTA is suggested. In patients with a hyperkalemic distal RTA, as seen with aldosterone deficiency, the urinary pH can be variable.

The clinical manifestations associated with a metabolic acidosis depend on the underlying cause. Patients usually develop rapid, deep respirations to compensate for the metabolic acidosis (Kussmaul's respiration).

Metabolic Alkalosis

Metabolic alkalosis results from an increase in serum HCO_3^- or loss of acid from the body.

A metabolic alkalosis can develop when there is either an increase in serum [HCO_3^-] or a loss of acid from the body with a relative increase in the serum [HCO_3^-].[14,15] A metabolic alkalosis leads to an increase in serum pH, associated with an increase in serum [HCO_3^-]. Compensation for metabolic alkalosis includes a decrease in alveolar ventilation, resulting in an increase in the $PaCO_2$. The appropriate compensatory increase in $PaCO_2$ can be calculated by the equation:

$$PaCO_2 \cong 0.7\ \Delta[HCO_3^-]. \tag{3-8}$$

The maximal compensatory response in measured $PaCO_2$ is 65 mmHg (see Table 3-3). A metabolic alkalosis can be categorized as either being chloride-responsive or chloride-unresponsive, and thus measurement of urine chloride can differentiate between the two conditions (Table 3-7).[16,17] In a chloride-responsive metabolic alkalosis, the loss of urinary chloride has played a significant role in producing the alkalosis, and the urine chloride will be low (<10 mmol/L). Metabolic alkalosis is corrected with the administration of chloride as NaCl. In chloride-unresponsive metabolic alkalosis, the urine chloride will be greater than 10 mmol/L and will not respond to NaCl administration. Some of the clinical manifestations of metabolic alkalosis include decreased cerebral blood flow, seizures, and altered mental status. Metabolically, it will result in a decrease in ionized calcium and cause hypokalemia.

Metabolic alkalosis can result in seizures or an altered mental status.

Treatment is aimed at the underlying cause, and chloride-responsive alkalosis usually responds to repletion with normal saline, which contains 154 mEq/L of chloride. The chloride-unresponsive disorders are usually associated with either primary or secondary mineralcorticoid excess, hypokalemia, or certain inherited disorders. Treatment is directed at the underlying cause.

    - Severe potassium depletion
    - Bartter's syndrome

Respiratory Acidosis

Under normal conditions, alveolar ventilation removes the metabolically produced CO_2 and maintains a normal $PaCO_2$ of 40 mmHg. If this balance is not maintained, because of either an ineffective alveolar ventilation or an increase in CO_2 production, $PaCO_2$ will increase, resulting in a respiratory acidosis.[18,19] The normal response to an increase in $PaCO_2$ is to increase alveolar ventilation, mediated by changes in the $[H^+]$ of the cerebrospinal fluid, which affects medullary chemoreceptors. A respiratory acidosis causes a decrease in pH and an increase in $PaCO_2$. Common causes are listed in Table 3-8.

Respiratory acidosis causes increased $PaCO_2$ and decreased pH.

Compensation for a primary respiratory acidosis is metabolic. The acute phase for compensation occurs almost immediately when $PaCO_2$ increases. Nonbicarbonate tissue buffers such as hemoglobin bind with $[H^+]$, resulting in a rapid generation of $[HCO_3^-]$. This initial increase in $[HCO_3^-]$ is modest, with 0.1 mEq/L increase in HCO_3^- for every 1 mmHg increase in $PaCO_2$ (see Table 3-3). The maximal increase in HCO_3^- during acute compensation is 31–32 mEq/L. In addition, with a respiratory acidosis, the pH also decreases by 0.008 U for every 1 mmHg increase in $PaCO_2$ (Table 3-3). With chronic compensation, the kidneys play a major role. Proximal reabsorption of filtered HCO_3^-, and excretion of $[H^+]$ in the form of ammonia, result in a 0.3 mEq/L increase in HCO_3^- for each 1 mmHg increase in $PaCO_2$, with a maximal increase in serum HCO_3^- of 45 mEq/L (Table 3-3). pH also decreases by 0.003 U for each 1 mmHg increase in $PaCO_2$ (Table 3-3).

The clinical manifestations of a respiratory acidosis depend on the acuity of the event leading to the acidosis and the degree of hypoxemia that is present. In patients with acute hypercapnia, there can be profound changes in mental status and hemodynamics. In patients with chronic hypercapnia, such as with severe chronic obstructive pulmonary disease (COPD), however, the $PaCO_2$ may rise into the 50–60 mmHg range without central nervous system (CNS) or cardiac changes. In response to an increase in $PaCO_2$, cerebral blood flow increases secondary to cerebral vasodilatation, leading to a concomitant increase in intracranial pressure. The hemodynamic changes associated with hypercapnia are tachycardia, hypertension, supraventricular arrhythmias, and peripheral vasodilation.

An increase in $PaCO_2$ results in cerebral vasodilatation.

Treatment is directed at the underlying cause (see Table 3-8). Because most causes of respiratory acidosis are associated with ineffective ventilation, treatment often consists of supportive care such as intubation and mechanical ventilation. In some cases, noninvasive ventilation can be used in a hemodynamically stable patient who is alert enough to protect their airway. Both these forms of ventilatory support increase alveolar ventilation, resulting in a decrease in $PaCO_2$ and an increase in pH. Posthypercapnic alkalosis is associated with rapid correction of a respiratory acidosis, in which the elevated $PaCO_2$ is lowered to normal but the compensatory increase in HCO_3^-, which takes longer to resolve, remains.

Respiratory Alkalosis

A respiratory alkalosis develops because of an increase in alveolar ventilation, resulting in a decreased CO_2 tension in the body.[20] Alveolar ventilation is controlled by several factors,

Respiratory alkalosis is the result of hyperventilation.

including (1) chemoreceptors in the medulla that are sensitive to changes in $[H^+]$, (2) carotid body receptors that are sensitive to changes in PaO_2, (3) voluntary cortical input to the respiratory control center, and (4) mechanicoreceptors in the lung and chest wall. Activation by any of these receptors can result in hyperventilation and a respiratory alkalosis. Table 3-9 lists the common causes of a respiratory alkalosis. The metabolic compensation for a respiratory alkalosis consists of both an acute component, utilizing nonbicarbonate buffers, and a more chronic compensation, through the renal loss of $[HCO_3^-]$. Serum $[HCO_3^-]$ will decrease 0.2 and 0.4 mEq/L for every 1 mmHg decrease in $PaCO_2$ during the acute and chronic compensatory phases, respectively (see Table 3-3). The change in pH can be calculated based on the change in $PaCO_2$, with an increase in pH of 0.008 and 0.003 during acute and chronic compensation, respectively, for every 1 mmHg decrease in $PaCO_2$ (see Table 3-3). With a chronic respiratory alkalosis (more than 2 weeks in duration), compensation may eventually result in a normalized pH.

Compensation for chronic respiratory alkalosis can result in normalized pH.

Clinical manifestations with a respiratory alkalosis include CNS symptoms such as confusion, seizures, parasthesias, and circumoral numbness. Muscular cramping and spasms may also be seen. Metabolically, hypokalemia and hypophosphatemia may result, as will a decrease in ionized calcium. Alkalosis also shifts the oxyhemoglobin dissociation curve to the left, which decreases the release of oxygen at the tissue level.

MIXED ACID–BASE DISORDERS

It is important when determining the acid–base status of a patient that there are not two primary processes present at the same time; this is referred to as a mixed acid–base disorder.[21,22] It should be made clear that the normal compensatory response to a primary acid–base disorder should not be considered as a secondary process. To determine the presence of a secondary process, the physician should make certain that the patient has the appropriate compensatory response to account for the observed laboratory values. As already discussed, a patient with an anion-gap metabolic acidosis should have a delta-gap that, when added to the serum $[HCO_3^-]$, results in a normal $[HCO_3^-]$. A significantly lower $[HCO_3^-]$ would suggest the coexistence of a nongap metabolic acidosis. In a patient with a chronic respiratory acidosis, a serum $[HCO_3^-]$ that is significantly higher than expected based on the aforementioned compensatory equation or that is greater than 45 mEq/L suggests the coexistence of metabolic alkalosis. Thus, it is important to assure that the compensatory response is appropriate and does not suggest the existence of a mixed acid–base disorder.

An inappropriate compensatory response suggests the existence of a mixed acid–base disorder.

ARTERIAL OXYGENATION

In addition to determining the systemic acid–base status, the arterial blood gas provides an accurate measurement of arterial oxygenation.[1] The arterial partial pressure of oxygen (PaO_2) is a measurement of the quantity of oxygen that is dissolved in the blood. Both the driving pressure and solubility of oxygen in the plasma determine the PaO_2.[23] The driving pressure is dependent on the partial pressure of oxygen in the alveolus (P_AO_2). If the alveolus is considered a fixed space, and the nitrogen present is disregarded, the only two gases that are present are oxygen and carbon dioxide. The P_AO_2 is then equal to the amount of O_2 inspired into the alveolus minus the amount of CO_2 of the alveolar space. The fraction of inspired oxygen (F_iO_2) must be multiplied by the barometric pressure at which the measurement is taken (760 mmHg at sea level). In addition, inspired air is warmed and becomes humidified in the upper airway; therefore, the partial pressure of water in the trachea (47 mmHg) must be subtracted from the barometric pressure. Thus, the P_AO_2 is determined by the following equation:

The driving pressure and solubility of oxygen in the plasma determine the PaO_2.

$$P_AO_2 = F_iO_2(\text{barometric pressure} - \text{partial pressure in the trachea}) - PaCO_2/R. \quad (3\text{-}9)$$

The P_AO_2 at sea level while breathing room air ($F_iO_2 = 0.21$) can be calculated as:

$$P_AO_2 = 0.21(760 - 47) - 40/0.8 \quad (3\text{-}10)$$

where the $PaCO_2$ is assumed to be equal to the tension of $PaCO_2$ in the alveolus, and 0.8 is the respiratory quotient, which assumes an "ideal" relationship between ventilation and perfusion.

The PaO_2 is normally less than the P_AO_2, resulting from the presence of physiologic shunting of blood from the bronchial veins emptying into the pulmonary veins and from the thesbian veins that originate in the coronary sinus and empty into the left atrium.[23] Thus, blood passes from the venous circulation into the arterial circulation without being exposed to oxygen in the pulmonary capillaries. This difference ($P_AO_2 - PaO_2$) is referred to as the alveolar–arterial oxygen tension gradient, or A-a gradient. In young adults, this is normally 8–12, with values increasing with age into the twenties. A correction factor (age/3 + 3) can be used to calculate the age-adjusted A-a gradient. This gradient is often elevated in disease states that cause hypoxemia (ventilation–perfusion inequality, shunting, and diffusion impairment), except in cases that are secondary to hypoventilation, where the A-a gradient is normal.

In disease states that cause hypoxemia, the A-a gradient is elevated except when hypoxemia is caused by hypoventilation.

When interpreting the arterial blood gas, it must be remembered that the amount of oxygen dissolved in the blood, the PaO_2, makes up only a small component of the arterial oxygen content. The oxygen content of arterial blood (CaO_2) consists of two components, the oxygen bound to hemoglobin and the oxygen dissolved in blood. The CaO_2 is provided by this equation:

$$CaO_2 = (1.3 \times Hb \times SaO_2) + (0.003 \times PaO_2) \quad (3\text{-}11)$$

where Hb is hemoglobin and SaO_2 is the arterial oxygen saturation. Thus, each gram of hemoglobin binds 1.3 mL of oxygen when completely saturated ($SaO_2 > 100\%$). As can be seen in the latter part of the equation, only a fraction of oxygen is dissolved in the blood and contributes little to the overall CaO_2. Thus, the SaO_2 is the most important blood gas variable for assessing the CaO_2 because the majority of oxygen is carried in the blood bound to hemoglobin.

PaO_2 contributes only a small amount to the overall oxygen content of the blood.

MIXED VENOUS BLOOD SAMPLING

Following oxygen extraction by the peripheral tissues, blood returns to the right side of the heart and is referred to as the mixed venous blood. True mixed venous oxygenation measurements are taken from the pulmonary artery because the inferior vena cava and superior vena

cava differ in their O_2 content. Factors that can affect the mixed venous O_2 content $C\bar{v}O_2$, and thus the mixed venous oxygen saturation ($S\bar{v}O_2$), can be appreciated by rearrangement of the Fick equation:

$$\dot{V}O_2 = CO \times (CaO_2 - C\bar{v}O_2) \quad (3\text{-}12)$$

$$C\bar{v}O_2 = CaO_2 - \dot{V}O_2/CO \quad (3\text{-}13)$$

where $\dot{V}O_2$ is oxygen consumption and CO is cardiac output. Thus, a decrease in hemoglobin, an increase in $\dot{V}O_2$, a decrease in SaO_2, and a decrease in CO can lead to a decrease in $S\bar{v}O_2$.

Mixed venous oxygen saturation is measured from the pulmonary artery.

Mixed venous blood is routinely sampled from the distal port of the Swan–Ganz catheter, located in the pulmonary artery. The sampled blood is then run through the blood gas analyzer and co-oximeter, similar to an arterial blood gas sample. Under normal conditions, the mixed venous PaO_2 is 40–45 mmHg, which corresponds to a $S\bar{v}O_2$ of 75%.

A 1 mmHg change in $P\bar{v}O_2$ is associated with a 2% change in $S\bar{v}O_2$.

At present, $S\bar{v}O_2$ can be continuously measured using a pulmonary artery oximetry catheter. Overall, there is a variability of ±6%; this must be considered both when monitoring stable patients and when determining when a rising or falling trend is significant.[24] Thus, a persistent drop in $S\bar{v}O_2$ from 77 to 70% should be considered significant. At the same time, if the goal of therapy is to maintain a $S\bar{v}O_2$ greater than 65%, keeping the $S\bar{v}O_2$ greater than 71% assures that this goal will be met with a 95% accuracy. Because the normal value for $S\bar{v}O_2$ of 75% is on the steep portion of the oxyhemoglobin dissociation curve, a linear relationship exists between $P\bar{v}O_2$ and $S\bar{v}O_2$, with a 1 mmHg change in $P\bar{v}O_2$ being associated with a 2% change in $S\bar{v}O_2$. Overall, cardiopulmonary instability is seldom seen with a $S\bar{v}O_2$ greater than 60%.[25] A reduction of $S\bar{v}O_2$ to less than 50% is commonly associated with development of anaerobic metabolism.[26] Changes in $S\bar{v}O_2$ have been utilized by clinicians to identify an alteration in the balance between oxygen delivery and consumption. For instance, a significant drop in $S\bar{v}O_2$ in a patient with congestive heart failure may indicate an associated decrease in CO. However, it has been demonstrated that in this patient population, as well as in those postcoronary artery bypass grafting (CABG), there is a relatively poor correlation between CO and $S\bar{v}O_2$. In addition, no threshold values for $S\bar{v}O_2$ that predict survival have been identified in patients with septic shock or postmyocardial infarction. In patients with septic shock or the acute respiratory distress syndrome (ARDS), the $S\bar{v}O_2$ can be normal to elevated, despite a significant decrease in tissue oxygenation, as a result of decreased extraction at the cellular level or the shunting of blood to organs that do not require the increased oxygen delivery.

Anaerobic metabolism may occur with a $S\bar{v}O_2 < 50\%$.

In addition, a decrease in $S\bar{v}O_2$ may reflect a change in peripheral utilization of oxygen, Hb, SaO_2, or CO. Thus, the $S\bar{v}O_2$ should never be used as a single parameter, but must be utilized in conjunction with clinical assessment and other measurements, such as CO, Hb, PaO_2, SaO_2, and VO_2, to determine the etiology of a change in tissue oxygenation.

SUMMARY

Blood gas sampling is an important modality in the assessment of the critically ill patient. Arterial blood gases are valuable in the determination of the patient's acid–base status as well as their arterial oxygenation. Mixed venous blood sampling, including the use of continuous monitoring of $S\bar{v}O_2$, can assess changes in the oxygen delivery–consumption relationship. Proper interpretation of both arterial and mixed venous blood gas samples allows appropriate clinical decision making, which may have an impact on patient outcome.

REVIEW QUESTIONS

1. **Which one of the following factors will not affect the results of arterial blood gas measurement?**
   - **A.** Too much heparin
   - **B.** Too much blood
   - **C.** Hypothermia
   - **D.** Air bubbles

2. **Which of the following statements regarding the anion gap is not true?**
   - **A.** If the pH is greater than 7.5, albumin becomes more negatively charged and the anion gap will increase secondary to an increase in unmeasured anions
   - **B.** The anion gap can increase if there is a decrease in unmeasured cations or if there is an increase in unmeasured anions
   - **C.** For every 1 g/dL decrease in albumin, a 2–3 mEq/L decrease in the anion gap will occur. Thus, the anion gap should be corrected for hypoalbuminemia
   - **D.** Common causes of an increased anion gap include paraproteinemias, hyponatremia, lithium toxicity, profound hyperkalemia, hypercalcemia, hypermagnesemia, and halide poisoning

3. **In which of the following clinical situations will the A-a gradient not be increased?**
   - **A.** A 23-year-old medical student who has had too much to drink and is found unconscious
   - **B.** A 45-year-old man with multiple trauma-related injuries who is in respiratory failure with adult respiratory distress syndrome (ARDS)
   - **C.** A 22-year-old dental student who has been complaining of shortness of breath and is newly diagnosed with asthma
   - **D.** A 65-year-old woman with idiopathic pulmonary fibrosis

4. **Which of the following is false concerning mixed venous blood?**
   - **A.** The normal $S\bar{v}O_2$ is between 70 and 75%, which reflects a $P\bar{v}O_2$ of 40–45 mmHg
   - **B.** The normal $P\bar{v}O_2$ and $S\bar{v}O_2$ lie on the steep portion of the oxyhemoglobin dissociation curve, so large changes in the mixed venous blood are needed to reflect changes in the mixed venous oxygen saturation
   - **C.** The major determinants of the mixed venous saturation are cardiac output, oxygen consumption, arterial oxygen saturation, and hemoglobin
   - **D.** A change in the $S\bar{v}O_2$ of ± 6% is needed before a rising or falling trend can be considered significant

ANSWERS

1. The answer is B. Heparin, hypothermia, and air bubbles will all affect arterial blood gas measurements. Heparin can affect blood gas analysis by lowering the $PaCO_2$ and calculated HCO_3^- by a dilutional effect. The pH is usually not affected due to the buffering effects of blood. Air bubbles in the sample will affect the PaO_2 and $PaCO_2$. CO_2 will diffuse from the sample into the bubbles, decrease the plasma $PaCO_2$, and increase the pH. The effect of air bubbles on PaO_2 depends on the concentration gradient between the blood and the PaO_2 in the bubble (PaO_2 159 mmHg). If the blood concentration is higher, it will falsely lower the concentration, and if it is lower, it will raise the concentration. If a patient's temperature is below 37°C, temperature-corrected $PaCO_2$ and PaO_2 will be lower, due to decreased solubility at lower temperatures. The pH will be higher because of the decreased dissociation of H_2O at lower temperatures. Thus, only the amount of blood in the syringe will not affect the arterial blood gas.
2. The answer is D. The blood pH can affect the anion gap by altering the anionic charge of proteins (including albumin), as well as changing the amount of organic acids that are present. An alkalemic state can thus increase the anion gap by 3–5 mEq/L. Because albumin is the major anion in the blood, a decrease in albumin will lead to a decrease in the anion gap. The normal anion gap of 12 ± 4 mEq/L basically reflects the amount of unmeasured anions in the blood. An increase in albumin will thus lead to an increase in the anion gap, as will a decrease in unmeasured cations, such as potassium and calcium. Therefore, paraproteinemias, hyperkalemia, and hypercalcemia all result in a decrease rather than an increase in the anion gap.
3. The answer is A. Of the four major causes of hypoxemia, only hypoventilation is associated with a normal A-a gradient because at the alveolar level, there are no anatomic abnormalities that would lead to hypoxemia. Rather, a decrease in ventilation decreases the alveolar oxygen concentration, which results in a decrease in the arterial oxygen content. Ventilation–perfusion (V/Q) inequality account for the hypoxemia that is seen with an acute exacerbation of asthma. Shunt and V/Q inequality are the major mechanisms for hypoxemia in patients with ARDS. Patients with end-stage pulmonary fibrosis have diffusion impairment that leads to hypoxemia.
4. The answer is B. The normal values for $P\bar{v}O_2$ and $S\bar{v}O_2$, 45 mmHg and 75%, respectively, do sit on the steep portion of the oxygen–hemoglobin dissociation curve, and thus small changes in $P\bar{v}O_2$ are associated with major changes in the $S\bar{v}O_2$. A change in $P\bar{v}O_2$ of 1 mmHg will result in a 2% change in $S\bar{v}O_2$. Although changes in cardiac output, oxygen consumption, arterial oxygen concentration, and hemoglobin concentration may all lead to a change in the $S\bar{v}O_2$, a ±6% change is needed before it can be considered significant.

Hemodynamic Monitoring

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the indications for placing arterial, central venous, and pulmonary artery catheters (PAC).
- Select catheter placement sites, based on patient characteristics and relative risk for complications.
- Establish a differential diagnosis based on the PAC measured and derived parameters.
- Understand the role of the PAC in managing and diagnosing specific critical care conditions.
- Interpret pulmonary artery (PA) waveforms and their significance.
- Understand the controversies associated with PAC use.

Many patients admitted to the intensive care unit (ICU) are, or become, hemodynamically unstable; the cause of this instability is often difficult to discern by physical examination alone. Invasive monitoring is often utilized to help diagnose the cause of hemodynamic instability and to assess the patient's response to therapy. This chapter reviews the use of hemodynamic monitoring, specifically, the indications, complications, and interpretation of data associated with arterial, central venous, and PACs.

PRECAUTIONS FOR CATHETER INSERTION

- Before placing any catheter, several steps must be taken to reduce the risk of complications:
- Review the patient's medical record to ensure that they are not on medications that will alter clotting (e.g., unfractionated heparinoids, plavix, etc) or have anatomical obstacles to catheterization or cannulation (prior existing venous clot or IVC filter).
- Obtain appropriate laboratory tests, including BUN (blood urea nitrogen), creatinine, electrolytes, ions, platelet count, and coagulation profile (prothrombin time, partial thromboplastin time).
- Correct abnormalities whenever possible. Consider using desmopressin (DDAVP) for uremic patients who may have platelet dysfunction and using blood products (fresh-frozen plasma, platelets, etc.) for a bleeding diathesis. Correct electrolyte abnormalities.
- Consider intravenous sedation, analgesia, or both.

ARTERIAL CATHETERS

Indications

Placement of an arterial catheter is indicated whenever precise or continuous measurements of blood pressure are needed.

The placement of an arterial catheter is indicated in clinical conditions where there is a need for precise and continuous measurement of arterial blood pressure. Such conditions include hypertensive crisis, where rapidly acting intravenous vasodilator therapy is used, cardiogenic shock requiring inotropic therapy, and septic shock that requires intravenous infusion of vasopressors.

Hypertensive crisis, cardiogenic shock, and septic shock are important indications for arterial cannulation.

Other indications for the insertion of an arterial catheter include the need for frequent arterial blood gas analysis, such as in patients with acute respiratory failure requiring mechanical ventilation. Arterial acid–base status, as well as systemic oxygenation, can be accurately assessed, thereby allowing prompt adjustment in ventilator settings or measurement of the response to certain therapeutic interventions (i.e., addition of PEEP [pulmonary end-expiratory pressure], effects of inotropes on oxygen delivery).

Contraindications

The insertion of an arterial catheter is a relatively safe and inexpensive procedure that has no absolute contraindications. Relative contradictions include bleeding diathesis, current anticoagulation, or the use of thrombolytic agents. The presence of a vascular prosthesis, local infections, and full-thickness burns are site-specific contraindications. Severe occlusive arterial disease with distal ischemia and poor collateral circulation is a concern. Historically, an Allen test, or a modified Allen test, has been performed to clinically assess the sufficiency of collateral circulation through the superficial palmar arterial arch.

Bleeding diathesis, anticoagulation, and use of thrombolytics are relative contraindications to arterial line placement.

In the modified Allen test, the hand is held high to allow blood to drain, is then clenched into a fist, and both ulnar and radial arteries are compressed. The hand is then lowered and opened. When pressure is released from over the ulnar artery, color should return to the palm within 6 s; if it takes longer than 10 s, the test is considered to be abnormal. The Allen test is identical; however, the procedure is performed twice, once with release of pressure from over the ulnar artery and once with release of pressure from over the radial artery.

Insertion Technique

Several anatomic sites are suitable for arterial cannulation. The radial artery is preferred because it is relatively superficial, easy to access, and carries a lower incidence of complications. Other sites include the dorsalis pedis, femoral, and brachial arteries.

When an anatomic site has been selected and aseptically cleaned, the operator localizes the artery with the index finger of the nondominant hand and the trajectory of insertion is palpated with the index and third fingers. Only slight pressure is applied to avoid collapsing the artery. The needle hub is held like a pencil with its bevel up.

- Radial artery cannulation: The arm is immobilized in the supine position with a dorsally placed armboard. The wrist is maintained in a partially extended position by a gauze roll. The armboard is secured with tape at the level of the metacarpal bones and arm. The needle is inserted 0.5–1.0 in. proximal to the wrist and advanced at a 30° angle (Fig. 4-1). The radial artery is commonly cannulated via one of two different methods using an over-the-needle catheter: (1) advancing the catheter directly into the artery over the needle following arterial puncture and observation of pulsatile blood flow or (2) using a guidewire technique. In the guidewire technique, an over-the-needle catheter is used to puncture the artery. Following arterial puncture, the needle-catheter combination is usually advanced several millimeters, at which point the needle is removed. If pulsatile blood flow is observed, a guidewire is inserted into the catheter and the catheter is then threaded into the artery. If pulsatile blood flow is not observed following the removal of the needle, the catheter is slowly withdrawn until pulsatile blood flow is observed and the guidewire is then inserted and the catheter advanced. The integral-guidewire technique is similar except that the guidewire is advanced through the needle when pulsatile blood flow is initially observed following arterial puncture. The outer catheter is then advanced into the artery over the needle and guidewire. Most commercial radial A-line kits are designed for the integral-guidewire technique. The choice of technique depends solely on operator preference.
- Brachial artery cannulation: The arm is immobilized in the supine position with an armboard, preventing elbow flexion. The needle is inserted at an angle of 30° and directed toward the pulsation in the antecubital fossa above the elbow crease (Fig. 4-2). Because of the paucity of collaterals and the risk of damage to the median nerve, this approach should be reserved for patients in whom other approaches are unsuccessful. The techniques described above for the radial artery are applicable in brachial artery cannulation.
- Femoral artery cannulation: The needle is inserted at a 45° angle 2–5 cm below the inguinal ligament at the inguinal crease (Fig. 4-3). Once blood is retrieved, the angle of entrance can be lowered to facilitate introduction of the catheter or a wire. If a large vessel such as the femoral artery is chosen, a Seldinger technique is often used in which a guidewire is

Because of its superficial location and low incidence of complications, the radial artery is the preferred site for arterial cannulation.

Because of possible damage to the median nerve, brachial artery cannulation should be used only when other approaches have failed.

Systolic pressures at the dorsalis pedis artery are generally 5–20 mmHg higher than radial artery pressures.

FIGURE 4-1

Radial artery cannulation. The arm is immobilized in the supine position with an armboard. The wrist is partially extended by placing a gauze roll underneath. The operator locates the pulse with the index finger of the nondominant hand and follows the trajectory of the artery with the third finger. The catheter is held like a pencil, with the needle bevel up. The catheter is inserted 0.5–1 in. proximal to the wrist and advanced at a 30° angle.

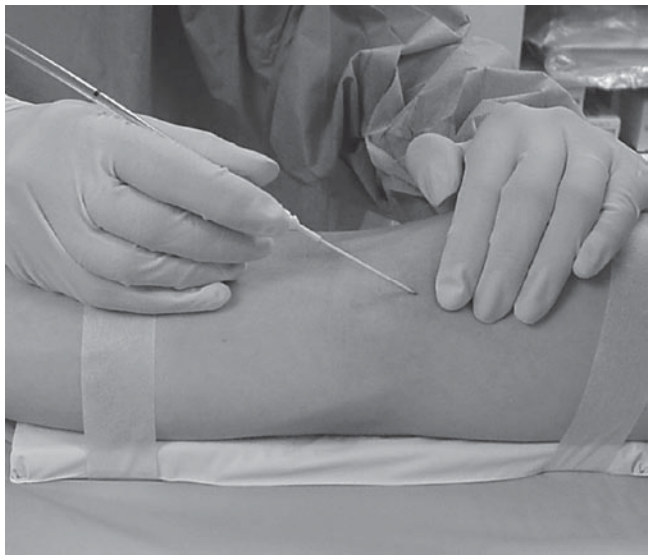

FIGURE 4-2

Brachial artery cannulation. The arm is immobilized, preventing elbow flexion. The operator palpates and localizes the artery in the antecubital fossa, following its trajectory with two fingers. Using the dominant hand, the catheter is inserted at a 30° angle toward the pulsation above the elbow crease.

FIGURE 4-3

Femoral artery cannulation. Using the index finger of the nondominant hand, the operator locates the femoral artery pulse at the inguinal crease. The catheter is inserted at a 45° angle, 2–5 cm below the inguinal ligament at the inguinal crease. Once blood is retrieved, the angle is lowered to facilitate passing the catheter or a guidewire if the Seldinger technique is employed.

FIGURE 4-4

Dorsalis pedis artery cannulation. The artery is palpated, generally lateral to the tendon of the extensor hallucis longus. After locating the arterial pulse and following the trajectory of the artery with the index and third fingers of the dominant hand, the operator inserts the catheter at a flat angle. The artery is entered midway along the dorsum of the foot.

inserted through the needle after the artery is entered; the needle is then removed and the catheter is placed over the wire into the artery.

- Dorsalis pedis artery cannulation: The artery runs over the dorsum of the foot, usually lateral to the tendon of the extensor hallucis longus. The artery is palpated and entered midway along the dorsum of the foot. It is important to remember that systolic pressures at the dorsalis pedis artery tend to be 5–20 mmHg higher than those measured at the radial artery (Fig. 4-4). The techniques described above for the radial artery are applicable in dorsalis pedis artery cannulation.

Hematoma formation	Arterial laceration	Infection

TABLE 4-1

COMPLICATIONS OF ARTERIAL CANNULATION

Complications

The rate of clinically relevant complications for arterial cannulation ranges from 2 to 5%; specific complications are listed in Table 4-1.

CENTRAL VENOUS CATHETERS

Indications

The use of central venous pressure (CVP) catheters has increased over the past few decades, paralleling advances in ICU technology. There has been an increased recognition of the usefulness of central hemodynamic monitoring in the ICU. Some of the most common uses of CVP catheters in ICU include the following:

- Rapid administration of intravenous (IV) fluids. It is important to note that the rate at which IV fluids are administered depends on both the radius and the length of the catheter. In some instances, a large-bore, short peripheral catheter is better suited for rapid administration of IV fluids than a long, thin central venous catheter. (For example, a peripheral 16-gauge venous catheter can infuse fluid more rapidly than a triple lumen catheter inserted into the superior vena cava.)
- Administration of specific medications such as chemotherapeutic agents or antibiotics that may be irritants to the peripheral veins, as well as vasoactive agents that may cause peripheral vasoconstriction and skin necrosis if extravasated.
- Administration of hyperosmolar fluids and total parenteral nutrition (TPN).
- Emergency venous access.

Large-bore peripheral lines are more suitable for fluid resuscitation than long, thin central vein catheters.

Vasoactive agents should be delivered via central venous catheters.

- Monitoring CVP.
- Long-term IV access.
- Placement of pulmonary artery catheter (PAC).
- Placement of temporary transvenous pacemaker.
- Access for right heart catheterization or arteriogram.
- Access for hemodialysis or plasmapheresis.

Contraindications

There are no absolute contraindications for the placement of a central venous catheter. The availability of multiple access sites allows the operator to choose a site that has the lowest risk for complications. Contraindications can thus be categorized as those related to securing central venous access in general and site-specific complications.

General contraindications for central vein cannulation:

- Distortion of local anatomy from previous trauma, surgery, or radiation.
- Injury to the vessels as a result of prior trauma or previous cannulation efforts.
- Bleeding diathesis or coagulopathy.
- Uncooperative or combative patients.
- Patients unable to tolerate the Trendelenburg (i.e., head-down) position.

Site-specific contraindications to central vein cannulation:

- Chest wall (C_W) deformities that make subclavian vein insertion more difficult.
- Inability to tolerate a potential pneumothorax (limited pulmonary reserve).
- Superior vena cava lesions or superior vena cava syndrome, preventing insertion of the catheter into the central venous system after cannulation.

There are no absolute contraindications to placement of a central venous catheter.

In patients with abdominal wounds, central venous access should only be attempted above the diaphragm.

The choice of central venous access should be based on patient characteristics.

The internal jugular vein is an easily compressible vessel, which makes it the preferred site in patients with an abnormal coagulation profile.

- Penetrating abdominal wounds (central venous access should be attempted above the diaphragm).
- Full-thickness burn or skin infection at the access site.
- Specific for internal jugular vein cannulation: severe carotid artery disease, contralateral hematoma from previous attempt (to avoid bilateral hematoma that may compromise the upper airway).

Insertion Technique

The choice of a central venous access site should be based on patient characteristics. Certain anatomic characteristics are likely to influence placement site, such as a short neck, which may favor a subclavian approach, as well as morbid obesity or indistinct landmarks. Other factors that are taken into account are the risk of bleeding, a patient's ability to tolerate the supine position, and the operator's familiarity with a particular approach.

Several venous sites can be chosen for access. The more commonly used sites are the internal jugular, subclavian, and femoral veins. Other access sites that can be used are the external jugular, axillary and brachial veins, but these sites have limitations that make them less desirable. Ultrasound guidance has been shown to be superior to blind, landmark-guided techniques, especially during cannulation of the internal jugular vein; the utility of ultrasound is less apparent for femoral and subclavian vein cannulation.

Internal Jugular

The internal jugular vein descends in the neck within the carotid sheath, which also contains the carotid artery and the vagus nerve. It traverses the neck and drains into the subclavian vein to form the innominate or brachiocephalic vein behind the head of the clavicle (Fig. 4-5). The internal jugular vein offers several advantages, including easy compressibility in case of bleeding and a lower incidence of pneumothorax compared to the subclavian approach. Disadvantages include an increased risk of carotid artery puncture, an increased risk of infection (especially in patients with a tracheostomy tube), and an increased risk of air embolism. The three different approaches to cannulating the internal jugular vein are based on accessing

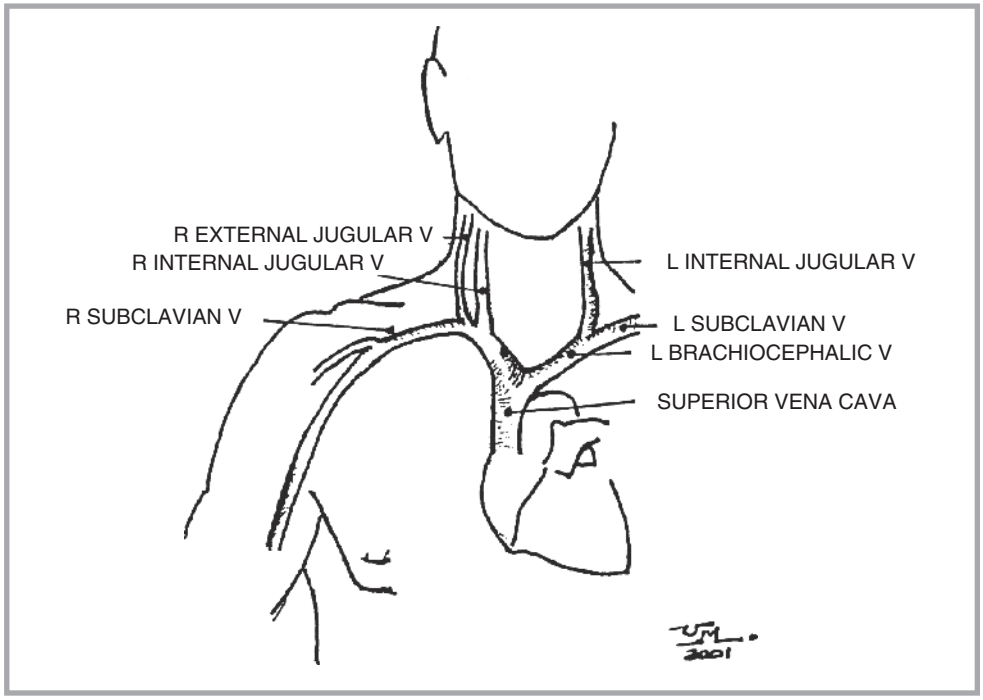

FIGURE 4-5

Anatomy of the neck veins.

the vein along the anterior, middle, or posterior aspect of the sternocleidomastoid (SCM) muscle. The right internal jugular vein is usually preferred because of its straight trajectory toward the superior vena cava and because potential injury to the thoracic duct is avoided. However, the apex of the right lung is slightly higher than the left, which may increase the rate of pneumothorax of right-sided cannulation. When using the anterior approach, the operator localizes the space between the trachea and the median head of the SCM muscle at the level of the cricoid cartilage. The carotid artery is palpated and a small gauge seeker needle is inserted into the space between the carotid and the medial head of the SCM muscle, pointing toward the ipsilateral nipple or shoulder. The anterior approach has been associated with an increased risk of carotid artery puncture. The middle approach requires the operator to localize the triangle formed by the medial and lateral heads of the SCM muscle with the clavicle. The internal jugular vein runs parallel to and below the lateral head of the SCM. The carotid artery is situated medial to the vein. The needle is inserted at the apex of the triangle (Fig. 4-6) and directed toward the ipsilateral nipple. It is important to palpate the carotid artery to establish its position, but excessive pressure may collapse the internal jugular vein, making cannulation more difficult. The vessel can usually be located at a depth of 2–4 cm. If blood is not aspirated, withdraw the needle slowly while maintaining negative pressure within the syringe; a significant percentage of jugular punctures are recognized during needle withdraw.

The internal jugular vein approach carries a higher risk of carotid artery puncture.

Because the carotid artery and the internal jugular vein share the same sheath, care must be exercised not to collapse the vein while palpating the artery.

The posterior approach requires the operator to identify the posterior aspect of the lateral head of the SCM muscle, which can be done holding both bellies of the muscle between the index and thumb finger. The needle is inserted above the point where the external jugular vein traverses the SCM muscle and is directed under its lateral belly toward the suprasternal notch. The vein is usually entered at a depth of 3–5 cm (Fig. 4-7).

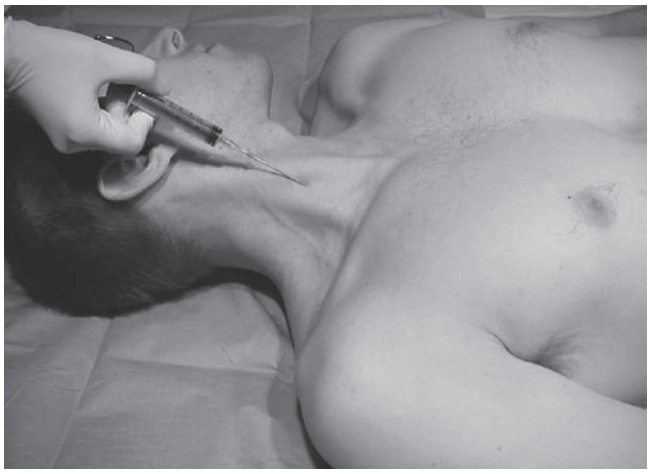

FIGURE 4-6

Internal jugular vein cannulation. When using the middle approach, the apex of a triangle formed by the medial and lateral heads of the sternocleidomastoid muscle (SCM) with the clavicle is localized. The vein runs parallel to and below the lateral head of the SCM. Applying gentle pressure (to avoid collapsing the vein that lies in the same sheath), the operator locates the carotid artery pulse with the index finger of the nondominant hand. The needle is inserted at the apex of the triangle and directed toward the ipsilateral nipple.

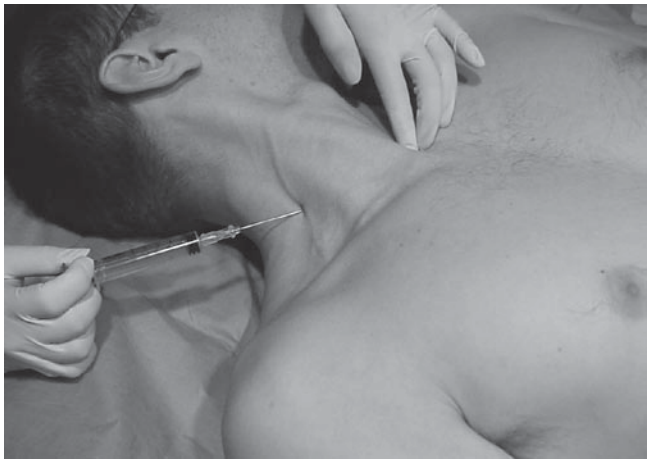

FIGURE 4-7

Internal jugular vein cannulation. When using the posterior approach, the operator locates the posterior aspect of the lateral belly of the SCM muscle. The needle is inserted above the point where the external jugular vein traverses the lateral belly of the SCM muscle and is directed (underneath the muscle) toward the suprasternal notch.

Subclavian Vein

The placement of a pillow behind the patient's shoulders during subclavian cannulation may decrease the space between the first rib and the clavicle, making cannulation more difficult.

The subclavian approach should be avoided in patients with a bleeding diathesis (noncompressible site).

The subclavian vein originates from the axillary vein and ends posterior to the medial head of the clavicle where it joins the internal jugular vein to form the innominate (brachiocephalic) vein (see Fig. 4-5). The usual approach to the subclavian vein is via the inferior route. The patient is positioned supine with the head lowered 15–30°. Although a common practice, placing a pillow or towel roll between the scapulae can actually decrease the space between the first rib and clavicle, making access to the vein more difficult. The needle is inserted 1 cm below the junction of the middle and medial thirds of the clavicle and directed toward the suprasternal notch (Fig. 4-8). The left subclavian vein is longer and follows a straighter pathway than its right counterpart, making it easier to insert the central line through this approach. Because the subclavian vein cannot be compressed, this approach is commonly avoided in patients with a bleeding diathesis. It also carries a higher risk of pneumothorax and air embolism as compared to the internal jugular vein approach. On the other hand, the landmarks are easier to identify, and there seems to be a lower incidence of catheter-related infections, especially if the patient is intubated or has a tracheostomy in place.[1] In addition, most conscious patients report less discomfort with a subclavian line.

Femoral Vein

The femoral vein lies medial to the femoral artery.

At the level of the inguinal ligament, the femoral vein lies medial to the femoral artery. To access the vein, the patient's lower extremity should be positioned in complete external rotation. The operator should palpate for the arterial pulse and insert the needle medial to it. The needle should be angled about 45° from the skin plane toward the head and slightly toward the midline (about 15°). The vein is usually entered at a distance 3–5 cm from the skin surface. The risk of mechanical complications is much lower with femoral lines; however, the risk of infection and thrombosis is considerably higher than with subclavian vein insertion.[1,2] The site can be easily compressed.

Clinical Utility

A properly placed CVP catheter can be used to measure right atrial pressure (P_{RA}). In the absence of tricuspid valve disease, the CVP closely mirrors right ventricular end-diastolic pressure (RVEDP). RVEDP can be used as a surrogate for right ventricular end diastolic volume (RVEDV) and thus preload. CVP is decreased in patients with hypovolemia and increased in patients with tricuspid regurgitation, right ventricular failure or infarction, and pericardial tamponade. In patients with normal cardiac function, a CVP that is greater than 10 cm H_2O signals an adequate intravascular volume. The absence of inspiratory variation in

FIGURE 4-8

Subclavian vein cannulation. The operator locates the junction of the middle and medial thirds of the clavicle. The needle is inserted 1 cm below this point and directed toward the suprasternal notch, which is marked by the operator's nondominant hand's index finger. The needle is maintained as parallel to the skin as possible.

the CVP waveform correlates with a lack of further increase in cardiac output with continued fluid resuscitation.[3] The CVP measurement, however, may not be an accurate assessment of cardiac function in critically ill patients, especially those with severe pulmonary hypertension, mitral valve dysfunction, or with right ventricular abnormal compliance or dysfunction.[3,4] In these patients, there is a poor correlation between right- and left-sided pressures.

The CVP should always be attached to an electronic pressure transducer that displays the CVP waveform and its different components. Analysis of the waveform can give valuable insight into the underlying pathology in patients with cardiovascular disorders. The CVP waveform should always be interpreted with the influence of respiratory variation taken into account, and be examined during end-expiration for consistency.

More recently, the CVP catheter has been shown to be useful in the initial treatment of patients with septic shock. Rivers et al[5] examined the effects of early goal-directed therapy for 6 h while in the emergency room prior to admission to the ICU in patients with septic shock. The protocol involved maximizing the CVP to >8 mmHg, and if the mean arterial pressure (MAP) was still less than 65 mmHg, then vasoactive agents were initiated. Once MAP was stabilized, central venous oxygen saturation was maintained at >70% by using red cell transfusions to achieve a hematocrit of at least 30%, and inotropic agents as needed. As compared to the control group, the protocol group demonstrated a significant 16% reduction in hospital mortality as well as a significant difference in vasopressor therapy, mechanical ventilation, time in hospital, and overall cost.[5] The combined hemodynamic goals were achieved in 99% of the protocol group as compared to 86% of the control group, which received standard therapy. Two more recent single center studies have demonstrated a similar decrease in mortality with early goal-directed therapy when compared to patients treated before the protocol was implemented.[6,7]

During the first 72 h, there is no increase in the incidence of catheter-related infections with femoral catheters.

The absence of inspiratory variation in the CVP waveform correlates with a lack of further increase in cardiac output with fluid resuscitation.

PULMONARY ARTERY CATHETER

History

Pulmonary artery wedge pressure (PAWP) was first measured nearly 50 years ago. Before 1970, hemodynamic monitoring was not done outside the cardiac catheterization laboratory. It was reserved for patients with congenital cardiac abnormalities and patients undergoing valvular surgery. The catheters initially employed were rigid and their insertion was frequently associated with bleeding and arrhythmias. In 1970, Swan and colleagues described the use of a flow-directed, balloon-tipped catheter that could be floated into the PA at the patient's bedside without the need for fluoroscopy.[8]

Description of the Pulmonary Artery Catheter

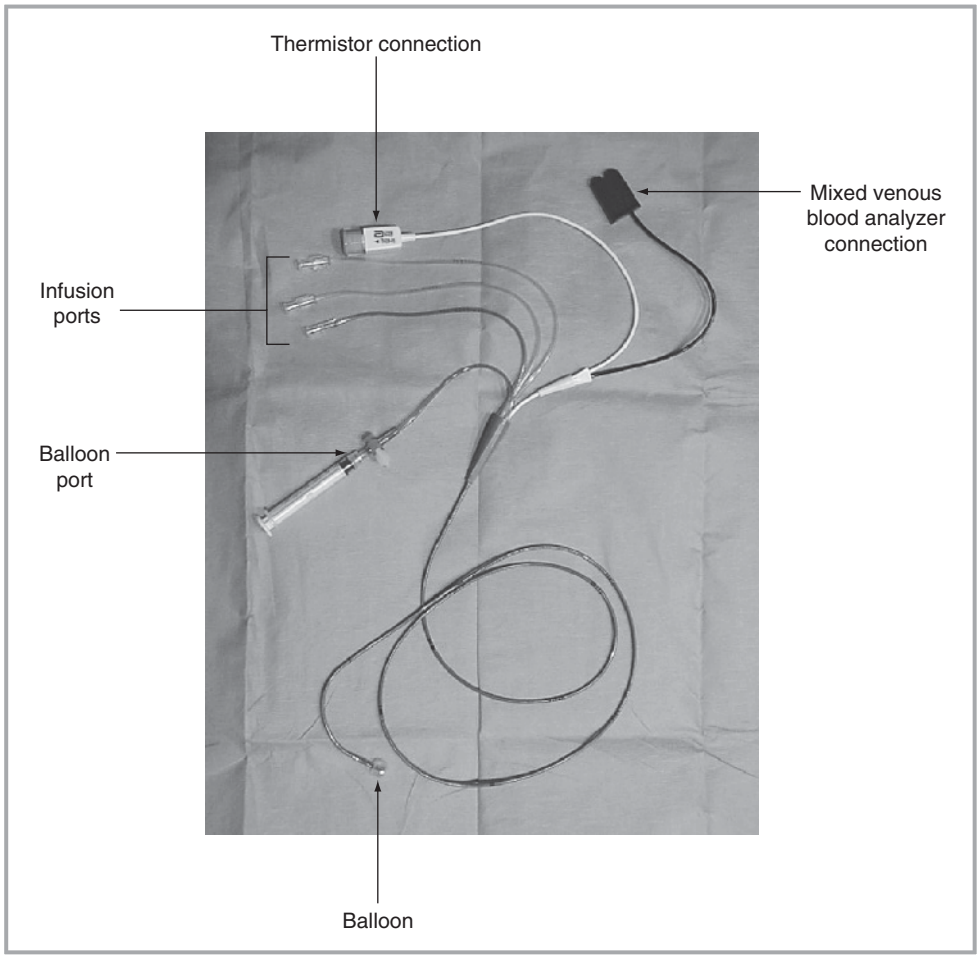
The PAC has undergone several modifications since its introduction in the 1970s. Modern catheters now allow for pressure monitoring, measurement of cardiac output, fluid and vasopressor infusion, and even therapeutic interventions such as cardiac pacing. The general design is similar among the different catheters. The PAC is 110 cm long and heparin-bonded throughout its entire length to decrease the incidence of catheter-associated thrombosis and microbial adherence. The four-lumen version allows for continuous measurement of cardiac pressures, as well as determination of the cardiac output (CO) using the thermodilution technique. The five-lumen catheter offers an additional port for administration of fluid and medications (Fig. 4-9).

The PAC is heparin-bonded to reduce the incidence of thrombosis and microbial adherence.

Modifications in the catheter have allowed for continuous monitoring of variables that in the past were only intermittently obtained, such as mixed venous oxygen saturation. The development of a fast-response thermistor has enabled the continuous measurement of CO or the right ventricular ejection fraction. Another modification allows for atrial or ventricular pacing.

FIGURE 4-9

The pulmonary artery catheter (PAC).



The PAC directly measures right atrial pressure, right ventricular and PA systolic and diastolic pressures, and pulmonary artery occlusion pressure (PAOP).

In the "wedge" position, the measured pressure reflects the hydrostatic pressure of the blood column at the confluence of the pulmonary veins.

What Does the Pulmonary Artery Catheter Measure?

The PAC directly measures the P_{RA}, right ventricular, and PA systolic and diastolic pressures, as well as the pulmonary artery occlusion pressure (PAOP) (Table 4-2). In addition, cardiac output (CO) can be intermittently obtained and mixed venous oxygenation and core body temperature can be continuously measured. With these measured variables, several calculated indices are obtained, including oxygen delivery and consumption and the oxygen extraction ratio (Table 4-3). Calculation of systemic and pulmonary vascular resistance, left and right ventricular stroke work, and work rate can also be obtained (Table 4-4).

To obtain the PAOP, the PAC is wedged into an interlobar PA, while the balloon is inflated with full volume. Wedging of the catheter with a partially inflated balloon (air volume less than 1.5 mL) indicates "overwedging" or too distal placement of the catheter tip. The measured pressure reflects the hydrostatic pressure of the column of blood at the confluence of the pulmonary veins (Fig. 4-10), allowing the clinician to estimate (not measure) two important parameters, the hydrostatic pressure gradient for pulmonary edema formation and the LVEDV.

Indications

Differentiation Between Cardiogenic and Noncardiogenic Pulmonary Edema

Attempting to clinically discern between cardiogenic and noncardiogenic pulmonary edema is a common dilemma in the ICU. In both situations, patients present with bilateral alveolar

TABLE 4-2

MEASURED HEMODYNAMIC VARIABLES

VARIABLE (ABBREVIATION)	UNIT	NORMAL RANGE
Systolic blood pressure (SBP)	mmHg	100–140
Diastolic blood pressure (DBP)	mmHg	60–90
Pulmonary artery systolic pressure (PASP)	mmHg	15–30
Pulmonary artery diastolic pressure (PADP)	mmHg	4–12
Right ventricular systolic pressure (RVSP)	mmHg	15–30
Right ventricular end-diastolic pressure (RVEDP)	mmHg	0–8
Central venous pressure (CVP)	mmHg	0–8
Pulmonary artery occlusion pressure (PAOP)	mmHg	2–12
Cardiac output (CO)	L/min	Varies with size

TABLE 4-3

DERIVED HEMODYNAMIC VARIABLES

TERM	ABBREVIATION	DEFINITION	NORMAL RANGE
Arterial blood oxygen content	CaO_2	Volume of gaseous oxygen/dL blood	16–22 mL/dL
Arterial blood oxygen content	DO_2	O_2 volume ejected from left ventricle: $DO_2 = CI \times CaO_2 \times 10$	500–650 L/min/m²
Oxygen consumption, mL/min/m²	VO_2	O_2 volume used by tissue: $VO_2 = CI \times C(a–v)\ O_2 \times 10$	110–150
Oxygen uptake, mL/min/m²	–	O_2 volume taken up by lungs	110–150
Extraction ratio	ER	$(ER = VO_2/DO_2)$	0.22–0.30

CI cardiac index (L/min/m²); *CaO_2* arterial oxygen (mL/dL blood); *C(a–v) O_2* arterial venous oxygen content difference (mL/dL blood); *BSA* body surface area (m²)

TABLE 4-4

OXYGEN TRANSPORT VARIABLES

TERM	ABBREVIATION	CALCULATION	NORMAL RANGE
Mean arterial pressure	MAP	MAP = DBP + ((SBP – DBP)/3)	70–105 mmHg
Mean pulmonary artery pressure	MPAP	MPAP = PADP + ((PASP – PADP)/3)	9–16 mmHg
Cardiac index	CI	CI = CO/BSA	2.8–3.2 L/min/m²
Stroke volume	SV	SV = CO/HR	Varies with size
Stroke index	SI	SI = CI/HR/beat/m²	30–65 mL
Left ventricular stroke work index	LVSWI	LVSWI = CI × (MAP – PAOP) × 0.0136	44–64 gm/m²
Right ventricular stroke work index	RVSWI	RVSWI = CI × (MPAP – CVP) × 0.0136	7–12 gm/m²
Systemic vascular resistance index	SVRI	SVRI = ((MAP – CVP)/CI) × 80	1,600–2,400 dyne sec/cm⁵/m²
Pulmonary vascular resistance index	PVRI	PVRI = ((MPAP – PAOP)/CI) × 80	250–430 dyne sec/cm⁵/m²

PADP pulmonary artery diastolic pressure (mmHg); *PASP* pulmonary artery systolic pressure (mmHg)

infiltrates, hypoxemia, and decreased lung compliance. Obtaining a thorough history, physical examination, and chest radiograph is mandatory; however, several studies have shown that in the ICU, physicians are limited in their ability to distinguish between cardiogenic and noncardiogenic pulmonary edema.[9,10] Based on clinical assessment alone, physicians were

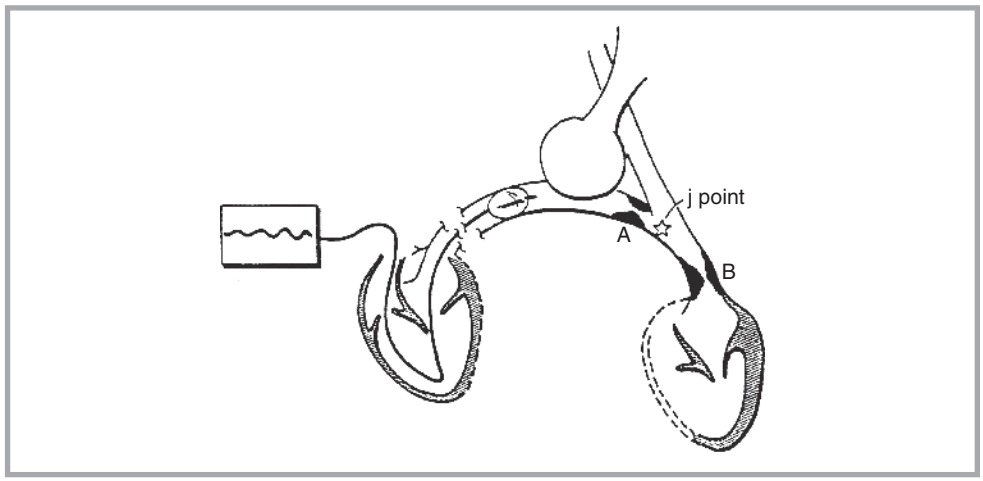


FIGURE 4-10

Principle of the pulmonary artery occlusion pressure (PAOP) measurement. When the balloon is inflated, the catheter records the pressure at the junction of the static and free flowing channels, the j point. An obstruction distal to the j point at B will cause the PAOP to overestimate left atrial pressure (From O'Quinn R, Marini JJ. Pulmonary artery occlusion pressure: clinical physiology measurement and interpretation. Am Rev Respir Dis 1983;128:319-326. ©American Thoracic Society).

able to determine PAOP and cardiac index (CI) correctly only 30–42% and 44–51% of the time, respectively.[9,10] In addition, using a PAC led to a change in therapy in approximately 50% of the cases.[9]

The ability to discern between cardiogenic and noncardiogenic pulmonary edema by clinical assessment alone is limited.

The American–European Consensus recognizes a PAOP of less than 18 mmHg as one of the diagnostic criteria for the acute respiratory distress syndrome (ARDS).

There are noninvasive alternatives to the PAC in determining the etiology of pulmonary edema. Using a long suction catheter, a lavage can be performed to determine the protein concentration in pulmonary edema fluid. The ratio of the pulmonary edema fluid protein concentration to the serum protein concentration can help differentiate cardiogenic from noncardiogenic pulmonary edema. A ratio greater than 75% is associated with increased permeability (noncardiogenic) pulmonary edema; a ratio less than 65% is highly suggestive of hydrostatic (cardiogenic) pulmonary edema.[11] This technique is useful only if performed very early in the course of edema formation. In addition, because this technique is not performed routinely in the ICU, the reproducibility of results may be suspect. Despite the noted limitations in identifying a cause for pulmonary edema, the initial clinical impression by the physician should direct therapy. Insertion of a PAC should be considered in patients who do not respond to initial therapy or have a rapid clinical deterioration. Traditionally, an elevated PAOP is taken to indicate a significant component of hydrostatic pulmonary edema, whereas a low PAOP is usually indicative, but not diagnostic, of noncardiogenic pulmonary edema.

Diagnosis of Shock

The PAC can be used to help establish the etiology of shock; the most common causes include hypovolemic, septic, and cardiogenic shock. Hypovolemic shock is suggested when there is a recent history of trauma, bleeding, or protracted volume loss from diarrhea or emesis. Physical examination reveals enophthalmos, dry mucous membranes, loss of skin turgor, and flattened neck veins. In addition, hypotension and postural changes in heart rate or blood pressure or both can be seen. Laboratory findings may demonstrate an elevated BUN and creatinine, as well as hypernatremia and hemoconcentration. The diagnosis of hypovolemic shock is usually made on the basis of clinical information.

In certain cases, it is difficult to differentiate between septic and cardiogenic shock. Echocardiography is an alternative to PAC placement in establishing the presence of left ventricular dysfunction. Nevertheless, septic shock can be associated with abnormal left ventricular function, and a more definitive diagnosis can be established with placement of a PAC. Patients with cardiogenic shock characteristically demonstrate a low CO and high systemic vascular resistance. In contrast, patients with septic shock have an abnormally high CO and low systemic vascular resistance. In addition to establishing the etiology of a patient's shock, the PAC is very useful in managing fluids as well as for monitoring the effects of inotropic and vasoactive agents.

However, whether the use of the PAC will affect outcome in patients with shock remains controversial. Studies that have included patients with shock have not demonstrated improved survival with the use of a PAC when compared to no catheter or use of a CVP to guide therapy.[12-15] However, many of these studies involved patients with multiple causes for shock, and some were meta-analyses of randomized trials with mixed patient populations.[13-15]

Management of Acute Respiratory Distress Syndrome

In patients with ARDS, a PAC is useful not only in establishing an accurate diagnosis but also in directing therapy. Possible therapeutic interventions include adjustment of vasoactive medications or a change in the rate of fluid infusion to minimize edema formation in the presence of capillary leak. The PAC also can be useful in titrating the amount of positive end-expiratory pressure (PEEP) in patients with ARDS.

The PAC can be useful in titrating PEEP in patients with the ARDS.

Recently, focus has increased on the use of higher levels of PEEP combined with lower tidal volumes to minimize the risk of ventilator-induced lung injury. PEEP will recruit collapsed alveoli and increase end-expiratory lung volume, decreasing ventilation–perfusion mismatch and shunt.[16] Unfortunately, higher levels of PEEP increase intrathoracic pressure and decrease venous return, resulting in a decreased CO. With a PAC, the decremental effects of PEEP on CO can be monitored and corrected with intravascular fluids or the initiation of inotropic agents.

However, as with patients in shock, it is controversial as to whether the use of a PAC will affect morbidity or mortality. A previous randomized study comparing use of a PAC to no catheter in patients with shock and ARDS found no difference in 14-, 28-, or 90-day mortality, as well as no difference in the number of days without organ failure, days in the ICU, or days on mechanical ventilation.[13] In a more recent study by the ARDS Clinical Trials Network, there was no difference in mortality during the first 60 days when hemodynamic management was guided by a PAC vs. a CVP catheter. In addition, there was no difference in the number of ventilator-free days, days spent in the ICU, lung or kidney function, or the use of dialysis or vasopressors.[12]

MANAGEMENT OF MYOCARDIAL INFARCTION AND CARDIOGENIC SHOCK

Shock may be one of the presenting manifestations of an acute myocardial infarction (MI). Patients can present with evidence of hemodynamic compromise, including hypotension, pulmonary edema, and oliguria. Shock may be secondary to relative hypovolemia with a decreased preload or to a low CO state. The use of a PAC in patients with an acute MI should be reserved for those with clinical signs of shock. A PAC guides preload and afterload reduction and the use of diuretics, as well as inotropic support. The PAC may also be useful in the diagnosis and management of right myocardial infarction. Right myocardial infarction occurs in about 30% of patients with an inferior wall MI. Patients generally present with precordial pain, associated with hypotension and clear lung fields. Kussmaul's sign (engorgement of the jugular veins during inspiration) and the hepatojugular reflex may be present. The diagnosis is made by electrocardiographic changes in the right precordial leads and elevation of cardiac enzymes. Placement of a PAC shows elevated mean right atrial pressure (see following). The PAC may also be useful in managing fluids in these patients, whose right ventricular preload can be compromised.

Patients with cardiogenic shock have a low cardiac output and a high systemic vascular resistance.

Patients who present with an acute myocardial infarction (MI) and signs of shock should be managed with a PAC.

The presence of elevated right atrium pressure and systemic hypotension are characteristic in patients with an acute right ventricular MI.

The PAC also allows diagnosing some of the complications of acute MI. Papillary muscle ischemia or rupture results in acute mitral regurgitation, which can be assessed by the presence of giant v waves in the pulmonary artery (PA) wedge tracing (see following). A rupture of the interventricular septum can be diagnosed by establishing the presence of an increase in the O_2 saturation in the blood samples from the right ventricle. Patients with advanced heart failure may also benefit from PAC insertion during episodes of decompensation. These patients often need similar therapeutic interventions that require close hemodynamic monitoring.

Papillary muscle ischemia or rupture results in acute mitral regurgitation, which will manifest as large "v" waves in the PA wedge tracing.

However, as in other groups, the benefit of a PAC in patients with congestive heart failure (CHF) is controversial. In the ESCAPE Trial, which was a randomized trial involving 433 patients with CHF at 26 sites, there was no difference in the number of days alive out of hospital during the first 6 months in the group assigned to clinical management and a PAC vs. clinical management alone.[17] There was also no difference in mortality, or the number of days hospitalized, but a higher adverse events rate in the PAC group.

Perioperative Management

Patients with left main coronary artery disease may benefit from perioperative PAC monitoring.

The role of the PAC in the perioperative setting is controversial. High-risk surgical patients, for example, those with decompensated heart failure and history of a MI in the previous 3 months, are likely to benefit from PAC insertion. There is little evidence to support the routine use of PACs in patients undergoing coronary artery bypass graft surgery. An exception may be the subgroup of patients with left main coronary artery disease. In one retrospective study, these patients had a 17% decrement in mortality when managed with a PAC in the perioperative period.[18]

The use of the PAC has been evaluated in patients undergoing peripheral vascular surgery with associated comorbidities. Despite a reduction in intraoperative hemodynamic complications, overall mortality did not differ between the group that was monitored with a PAC and the group that was not.[19] In patients undergoing elective abdominal aortic aneurysm repair, no difference in morbidity and mortality was noted between patients monitored with a CVP catheter and those patients with a PAC.[20]

In a study by Shoemaker et al, patients who underwent surgery for high-risk conditions (abdominal catastrophe, multiple trauma, etc.) were randomized to three different groups.[21] Groups 1 and 2 were monitored with CVP and PACs, respectively. A third group was monitored with PACs, but therapy was guided to increase CI and DO_2 to supraphysiologic levels, based on prior data collected from survivors of high-risk surgical interventions. The third group showed a significant reduction in mechanical ventilator days, ICU/hospital days, and hospital costs. The results of this study were not reproducible when supraphysiologic parameters were used in high-risk medical patients.[22-24] More recently, in a large multicenter trial of 1994 patients scheduled for urgent or elective major surgery, the use of the PAC for goal-directed therapy did not result in improved survival at 6 and 12 months.[25] In addition, the use of a PAC was associated with an increased risk of pulmonary embolism.

In summary, there is no definitive evidence that critically ill patients managed with a PAC have improved outcomes. Accepted indications have relied on clinical experience, and specific questions related to patients' hemodynamic status that cannot otherwise be satisfactorily answered by noninvasive studies or clinical evaluation. A careful consideration of the risks and benefits is warranted prior to inserting a PAC.

Insertion Technique

Preliminary Steps

In addition to the general precautions and preliminary steps undertaken each time an intravenous catheter is placed, the placement of a PAC warrants several particular measures such as continuous electrocardiographic monitoring, frequent blood pressure measurements (manual or automatic devices), and oxygen saturation monitoring with pulse oxymetry.

The balloon should always be deflated before retracting the PAC.

There is no definitive evidence that critically ill patients managed with a PAC have improved outcomes.

Modern PACs are placed in an interlobar artery.

When venous access has been obtained, an introducer is placed. The PAC is placed through the introducer and advanced to about 15–20 cm. From this point, it is important that the operator is able to recognize the different waveforms that will be displayed on the monitor. The PAC balloon is inflated and the catheter is advanced, observing the changes in waveforms on the monitor (Fig. 4-11). On entering the right ventricle from the right atrium, a sharp increment in systolic pressure is observed. The catheter is then advanced into the PA. Diastolic pressure increases, and a dicrotic notch is noted in the PA waveform. As the catheter is advanced further into the PA, progressive dampening of the waveform is observed.

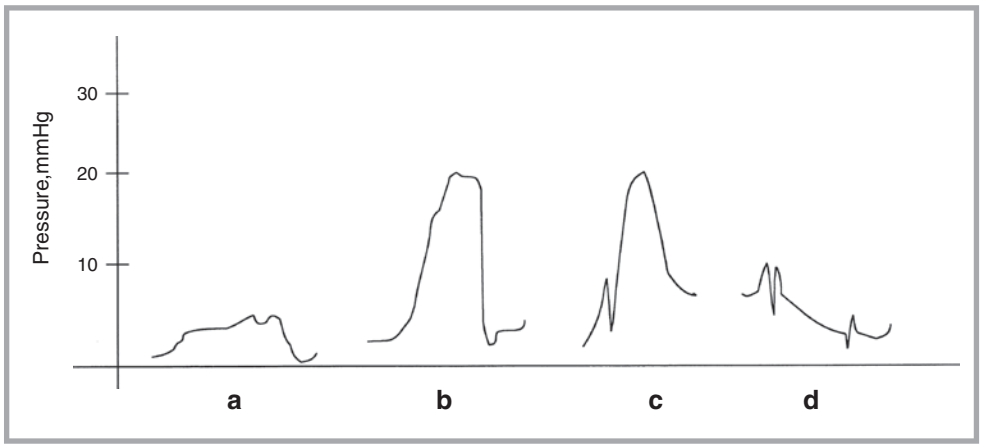

FIGURE 4-11

As the PAC is inserted, the different waveforms and pressures should be carefully observed. As the catheter is inserted, a central venous pressure (CVP) tracing (**a**), characterized by a and v waves, is seen. On entering the right ventricle from the right atrium, a sharp increment in systolic pressure is noted (**b**). The catheter is then advanced to the pulmonary artery (PA), characterized by an increment in diastolic pressure and the presence of a dicrotic notch, the waveform (**c**). As the catheter is advanced further into the PA, a progressive dampening of the waveform is noted. The "wedge" position is characterized by a sine wave that oscillates with respiration (**d**).

The wedge position is characterized by a sine wave that oscillates with respiration. The wedge position is usually reached 10–15 cm after passage through the right ventricle or at 45–55 cm from the skin when the right internal jugular vein is used for access. Failure to detect a wedge waveform should prompt the operator to deflate the balloon and retract the catheter to the right atrium in order to refloat the PAC. Advancing the catheter beyond the expected distance that a wedge waveform should be obtained can result in coiling or knotting. The balloon should always be deflated before retracting the catheter. The term wedge is a misnomer that relates to the way pressures were measured with stiff catheters before the advent of flow-directed, balloon-tipped catheters. Stiff catheters had to be introduced deep into the PA until the catheter wedged, which increased the incidence of complications. In contrast, modern PACs are easier to place because of balloon flotation and need only be advanced into an interlobar artery. This minimizes overwedging and arterial rupture.

If there is difficulty advancing the catheter into the PA (patients with pulmonary hypertension, cardiomyopathy, enlarged right ventricle), several maneuvers can be attempted. If the patient is awake, a deep inspiratory effort will increase venous return and help float the catheter into position. Placing the patient in the supine position with a slight elevation of the head, or turning to the left lateral decubitus position, may also help. If the catheter is in the circulation for several minutes, it may warm up and become more compliant. In that case, infusing a small amount of ice-cold saline may increase the stiffness of the catheter. Stiffer catheters are available, but the operator must be aware that there may be an increased risk of perforation. If these maneuvers are not successful, the catheter should be placed under fluoroscopy. Once the wedge position is reached, the balloon should be deflated and the PA waveform observed to return. A chest radiograph should always be obtained to confirm the catheter's position and to rule out a pneumothorax.

A chest radiograph should always be obtained to verify catheter position and rule out the presence of pneumothorax.

Measurement of Cardiac Output

Measurement of CO plays an important role in clinical decision making in the ICU. CO reflects a measurement not only of pump function but of overall circulatory function as well and is important in determining the cause of hypotension. In conjunction with other

parameters measured with the PAC, CO enables the physician to diagnose and treat shock regardless of its etiology.

CO is directly related to the metabolic rate and thus oxygen consumption (VO_2). The relationship in normal individuals is linear, with an increase in VO_2 (as during exercise) resulting in a parallel increment in CO. This linear relationship allows CO to be calculated with a margin of error of only about 5%. A decrement in CO is not necessarily related to a decrease in VO_2. For example, in patients who develop CHF, a decrease in CO will not affect VO_2 because of an increase in oxygen extraction at the tissue level. In other disease states, such as ARDS, the tissues are not able to increase their extraction of oxygen and thus the VO_2 can be dependent on CO.

The relationship between blood pressure and CO is best expressed by the formula:

$$\text{Blood pressure} = \text{CO} \times \text{SVR}, \tag{4-1}$$

where SVR is systemic vascular resistance. In other words, the development of hypotension can be directly related to a decrement in CO (e.g., cardiogenic shock) or a decrease in SVR (e.g., septic shock). Cardiac output can be measured by thermodilution or the Fick method.

Fick Method

Measurement of CO by the Fick method requires an indicator that is added at a constant rate. Oxygen is a very good indicator because oxygen uptake and the arterial and venous oxygen contents can be measured with relative ease. The formula for cardiac output using oxygen as an indicator is:

$$\text{CO} = \dot{V}O_2/(CaO_2 - C\bar{v}O_2), \tag{4-2}$$

where CaO_2 is the arterial oxygen content and CvO_2 is the mixed venous oxygen content. VO_2 can be determined from the difference between oxygen content in inspired and expired air as measured by a gas analyzer. The arterial content of oxygen can be calculated from the following formula:

$$CaO_2 = 1.36 \times \text{Hb} \times SaO_2, \tag{4-3}$$

where Hb is hemoglobin, 1.36 is a constant that gives the amount of oxygen bound to each fully saturated molecule of hemoglobin, and SaO_2 is arterial oxygen saturation, which can easily be determined by arterial blood gas analysis.

Cardiac output is directly related to oxygen consumption.

The mixed venous oxygen content can be calculated from the formula:

$$C\bar{v}O_2 = 1.36 \times \text{Hb} \times SvO_2, \tag{4-4}$$

Measurement of cardiac output can be obtained by thermodilution or the Fick method.

where $S\bar{v}O_2$ represents the mixed venous oxygen saturation. A sample of mixed venous blood should be obtained from the distal port of the PAC. Equation 4-2 can then be rewritten as:

$$\text{CO} = \dot{V}O_2/1.36 \times \text{Hb} \times (SaO_2 - S\bar{v}O_2). \tag{4-5}$$

To avoid errors in measurement of cardiac output with the Fick method, mixed venous blood samples should be obtained from the right ventricle or the PA.

Several sources for error can occur when using the Fick method to calculate cardiac output. The mixed venous blood sample must come from the RV or PA. The presence of an intracardiac shunt can alter the oxygen content of the sample. Although dissolved oxygen in the arterial blood (PaO_2) normally contributes little to the overall oxygen content (not even included in Eq. 4-4), at a high FiO_2 its contribution can be underestimated. Errors may also occur as a result of inaccurate measurement of VO_2 from the exhaled gases.

Changes in pulmonary gas volume, performing a Valsalva maneuver, or receiving a transfusion can all affect the measurement of CO using the Fick method. In addition, inflammatory disorders in the lungs, such as pneumonia, increase the consumption of oxygen by the lungs before it reaches the blood, leading to an overestimation of VO_2 by as much as 15%.

Thermodilution Method

The thermodilution technique has become the method most commonly used to determine CO in the ICU. The technique involves injecting either 10 mL of ice-cold dextrose in water, or dextrose in water at room temperature, through the proximal port of the PAC into the RA. The change in temperature is sampled by a thermistor located in the distal end of the PAC that is located in the PA. A computer records the change in temperature from baseline and the cardiac output is calculated by the integration of temperature over time (Fig. 4-12). Traditionally, an ice-cold injectate was used, but more recent studies have demonstrated room temperature injectates to be as accurate and more convenient. Sources of error using this technique include inaccurate baseline temperature measurements and injecting the wrong volume. During respiration, variation in lung temperature may occur, resulting in fluctuations in the thermistor's baseline temperature reading. Volumes smaller than 10 mL are associated with a greater magnitude of error. Other sources for error include arrhythmias, tricuspid regurgitation (which may under or overestimate CO), intracardiac shunts, and a low cardiac output.

Modern PACs allow for continuous measurements of CO, which can be accomplished by two methods. A continuous CO derived from the Fick equation can be obtained by measuring oxygen consumption using indirect calorimetry and the analysis of inspired and expired gases, continuous pulse oximetry for the assessment of arterial oxygen saturation, and continuous mixed venous oximetry for the assessment of mixed venous oxygen saturation. When the outputs of these three devices are computed using the Fick's equation, a near real-time assessment of CO can be obtained. The second method is based on the thermodilution theory. Instead of measuring changes in an injectate temperature, CO is calculated using thermal boluses generated by a heating filament on the catheter to produce temperature changes.

Interpretation of Pressures

Right Atrial Pressure

The normal range for P_{RA} is 2–8 mmHg. P_{RA} reflects right ventricular end-diastolic pressure (RVEDP) if tricuspid regurgitation or stenosis is not present. P_{RA} is usually lower than PAOP, but with normal cardiac function, there is a good correlation between these pressures. In patients with left ventricular hypertrophy, CHF, or ischemia, this close correlation may not be present. In these cases, PAOP may be markedly elevated with only a modest elevation in P_{RA}. P_{RA} will be higher than PAOP in the presence of pulmonary hypertension, such as with

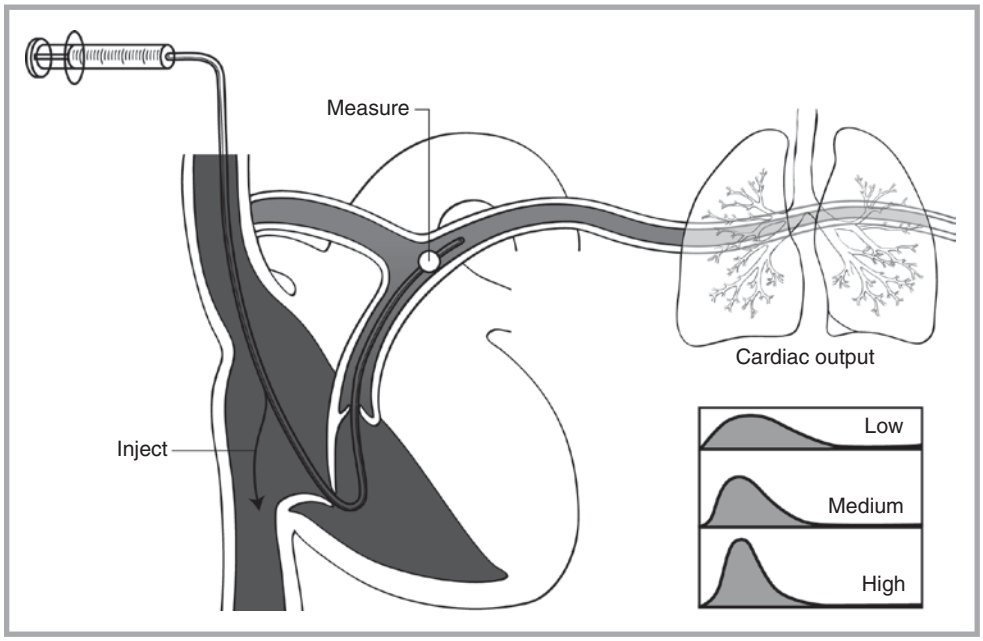

FIGURE 4-12

Cardiac output (CO) measured by thermodilution. A bolus of crystalloid solution is injected into the central venous circulation, and temperature is measured by a thermistor at the tip of the PAC. Typical thermal dilution curves are shown (Illustration by Alice Chen).

massive pulmonary embolism or tricuspid regurgitation. In patients with normal cardiac function, a P_{RA} that is greater than 10 mmHg indicates an adequate intravascular volume. The P_{RA} normally falls during inspiration because of transmission of the negative intrathoracic pressure. The absence of a decrement in P_{RA} during inspiration indicates that CO cannot be further increased by volume infusion.[26]

Pulmonary Artery Pressure

The normal values for pulmonary artery pressure (PAP) are a systolic pressure of 15–30 mmHg, a diastolic pressure of 4–12 mmHg, and a mean of 9–18 mmHg. The difference between the PA diastolic pressure and the PAOP is normally 1–4 mmHg, and this difference can often narrow the differential diagnosis of an elevated PAP. A PA diastolic – PAOP greater than 5 mmHg suggests increased pulmonary vascular resistance, as in patients with acute (ARDS) and chronic (pulmonary fibrosis) hypoxemia, or pulmonary emboli. In contrast, pulmonary hypertension resulting from increased downstream pressures (elevated PAOP in patients with CHF) usually maintains a normal gradient.

Arrhythmias, tricuspid regurgitation, and low cardiac output may result in an erroneous estimation of cardiac output by thermodilution.

Pulmonary Artery Occlusion Pressure

A poor correlation between PAOP and right atrial pressure is observed in patients with heart failure, ischemia, and left ventricular hypertrophy.

One of the most common indications for insertion of a PAC is to measure the PAOP. By occluding a branch of the PA, a static column of blood is created distal to the occluded vessel. The hydrostatic pressure at the confluence of the pulmonary veins can then be determined. PAOP is the pressure measured at the point at which the vascular segment of the pulmonary veins that is occluded joins the rest of the pulmonary veins, which contain free flowing blood; this point is also known as the j point. It is therefore clear that PAOP estimates, but does not measure, two parameters: the hydrostatic pressure gradient for edema formation at the pulmonary capillaries and the left ventricular end-diastolic volume.

A gradient >5 mmHg between the pulmonary artery diastolic pressure (PADP) and the PAOP suggests the presence of increased pulmonary vascular resistance.

Several technical problems that can result in an erroneous reading of the PAOP must be considered.

To accurately measure intravascular pressures, the tip of the PAC must be in a position where zone 3 conditions prevail.

Invalid Waveform

The validity of the waveform needs to be assessed in several ways. The first is to make sure that when the balloon is deflated a PA waveform tracing is observed. On wedging, the tracing should have characteristics typical of a left atrial pressure waveform. The mean PAOP pressure should be less than mean PA pressure and generally less than PA diastolic pressure (tracings with cannon a waves may be an exception).

Inaccurate Zero Pressure Reference

Alterations in the zero hydrostatic pressure reference can cause important errors in measuring PAOP. A deviation of 10 cm from the true zero point will cause a change (in the opposite direction) of 10 cm H_2O, or about 7.5 mmHg, in the measured PAOP. There are two ways to set the zero pressure reference level. In the first, the pressure transducer is leveled at the midaxillary line using a ruler with a leveler. The transducer is then opened to air, and thus atmospheric pressure, and zeroed. In the second method, the more distal three-way stopcock going to the PA port is placed at the midaxillary line, opening it to air, adjacent to the patient. The catheter is thus zero referenced at this level. After zero referencing has been completed, if either the patient or the transducer is raised or lowered, there will be a need to rezero the system.

Catheter Tip Not in Zone III

Regional differences in pulmonary perfusion result from the interactions of several factors, including gravity, PA pressure, pulmonary venous pressure (PVP), and alveolar pressure

(PALV). Three different zones can be identified within the lung, with zone 1 at the apex, zone 2 in the midlung field, and zone 3 at the base. Zone 2 is characterized by PAP > PALV > PVP and zone 3 by PAP > PVP > PALV. For practical purposes, when the balloon is inflated, PAP becomes irrelevant because pressure is measured distal to the balloon. When PVP exceeds PALV (zone 3), intravascular pressure is recorded. If PALV is greater than PVP, the measured pressure will reflect alveolar pressure (zone 2) (Fig. 4-13). In clinical practice, the effects from zone 2 are relatively uncommon because the catheter is flow-directed and has a tendency to find its way to a position lower than the left atrium. It is theorized that applied PEEP to the airway in patients with ARDS results in increased alveolar pressure and nonzone 3 placements. However, Teoul et al[27] noted a close correlation between PAOP and LVEDP in 12 patients with ARDS with PEEP pressures as high as 20 cm H_2O, suggesting that decreased lung compliance causes poor transmission of airway pressure to the intravascular compartment.

It is important to read the PAOP at the end of expiration, a point at which there is the least effect of intrapleural pressure changes on transmural cardiac pressure measurements. Failing to accurately identify the point of end-expiration is the most common error in measuring PAOP. End-expiration can be identified by careful examination of the patient or, if that fails, by using an esophageal balloon.

It is also important to determine the contribution of increased intrathoracic pressure caused by tachypnea or asynchrony with the ventilator. Increased intrathoracic pressure occurs with conditions such as pneumothorax, applied PEEP, or intrinsic PEEP. These problems should be addressed and corrected before the PAOP is measured. Increased intrathoracic pressure will increase juxtacardiac pressure. The effect of PEEP on juxtacardiac pressure can be estimated as follows. The change in pleural pressure (PPL) for a given change in airway pressure (PAW) has been shown to be a function of the relative compliances of the lung (C_L) and the chest wall (C_W).

Increased intrathoracic pressure will cause an increment in pleural or juxtacardiac pressure.

The change in PPL for a given change in airway pressure is a function of the relative lung and C_W compliances.

Left ventricular preload is defined as left ventricular end-diastolic volume.

$$\Delta PPL/\Delta PAW = C_L/C_L + C_W \quad (4\text{-}6)$$

or

$$\Delta PPL = \Delta PAW \times (C_L/C_L + C_W). \quad (4\text{-}7)$$

In normal lungs, the relative contributions of C_W and C_L are similar in magnitude. Equation 4-7 can be rewritten as:

$$\Delta PPL = \Delta PAW \times 1/(1 + 1) \quad (4\text{-}8)$$

or

$$\Delta PPL = \Delta PAW\ (0.5)$$

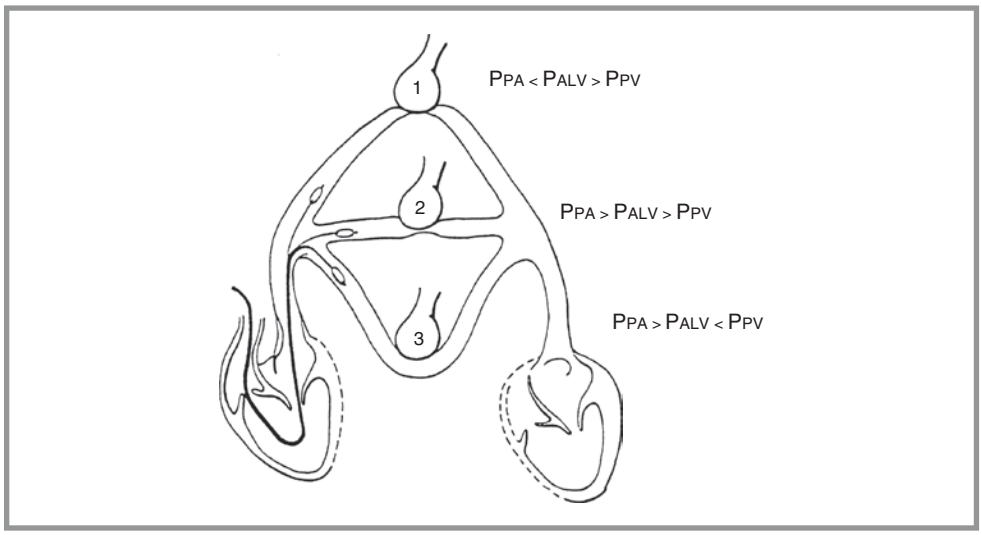

FIGURE 4-13

Physiologic lung zones, based upon the relationship between pressures in the pulmonary artery (PPA), alveolus (PALV), and pulmonary vein (PPV) (From O´Quinn R, Marini JJ. Pulmonary artery occlusion pressure: clinical physiology measurement and interpretation. Am Rev Respir Dis 1983;128:319-326. ©American Thoracic Society).

In other words, PPL will increase by about one-half the increase in applied PEEP. In the setting of ARDS, C_L is substantially lower than C_W. For example, if C_L is reduced to 25% of its normal value,

$$\Delta PPL = \Delta PAW \times 0.25/(0.25 + 1) \quad (4\text{-}9)$$

or

$$\Delta PPL = \Delta PAW(0.2).$$

In this particular case, the application of 10 cm H_2O PEEP would result in an increment of 2 cm H_2O in PPL, which is equivalent to 1.47 mmHg (using 1.36 to convert cm H_2O to mmHg).

Hydrostatic Gradient for Pulmonary Edema Formation

Under normal conditions, the pulmonary capillary bed is the most important site where fluid filtration can occur in the lungs. According to the Starling relationship, two kinds of pressure determine fluid filtration across the capillary vessel wall, hydrostatic and osmotic pressures. The balance of these forces is determined by the pressure differences between the microvascular and interstitial compartments. An imbalance between these forces will result in net movement, or filtration, of fluid from one compartment to the other. For example, in a patient with CHF, in whom the microvascular pressure (P_{MV}) is increased, fluid moves from the intravascular to the interstitial compartment. The value of PAOP is that it serves as a minimum estimate for P_{MV} and can be monitored after therapeutic interventions aimed at decreasing the hydrostatic pressure gradient are implemented.

PAOP as an Index of Left Ventricular Preload

The PAC reflects left ventricular end-diastolic pressure (not volume); hence, it does not always reflect preload.

In patients with cardiovascular disease, left ventricle (LV) preload cannot be accurately estimated by measuring RV preload, as assessed by a CVP catheter. The use of the PAC to estimate LV preload remains controversial. It is important to recognize that LV preload is defined by LVEDV and not by LVEDP. Although LVEDP is correlated to LVEDV, LVEDP can be influenced by other factors, such as ventricular compliance and intrapleural pressure changes, making the relationship between pressure and volume inaccurate. Alterations in left ventricular end-diastolic compliance can occur with LV hypertrophy or fibrosis. Because juxtacardiac pressure determines LV transmural (distending) pressure, factors that affect juxtacardiac pressure, such as pericardial tamponade, PEEP, and autoPEEP, will also alter the LVEDP–LVEDV relationship. Therefore, a relationship between LVEDP and LVEDV can only be inferred after careful consideration of factors that may alter LV compliance. The juxtacardiac pressure can be measured by subtracting esophageal pressure (as measured by an endoesophageal balloon) from PAOP.

The correlation between PAOP and LVEDV can also be affected by the presence of valvular heart disease. PAOP measures the pressure at the confluence of the pulmonary veinss; it is generally in good agreement with LAP. In the absence of valvular disease, LAP correlates with LVEDP. In mitral stenosis, PAOP overestimates LVEDP because of the pressure gradient between LA and LV. In aortic regurgitation, PAOP underestimates LVEDP because of early closure of the mitral valve from retrograde filling of the LV.

Normal Waveforms

Right Atrium

The onset of the right atrial waveforms follows the appearance of the p wave on the EKG (Fig. 4-14). Several waveforms can be identified in the right atrial tracing. The first positive wave is the a wave, which is caused by the contraction of the right atrium; this is followed by the x descent, which signals the relaxation of the right atrium after systole. The x descent can be interrupted by a positive deflection called a c wave, which is the result of closure of the tricuspid valve. During ventricular systole, the atrium is filled passively, creating the

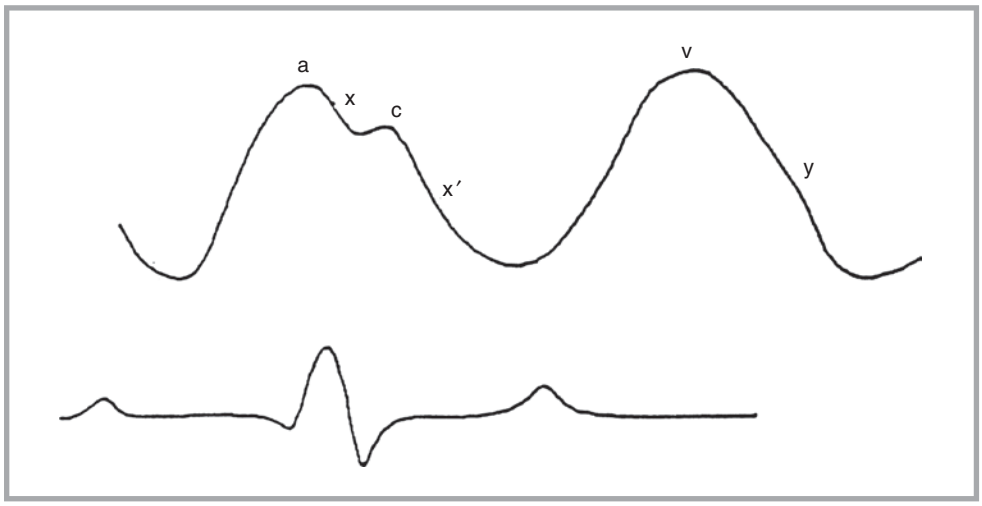

FIGURE 4-14

Schematic drawing of the right atrium waveform. The first positive wave is the *a* wave, caused by contraction of the right atrium; this is followed by the *x* descent, which signals the relaxation of the atrium after atrial systole. The *x* descent can be interrupted by a positive deflection, the *c* wave, which is the result of the closure of the tricuspid valve. The second major positive wave, the *v* wave, occurs during passive filling of the atria during ventricular systole. The *v* wave is followed by the *y* descent, signaling the opening of the tricuspid valve.

second major positive wave, called the v wave. The v wave is followed by the y descent, signaling the opening of the tricuspid valve.

Pulmonary Artery

The PA wave has a systolic pressure wave and a diastolic trough. The systolic wave can have an indentation or dicrotic notch caused by the closure of the pulmonic valve.

Pulmonary Artery Wedge

The waveforms obtained with the balloon inflated, and the PAC advanced into the interlobar artery position, are similar to those seen in the right atrium.

Waveform Analysis: Pitfalls

Overdamping

Overdamping decreases systolic and increases diastolic pressures, resulting in an inaccurate PAP measurement. Overdamping can be the result of air bubbles in the tubing, clots at the tip of the catheter, or a partially occluded or kinked catheter (Fig. 4-15). Flushing the

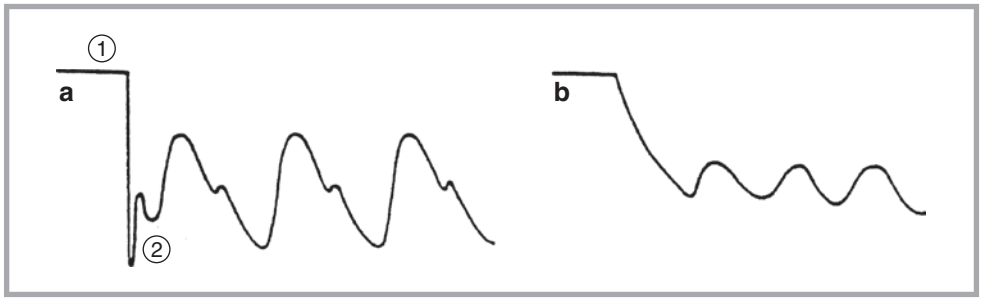

FIGURE 4-15

Overdamping can be caused by a kinked catheter, air bubbles in the transducer, or a fibrin clot. Flushing the catheter helps in determining the presence of overdamping. (**a**) Normally, flushing the catheter results in high pressure at the transducer (*1*); when flushing is stopped, a rapid fall in pressure results in an overshoot (*2*), followed by a return to the waveform. (**b**) An overdamped system lacks the overshoot seen in (**a**) and shows a flattened waveform.

catheter should generate a very high pressure reading, followed by a rapid fall in pressure, or overshoot, after the flush is stopped. The absence of a sharp decrement in the pressure reading and lack of an overshoot should raise the suspicion of an inappropriately dampened catheter.

Whip Artifact

Cardiac contractions and the resulting changes in intracardiac pressure cause whip artifact (Fig. 4-16). When prominent, this artifact can lead to difficulty in interpreting pressure waveforms, causing a fictitious rise in systolic pressure and an underestimation of the diastolic pressures.

Overwedging

Overwedging most commonly occurs when catheters migrate too far distally. In these cases, the catheter needs to be withdrawn to a more proximal position in the PA and refloated. Rarely, overwedging occurs when the balloon protrudes over the catheter tip or pins the tip against a vessel wall (Fig. 4-17).

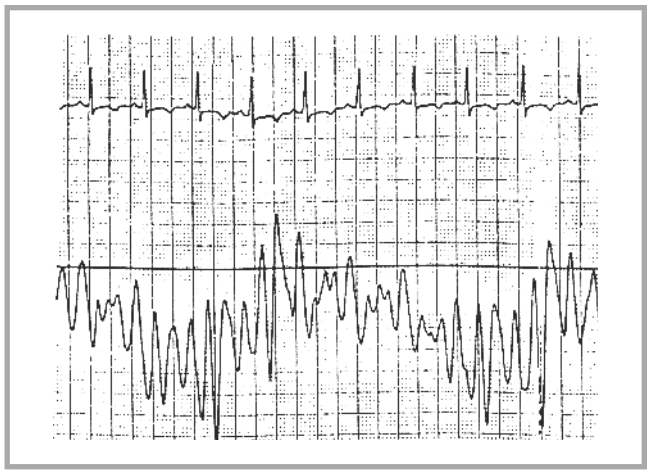
Abnormal Waveforms

Acute Mitral Insufficiency

Acute mitral insufficiency can occur with papillary muscle rupture or ischemia. The incompetent valve allows blood to enter the left atrium during ventricular systole, causing a prominent v wave in the PAOP tracing. The PA waveform will acquire a bifid shape (Fig. 4-18).

FIGURE 4-16

Catheter whip. Right ventricle contractions are transmitted to the PAC, resulting in prominent excursions.



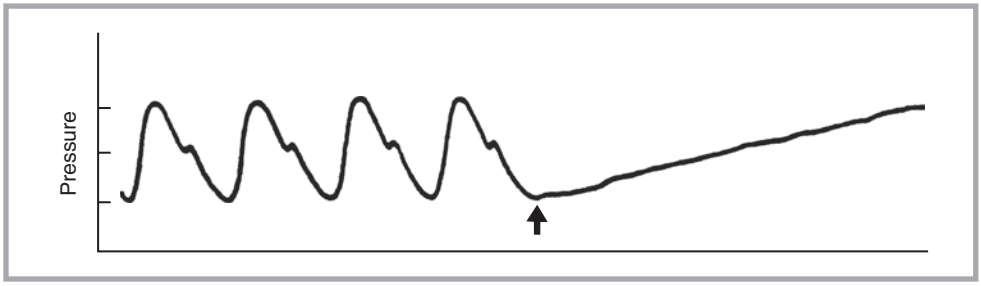


FIGURE 4-17

Overwedging. The *arrow* indicates the point at which the balloon is inflated. A sustained increment in pressure reading can be seen.

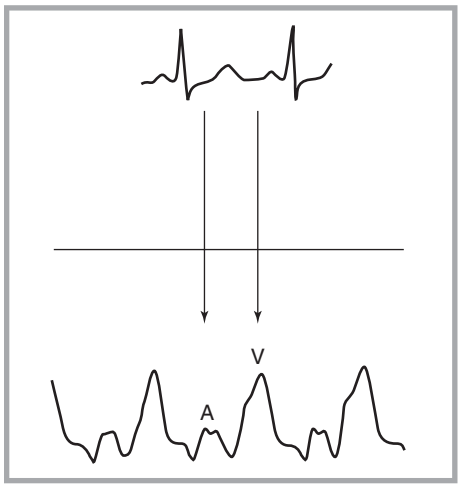

FIGURE 4-18

Acute mitral insufficiency. The incompetent valve allows blood to enter the left atrium during ventricular systole, resulting in a prominent *v* wave.

Tricuspid Regurgitation

Tricuspid regurgitation can result from pulmonary hypertension or endocarditis. A prominent v wave can be seen in the RA tracing, as well as a broad c-v wave (Fig. 4-19).

Right Ventricular Infarction

Right ventricular (RV) infarction complicates about 30% of patients with an inferior myocardial infarction. RV infarction should be suspected in patients with a positive hepatojugular reflex, engorged internal jugular during inspiration (Kussmaul sign), and clear lung fields. Right precordial leads are useful in identifying this entity. The RA waveform shows deep x and y descents, causing the RA waveform to resemble the letter W (Fig. 4-20).

Pericardial Tamponade

Accumulation of fluid in the pericardial space can result in pericardial tamponade, which is a limitation of cardiac filling during diastole. The pericardium is able to accommodate large amounts of fluid if accumulation occurs gradually, but rapid accumulation of fluid does not allow for changes in pericardial compliance, resulting in tamponade even with relatively small amounts of fluid. As intrapericardial pressure rises, it equalizes with RA and then with LA pressure. At this point, the RA pressure and PAOP are determined by intrapericardial

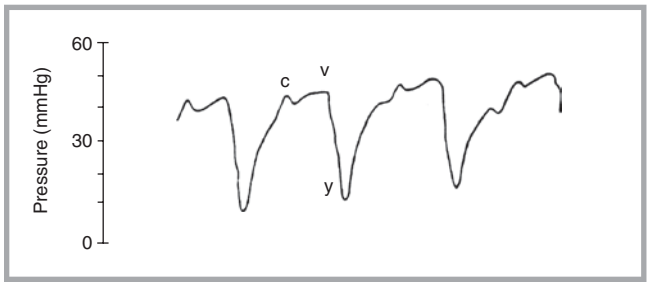

FIGURE 4-19

Tricuspid regurgitation. A broad *c–v* wave can be observed.

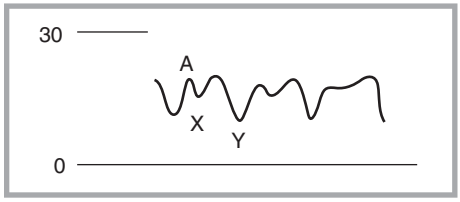

FIGURE 4-20

Right ventricular infarction often results in marked acute dilatation of the right ventricle. Acute dilatation is limited by the pericardium. Deep *x* and *y* descents, resembling the letter W, characterize the waveform.

pressure, accounting for the equalization of pressures seen in pericardial tamponade. The RA waveform usually has a preserved x descent and a blunted y descent.

Constrictive Pericarditis and Restrictive Cardiomyopathy

The pathophysiologic abnormality in constrictive pericarditis and restrictive cardiomyopathy is limitation of ventricular filling. In both cases, there is a marked elevation of the RA pressure and PAOP. In restrictive cardiomyopathy, the PAOP is usually greater than the RA pressure, whereas in constrictive pericarditis, the pressures are similar. Constrictive pericarditis is associated with prominent x and y descents, with the y descent usually being deeper.

Complications Associated with Pulmonary Artery Catheters

Complications of PAC placement can be divided into those occurring during catheter insertion and those occurring once the catheter is in place.

Pneumothorax

The incidence of pneumothorax varies from 1 to 3%. Risk factors associated with the formation of a pneumothorax include multiple attempts at needle insertion, an inexperienced operator, patients with respiratory distress, cachectic or extremely obese patients, and catheter placement under emergent conditions. The risk is greater when using a subclavian and middle internal jugular approach compared to other sites. Forcing the guidewire can also result in a pneumothorax. A chest radiograph should always be obtained following insertion.

Arterial Puncture and Hemorrhage

Arterial puncture has been reported to occur in up to 15% of central venous catheter placements. In most cases, applying pressure to the area for 5–15 min easily controls the bleeding. Rarely, hemorrhage into the area may result in the formation of a hemothorax or cause an expanding hematoma that compromises the airway. Inadvertent arterial cannulation can result in cerebral ischemia and infarction. The catheter should ideally be removed by a vascular surgeon in the operating room in order to completely visualize and repair the injury. Correcting coagulation disorders and replacing platelets can minimize the risks of arterial hemorrhage. If a coagulopathy cannot be corrected, it is prudent to use ultrasound guidance, which has been shown to be superior to blind, landmark-guided techniques, especially with the internal jugular vein. The subclavian approach is often avoided because it is a noncompressible site; though data supporting a poorer outcome when this site is chosen in coagulopathic patients is lacking.

Miscellaneous Complications

Other complications reported to occur in less than 1% of patients include knotting of the catheter, fragmentation, and cardiac perforation.

Complications during Catheter Insertion

Arrhythmias

Transient cardiac arrhythmia is the most common complication of PAC insertion.

Cardiac arrhythmia is the most frequently cited complication of PAC insertion, with a prevalence of 10–80%. Arrhythmias are thought to arise from mechanical irritation of the right atrium or ventricle. They are usually transient and quickly disappear after advancing the

catheter beyond the right ventricle or withdrawing from it. The incidence of minor arrhythmias, including premature atrial or ventricular contractions, has been reported to occur in 4–69% of all PAC insertions. The incidence of transient ventricular tachycardia or fibrillation is between 0.5 and 63%, with sustained ventricular arrhythmias being uncommon. Despite a low incidence of tachyarrhythmias, an effort should be made to prevent their development by correcting conditions that increase myocardial irritability, such as hypoxemia, hypothermia, acidosis, alkalosis, and electrolyte abnormalities. There is no evidence that prophylaxis with antiarrhythmic drugs such as lidocaine is useful.

A right bundle branch block can occur with PAC insertion, but it is usually transient. In patients with a preexisting left bundle branch block (LBBB), the formation of a right bundle branch block during PAC insertion results in complete heart block. The risk of complete heart block is small, however, and the placement of a temporary pacer before PAC insertion is not recommended in patients with LBBB.

Complications After PA Catheter Insertion

Infection

Infection is the most common cause for clinical intervention once PACs are in place. Infectious complications range from colonization with pathogenic organisms to overt sepsis and shock. As authors' definitions have varied from study to study, it is difficult to establish the overall prevalence of catheter-associated infection. Infection of the insertion site has been reported to occur in 0–22% of all patients. The prevalence of sepsis is much smaller, ranging from 1 to 3% in large series. Coagulase-negative *Staphylococcus* is the most frequently isolated pathogen, followed by *Staphylococcus aureus* and enteric gram-negative bacteria. Several steps may reduce the incidence of infection, including sterilizing the skin at the insertion site, use of full barrier precautions (wearing masks, hats, gowns, and gloves), minimal manipulation of infusions, use of antibiotic-coated catheters, and reducing the time the catheter is left in place (ideally less than 5 days).

Thrombosis

The overall incidence of thrombosis is uncertain. Although mural thrombus has been reported in 30–60% of patients, the clinical significance of this finding is uncertain. Furthermore, because special studies such as venography and Doppler ultrasound are needed to diagnose this entity, it may be underreported. Interestingly, complications of thrombotic events, namely pulmonary embolism, superior vena cava syndrome, and thrombosis of the internal jugular vein, are rare, with an incidence ranging from 0.1 to 6%. In addition to the physical findings, dampening of the PA waveform and difficulty withdrawing blood from the catheter should alert the physician to the possibility of thrombus formation. Modern PACs are heparin bonded throughout their entire length, which reduces the incidence of thrombosis. Treatment consists of anticoagulation and removal of the catheter. Prevention of thrombosis is extremely important and entails limiting dwell time, especially in patients at high risk for thrombotic events (cancer patients and those with hypercoagulable disorders).

Rupture of the Pulmonary Artery

Although the incidence of rupture or perforation of the PA is low (less than 1%), it is associated with a high mortality (45–60%). Several mechanisms have been proposed to explain PA rupture, such as overinflation of the balloon in a proximal vessel, normal inflation in a distal vessel, and direct perforation while placing the catheter. Manifestations of PA rupture include hemoptysis, hemothorax, or a new asymptomatic parenchymal infiltrate. Treatment depends on the presentation; hemoptysis should be managed by positioning the patient with the affected side down. Localization should be attempted with chest radiography or bronchoscopy if needed. Options to stop the hemorrhage include bronchial balloon

tamponade or embolization performed by an interventional radiologist. Hemothorax should be managed with chest tube placement and blood products. Surgery becomes an option if bleeding persists or the patient is unstable.

Mortality in PA rupture ranges from 45 to 60%.

The formation of a false aneurysm should be considered if a "halo sign" is seen on chest X-ray adjacent to the distal tip of the PAC. False aneurysms have also been reported in patients with normal chest X-rays whose only symptom has been nominal hemoptysis.[28] These aneurysms lack an endothelium, contain clot, and are unstable; progression to frank hemoptysis can occur suddenly. The diagnosis can be made with a contrast-enhanced CT scan of the chest; a pulmonary angiogram can be obtained if confirmation is required and may allow coil embolization. Regularly checking the position of the catheter with radiographs, avoiding overinflation of the balloon, and avoiding inflation if resistance is met can minimize rupture and perforation.

Miscellaneous Complications

Other complications include pulmonary infarction, intracardiac injury, and air embolism and balloon rupture. Finally, death directly attributable to catheter-related complications has been reported in less than 0.1% of patients.

CONTROVERSIES

In 1996, Connors et al,[9] seeking to determine whether placement of a PAC improved survival in the ICU, evaluated previously collected data from more than 5,000 patients in five U.S. hospitals. Right heart catheterization was performed in 2,184 patients within the initial 24 h of ICU stay. The control group consisted of ICU patients who did not have a PAC inserted. Cases were matched for baseline characteristics and prognosis. Following adjustment, the PAC group showed an increased relative risk of death at 30 days. PAC use was associated with a significantly higher relative risk of death among patients with acute respiratory failure and multiorgan failure. Subgroup analysis did not reveal an association between increased mortality and elderly patients, women, shock, sepsis, and postoperative care. Following this article, a number of prospective randomized trials have been conducted in both medical and surgical patients evaluating the effectiveness of the PAC. As noted in the previous sections, most have shown no significant benefit as it relates to mortality or other secondary outcomes when compared to either routine clinical care or the use of a CVP to guide therapy.[12-15,17,25] However, many of these studies included mixed patient groups, including medical and surgical patients in the same studies. Overall, the use of the PAC as a diagnostic tool and to evaluate the response to therapy must be individualized, with the risk-to-benefit ratio determined for each patient.

SUMMARY

In the ICU, critically ill patients often require invasive monitoring for diagnostic purposes as well as to assess the response to therapeutic interventions. Arterial catheters enable continuous monitoring of systemic blood pressure and blood sampling to assess arterial oxygenation and acid–base status. Central venous access, with either a CVP line or a PAC, allows for important hemodynamic monitoring, including an assessment of cardiac function and measurement of intravascular filling pressures. Use of PACs should be individualized, with its limitations understood as they relate to morbidity and mortality in selective disease states.

REVIEW QUESTIONS

1. **All the following are correct regarding CVP catheters except:**
   - **A.** CVP catheters can be used to measure right atrial pressure
   - **B.** In the absence of tricuspid disease, CVP mirrors RVEDV
   - **C.** CVP is decreased in patients with right ventricular infarction
   - **D.** In patients with normal cardiac function, adequate intravascular volume is considered when CVP is greater than 10 mmHg

2. **Regarding the placement of the PAC, all the following statements are correct, except:**
   - **A.** The left subclavian vein has a straighter trajectory than the right subclavian vein, making insertion of the PAC easier
   - **B.** The PAC is generally placed into an interlobar artery
   - **C.** To obtain an accurate measurement, the catheter trip should be placed in zone 3 of the lung
   - **D.** The inability to fully inflate the catheter's balloon signals that the catheter is in the "wedge" position

3. **All the following statements regarding measurement of cardiac output with a PAC are correct, except:**
   - **A.** Measurement of cardiac output with the Fick method can be affected by blood transfusions and changes in pulmonary gas volume
   - **B.** Inflammatory processes, such as pneumonia, may cause an overestimation of VO_2
   - **C.** Ice-cold injectates are necessary to measure cardiac output using the thermodilution method
   - **D.** Arrhythmias, intracardiac shunts, and tricuspid regurgitation may result in an erroneous measurement of the cardiac output by the thermodilution method

4. **Regarding PAOP measurement, which of the following statements is correct?**
   - **A.** It should be measured at the end of expiration
   - **B.** The application of PEEP results in increased intrathoracic pressure and generation of zone 3 conditions
   - **C.** The transmission of PEEP to the vascular compartment is independent of lung and C_W compliance
   - **D.** PAOP closely reflects left ventricular preload

ANSWERS

1. The answer is C. The CVP catheter can be used to measure right atrial pressures. In patients without tricuspid disease, it reflects RVEDV and right ventricular preload. Patients with right ventricular infarction typically present with chest pain, hypotension, and clear lung fields. Kussmaul's sign and hepatojugular reflex are usually present. Characteristically, CVP is elevated in these patients.
2. The answer is D. Because modern PACs are flow-directed, balloon-tipped catheters, they generally "float" to an area where zone 3 conditions (PV > PALV) exist. The PAC is generally inserted into an interlobar PA, where the balloon can be inflated. The inability to fully inflate the balloon should alert the physician to the possibility of a too-distal positioning of the catheter tip. Because this error may increase the risk of complications (such as pulmonary infarct), no further attempts to inflate the balloon should be made before radiographic confirmation of the catheter's position.
3. The answer is C. Measurement of cardiac output with the Fick method requires an indicator that is added at a constant rate. Oxygen is a good indicator because oxygen uptake and arterial and venous oxygen content can be measured with relative ease. The major determinants of the Fick equation are hemoglobin and oxygen uptake. The thermodilution method allows measurement of the cardiac output by recording the change in temperature of an injectate. The technique involves injecting 10 mL of an injectate through the proximal port of the PAC. The change in temperature is sensed by a thermistor at the tip of the PAC, and cardiac output is calculated by integration of temperature over time. Arrhythmia, intracardiac shunt, and tricuspid regurgitation distort the flow of the injectate and cause temperature changes by admixing blood, resulting in erroneous estimations of cardiac output. Although ice-cold injectates were used in the past, recent studies have demonstrated that room temperature injectates are more accurate and easier to handle.
4. The answer is A. The measurement of PAOP should be performed at the end of expiration when the influence of intrathoracic pressure is the least. The presence of PEEP and autoPEEP will result in generation of zone 2 conditions (PALV > PV). The transmission of PEEP or PAW in general has been shown to be a function of the relative compliances of the lung and the C_W. Preload is defined as left ventricular end-diastolic volume (LVEDV). The PAOP is not a measurement of LVEDV but an estimate of left ventricular end-diastolic pressure. Therefore, preload can only be estimated, taking into careful consideration factors that may alter LV compliance (LV hypertrophy, pericardial effusion, high PEEP).

CHAPTER 5

MICHAEL S. LAGNESE AND JOHN M. TRAVALINE

Drainage Tube Management

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to do the following:

- Know the most common indications for various drainage tubes used in the management of critically ill patients.
- Know the methods of insertion of various drainage tubes and how to maintain their proper function.
- Recognize the potential complications associated with drainage tubes used in critical care.

This chapter describes management of the more commonly used drainage tube systems in the critical care setting.

CHEST TUBES

The insertion of tubes into the thorax has been a technique in medicine since ancient times. Hippocrates used metal tubes in the pleural space to drain "bad humors." Hewett in 1876 applied closed chest drainage tube with an underwater seal. During World War II, there was a widespread use of tube thoracostomy for traumatic hemopneumothorax and empyema.

TABLE 5-1

INDICATIONS AND CONTRAINDICATIONS FOR CHEST TUBE INSERTION

Indications
Traumatic hemothorax or pneumothorax (PTX)
Hemopneumothorax
PTX with or without tension
PTX in patient on positive pressure ventilation
Pyothorax
Complicated parapneumonic effusion
Bronchopleural fistula
Chylothorax
Postthoracic surgery
Contraindications
Coagulopathy (relative)
Large bullae mistaken for PTX
Large pleural effusion or PTX with mainstem bronchial occlusion (relative)
Hemidiaphragm elevation (relative)
Massive hemothorax when accumulated blood may aid in hemostasis (relative)

Indications

In general, chest tubes are placed for the drainage of air or fluid from the pleural space.

There are a multiple indications for the placement of a thoracostomy tube. In general, the indications can be divided into placement of the drainage of air from the pleural space or for the drainage of fluid. In the critical care setting, chest tubes are generally placed because of the presence of air or fluid or both in the pleural space. Tubes placed during thoracotomy procedures are inserted in anticipation of air and fluid remaining or collecting within the pleural space following an operative procedure. Table 5-1 lists the indications and contraindications for chest tube insertion.

Insertion Techniques

The size of the chest tube and the insertion site depend on the indication for placing the chest tube.

Once the need for a chest tube is established, the next steps are to determine the size of the chest tube needed and the insertion method. The size of the tube depends largely on the indication of the tube. For example, on the one hand, a small (12–22 Fr) tube is sufficient to drain air from a simple pneumothorax (PTX). On the other hand, a much larger tube (e.g., 36–40 Fr) (Fig. 5-1) is likely needed to manage thick, viscous empyema material.

The insertion site and method are also determined by the indication. For example, if the tube is being placed for free air in the pleural space, the tube is directed apically from the fifth intercostal space in the midaxillary line (Fig. 5-2) or the second intercostal space in the midclavicular line (on the right only). For free fluid, the sixth intercostal space with the tube directed posterobasally may be more suitable. For loculated fluid or air, tube placement is based upon the location of the loculations.[1]

Specific insertion methods include the use of a trocar, blunt dissection, and guidewire technique. The use of a trocar to establish an opening in the chest wall through which a tube

FIGURE 5-1

Two 36-Fr. chest tubes. The top tube has an introducer catheter within it to facilitate placement of the chest tube over a guidewire. The tube shown below is typically placed using a blunt dissection technique.

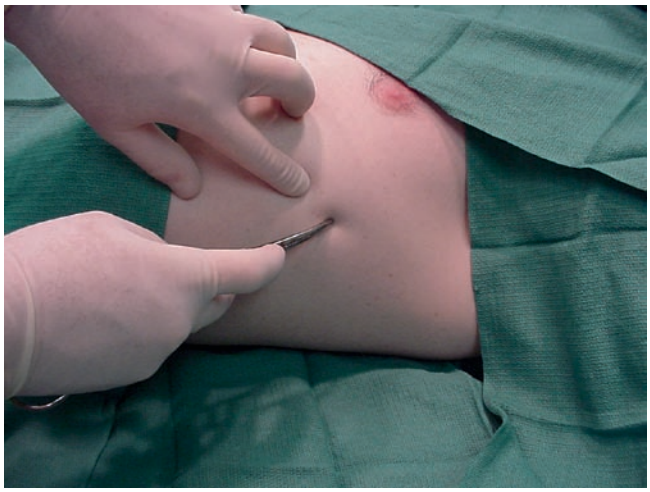

FIGURE 5-2

Chest tube insertion site as shown here is the fifth intercostal space in the midaxillary line.

is placed may be associated with more complications and is generally not favored. Tube thoracostomy using blunt dissection is probably the most commonly employed technique. Guidewire placement of a chest tube is perhaps the least traumatic for a patient but is limited by the size of the tube that can be placed using this technique and the inability to digitally palpate the lung away from the insertion tract. Moreover, if pleural adhesions are present, the blunt dissection technique allows the physician to palpate for such adhesions and thus avoid malpositioning of the tube and injury to the underlying lung.

The guidewire technique involves entering the pleural space with an introducer needle. A guidewire (0.89 mm in diameter) is placed through the introducer needle, and the introducer is removed. A small skin incision is made around the wire, and then dilators are placed over the guidewire into the pleural space to create a tract for tube insertion. Dilators of increasing size are sequentially used to progressively dilate the tract. Finally, the chest tube is inserted with the last dilator (Fig. 5-3). The wire and dilator are then removed, and the tube is secured to the chest wall and connected to the collection device.

Maintenance

Pleural collection devices contain three compartments: a suction control chamber, a water seal chamber, and a collection chamber.

Once the chest tube is inserted and properly secured, it is connected to a pleural collection device (Fig. 5-4). These collection devices have three distinct compartments. The first is a suction control chamber that allows for the regulation of negative pressure applied to the pleural space via the tube. The second is a water seal chamber that allows for the determination of air leakage in the system. The third is a chamber that collects any fluid material that may drain from the pleural space. Once the chest tube is inserted, secured, and attached to a

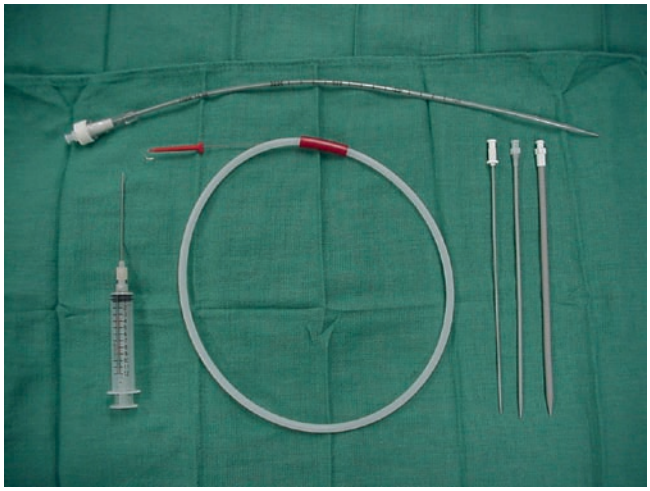

FIGURE 5-3

An introducer needle and syringe, guidewire, dilators, and 14-Fr. chest tube with an introducer catheter within it.

FIGURE 5-4

Pleural collection device.

collection device, usually little maintenance is required. Table 5-2 suggests a checklist guide for the ongoing assessment and care of a patient with a chest tube.

Antibiotics

Pleural space infection caused by a chest tube is rare.

Antibiotic prophylaxis for chest tube insertion is not recommended.

Antibiotic prophylaxis with chest tube insertion is sometimes considered; however, available data generally do not support this practice. Although some studies have shown a lower incidence of infection in some groups of patients, such as those with penetrating chest wounds,[2,3] for other indications, such as spontaneous PTX, antibiotic prophylaxis may be associated with increased complications.[4-6] Antibiotic therapy should be based on suspected or proven infection. The routine use of antibiotic prophylaxis is not warranted in the management of chest tubes.

Fibrinolytic Therapy

Instillation of a fibrinolytic agent into the pleural space may facilitate drainage through a chest tube.

In the management of complicated parapneumonic effusions and empyema, intrapleural streptokinase may be useful. This agent may liquify the viscous material often present in pleural infections and hemothoraces. The typical dose for streptokinase is 250,000 U diluted in 50–100 mL normal sterile saline solution instilled via the chest tube.[7] The tube is typically clamped for 2–4 h before opening it again to drain. There are no systemic effects of the fibrinolytic agent on the systemic coagulation profile when administered intrapleurally. This technique generally results in a dramatic improvement in about one-third of patients, a slight improvement in another third, and no significant effect in the remaining third.

KEY ASPECTS IN EVALUATION OF A PATIENT WITH A CHEST TUBE

Patient assessment (chest sounds, site, etc.)
Look for air leak
Assess chest radiograph
Tube inspection (respiratory variation)
Output assessment

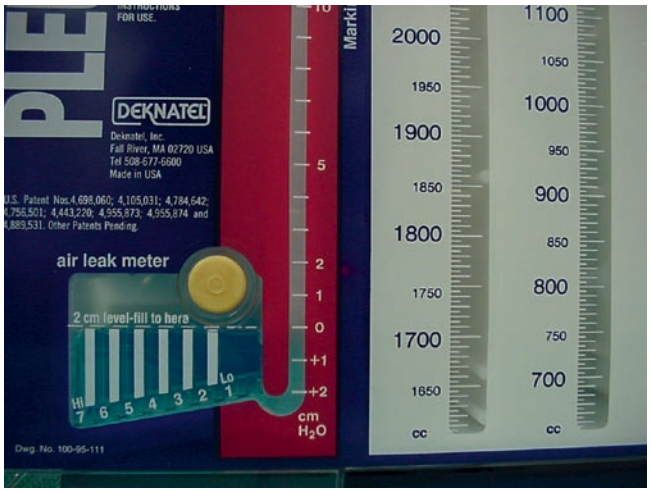

FIGURE 5-5

Closer view of pleural collection device and the water seal chamber used in the determination of air leakage.

Bronchopleural Fistulae

The presence of air in the pleural space most commonly results from disruption of lung parenchyma such that air entering the lungs via the bronchi is in direct communication with the pleural space; this defines a bronchopleural fistula. Although a chest tube may effectively evacuate air from the pleural space, if the defect in the lung parenchyma is large and remains, air flow through the fistulous tract will continue. A chest tube may help to diagnose this problem by allowing observation of bubbling in the water seal compartment of the pleural collection device (Fig. 5-5). Table 5-3 describes grading the degree of air-leak from a bronchopleural fistula.

Complications

The incidence of complications related to chest tubes is approximately 5–25%.[8] Table 5-4 lists many of these complications. Pleural space infection after chest tube removal is ≤5% and is usually related to the underlying disease process. Another rare complication associated with chest tubes is reexpansion pulmonary edema, which results from the removal of a large volume of fluid or air from the pleural space. The clinical manifestations of this complication include pernicious cough and chest tightness during or immediately following the procedure. The chest X-ray may show unilateral changes consistent with pulmonary edema, although contralateral pulmonary edema has also been reported. Generally the symptoms are progressive over 24–48 h, and there is usually complete recovery.[9] The incidence is unknown, but the condition is thought to be uncommon.

TABLE 5-3

GRADES OF AIR LEAKS

Grade 1: infrequent with cough
Grade 2: with every cough
Grade 3: present with some spontaneous breaths
Grade 4: present with every spontaneous breath

TABLE 5-4

COMPLICATIONS OF CHEST TUBES

Improper position
Soft tissue bleeding, intercostal vessel injury
Intercostal nerve damage
Long thoracic nerve (serratus anterior) damage "winged scapula"
Visceral organ and diaphragm damage
Pulmonary edema
Bronchopleural fistula
Infection

The likelihood of reexpansion pulmonary edema is higher when lung reexpansion occurs following the removal of air (more so than fluid), following a long duration (>3 days) of lung collapse, and following the use of negative pressure devices to remove the air or fluid.[10] To avoid this complication, it is generally recommended to remove less than 1 L of fluid within the first 30 min of pleural drainage.

The pathogenesis of reexpansion pulmonary edema is thought to involve anoxic damage to the pulmonary capillary endothelial cells during chronic lung collapse followed by an increased permeability after reexpansion and restoration of blood flow. A sudden and large increase in negative pleural pressure may then lead to transudation and exudation across the capillaries. Reperfusion injury involving free radical formation may also be involved in promoting lung injury.[9]

Removal

Chest tubes are usually removed when an air-leak has resolved for at least 24 h or fluid drainage output is less than 100 mL in a 24-h period.

General guides to help determine when a chest tube is no longer needed include air-leak resolution for at least 24 h on water seal, or fluid or blood drainage of less than 100 mL in a 24-h period.[11] However, these guidelines are not absolute.

Ideally, a chest tube should be removed when pleural pressure is positive. For a patient on positive pressure mechanical ventilation, pleural pressure is maximum during the inspiratory phase of an assisted breath, so the tube should ideally be withdrawn during an inspiratory hold. In a spontaneously breathing patient, one asks the patient to inspire to total lung capacity, then to perform a valsalva maneuver to maximize pleural pressure while the tube is removed. Once the tube has been removed, one should establish an airtight seal of the skin and subcutaneous tissue and apply a gauze dressing to the site.

NASOGASTRIC TUBES

Indications

Generally, NG tubes should be placed in all patients with suspected gastrointestinal bleeding.

Perhaps the biggest role for the nasogastric (NG) tube in the critical care setting is in the management of acute gastrointestinal bleeding (Table 5-5). Generally, a NG tube should be placed in all patients with gastrointestinal bleeding, even if the suspected site of bleeding is in the lower gastrointestinal tract. In upper gastrointestinal tract bleeding, the stomach acts as a pool for blood accumulation from the esophagus, the stomach itself, or even the duodenum because blood will often reflux into the stomach. Placement of the tube in the stomach, therefore, serves as a means to diagnose the problem, allows monitoring of ongoing bleeding and detection of recurrent bleeding, and, in a limited way, can serve as a means for therapy. Gastric lavage may help to determine the rate of bleeding or if bleeding has stopped. In addition, decompression of the stomach (or evacuation) will allow the stomach walls to collapse and possibly aid in gastric hemostasis.

Other uses of the NG tube in critical care include a means for gastric lavage in certain toxic or drug ingestions, decompression of the stomach in cases of gastric distension from air, a means for medication delivery, and a route for nutritional support. In situations in which it is important to clear the stomach of pills or pill fragments, a large diameter tube (Ewald) may be used. For decompression or medication delivery, a Levine tube is advised (Fig. 5-6). For enteral feeding, a duotube is recommended.

NG tubes are removed from the patient once their presence is no longer indicated.

Orogastric tube placement is sometimes necessary in patients with bleeding diathesis, sinusitis, or maxillofacial fractures.

Contraindications to NG tube placement include a bleeding diathesis that may result in uncontrollable nasal bleeding, sinusitis, and maxillofacial fractures. In such cases, the tube may be inserted via the oropharynx.

TABLE 5-5

USES OF NG TUBES IN THE MANAGEMENT OF GASTROINTESTINAL BLEEDING

Determining bleeding source	Gastric lavage
Monitoring rate of bleeding	Gastric decompression

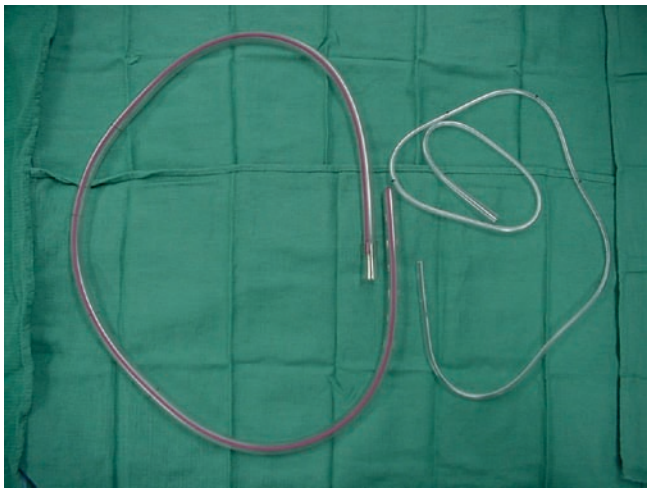

FIGURE 5-6

Nasogastric (NG) tubes: Ewald tube (*left*); Levine tube (*right*).

Insertion Technique

Placement of a NG tube is generally achieved most effectively with the patient in an upright position. Prior to insertion, a lubrication substance should be applied to the distal portion of the tube. Next, an assessment should be made as to which nares will most easily accept the NG tube. This can be done by simple visual inspection of the nares with the use of a flashlight. The NG tube is then gently and slowly inserted through the nares. Maintaining the patient's head in a semiflexed position may facilitate placement of the tube into the hypopharynx and esophagus. The tube is then advanced to approximately 60 cm from the tip of the nose. Markings on the NG tube will indicate the length of tube inserted. Resistance to tube advancement is not usual, and if encountered, indicates that the tube is not passing freely into the esophagus and stomach. If resistance is encountered, the tube should not be forcefully advanced. Rather it should be removed, the patient repositioned, and reinsertion attempted again.

Once the NG tube is advanced into the stomach, confirmation of its position can be obtained by the instillation of a 50 mL bolus of air into the tube with simultaneous auscultation over the patient's stomach; a loud gurgling sound indicates proper placement. In addition, aspiration of gastric contents through the tube can confirm its position within the stomach, as will a radiograph to confirm presence of the tube in the stomach.[12]

Complications

Table 5-6 lists common complications associated with NG tubes.

URINARY CATHETERS

Indications

The chief indication for urinary catheters in the ICU is the need to closely monitor urine output in the critically ill patient. Other indications include urinary obstruction from uretheral stricture or prostatic obstruction. The need to keep the perineum clean and dry because of the presence of surgical wounds in the area or because of the presence of sacral decubitus ulcers is also an important indication for a urinary catheter.

TABLE 5-6

COMPLICATIONS OF NG TUBES

Nasal and throat discomfort	Exacerbating existing bleeding site
GE reflux	Nosocomial pneumonia
Aspiration	Sinusitis
Mucosal trauma	

Insertion Technique

Urinary catheters are available in single-use kits that ensure the sterility of the catheter and provide the necessary drapes, antiseptic swabs, and lubricant. Sterile technique is mandatory in the insertion of these catheters. Insertion begins with the application of an antiseptic cleansing solution to the urethral meatus. Appropriately placed sterile drapes and the use of sterile gloves then allow the lubricated catheter to be advanced through the urethral meatus and into the bladder. Placement in the bladder is confirmed by the urine flow through the catheter. Once positioned in the bladder, a distal balloon at the tip of the catheter is inflated with approximately 10 mL of saline to provide an anchoring action that will hold the catheter in place.

In addition to the above-described technique for transurethral insertion of a urinary catheter, occasionally a supra-pubic approach for bladder catheterization is required. It is best to obtain urologic consultation, however, in order to evaluate the patient and to perform this procedure.

Complications

Complications associated with urinary catheters include trauma to the urethra, either from traumatic insertion or a patient inadvertently pulling on the catheter, patient discomfort, and urinary tract infection.[13,14]

RECTAL TUBES

Indications

Rectal tubes are used in critically ill patients in many clinical situations (Table 5-7). Traditionally, they serve to relieve the discomfort associated with bowel ileus and retained gas and stool. These conditions can be associated with a variety of medical and surgical diseases seen in the ICU. Interestingly, most of these processes are nongastrointestinal in origin.

Frequent and watery stool, particularly in a bedbound patient, is a common indication for the use of rectal tubes.

Perhaps one of the most common uses of the rectal tube is to redirect diarrhea.[15] Frequent or watery stool can be extremely irritating to the perineum and pose significant risk of skin breakdown in this area, thus predisposing to infection; this can occur even when diarrhea is not voluminous. In addition to collection of stool to avoid potential problems related to skin breakdown in the bedbound patient, at times it is important to quantitate the expelled stool in the attached reservoir bag.

Although rectal tubes are generally considered to be among the safer of the procedures performed in the modern ICU, often being used at the discretion of the critical care nurses, there are contraindications to their use (Table 5-8). Generally, contraindications to rectal tubes involve local anatomic or functional abnormalities that might be worsened by an invasive catheter, especially given the nature of the material it is intended to drain. Any real or suspected perianal infectious processes, including abscesses, cellulitis, and fistulae, generally require that the lesion be explored and drained surgically. Adequate drainage of these lesions can be impeded by a rectal tube, even when tubes of small caliber are used.

TABLE 5-7

INDICATIONS FOR RECTAL TUBES

Symptomatic abdominal distension
Retained flatus
Retained stool
Large bowel ileus
Medical/surgical disease
Medication side effects
Stool control
Voluminous diarrhea
Stool quantification

TABLE 5-8

CONTRAINDICATIONS TO RECTAL TUBES

- Absolute
  - Acute surgical abdomen
  - Paralytic ileus
  - Staff convenience
- Relative
  - Local infections of the perineum or rectum
    - Abscess
    - Cellulitis
    - Fistulae
  - Anatomic or functional disorders
    - Hemorrhoids
    - Perforations
    - Fistulas
    - Perineal irritation
    - Perineal edema
    - Rectosigmoid obstruction
      - Stool
      - Tumor

Certain ano-rectal processes such as hemorrhoids, perforations, irritations, edema, or rectosigmoid obstructions of any cause may relatively contraindicate the use of a rectal tube. When any of these disorders is suspected or present, the risk/benefit ratio must be carefully considered before a rectal tube can be safely inserted. Rectal tubes are also contraindicated following any rectal or prostatic surgery unless, of course, a tube has been placed perioperatively by the surgical team as part of the procedure. Last, rectal tubes should not be placed as a mere convenience to spare the time and effort required to care for patients who have voluminous diarrhea or frequent gas or stool expulsion.

Insertion Technique

Although commercial rectal tube kits are available, any soft, flexible catheter of sufficient diameter can be used. Foley urinary catheters are commonly used. Usually, a 22–32 Fr catheter is used for adults. After determination that a rectal tube could benefit the patient, careful examination of the anus and perineum should be done to ensure that no obvious contraindications exist, including a digital rectal examination to verify that the rectal vault is empty. Manual disimpaction of any formed stool should be performed to facilitate tube insertion. The abdomen should also be examined for signs of acute obstruction or other urgent processes that may require a surgical intervention and possibly preclude rectal tube insertion.

Following inspection and palpation of the anus and rectum, a generous amount of water-soluble lubricant should be placed on the tip of the rectal tube. The tube is then introduced gently into the anus. If the patient is conscious and can perform a Valsalva maneuver as the tube is inserted, this will reduce the anal sphincter tone and usually result in a less uncomfortable experience. The tube should be advanced 5–10 cm with the tip directed toward the patient's umbilicus. The ideal position of the tip is just proximal to the rectal vault, as this will help prevent stool and gas from entering and uncomfortably distending the rectum. The tube should be then secured with adhesive tape, and the distal end can be connected to a reservoir collection container. If a catheter with a retention balloon is used as the rectal tube, this should be left deflated, as inflation usually results in eventual expulsion of the catheter by normal rectosigmoid peristalsis.

Maintenance

The length of time the rectal tube is left in place is determined by the specific indication. For intermittent relief of retained gas associated with abdominal distension, the tube should be removed after no more than 30 min, and reapplied at regular intervals or as needed for patient comfort. If the tube has been inserted for stool evacuation or quantification, it may be left in place for longer periods; however, careful and frequent evaluation of the tube's placement and monitoring for mucosal irritation, ulceration, or perforation are required.

Complications

Daily reassessment of the need for continued use of a rectal tube is important. The tube should be removed when there is no longer an indication for its use.

Rectal tubes are not without inherent complications and, as their application becomes more prevalent in the ICU, an increase in the absolute number of complications can be expected. The most common complication is patient discomfort. Sedation and anxiolysis often minimize discomfort, but as the patient becomes more conscious, pain and discomfort may become more prominent. Other real but relatively uncommon complications include rectal mucosal irritation, ulceration, perforation, and necrosis. Infection introduced by a rectal tube is probably very uncommon; however, secondary infection of a breached rectal wall mucosa can occur. Daily reassessment of the indication for the rectal tube is important. The tube should be removed when there is no longer an indication for its use.

SUMMARY

The practice of critical care frequently involves the use of various tubes placed into patients. These procedures are performed mostly for therapeutic indications, as is most evident in the use of chest tubes. Similarly, NG tubes have an important therapeutic role but are also useful in diagnostic monitoring in some cases of upper gastrointestinal bleeding. Rectal tubes also play an important role in both monitoring patients and facilitating their management in the critical care setting.

REVIEW QUESTIONS

1. **A patient with pneumonia is found to have a free-flowing pleural effusion. A thoracentesis reveals serosanguinous fluid that is not particularly viscous. You determine that a chest tube is needed for this patient. Which chest tube size would you select?**
   - **A.** Large-bore (42 Fr.) chest tube
   - **B.** 28-Fr. chest tube
   - **C.** Any size but with a trocar
   - **D.** 12-Fr. chest tube

2. **Which of the following are complications of chest tube insertion?**
   - **A.** Bleeding
   - **B.** Pulmonary edema
   - **C.** "Winged scapula"
   - **D.** All the above

3. **Chest tube removal should be considered in all of the following except when:**
   - **A.** Air-leak through the tube is intermittent.
   - **B.** The lung is fully expanded.
   - **C.** The fluid drainage is less than 100 mL in a 24-h period
   - **D.** The tube is not functional.

4. **Indications for NG tubes include all the following except:**
   - **A.** Gastric lavage in the case of toxic substance ingestion
   - **B.** Gastric decompression
   - **C.** Minimization of gastroesophageal reflux and aspiration
   - **D.** Diagnostic adjunct for gastrointestinal bleeding

5. **Which of the following statements regarding rectal tubes is false?**
   - **A.** The most common indication is convenience for the staff.
   - **B.** Paralytic ileus is a contraindication to their use.
   - **C.** Patient discomfort is the most common complication.
   - **D.** If a catheter with a retention balloon is used, the balloon should be kept deflated.

6. **Concerning urinary tract catheterization, which of the following statements is false?**
   - **A.** Commonly performed to facilitate monitoring urine output.
   - **B.** Should be performed using a sterile technique
   - **C.** Has no role in a patient with ureteral obstruction
   - **D.** May be complicated by a urinary tract infection

ANSWERS

1. The answer is B. For free-flowing, nonviscous fluid in the pleural space, generally a relatively small to medium-sized tube is appropriate. A large tube is not necessary in this case, and trocar insertion techniques are not recommended. A 12-Fr. tube may work but, because of its small lumen, may be prone to obstruction.
2. The answer is D. Bleeding, reexpansion pulmonary edema, and injury to the long thoracic nerve producing a "winged scapula" are all reported complications from chest tube insertion.
3. The answer is A. The presence of an air-leak into the pleural space, as assessed through "bubbling" in the water seal chamber of a pleural collection device suggests that a bronchopleural fistula exists. Even if the leak is intermittent, removal of the chest tube may result in air flowing through the bronchopleural fistula, being trapped in the pleural space, potentially causing PTX and compromising the patient's respiratory status.
4. The answer is C. Gastric lavage, gastric decompression, and management of gastrointestinal bleeding are all important indications for NG tubes. Gastroesophageal reflux and aspiration are potential complications of the use of NG tubes.
5. The answer is A. The presence of a paralytic ileus is a contraindication to rectal tube insertion. Patient discomfort is the most common complication of rectal tubes. Often sedation is helpful, but as a patient becomes more awake, discomfort from the tube is more prominent and limits its continued use. When a catheter with a retention balloon is placed in the rectum, if the retention balloon is inflated, it may facilitate the expulsion of the catheter secondary to normal peristalsis. Therefore, when such catheters are used, the retention balloon should be kept deflated. Rectal tubes should never be used simply for convenience.
6. The answer is C. Urinary tract catheterization is a common procedure in critically ill patients and is used to monitor urine output. Although catheterization should be performed using sterile techniques, the presence of the catheter over a period of time predisposes a patient to a urinary tract infection. Even in patients with ureteral obstruction, monitoring urine output is important.

CHAPTER 6

HENRY H. HSIA

Cardiac Pacing and Defibrillation

CHAPTER OUTLINE

LEARNING OBJECTIVES

After reading this chapter you should be able to do the following:

- Be familiar with the coding of implantable pacemakers and implantable cardioverter-defibrillators (ICDs).
- Understand the basic operations of implantable devices.
- Be familiar with the indications of implantable pacemakers and ICDs.
- Be familiar with the indications for cardiac resynchronization therapy (CRT).
- Be able to systematically evaluate possible device malfunctions.
- Be able to better manage patients with implantable devices.

INTRODUCTION

This chapter is intended to introduce the basic concepts of pacemakers, implantable cardioverter-defibrillators (ICDs), as well as cardiac resynchronization devices. It will discuss the indications and management of patients with implantable devices. The purpose of this chapter is not to provide a comprehensive review of pacemakers and ICDs, but rather to provide basic knowledge for the understanding of implantable devices for cardiac arrhythmia management. It allows a systematic evaluation of possible device malfunction as well as other relevant issues in a critical care setting.

CASE STUDY: PART 1

A 76-year-old man with a diagnosis of sick sinus syndrome (SSS) who underwent a VVIR pacemaker implantation 6 years ago for symptomatic atrial fibrillation and bradycardia presented with palpitations, dizziness, and near-syncope.

What additional clinical information would you like to have?
How would you deal with the abnormalities?
Two ECG tracings showed the following:

BASIC PRINCIPLES

To evaluate patients with implantable devices, physicians must consider the "system." The implantable "system" typically includes a pulse generator (pacemaker or ICD), the lead(s), the myocardium, and the connections/interface between those components.

In addition, the implantable systems also consist of both the "hardware" (leads, myocardium, and implanted generator) and the "software" (programmable device parameters). A comprehensive evaluation requires determination of the appropriateness of pacemaker behaviors or ICD responses, as well as a systematic analysis of all components of the implanted "system."

The implantable "system":
1. The device: pacemaker or ICD
2. The lead(s)
3. The lead–heart interface and the lead connections

A detailed review of the patient's underlying cardiac diagnoses and arrhythmia history is essential.

Since the behavior and function of the implanted devices are often influenced or altered by patients' underlying cardiac and medical conditions, a "holistic" approach in management is recommended. Various factors such as hypoxia, electrolyte imbalance, ischemia, sepsis, heart failure (HF), or drug toxicity may alter cardiac depolarizations and repolarizations, induce arrhythmias, as well as change thresholds. The physician should be familiar with the patients' bradycardia indications for back-up pacing or the tachyarrhythmia indications for ICD implantation. Information on the manufacturer and model number of the device must also be available for interrogation using the dedicated programmer. Finally, a careful history should be obtained; the questions are geared to detect any symptoms that may suggest possible device malfunction or inappropriate interactions, such as pacemaker syndrome, palpitations, dizziness, syncope, or shock delivery.

History:
1. Underlying cardiac and arrhythmia diagnoses
2. Indications of device implantation
3. Name and model of the device
4. Symptoms of possible device malfunction

The physical examination should start with the patient's basic vital signs. An elevated body temperature may suggest an underlying infection along with an "appropriate" sinus tachycardia. An elevated resting heart rate may reflect new onset of atrial fibrillation/flutter, an "inappropriate" pacemaker activity response, or pacemaker-mediated tachycardia (PMT). High respiratory rate can induce a tachycardia in patients with minute-ventilation (MV)-based rate modulation devices. An examination for signs of local venous obstruction, atrioventricular (AV) dissociation, high filling pressure, or congestive HF is also crucial. The device pocket should also be evaluated for signs of inflammation, infection, hematoma, and erosion.

The 12-lead ECG provides valuable information on the patient's underlying heart disease (prior myocardial infarction, ventricular hypertrophy, and long QT syndrome), intrinsic rhythm (sinus bradycardia, atrial fibrillation, or flutter), underlying conduction disturbances (PR prolongation, bundle branch block [BBB], and heart block), and the current operating mode of the device. It is important to recognize that the patient's arrhythmias and the "device-rhythm" interactions may be intermittent, such as "mode switch" induced by paroxysmal atrial fibrillation, antitachycardia pacing (ATP) triggered by ventricular tachycardia (VT), or pacing for intermittent heart block and bradycardia. Therefore, continuous electrocardiographic monitoring is essential in all the patients with suspected device malfunction.

Magnet application causes a temporary asynchronous (nonsense) operation of a pacemaker with asynchronous pacing. It is also used to perform a threshold margin test (TMT) to verify, capture, and display the programmed pacing mode and intervals. Magnet application can also induce specific "beginning of life" (BOL), "elective replacement index" (ERI) or "end-of-life" (EOL) pacing rate responses used to check battery status. Each model of pacemaker has its unique ERI and EOL rate responses and can be referenced. Although the magnet test is a part of routine evaluation in patients with pacemakers, it is generally avoided in patients with ICDs. This is because the asynchronous magnet mode temporarily deactivates tachyarrhythmia detection of the device; furthermore, a prolonged magnet application may permanently deactivate some models of ICDs.

MANAGEMENT OF PATIENTS WITH PACEMAKERS

NBG Code

Pacemaker operation can vary from beat-to-beat depending on the mode, programmed parameters, and patients' underlying rhythm. As a result of a joint approach of NASPE (North American Society of Pacing and Electrophysiology) and the BPEG (British Pacing and Electrophysiology Group), a NBG (NASPE and BPEG Generic) Code was developed (Table 6-1). This is a three-to-five positions code to designate the programmed functionality of the device. The first letter designates the chamber(s) paced: *A* for atrium, *V* for ventricle, *D* for pacing capability in both atrium and ventricle, and *O* if the unit is deactivated without pacing. The second letter designates the chamber(s) sensed: *O* for asynchronous operation without sensing. The third letter describes the unit's response to a sensed signal: *I* indicates that the pacing is inhibited by a sensed event; *T* indicates that a pacing stimulus is triggered by a sensed event; and *D* represents an operating mode that a stimulus may be inhibited by a sensed event in the same chamber and is triggered by a sensed event in the opposite chamber. For example, a *DDD* senses an atrial signal that triggers a ventricular pacing (VP) output; however, a sensed ventricular signal will inhibit the pacing output in the ventricle. The fourth letter most commonly describes the degree of programmability and rate-modulation capability. Position V of the NBG Code is reserved for devices with antitachycardia functions and is applicable only to current ICDs.

Since the development of pacemakers in the early 1960s, the goals of pacing therapy have evolved from basic pacing support to sustain life to optimizing physiologic functions using rate responsive pacing. The pacemakers have developed from VOO to DDDR systems. Most pacemakers today have activity-responsive, rate-modulating capability that reacts to the patient's physiologic demand. An example of an activity response curve is illustrated in Fig. 6-1. Many activity sensor technologies have been developed, but only a few have been deployed successfully. The most popular activity sensors are based on the piezoelectric effects. Distortion of piezoelectric crystals can generate electric signals as indirect measures of the patient's physiologic activity demand. In response to chest muscle activities (upper body/arm movement) or motion (changes in inertia/momentum), a vibration sensor or an accelerometer will adjust the pacing rate according to the programmed "threshold" and the "slope" (Fig. 6-2). An alternative activity sensor is based on MV measured by the changes in the transthoracic impedance over time. An increased MV is translated to an increased physiologic demand and pacing rate.

Indications for Pacemaker Implantation

Indications for permanent pacemaker implantation can be grouped into several categories. These include (1) acquired AV block, (2) chronic fascicular block, (3) AV block associated with acute myocardial infarction, (4) sinus node dysfunction, and (5) carotid sinus hypersensitivity and neurally-mediated syncope. Other newer indications for pacing are continually expanding, such as biventricular pacing in cardiac resynchronization therapy (CRT) for

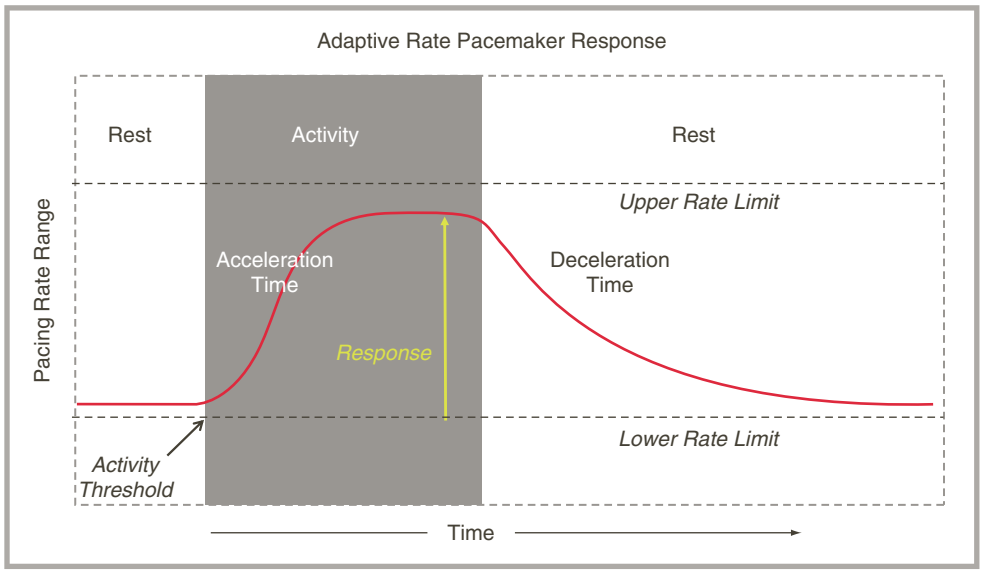

FIGURE 6-1

Adaptive rate response: the *X*-axis is the time and the *Y*-axis is the pacing rate. As the patient's physical activity changes from rest to active states, the pacing rate increases from the lower rate limit towards the upper rate limit, following a programmable acceleration and deceleration time profiles.

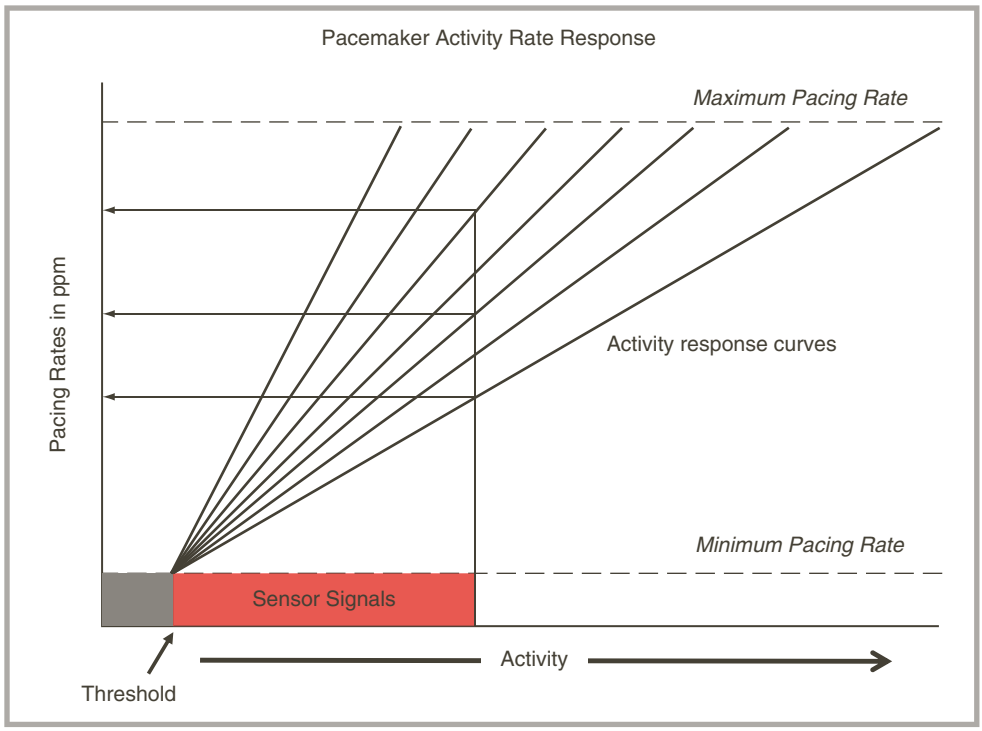

FIGURE 6-2

Activity response curves. The *X*-axis is the activity level and the *Y*-axis is the delivered pacing rate. As the sensor signals rise beyond the threshold, different pacing rates result, depending on the amplitude of sensor signals and the slopes of the activity response curves. Higher slope and lower threshold result in a higher pacing rate for any given activity level. The patient's activity response can be individualized by selecting a particular activity response curve and activity threshold.

symptomatic HF. In general, the decisions about the need for a pacemaker are influenced by the presence and absence of symptoms that are directly attributable to bradycardia or heart block. Other considerations for pacing therapy are prophylactic, such as in patients with chronic multifascicular block who present with syncope, or the development of new BBB in the setting of acute myocardial infarction.

The long-term prognosis of survivors of acute myocardial infarction who develop conduction defect is related primarily to the extent of myocardial damage. Indications for pacing in this setting do not necessarily depend on the presence of symptoms. The risk of developing complete heart block following acute myocardial infarctions can be predicted based on the results of several large studies. The presence (new or preexisting) of any of the following conduction disturbances was considered as a risk factor: first-degree AV delay, second-degree AV block (Mobitz I or II), hemiblock (left anterior or posterior fascicular block), or right or left BBB. Each electrocardiographic risk factor was assigned a score of 1 and a risk score can be calculated as the sum of all risk factors. The incidence of complete heart block

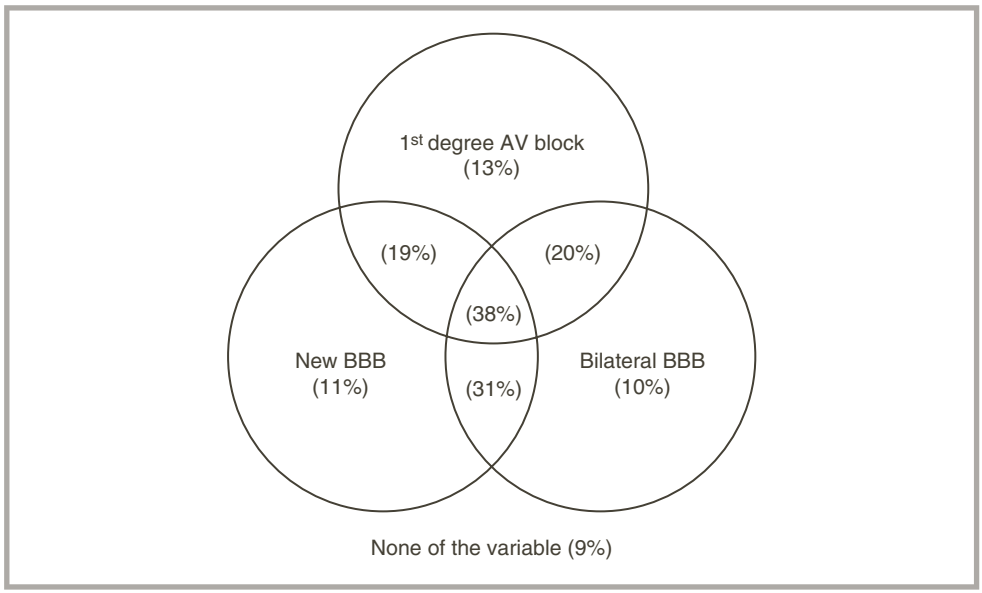

FIGURE 6-3

Risk of developing complete heart block in acute myocardial infarction. "Bilateral BBB (bundle branch block)" includes right BBB with either left anterior fascicular block (RBBB + LAFB), or left posterior fascicular block (RBBB + LPFB); "new BBB" includes the development of any new bundle branch aberrancy associated with an acute myocardial infarction.

occurred as follows: 1.2–6.8% (risk score 0), 25–30.1% (risk score 2), and the risk increased to greater than 36% for higher scores (Fig. 6-3).

In addition, the decision to implant a pacemaker for conduction defects complicating an acute infarction depends on the *location* of the myocardial infarction and the *type* of conduction disturbances. An inferior infarction is often associated with an increased vagal tone and AV node ischemia with a lesser degree of Purkinje system necrosis. Even in the presence of complete heart block, the conduction disturbance is generally at the nodal level that improves with time. An adequate escape rhythm is commonly available that responds to autonomic maneuvers such as atropine or catecholamine administration. However, an anterior myocardial infarction involving the septal arteries causes necrosis of His bundle or bundle branches in addition to extensive myocardial damage. Complete heart block may develop suddenly with a widened QRS complex escape rhythm and severe bradycardia that frequently does not respond to atropine. Pacing is indicated in patients who developed a *new* high-grade AV block, complicating anterior myocardial infarctions.

Although peri-infarction conduction defects have been associated with an unfavorable outcome and an increased incidence of sudden death, pacing therapy has not improved the overall prognosis. This probably reflects the overwhelming negative impact on mortality by the extensive myocardial damage. The presence of conduction defect in the setting of acute infarction identifies patients with large myocardial necrosis and ischemic burden. These patients are at risk for not just the development of complete heart block but also ventricular tachyarrhythmia and hemodynamic deterioration.

Pacing System Timing Operation

Pacemakers sensing and pacing operations are determined by a series of timing intervals (Fig. 6-4). These timing intervals are usually expressed in millisecond (ms), and are often, but not always, programmable. The physicians should be familiar with the nomenclature and definition of the timing intervals, as well as the basic rules that govern their behaviors.

The lower and upper rate intervals define the lowest and the fastest rates that the pacemaker will pace. Refractory period is the interval initiated by a sensed or paced event. During the refractory period, signals are either "nonsensed" or ignored, to prevent inappropriate inhibition by cardiac or noncardiac signals. Blanking period is the interval of time following a paced output. It constitutes the first portion of the refractory period during which the device is completely "blanked" to any signal. It is designed to prevent oversensing of its own pacing stimuli. The upper sensor rate interval (maximum activity rate) defines the shortest interval (highest rate) the pacemaker can pace as dictated by the sensor (AAIR, VVIR, or DDDR modes).

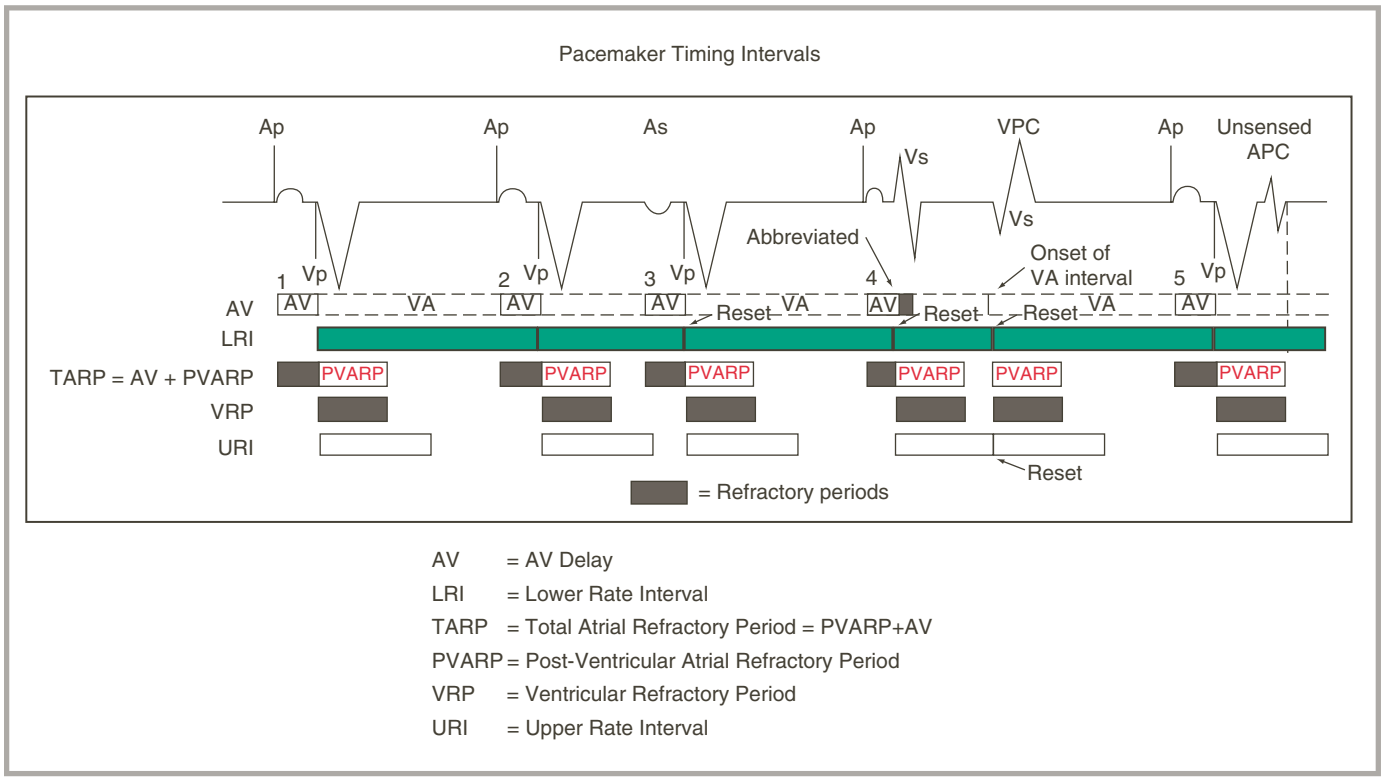

FIGURE 6-4

Pacemaker timing operation. An example of the sensing and pacing behaviors of a dual-chamber pacemaker in DDD mode. A series of timing intervals that govern interactions between the pacing system and patient's intrinsic rhythm.

In a typical DDD(R) mode, an atrial sensed or paced event (As, Ap) *triggers* the programmable AV interval (AV). A VP stimulus is delivered at the end of the AV unless it is *inhibited* by a ventricular sensed signal (VS) (Fig. 6-4). A ventricular event (VS or VP) *triggers* various refractory periods as well as the VA interval (VA), which is determined by the programmed lower rate (LRI). The subsequent atrial pacing is *triggered* at the end of VA unless it is *inhibited* by a spontaneous atrial event.

Pacing Mode Considerations

Choice of pacing mode depends on many factors: sinus chronotropic response, status of the AV conduction, and the presence of chronic vs. paroxysmal atrial arrhythmias. In patients with chronotropic insufficiency, i.e., inadequate heart rate response to activity or demand, a rate-adaptive, activity-responsive pacing mode is recommended. In patients with AV block, dual-chamber pacing is the mode of choice to maintain AV synchrony. Data strongly support the benefits of preserving AV synchrony, so as to reduce the risk of atrial fibrillation, strokes, and congestive HF (Table 6-2). In patients with paroxysmal atrial arrhythmias, atrial (physiologic) pacing may be effective in preventing arrhythmia recurrence. Thus, DDD or DDDR mode is preferred over VP alone. Dual-chamber pacing has also been shown to provide an improved cardiac output and exercise tolerance, as well as avoiding AV dissociation and pacemaker syndrome. Conversely, VVI pacing is ideal in patients with chronic atrial fibrillation and intermittent bradycardia. VVIR pacing is recommended for the subset of patients who are active and would benefit from activity-responsive pacing due to "relative" bradycardia for their physiologic demands (Fig. 6-5).

However, several recent trials have demonstrated that ventricular desynchronization imposed by right ventricular (RV) pacing increases the risk of developing HF, especially in

TABLE 6-2

CLINICAL OUTCOMES OF CHRONIC RV PACING

	DANISH II[3]	*CTOPP*[28]	*DAVID*[29]	*MOST SUBSTUDY*[4]
	AAI(R) VS DDD(R)-SHORT AV VS DDD(R)-LONG AV	**DDD/AAI(R) VS VVI(R)**	**DDD(R) VS VVI**	**DDDR VS VVIR**
HF Hospitalization	high proportion of RV pacing ↓ LV function	Not measured	Increased death or HF hosp with >40% RV-pacing in DDDR group	2.6-fold ↑ risk with >40% V-pacing in DDDR
Hemodynamic Performance	DDDR pacing ↓ LA dilation and ↑ RV pacing ↓ LV function	mostbenefit from physiologic pacing	Not measured	dyssynchrony imposed by RV-pacing ↑ in patients with LV dysfunction

Data from [3,4,27,28]

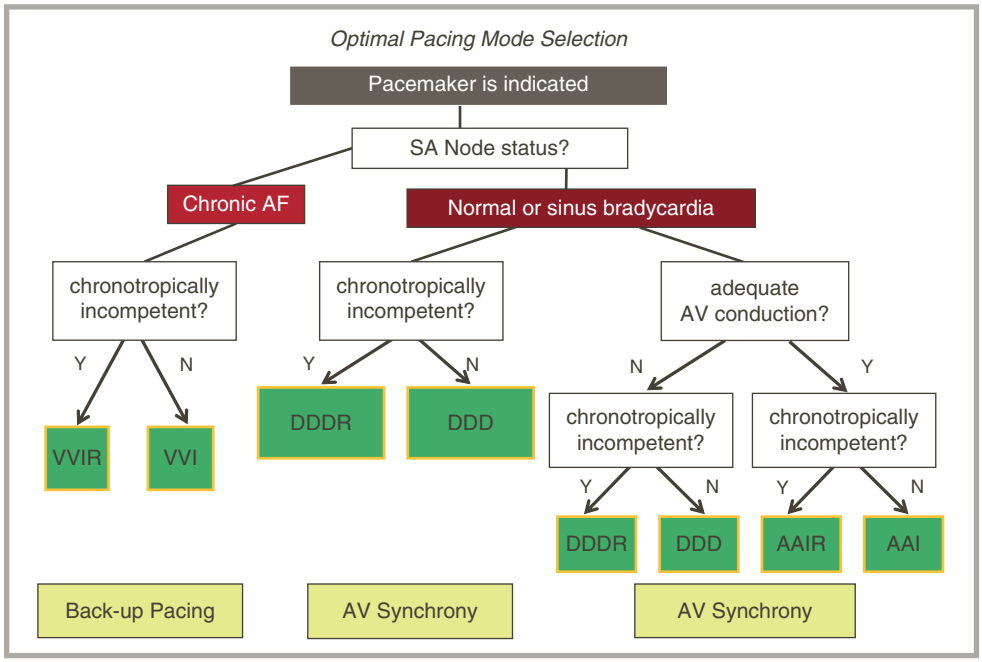

FIGURE 6-5

Pacing mode selection. The optimal choice of pacing mode depends on several factors. One must consider the status of patient's chronotropic response, presence or absence of heart block, ventricular function, and presence of chronic vs. paroxysmal atrial arrhythmias. In patients with chronotropic insufficiency, a rate-adaptive, activity-responsive pacing mode is recommended. In patients with atrioventricular (AV) block, dual-chamber pacing to maintain AV synchrony is essential. In patients with paroxysmal atrial arrhythmias, atrial (physiologic) pacing may be effective in preventing arrhythmia recurrence. In addition, biventricular pacing may be considered in patients with systolic dysfunction.

patients with impaired systolic function (Fig. 6-6). Biventricular pacing provides significant improvements in both subjective and objective hemodynamic parameters compared with RV pacing in this patient population.[1-4]

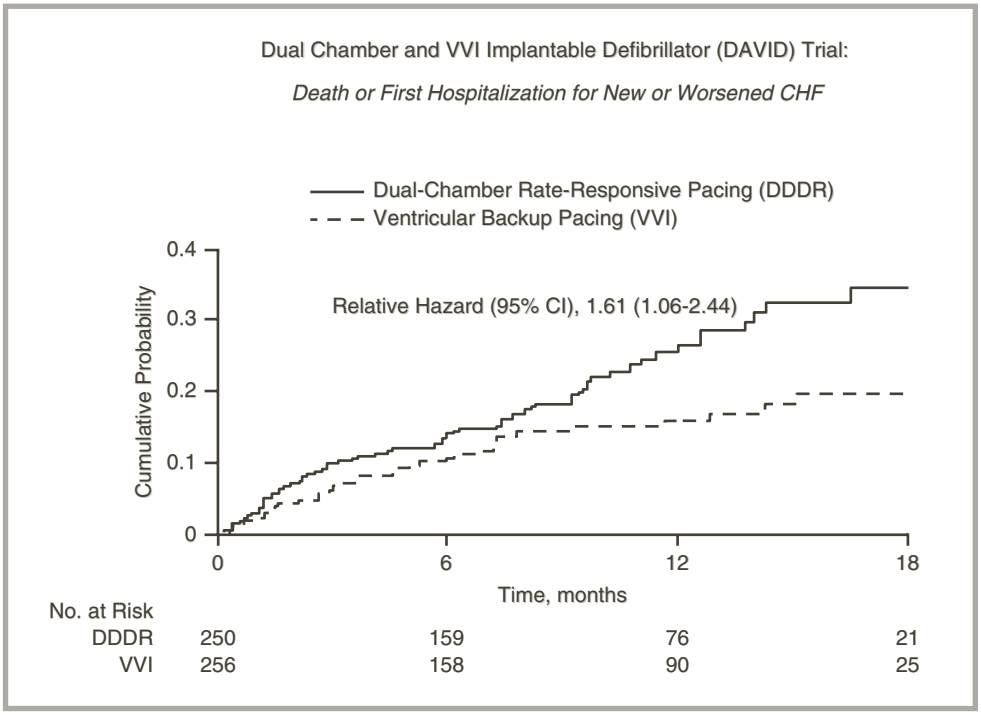
AMS (automatic mode switch) is a function available in the newer generations of dual chamber pacemakers. In patients with atrial arrhythmias, the device can detect the "inappropriate" atrial high rate and "mode-switches" from DDD/DDDR to either VVI/VVIR or DDI/DDIR modes as to avoid rapid atrial sensing (AS) and tracking during episodes of atrial fibrillation, flutter, or atrial tachycardia. Selecting pacemakers with AMS function should be considered in patients with a history of paroxysmal atrial tachyarrhythmias.

CASE STUDY: PART 2

The CASE STUDY ECG showed the presence of sinus P waves. The more appropriate pacing mode selection should be a DDDR mode with a dual chamber pacemaker implantation in an elderly patient with SSS and likely sinus node dysfunction. The DDDR mode would provide physiologic AV synchrony and activity rate response.

FIGURE 6-6

The dual chamber and VVI implantable defibrillator (DAVID) trial. A total of 506 patients with standard indications for implantable cardioverter-defibrillator (ICD) therapy were enrolled. All the patients had LVEF ≤40%, without bradycardia pacing requirement or persistent atrial arrhythmia. The composite end point is death or hospitalization for congestive heart failure (HF). One-year survival free of the composite end point was 83.9% for patients treated with VVI-40 compared with 73.3% for patients treated with DDDR-70 (relative hazard, 1.61). In this patient population, dual-chamber pacing may be detrimental; furthermore, percent RV pacing has been shown to be a continuous variable and independent predictor of end points of death or HF hospitalization.



Pacemaker malfunction:
1. Undersensing
2. Oversensing
3. Failure to pace
4. Failure to capture
5. Altered pacing rate
6. Undesirable interaction

Pacemaker Malfunction

Proper approach to a patient with suspected pacemaker malfunction begins with the understanding of the bradycardia pacing indications and the underlying intrinsic rhythms (atrial arrhythmias, chronotropic competence, and status of AV conduction). Physicians must consider all components of the pacing "system" that include the generator, the lead(s), the myocardium, and the connections between the lead(s) and generator or the interface between the lead(s) and cardiac tissue. A methodical analysis is required for both "hardware" and "software" of the system. Pacemaker malfunction can be categorized to (1) undersensing, (2) oversensing, (3) failure to pace, (4) failure to capture, (5) altered pacing rate, and (6) undesirable interactions.

A 12-lead ECG with magnet application and a long rhythm tracing should be obtained. Device malfunction is often intermittent and a comprehensive interrogation of the programmed parameters and the measured data is essential. High lead impedance (resistance) suggests "obstruction" of current flow, such as in the case of lead (conducting wire) fracture. Conversely, low lead impedance with high current drainage suggests "leakage" of current, such as in the case of lead insulation failure (Fig. 6-7). In devices with intracardiac electrogram (EGM), high-frequency "noise" during manual manipulation of the pacing system may imply lead fractures or defective/loose connections with "make–break" contact potentials. Abnormal, variable amplitude and morphology of the EGM may indicate unstable lead position or dislodgment. In addition, a chest X-ray should be obtained to confirm lead position and examine lead integrity (Fig. 6-8). A discontinuity in the conducting element implies lead fracture and a lead lucency may represent a breach of insulation.

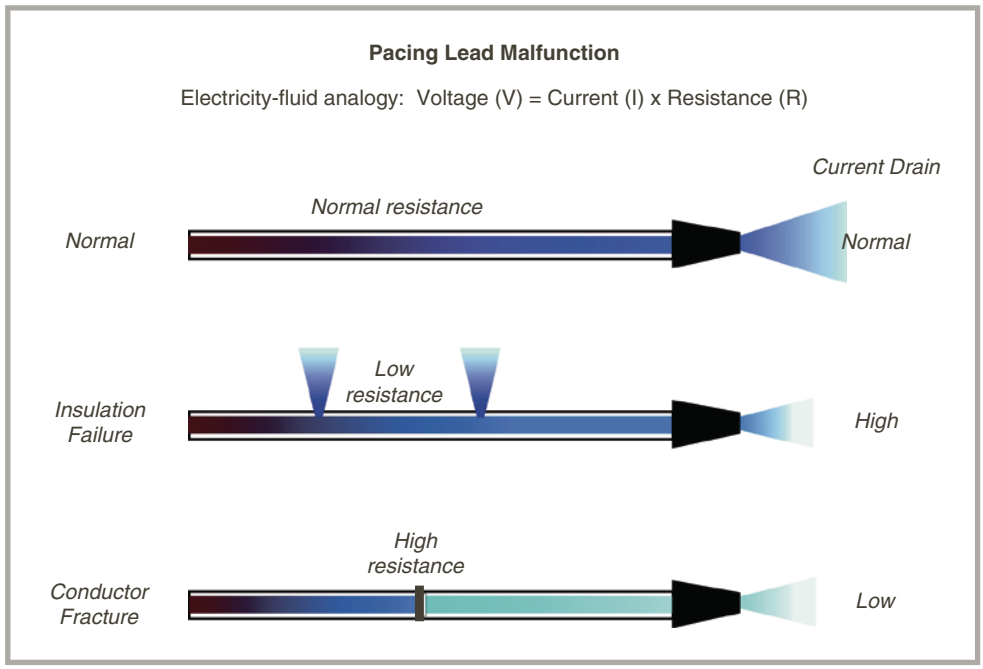


FIGURE 6-7

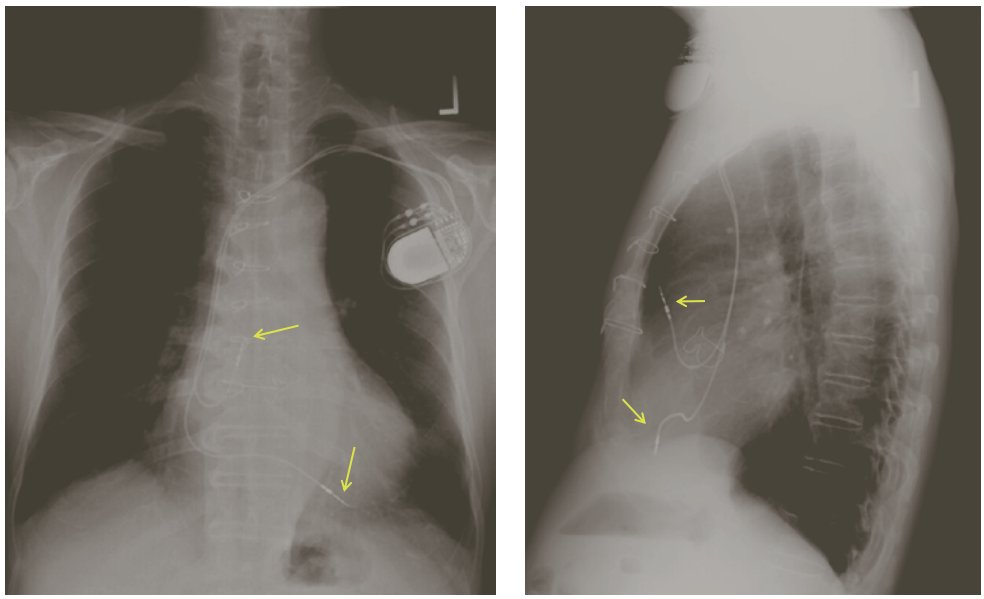
A diagrammatic representation of lead malfunction. A lead is similar to a garden hose using water for irrigation. With Ohm's law ($V>IR$), impedance (resistance) can be used to assess the integrity of the pacing lead. Insulation failure results in a higher current (fluid) leakage and a lower resistance, with less current (fluid) reaching the end (myocardium). Lead fracture results in low current flow associated with a high resistance. Both types of malfunction can be intermittent.



PA Lateral

FIGURE 6-8

A standard PA and lateral chest X-ray in a patient with an implanted dual chamber pacemaker. The atrial and ventricular leads (*arrows*) are in their typical locations of right atrial appendage and right ventricular (RV) apex.

Undersensing

"Undersensing" refers to the presence of inappropriately timed pacing stimuli due to "nonsense" of intrinsic P or R waves. This results in a faster than expected paced rate with more pacing events. Such asynchronous pacing could result in the induction of new arrhythmias such as atrial fibrillation or ventricular tachyarrhythmia from premature atrial depolarization, or "R-on-T" phenomenon. The most common cause of "undersensing" is lead dislodgment with failure to sense intracavitary signals (Fig. 6-9). Other causes of inadequate electrogram amplitude include myocardial infarction, scarring, and local fibrosis at the lead tip-tissue junction. Some drugs or electrolyte imbalance may also influence the signal quality. Occasionally, improper programming of inadequate sensitivity or inappropriately long "refractory periods" may also result in apparent "undersensing." During sinus tachycardia, intermittent atrial "undersensing" may occur as rapid atrial rate encroaches upon the atrial refractory periods (Fig. 6-10). This is described as "pacemaker Wenckebach" or "upper rate behavior" of dual chamber pacemakers.

Undersensing: inappropriately timed pacing spikes due to nonsense of intrinsic signals.

1. Lead dislodgment
2. Poor electrogram signals
3. Inappropriate programming
4. Lead insulation or conductor defect
5. Connector defect
6. Component failure

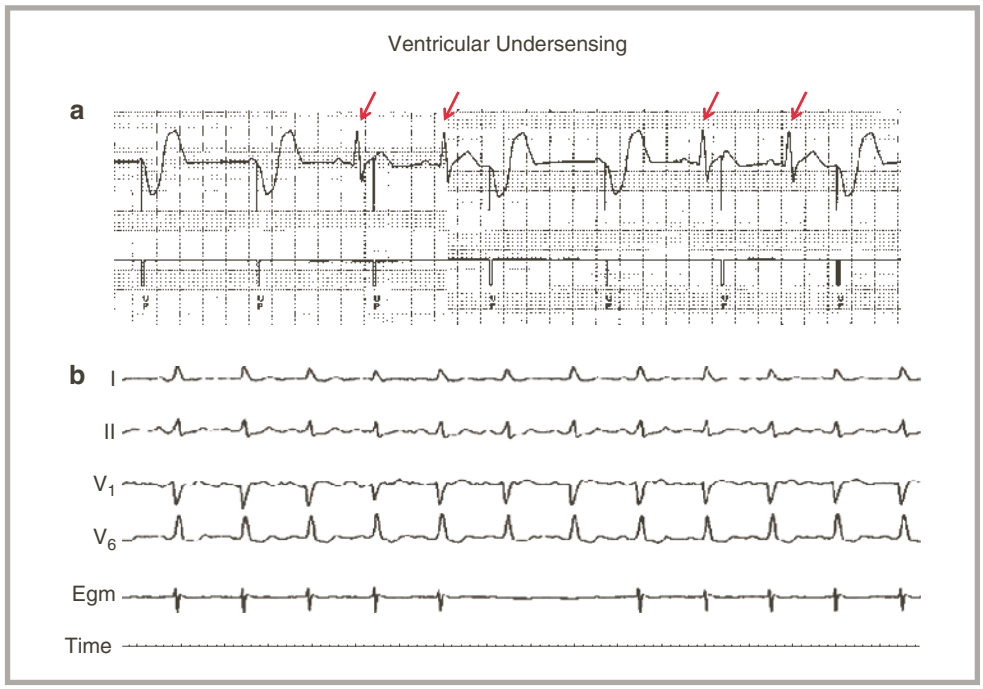


FIGURE 6-9

Ventricular undersensing. *Panel A*: AV dissociation without atrial tracking was present. The pacemaker is programmed in the VVI mode. Inappropriately timed pacing artifacts are present after intermittent failure to sense the intrinsic QRS (*arrows*). *Panel B*: the intracardiac electrogram (EGM) recordings that demonstrate intermittent loss of sensed signals.

FIGURE 6-10

Pacemaker Wenckebach. Apparent atrial "undersensing" with *upper* rate behavior during sinus tachycardia. The rapid atrial rate impinges on the atrial sensing (AS) refractory periods that results in atrial "drop-outs" and intermittent atrial "undersensing." The intracardiac markers that demonstrated AS with ventricular pacing (VP). The top tracing showed 1:1 AS and tracking. The bottom tracing showed intermittent atrial undersensing in the refractory periods (AR).

Oversensing

"Oversensing" refers to the absence of pacing artifacts due to inhibition of "inappropriately" sensed signals or artifacts. This results in slower than expected heart rate with fewer pacing outputs. "Oversensing" may be caused by lead dislodgment or poor positioning with sensing of far-field signals. A dislodged atrial lead or an atrial lead placed too close to the tricuspid valve may sense far-field ventricular signals with subsequent atrial inhibition (cross talk). "Oversensing" is often intermittent and one must exclude the possibility of a lead fracture (Fig. 6-11). Sensing of the "make–break" potentials generated by intermittent contacts of fractured wires can be provoked by manipulations of the generator or surrounding tissues (arm movement).

Other cardiac, extracardiac, or nonphysiologic signals can also contribute to oversensing. In general, unipolar leads are more prone to oversensing than bipolar leads due to the large sensing field (Table 6-3). Unipolar system senses and paces between the intracardiac distal tip of the lead and the pulse generator. Bipolar leads have both the electrodes located at the distal tip within the chamber (Fig. 6-12, Table 6-3). Myopotential oversensing of muscle artifacts with pacing inhibition and asystole may result in syncope and can be observed in patients with unipolar lead systems (Fig. 6-13). Occasional, inappropriate "atrial tracking" with rapid VP may occur in a dual chamber system. Again, this phenomenon may be elicited by arm motion or chest muscle contraction. EMI is another important cause of nonphysiologic signals. This is a crucial topic relating to both pacemaker and ICD and will be discussed at the end of this chapter.

Oversensing: absence of pacing due to inhibition of "inappropriately" sensed signals.
1. Inappropriate programming
2. Lead fracture
3. Skeletal muscle artifacts
4. Electromagnetic interference (EMI)
5. Lead dislodgement
6. Repolarization potential

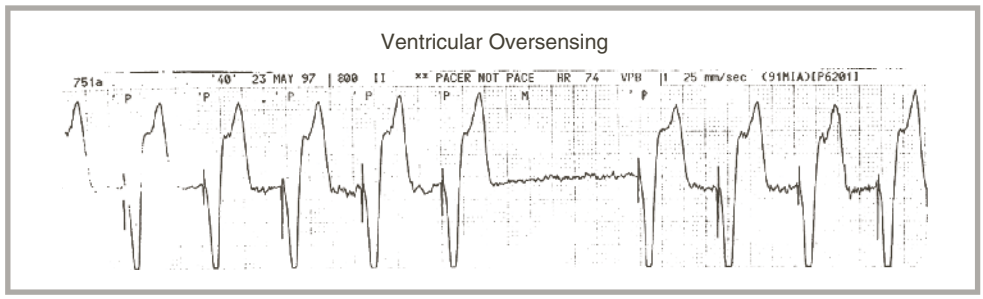

FIGURE 6-11

Oversensing associated with a lead fracture. Intermittent "make–break" potentials generated by contacts of the fractured lead elements were sensed as intrinsic signals. The pacing intervals were "reset" and pacing outputs were inhibited. The pauses were not multiples of a basic pacing interval suggesting oversensing rather than failure to pace.

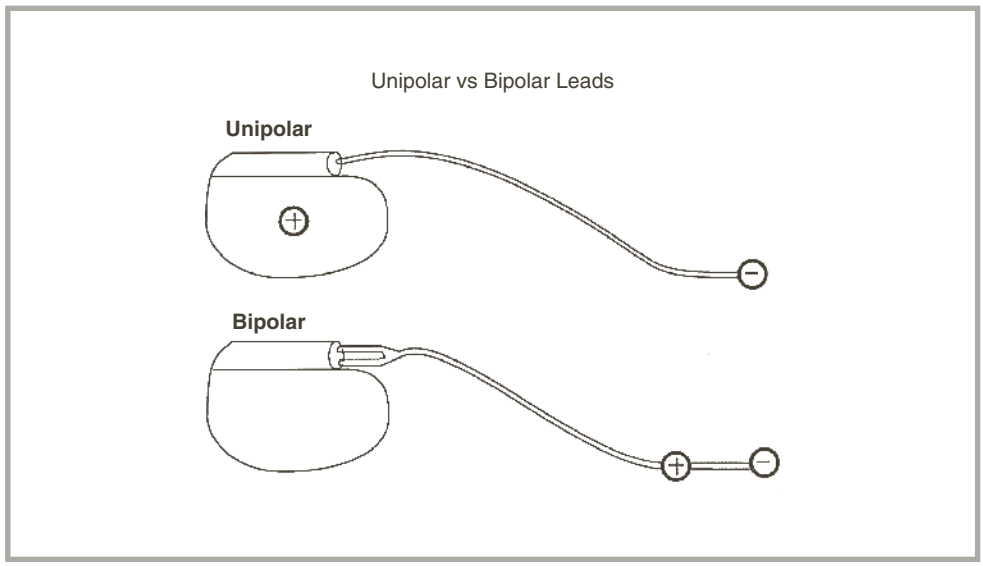

FIGURE 6-12

Unipolar vs. bipolar lead systems. Unipolar lead senses and paces between the intracardiac electrode (anode) with the pulse generator itself as the cathodal electrode. Bipolar leads have both anodal and cathodal electrodes located at the distal tip within the chamber of interest. Unipolar lead systems have a simpler design and construction compared with the bipolar leads, but are subjected to greater sensing interference.

TABLE 6-3

UNIPOLAR VS. BIPOLAR LEADS

UNIPOLAR LEADS	BIPOLAR LEADS
Large pacing artifacts	Small pacing artifacts, T waves
Myopotential oversensing	Less muscle inhibition
Pocket stimulation	Less pocket stimulation
Less stiff, smaller size	larger size
Simple design, more reliable, better longevity	Less cross talk, oversensing
EMI	EMI protected

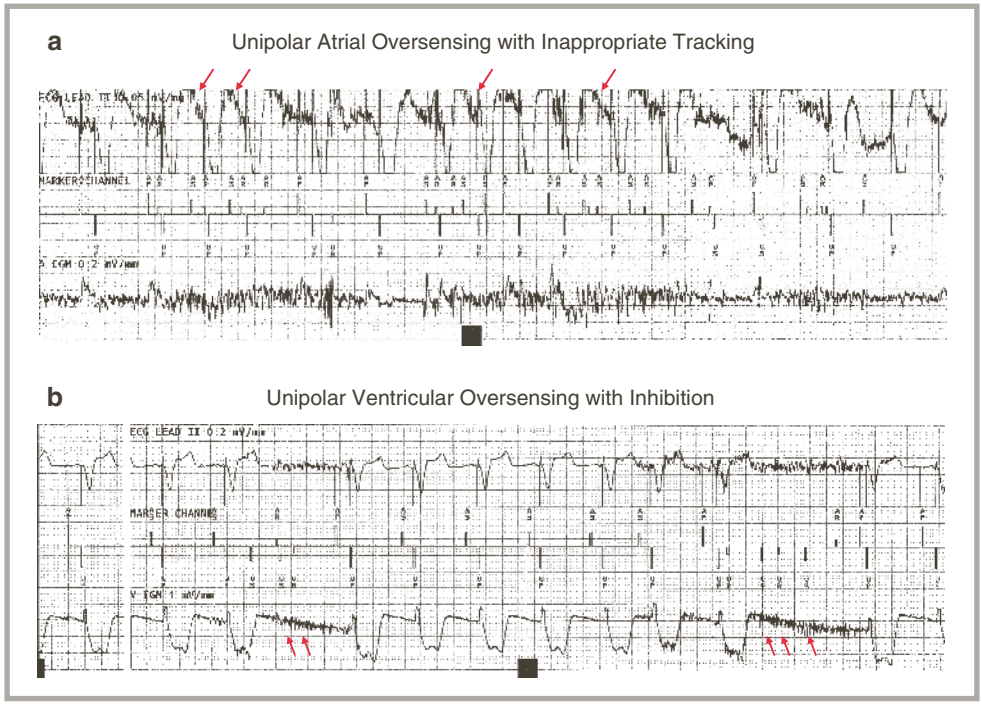

FIGURE 6-13

Myopotential oversensing of unipolar lead systems. Unipolar lead system may result in both oversensing inhibition and inappropriate tracking and pacing. (**a**) The surface ECG showed motion artifacts and the intracardiac recordings showed myopotential oversensing of skeletal muscle artifacts. Inappropriate atrial oversensing (AS, AR) and VP (*arrows*) result. (**b**) Myopotential oversensing on the ventricular lead (VS, VR) results in pacing inhibition and a pause (*arrow*).

Occasionally, repolarization potentials following either spontaneous or paced complexes may be detected, particularly in patients with prominent T waves or unipolar lead systems. This phenomenon may be further exacerbated by electrolyte imbalance, antiarrhythmic drugs, and high rate pacing at high outputs (Fig. 6.14). Similar to the issues in "undersensing," "oversensing" may occur with inappropriate programming. A too sensitive setting or an inappropriately short "refractory period" may result in T waves or myopotential interference.

The CASE STUDY ECG showed both "undersensing" (top) with more than expected pacing stimuli, as well as "undersensing" (bottom figure) with fewer than expected pacing outputs with pauses. Such sensing abnormalities raise clinical suspicions of lead dislodgement or loss of lead integrity. A chest X-ray is recommended to exclude lead dislodgement. Device interrogation showed a breach of insulation with impedance measurements of <300 Ω. A ventricular lead revision with a simultaneous upgrade to a dual chamber system was recommended.

Failure to Pace

Failure to pace: absence of pacing stimulus at the expected interval.
1. Lead and generator not connected
2. Complete lead fracture
3. Battery depletion
4. Hysteresis, sleep rate
5. Oversensing
6. Component failure

"Failure to pace" indicates absence of pacing stimulus at the expected time interval. The most common cause is "oversensing" inhibition or misinterpretation of the electrocardiographic tracings. Often, "hysteresis" or "sleep function" of the device may be activated and the pacemaker appears to pace at a slower than expected rate (see below). Other reasons of "failure to pace" include complete lead fracture, battery depletion, or a loose pin connection (Fig. 6-15). Rarely, component defects or oversight of connecting the leads to the generator at implant can result in the absence of stimulus artifact.

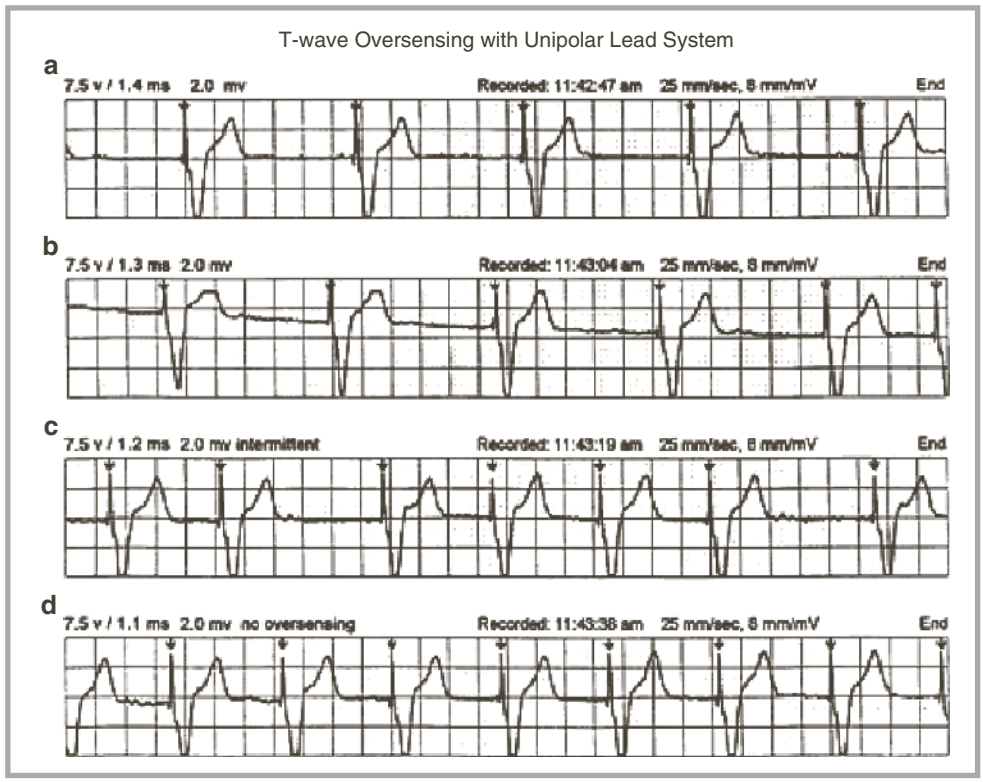

FIGURE 6-14

Intermittent T-wave oversensing. Intermittent bradycardia with slower than expected pacing rate. The pacing intervals were "reset" by oversensing at the peak and trailing edge of the T waves. The prominent pacing artifacts suggest a unipolar system. T wave oversensing may be exacerbated by metabolic abnormalities, antiarrhythmic drugs, or high pacing outputs. T wave oversensing was persistent at high output (7.5V/1.4 ms: **a**), intermittent at intermediate outputs (7.5V/1.3 ms, 7.5V/1.2 ms: **b**, **c**), and absent at low output (7.5V/1.1 ms: **d**).

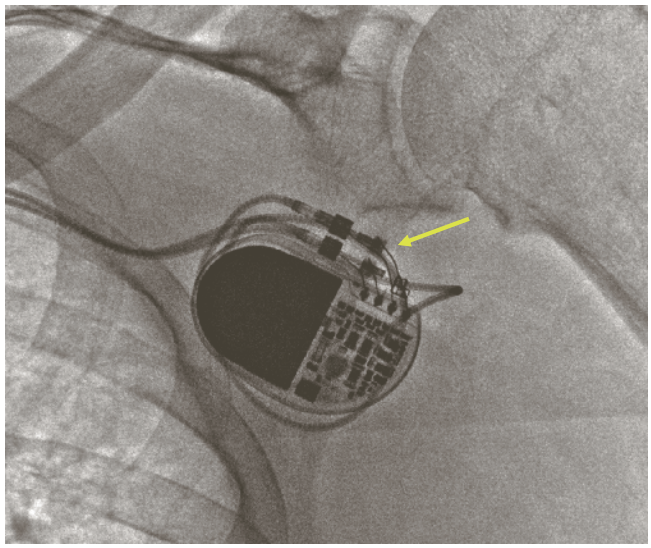

FIGURE 6-15

An example of a loose connector pin. The distal pin of the bipolar atrial lead (*arrow*) was not completely through the connector block in the pacemaker header. This results in a failure to deliver the pacing stimulus.

Failure to Capture

"Failure to capture" indicates a failure to generate local depolarizations (P or R waves) despite the presence of pacing stimuli (Fig. 6-16). The stimulus artifacts are present but ineffective. The most common cause of failure to capture is an elevated pacing threshold. Many factors influence the capture threshold (Table 6-4). In the early postimplant period, the possibility of lead dislodgment must be excluded. The newly implanted lead induces localized inflammatory process that significantly elevates the pacing threshold (up to 2–4 times of the implant threshold value). This "maturation process" may last up to 8 weeks postoperation as the local inflammation resolves. With the development of new technology, such as "steroid-eluting" leads, the acute elevation of thresholds soon after implantation may be blunted. For chronic lead systems, elevated pacing thresholds may be due to antiarrhythmic drug use, lead

Failure to capture: ineffective pacing stimuli that fail to capture.

1. Lead dislodgment
2. Myocardial perforation
3. Insulation defect: low impedance and high current flow
4. Conductor failure: high impedance
5. Threshold elevation
6. Inappropriate programming: output too low

FIGURE 6-16

Failure to capture with VP. There is a lack of local capture (R waves) despite the presence of pacing stimuli.

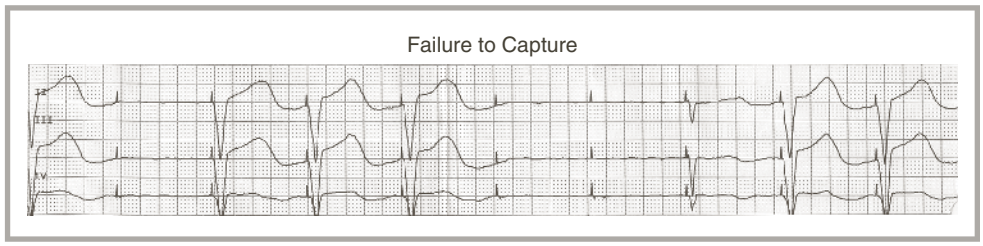

TABLE 6-4

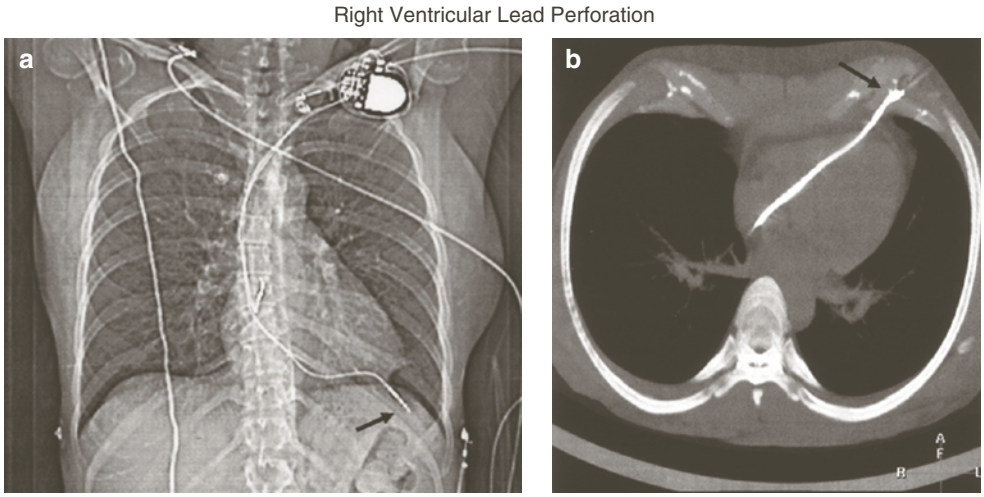
FACTORS AFFECTING THE PACING THRESHOLDS

INCREASE	DECREASE
Lead maturation: Trauma, inflammation	Lead technology: Steroid-eluting lead New metallic element Fractal lead design with high surface area
Lead dislodgement	
Drug effects: Flecainide, class IC Procainamide, class IA Propanolol Amiodarone/class III	Drug effects: Glucocorticosteroid Catecholamines
Acidosis, alkalosis	
Hyperkalemia	
Infarction, scar	
Local fibrosis: exit block	

FIGURE 6-17

Right ventricular lead perforation (*arrow*) as shown on a chest X-ray (**a**) and CT scan (**b**). The *arrow* indicates the perforated RV lead.



damage, local scarring with "exit blocks" at the lead-tissue junction, or interim myocardial infarctions. Other reasons include a poor lead-tissue contact, such as lead dislodgment or myocardial perforation (Fig. 6-17), or inadequately programmed pacing outputs. Careful evaluation of the lead integrity must be performed since lead insulation defect or fracture can progress and result in loss of capture.

Altered pacing rate:
1. Battery depletion (EOL)
2. Rate drift in old pacemaker
3. Activity responses
4. Hysteresis
5. Recorder defect: altered paper speed

Altered Rate

One other manifestation of pacing system malfunction is "altered pacing rate." The pacemaker paces at a rate other than the apparent programmed rate, either faster or slower. Pacemaker battery depletion is a common cause of altered pacing rate. As the device reaches the "ERI" status, the pacemaker automatically decreases its pacing rate to conserve battery. Occasionally, asynchronous pacing at a slow rate can be observed at the "EOL" status. Another

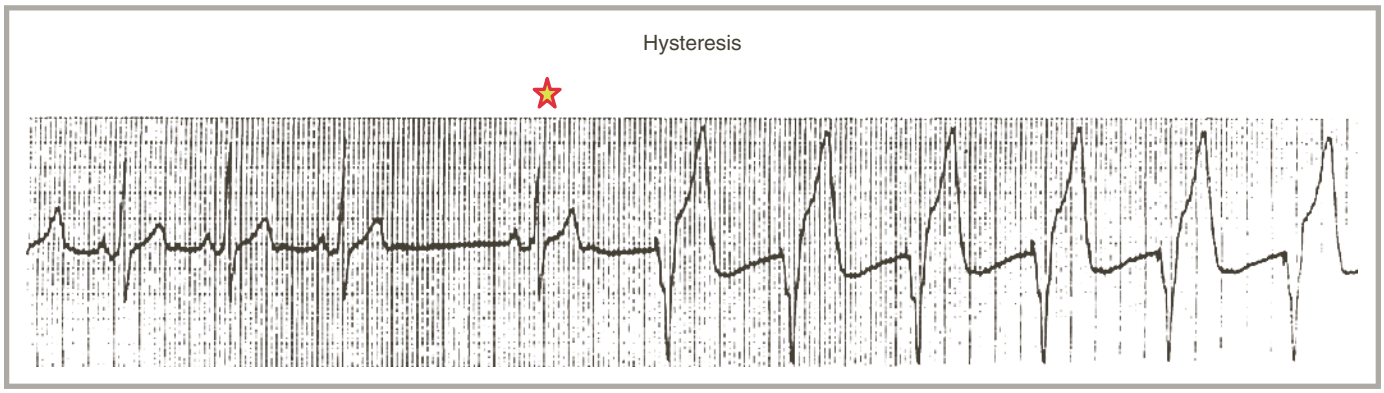


FIGURE 6-18

An example of pacemaker hysteresis. The pacemaker is programmed to a pacing rate of 60 ppm and a hysteresis rate programmed to 40 ppm. In response to sensed spontaneous R waves, the pacing was inhibited at 40 ppm in the VVI mode. However, the device paces at 60 ppm after the pause (*star*).

common cause for a slower than expected pacing rate is the "hysteresis" function. "Hysteresis" is defined as a slowing of pacing rates in response to sensed events (Fig. 6-18). Hysteresis is designed to avoid unnecessary Ventricular pacing and VA dissociation and to facilitate AV synchrony.

Pacing faster than expected rate is a less common observation. This is usually related to "inappropriate" programming of an activity-responsive pacemaker (DDDR, VVIR). Rarely, defective recording instruments with *slow* paper speed can create an apparent accelerated heart rate.

Undesirable Interactions

Undesirable interaction:
1. Infection
2. Hematoma
3. Erosion
4. Extracardiac stimulation
5. Inappropriate programming

A discussion of malfunction of implantable devices would not be complete without mentioning the "undesirable interactions." The "undesirable interactions" can be divided into "acute" vs. "chronic." The "acute" interactions are related to surgical complications that include infection, hematoma, pericarditis, cardiac perforation, and tamponade. The "chronic" adverse side effects include erosions of the lead or the generator, venous thrombosis, or vascular obstruction. Furthermore, physicians should be cognizant of the fact that apparent device malfunctions are frequently related to the "undesirable interactions" between the programmed parameters (outputs, sensitivity, intervals, and rates) and the individual patient's rhythm.

CARDIOVERSION AND DEFIBRILLATION

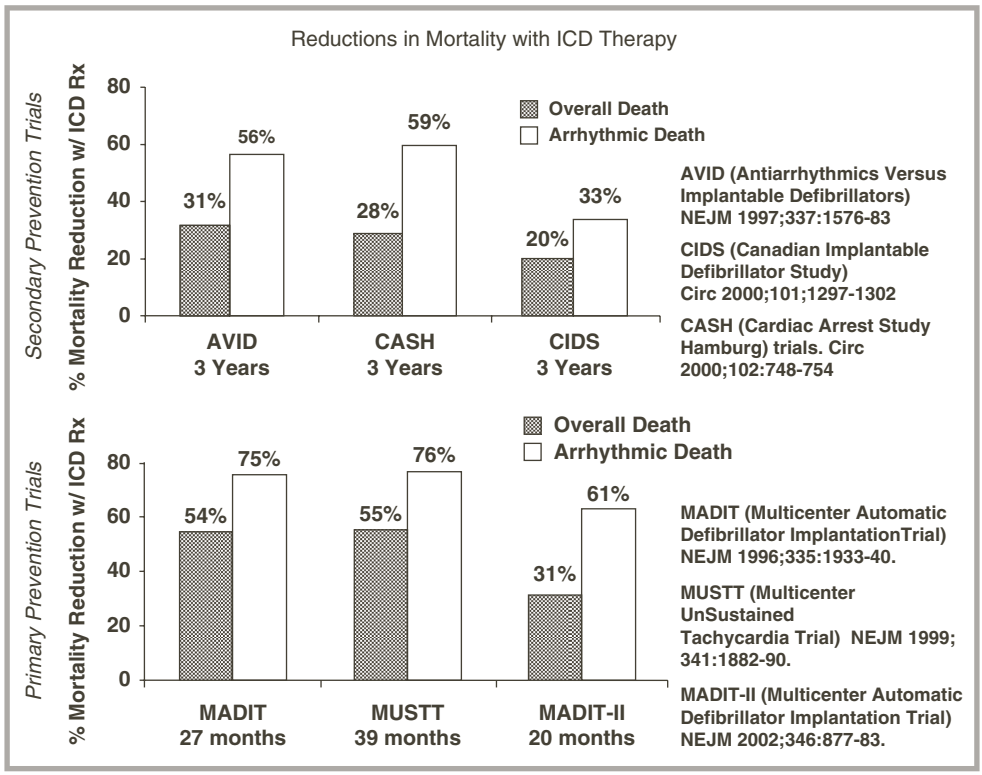
Cardioversion delivers a shock that is *synchronized* to patient's intrinsic R waves and is used for the termination of sustained VT or atrial arrhythmias. Defibrillation delivers a high-energy *asynchronized* shock that provides the only effective therapy for ventricular fibrillation (VF). The cardioverter-defibrillator charges the capacitors to create a voltage (*V*) gradient between the electrodes (leads). During shock delivery, current passage occurs between the electrodes through the myocardium. Such transmyocardial current flow induces cellular membrane changes that terminate arrhythmia wavefront propagations.[5, 6] The defibrillation threshold (DFT), or the cardioversion energy requirement (CER) is related to the underlying arrhythmias, electrolyte/metabolic milieu, ischemic burden, current vectors, system resistance, and the duration of arrhythmia.

Implantable Cardioverter-Defibrillator (ICD)

Since the advent of ICDs in the 1980s, antitachycardia device has evolved from a "last resort" therapy for survivors of sudden cardiac death (SCD) to a prophylactic treatment option for the management of patients who are at risk of developing tachyarrhythmias (VT, VF, or SCD).

FIGURE 6-19

Reductions in mortality with ICD therapy. Randomized controlled secondary prevention trials (*top panel*) involving ICD implantation in cardiac arrest survivors demonstrated statistically significant survival benefit in total mortality and sudden death mortality (AVID, CASH, CIDS). The relative reduction ranged from 20 to 31% for total mortality and 33–59% for arrhythmic death mortality. Primary prevention trials ((MADIT, MUSTT, MADIT-II) (*bottom panel*) with prophylactic ICD implantation in patients with prior myocardial infarction and ventricular dysfunction demonstrated a relative mortality reduction ranging from 31 to 55% for total mortality and 61–76% for arrhythmic death mortality. The mortality reductions with ICD in primary prevention trials are equal to or greater than those in secondary prevention trials.



Major randomized, secondary prevention trials (AVID, CASH, CIDS) involving ICD therapy have consistently demonstrated a significant survival benefit in cardiac arrest survivors with a reduction in total mortality (20–31%) and in arrhythmic death mortality (33–59%).[7-9] It is important to note that the survival benefit with prophylactic ICD implantation in primary prevention trials (MADIT, MUSTT, MADIT-II) were equal to or greater than those observed in secondary prevention trials, with a reduction in total mortality of 31–55% and in arrhythmic mortality of 61–76%[10-12] (Fig. 6-19).

Other important primary prevention trials such as SCD-HeFT (sudden cardiac death in heart failure) and DEFINITE (defibrillators in nonischemic cardiomyopathy treatment evaluation) also demonstrated the survival benefit of ICDs compared with optimal medical therapy for HF and empiric antiarrhythmic drugs.[13, 14] SCD-HeFT included a large cohort with both ischemic and nonischemic cardiomyopathies without spontaneous arrhythmia, whereas DEFINITE focused exclusively on patients with dilated nonischemic cardiomyopathy and ventricular dysfunction.

ICD Configurations

Physicians in an ICU setting should be familiar with the basic design and function of ICDs and be able to trouble-shoot in an emergency. Electrophysiologist should be consulted for device interrogation, reprogramming, and follow-up. In general, an ICD consists of sensing circuits, detection algorithms, and therapy delivery systems. In contrast to pacemakers with a "fixed," programmed sensitivity (usually 2.0–10.0 mV for ventricular leads and 0.5–4.0 mV for atrial leads), ICDs automatically adjust the sensitivity or the gain on a "beat-to-beat" basis in order to maintain accurate sensing of low-amplitude signals (as low as 0.2–0.5 mV) during arrhythmias. These "auto-gain" or "auto-adjusting sensitivity" functions are essential for arrhythmia detections. Once a tachyarrhythmia event occurs at heart rates faster than the programmed rate detection, proprietary detection algorithms confirm and declare the presence of sustained episodes prior to therapy delivery. A "rolling window" algorithm is often deployed (for example, 12 out of 16 or 18 out of 24 intervals). A "fixed" number of beats or an "averaged" heart rate above the "rate cut-off" is required to satisfy arrhythmia detection.[15]

These basic features were present since the first-generation automatic implantable defibrillator (AID) developed by Drs. Mirowski and Mower.

In contrast to the first-generation ICDs, the current devices have extensive programmable options. Multiple detection "modifiers" have been developed to improve the ability of the device to distinguish supraventricular arrhythmias (most often atrial fibrillation/flutter or sinus tachycardia) from ventricular tachyarrhythmias. Once episodes of tachyarrhythmia (SVT or VT) are sensed, programmable options such as "sudden onset" or "heart rate stability" may delay the arrhythmia detection and minimize "inappropriate" ICD therapy delivery for supraventricular arrhythmias. In addition, extensive recording and data storage capability have been incorporated into the newer generations of devices. To enhance detection specificity, EGM characteristics such as "width" or "morphology" can be processed for automatic, real-time analysis and templates comparison. Other safety features such as "sustained rate duration" (SRD) or "extended high rate" (EHR) are designed to counteract potential delays in therapy with inappropriate programming. After a predetermined time period, the ICD will deliver therapy regardless of the nature of the tachycardia.

All ICDs have charge-capacitor systems for the delivery of high-energy defibrillation shocks or low-energy cardioversion shocks. In addition, ATP has been incorporated for potential painless termination of VTs (Fig. 6-20). Current generations of ICDs are capable of delivering "tiered" therapies for multiple tachyarrhythmias detected in different "zones," for example, ATP for slow tachycardias, low-energy cardioversion for VTs, and defibrillation shock for fast VT/VF. In addition, all ICDs have integrated bradycardia back-up pacing within the devices, originally designed to prevent bradycardia after shock termination of VT/VF and "bradycardia-induced tachycardia."

Frequent ICD Therapy

The management of patients with implanted ICDs is similar to those with pacemakers. However, frequent ICD discharge represents a unique challenge in this patient population and the treatment strategy must be individualized. The potential causes for frequent ICD shocks include (1) increased ventricular arrhythmia recurrences, either sustained or nonsustained episodes; (2) increased frequency of supraventricular arrhythmias, such as sinus tachycardia, atrial fibrillation/flutter, or other reentrant SVTs; (3) sensing malfunction; and (4) "phantom" shocks[16] (Fig. 6-21).

Causes of frequent ICD therapy delivery:
1. Appropriate therapy for frequent episodes of VT/VF (sustained vs. nonsustained)
2. Inappropriate therapy for frequent supraventricular tachyarrhythmias (sinus tachycardia, atrial arrhythmias, and other SVTs)
3. Sensing malfunction
4. "Phantom" shocks

A comprehensive interrogation is essential to establish the correct diagnosis, focusing on the integrity of the system, programmed parameters, as well as the arrhythmia events (Table 6-5). The most common cause of frequent shocks is recurrent ventricular arrhythmias with "appropriate" ICD responses. This may be caused by changes in the arrhythmogenic substrate such as new infarction, ischemia, metabolic derangement, or worsening HF. Addition or withdrawal of antiarrhythmic drugs may also promote arrhythmia recurrences or convert nonsustained to sustained episodes. Improper detection criteria with a short NID (number of intervals detected), or slow "rate cut-off" can lead to frequent therapy delivery for nonsustained episodes, especially in a "committed" device. Management of recurrent

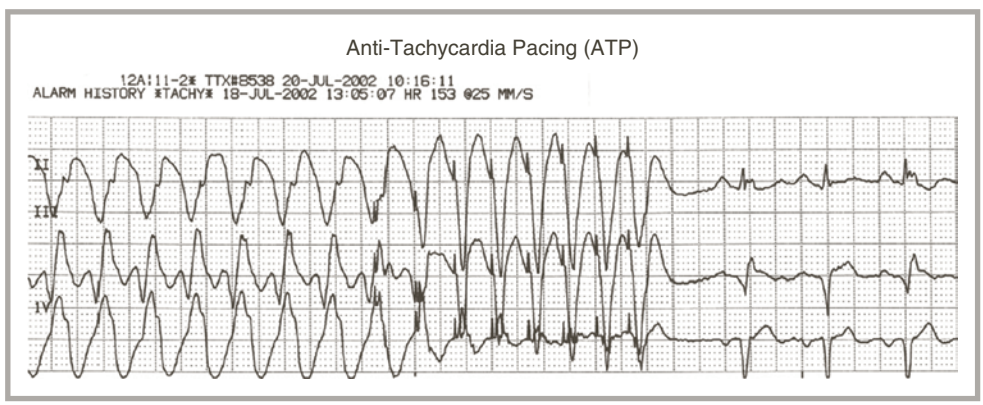


FIGURE 6-20

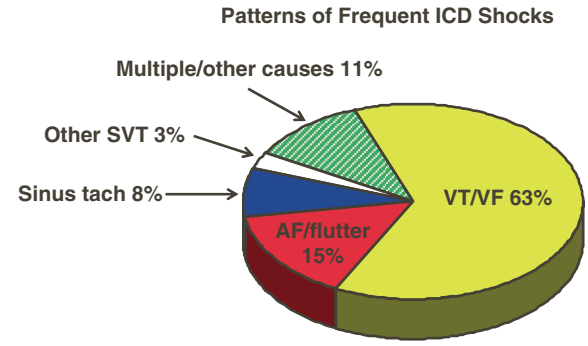
Antitachycardia pacing (ATP) for pacing termination of ventricular tachycardia (VT). Episodes of VT *(left)* was detected and ATP was delivered (*middle*) before restoration of sinus rhythm (*right*).

FIGURE 6-21

Patterns of frequent ICD therapy delivery. The most common cause of frequent ICD shocks was recurrent VT/VF that triggered "appropriate" ICD response. Out of all the causes of "inappropriate" ICD shocks, atrial fibrillation or sinus tachycardia were most often encountered. (Data from [16])



common causes:

(1) increased frequency of VT/VF, sustained or nonsustained episodes
(2) increased frequency of SVT/AF/flutter
(3) sensing malfunction
(4) "phantom" shocks.

TABLE 6-5

MANAGEMENT OF FREQUENT ICD THERAPY DELIVERY

ICD interrogations:
Episode history
Delivered vs. aborted therapy
Reconstruct event sequences: therapy efficacy
Recorded EGM
SVT vs. VT (inappropriate vs. appropriate therapy)
Tachycardia initiation and termination
Real-time EGM
Lead analysis:
Lead sensing and pacing thresholds
Lead stability, noise
Respiration, lead manipulation
Lead impedance
Low: insulation failure
High: lead fracture
Telemetry, Holter monitor, event recorder:
AF/flutter, atrial tachycardia, sinus tachycardia
Nonsustained ventricular arrhythmias
Chest radiography/fluoroscopy:
Lead dislodgment, lead fracture
Electrolytes/drug levels
Environmental interference

VT/VF should be centered on correcting the underlying substrate, such as improving HF and eliminating ischemia. Indiscriminate use of antiarrhythmic drugs must be avoided because of the potential proarrhythmia as well as interference with ICD functions (Table 6-6).

Inappropriate ICD shocks for supraventricular arrhythmias, most often sinus tachycardia or atrial fibrillation, are also common in critically ill patients. Conditions such as fever, pneumonia, pericarditis, exercise/exertion, mental stress/anxiety, or worsening HF may cause rapid heart rates and trigger ICD therapies. Such "inappropriate" therapy may in turn induce ventricular arrhythmias and result in a vicious cycle of incessant shocks. A magnet application in this situation inhibits ICDs' tachyarrhythmia sensing circuits and avoids inappropriate detection and therapy. In most patients with recurrent supraventricular arrhythmias, the device can be reprogrammed to a higher "rate cut-off" or longer detection intervals to delay tachycardia detection. Detection "inhibitors" such as "rate stability" or "sudden onset" can also be activated to enhance discrimination between supraventricular and VTs. Furthermore, judicious use of antiarrhythmic agent(s) may reduce SVT recurrences or provide a better rate control during atrial arrhythmias.

Decrease the frequency of sustained VT/VF
Decrease/eliminate nonsustained episodes of arrhythmia
Minimize supraventricular arrhythmias to reduce "inappropriate" device therapy
Increasing (or potentially decreasing) the defibrillation thresholds (DFTs)
Altered VT rate:
Underdetection by the ICD due to slowing of VT rate
Improved hemodynamic tolerance with slowing of VT
Slower VT may improve the efficacy of cardioversion or ATP
Conduction disturbances:
QRS widening/aberrancy may interfere with ICDs' VT-SVT discrimination algorithm and result in inappropriate therapy for SVT
AV conduction disturbances that necessitate pacing and potentiate pacing induced dyssynchrony and HF
Proarrhythmia with frequent arrhythmias

TABLE 6-6

POTENTIAL INTERACTIONS OF ANTIARRHYTHMIC DRUGS AND THE ICDs

Interactions of Antiarrhythmic Drugs and ICDs

The use of antiarrhythmic drugs in patients with ICDs is associated with a multiplicity of complex interactions (Table 6-6). Careful considerations of the "risk–benefit ratio" must be given prior to therapy initiation. A rapid polymorphic VT or fibrillation may be converted to a slower monomorphic VT in the presence of antiarrhythmic drugs. While this may improve the hemodynamic tolerance and enhance the efficacy of ATP therapy, the slowed arrhythmia can fall below the programmed detection rate, resulting in "underdetection" and delayed ICD intervention. Antiarrhythmic drugs can also induce aberrant conduction or BBB with QRS widening. During supraventricular arrhythmias, such altered conduction with abnormally wide QRS may negate ICDs' ability to discriminate SVT from VT and results in "inappropriate" therapy.

In addition, antiarrhythmic drugs can cause AV conduction delay or heart blocks. AV desynchronization from abnormally prolonged PR intervals or interventricular (VV) desynchronization from excessive RV pacing can produce adverse hemodynamic decompensation and HF.[17, 18] Finally, the risk of proarrhythmia (induction of new arrhythmias or development of incessant episodes) must be considered, especially in a patient population with arrhythmogenic substrates and unstable triggering factors.

It is also important to understand the effects of antiarrhythmic drugs on the DFTs (Table 6-7).

In general, membrane-active drugs such as Vaughan William's Class I and Class III agents can affect the defibrillation energy requirement. No consistent effect on DFT was observed with the use of Class IA drugs in therapeutic dosages. Class IB drugs (lidocaine and mexiletine) can cause a reversible mild increase in DFTs. The use of Class IC drugs is often associated with a significant elevation in DFT in addition to proarrhythmia. The effects of Class III drugs can be variable. It appears that amiodarone lowers the DFT when administered acutely (intravenous or orally), but chronic use of amiodarone may significantly elevate the DFT. Therefore, repeated testing of ICD functions is recommended after the initiation of antiarrhythmic drugs. This should include induction of arrhythmias, assessment of detection accuracy, efficacy of ATP, and DFT determination. Other drugs, including *D*-sotalol, *N*-acetylprocainamide (NAPA), and catecholamines, may facilitate ventricular defibrillation and decrease the DFT.

Effects of antiarrhythmic drugs on DFTs:
Class IA: minimal effect on DFT in therapeutic dosage
Class IB: mild elevation of DFT
Class IC: significantly elevate DFT
Class II: minimal effect on DFT
Class III – variable, chronic amiodarone: significantly elevate DFT

TABLE 6-7

EFFECTS OF DRUGS ON DFTS

INCREASE DFT	DECREASE DFT	CONFLICTING REPORTS
Encainide	Sotalol	Quinidine
Flecainide	NAPA	Mexiletine
Amiodarone (chronic)	Amiodarone (acute)?	Lidocaine
Sildenafil Citrate		Bretylium
Cocaine?		Amiodarone (acute)
Atropine		Isoproterenol

Data from[29]

ICD Sensing Malfunctions

Causes of ICD sensing malfunction:
1. Lead fracture
2. Lead migration
3. Oversensing of cardiac/extracardiac signals
   - T-wave oversensing
   - Electromagnetic interferences
4. Sensing circuit component malfunction
5. Interaction with other devices

In addition to the usual device malfunctions associated with pacemakers such as lead dislodgment, or insulation failure, sensing abnormalities in ICDs can have potentially disastrous complications. In patients who present with multiple asymptomatic shocks, an ICD lead fracture must be excluded. Intermittent "make–break" contacts of a fractured lead can generate high-frequency electric noise (often with nonphysiologically short intervals) that is sensed as ventricular fibrillatory signals with subsequent "spurious" shocks (Fig. 6-22). A suspected lead fracture requires immediate attention and surgical revision, since effective ICD therapy cannot be delivered and there is a risk of VF induction from inappropriately timed shocks.

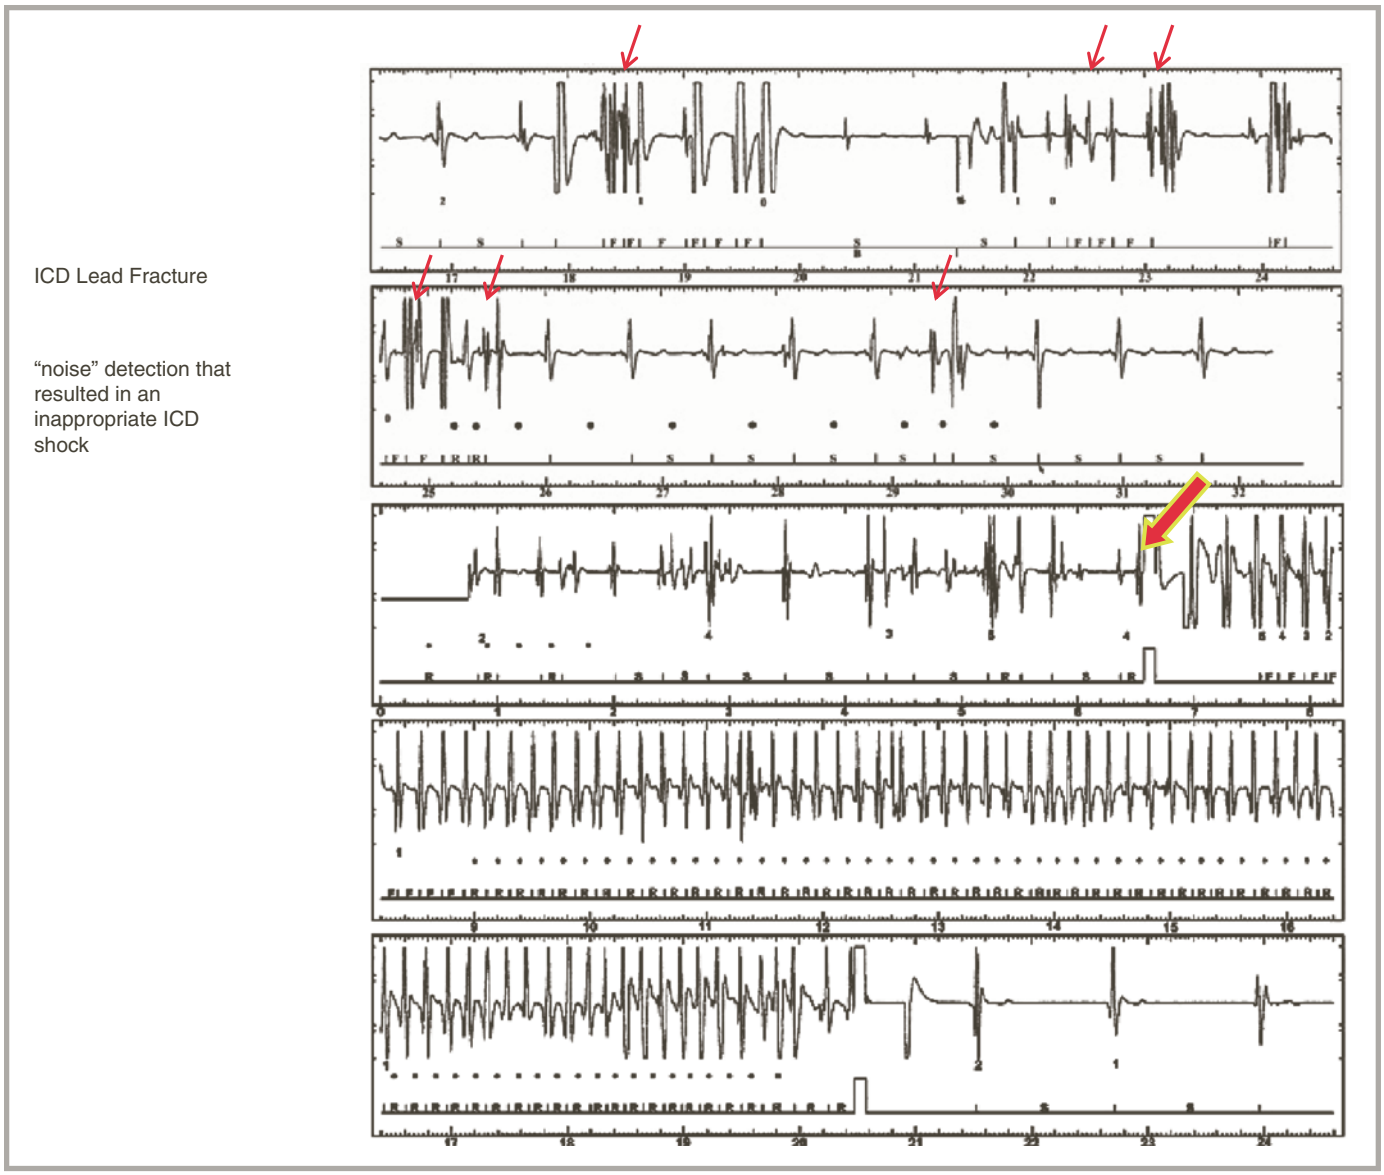


FIGURE 6-22

Spurious intracardiac signals generated by a fractured lead. The intrinsic regular signals represent sinus rhythm. The high-frequency signals (*arrows*) were detected with nonphysiologically short intervals as "noise" by the device and resulted in an inappropriate ICD shock (*bold arrow*) that induced ventricular fibrillation (VF).

Occasionally "oversensing" of cardiac or extracardiac signals can be observed. T-wave oversensing during sinus or atrial tachycardias can result in inappropriate arrhythmia detection with ensuing therapy delivery, especially in patients with metabolic abnormalities, electrolyte imbalance, or antiarrhythmic drug use (conditions that augment repolarization abnormalities).

Adverse Device Interactions

Adverse ICD interactions with other devices such as a pacemaker or a neuromuscular stimulator have been well documented. In an ICD patient with a separate pacemaker, whether it is an implanted system or an external temporary pacing wire, extreme care must be taken to avoid potentially lethal interaction between the devices. During VT or VF, the pacemaker often undersenses the low-amplitude signals and behaves asynchronously. The large pacing artifacts are detected as "sinus" by the robust sensing function of the ICD system, and the underlying ventricular fibrillatory signals are ignored. This may result in significant delays in VT/VF detection and inhibition of life-saving therapy[19] (Fig. 6-23).

Given the expanding indications of ICDs and pacemakers, EMI is a growing concern for patients (Table 6-8). Fortunately, it is usually not a clinically significant problem with proper precaution. Any strong electrical or magnetic field should be avoided. In a hospital environment, EMI is most commonly encountered with high-energy defibrillation/cardioversion shocks, electrocautery, or neuromuscular stimulator units (TENS). Electric current can be sensed by the implanted leads as either intrinsic signals or "noise." Such EMI can cause pacing inhibition and asystole in patients with implanted pacemakers. In patients with ICDs, the high-frequency signals may be detected as VF with subsequent shock delivery (Fig. 6-24). These situations are most commonly encountered intraoperatively and can be easily circumvented by a magnet application that renders the device "nonsense" and behave asynchronously.

Magnetic resonance imaging (MRI) produces magnetic fields that interfere with the metallic components of the implantable system; in addition, thermal injury can occur from secondary electrical currents generated by the implanted leads.

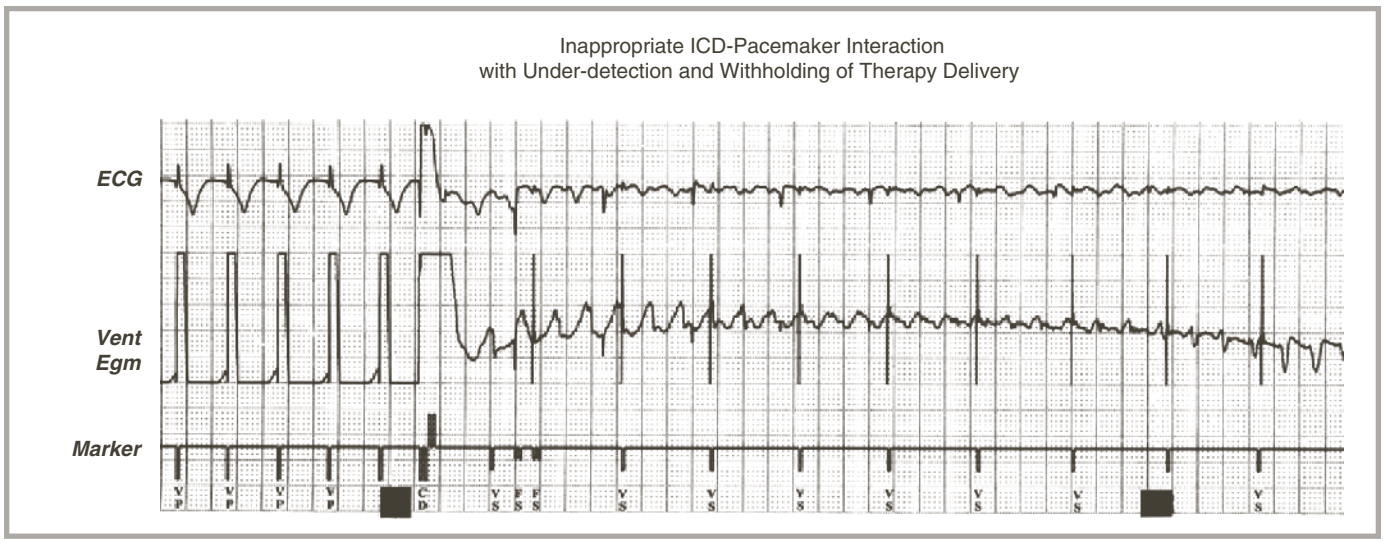

FIGURE 6-23

Inappropriate ICD-pacemaker interactions. An episode of VF was induced by a T-wave shock after a pacing train. Undersensing of VF by the separate pacemaker resulted in "asynchronous" pacing with large pacing artifacts that were sensed as sinus (VS) by the ICD. The underlying VF signals were not detected by the ICD that resulted in significant delays in VT/VF detection and inhibition of therapy delivery.

TABLE 6-8

ELECTROMAGNETIC INTERFERENCES (EMI)

In home and work environment:
- TENS unit
- CB/amateur radios
- Large magnets
- Ignition cables, power tools
- Security systems/antitheft devices
- Electric arc welding, induction furnace

In hospital and clinic environment:
- Defibrillation, cardioversion
- Electrosurgery, electrocautery
- TENS unit
- Diathermy
- Ultrasound therapy, lithotripsy
- Magnetic resonance imaging (MRI)

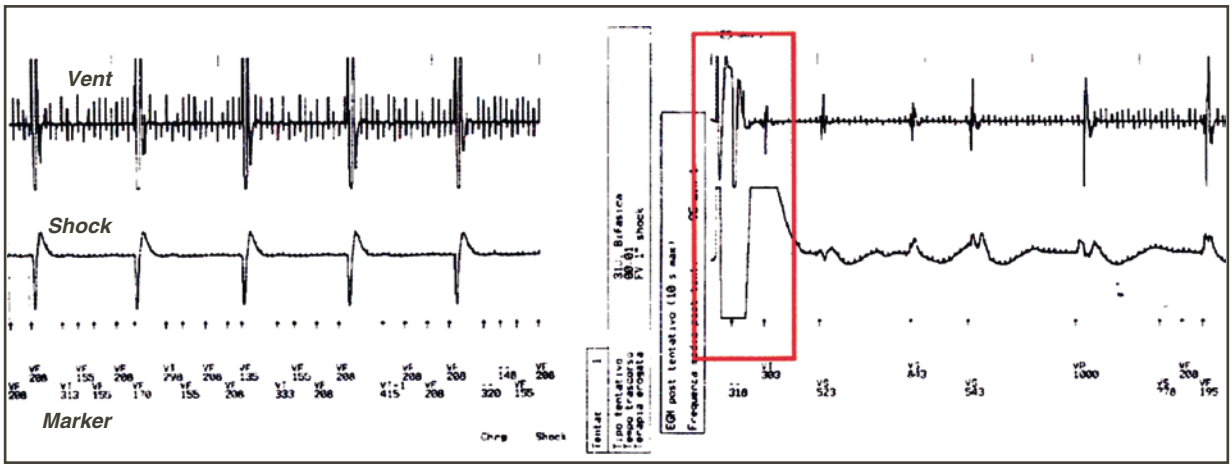

FIGURE 6-24

Electromagnetic interferences (EMIs) from a transcutaneous electrical nerve stimulation (TENS) unit. Nonphysiologic, high-frequency signals were detected by the pace/sense electrodes (vent) but not the ICD coil (shock) electrodes. The electrical stimulation resulted in VF detection (marker) and inappropriate shock delivery.

Potential adverse effects of shocks on implanted system:
1. Irreversible damage to the generator
2. Reprogramming: reversion
3. Stimulation thresholds: acute rise with loss of capture and chronic rise with "exit block."
4. Transient undersensing

The physicians should also be familiar with the adverse effects of high-energy shocks on implanted devices. Irreversible damage to pulse generators or leads is uncommon, albeit possible with direct electrode contact.

Occasionally, reprogramming of the device with "reversion" to the "nominal" parameter setting can be observed. Direct effects of shocks on myocardium also can cause changes in thresholds. An acute rise in stimulation threshold with loss of capture or a transient "undersensing" can occur immediately after shocks. Occasionally, a chronic rise in pacing threshold with progressive scarring at the distal lead–tissue interface can be observed. Therefore, it is important to interrogate the implanted devices after electrocautery, shock delivery, or other EMIs to exclude changes in programmed parameters or alteration of thresholds. In addition, ionizing radiation can also cause direct damage to the electronic circuitry of the devices. The portals for radiation therapy should not include the generator and be as far away from the implantable system as possible. Electrophysiologists, radiation oncologist, as well as the device manufacturer should be consulted before treatment initiation.

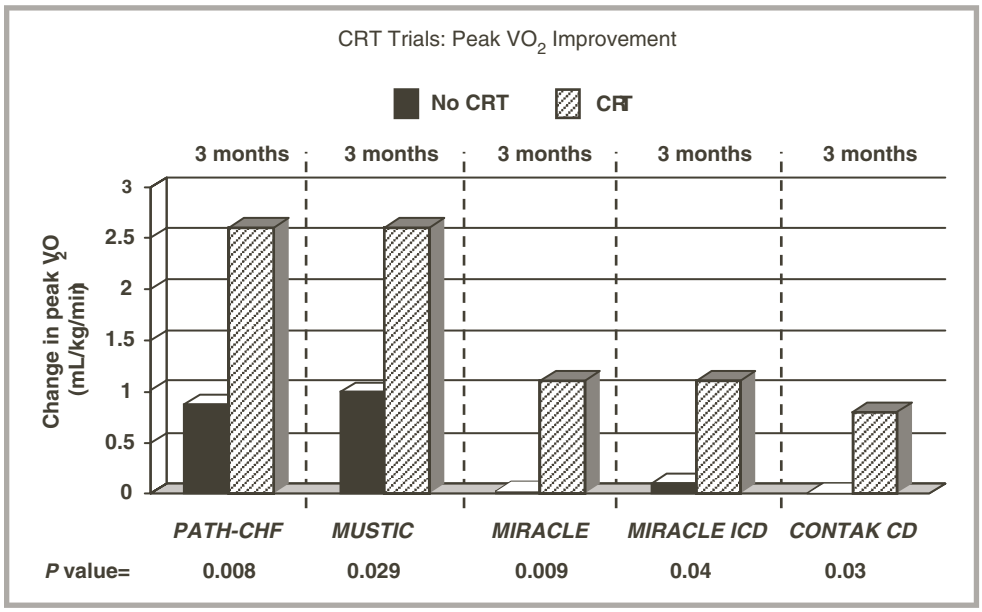

FIGURE 6-25

A summary of representative trials of cardiac resynchronization therapy (CRT). A significant improvement in peak oxygen consumption can be observed with CRT, with or without ICD implantation. Similar improvements can be observed with 6-min walk test, left ventricular dimensions, New York heart association functional class assessment, and mortality.[21, 22, 24-26]

TABLE 6-9

CURRENT INDICATIONS FOR CRT

Symptomatic congestive HF
NYHA class II–III
Left ventricular ejection fraction (EF) <35%
Baseline QRS duration >120–130 ms
Sinus rhythm

CARDIAC RESYNCHRONIZATION THERAPY (CRT)

The current generations of implantable devices have evolved from an antibradycardia, tachycardia platforms to hemodynamic support and arrhythmia prevention. Biventricular pacing for CRT, with or without an ICD (CRT-D), has assumed an important role in the management of patients with HF, especially in patients with prolonged baseline QRS durations on surface electrocardiogram.[20] Transvenous left ventricular epicardial lead placement via the coronary sinus and cardiac veins can be achieved in >90% of the patients. Multiple randomized trials have demonstrated significant improvements in survival, clinical symptoms, hemodynamics, as well as structural parameters with biventricular pacing[21-23] (Fig. 6-25). The accepted indications for resynchronization therapy include (1) symptomatic congestive HF at greater than New York heart association class II; (2) electrical dyssynchrony with a wide QRS duration >120–130 ms; (3) a depressed left ventricular ejection fraction of <35%; and (4) sinus rhythm (Table 6-9).

SUMMARY

The management of patients with implantable devices should include a thorough understanding of the indications of pacemaker or ICD implantation, the device hardware and electronics, and a systematic evaluation to identify the potential causes of device malfunction. A combination of medical history, physical examination, and careful analysis of the interrogation data enables one to establish the correct diagnosis and develop a treatment strategy. Most patients can be managed with medication adjustment, device reprogramming, or a combination. Occasionally, surgical revision of the generator or the lead(s) may be necessary. For those patients who present with frequent ICD shocks due to arrhythmia recurrences, a formal electrophysiology consultation and evaluation is highly recommended.

REVIEW QUESTIONS

1. **With magnet application, the implanted pacemaker will:**
   - **A.** Slow the pacing rate
   - **B.** Deactivate the pacemaker
   - **C.** Perform a threshold test
   - **D.** Pace asynchronously

2. **For a 73-year-old woman with a history of sinus node dysfunction and paroxysmal atrial fibrillation, who presented with complete heart block and syncope, the best selection of pacing mode is:**
   - **A.** VVI
   - **B.** DDDR
   - **C.** VVIR
   - **D.** AAIR

3. **In a patient with suspected pacemaker malfunctions, what is the first step for proper evaluation?**
   - **A.** Device interrogation
   - **B.** Chest X-ray
   - **C.** Electrocardiograms and rhythm tracings
   - **D.** Patient's indications for pacemaker implantation
   - **E.** Patient's medication record, electrolyte, and metabolic status

4. **A 65-year-old man with a history of prior myocardial infarction and cardiac arrest with an implantable defibrillator (ICD) underwent an aortic valve replacement and coronary artery bypass graft surgery. The day after the surgery, the patient suffered multiple ICD shocks. Telemetry monitor revealed atrial fibrillation with a rapid ventricular rate. Which of the following should be the first response?**
   - **A.** Administering beta-blocker or calcium channel blocker for better rate control in atrial fibrillation
   - **B.** Placing a magnet over the ICD
   - **C.** Surgical exploration to rule out valvular dysfunction or graft occlusion
   - **D.** Reprogramming the ICD

5. **The current indication for CRT includes:**
   - **A.** Symptomatic HF
   - **B.** Wide QRS duration >120–130 ms
   - **C.** Depressed left ventricular EF < 35%
   - **D.** All of the above

ANSWERS

1. The answer is D. Magnet placement over the pacemaker renders the device to pace in an asynchronous mode without sensing inhibition. This specific "magnet rate" reflects the battery status and displays the programmed pacing mode and intervals. It should be a routine for pacemaker evaluation.
2. The answer is B. A dual chamber pacing system is preferred over a single chamber ventricular pacemaker. Preservation of AV synchrony has been shown to provide an improved exercise tolerance and cardiac output. Atrial pacing may reduce the incidence of recurrent atrial fibrillation. An activity-responsive device is recommended in a patient with sinus node dysfunction and bradycardia. VVIR would be a reasonable choice if the patient has chronic atrial fibrillation and AV synchrony cannot be restored.
3. The answer is A. Although ALL, the choices are important in managing patients with pacemaker malfunction; device interrogation should be the first step. A comprehensive analysis of lead integrity, thresholds, and stored rhythm data is essential for proper management of the patient.
4. The answer is B. A magnet application should be the first response. Magnet temporarily renders the ICD "nonsense" and thus avoids "inappropriate" shocks for supraventricular arrhythmias. Administration of AV nodal blockers may be considered for better rate control during rapid atrial fibrillation. The ICD can be reprogrammed to a higher rate "cut-off" to avoid inappropriate detection of supraventricular arrhythmias.
5. The answer is D. The current indications for CRT include symptomatic HF, wide QRS duration (>120–130 ms), a depressed left ventricular EF of <35%, as well as in sinus rhythm.

CHAPTER 7

DAVID E. CICCOLELLA

Enteral Feeding Tubes

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to do the following:

- Be familiar with the various methods of delivering enteral feeding.
- Know the indications and contraindications for using enteral feeding tubes.
- Know the complications associated with enteral feeding tube insertion.

The use of enteral nutrition dates from the ancient Egyptians and Greeks, who instilled nutrient directly into the rectum. Although the concept of enteral nutrition to treat disease and foster health remains the same, the delivery route has been modified only during the last century. The current consensus among intensivists is that nutritional support should be initiated early in the course of the critically ill patient. Early nutritional support is thought to shorten hospital length-of-stay and to support the increased metabolic demand resulting from illness or injury.

The initiation of nutrition in the intensive care unit can begin as either enteral and/or parenteral feeding; parenteral feeding is considered in patients who are not suitable for enteral feeding. It is generally agreed that enteral nutrition is superior to parenteral nutrition because it is associated with fewer complications (i.e., infectious)[1,2] and is more cost-effective (Table 7-1). In general, enteral nutrition should be initiated in patients with current or potential malnutrition caused by inadequate oral intake. An absence of clinical shock and an intact gastrointestinal tract are requisite. Indications and contraindications for enteral nutrition are shown in Table 7-2. In certain cases, the family or legal guardian and physicians

TABLE 7-1

ADVANTAGES OF ENTERAL COMPARED TO PARENTERAL SUPPORT

GI tract structure/function preservation
More efficient nutrient use
Avoid central venous catheter insertion/postinsertion complications
Less infectious/metabolic complications
Easier administration
Lower cost

TABLE 7-2

INDICATIONS AND CONTRAINDICATIONS TO ENTERAL FEEDING

Indications: consider full support
Patients with current or potential malnutrition with inadequate oral intake
Full-thickness burns
Post-massive (up to 90%) small bowel resection
Low output enterocutaneous fistula (output <500 mL/day)
Indications: consider partial support
Partial bowel obstruction
Severe diarrhea
High output enterocutaneous fistula (output >500 mL/day)
Severe pancreatitis or pseudocyst
Help maintain GI integrity
Contraindications: full or partial support
Clinical shock
Gastrointestinal disease
Complete bowel obstruction
Bowel ischemia
Severe protracted ileus
Massive GI bleeding
GI anastomosis distal to feeding site
Intractable vomiting
Peritonitis

may decide that feeding is inappropriate. Selected patients may be helped with partial enteral support. Partial enteral support with low-volume feedings may help maintain gastrointestinal (GI) integrity.[3,4]

Bowel sounds and flatus passage do not predict enteral feeding tolerance.

To determine if a patient can safely tolerate enteral feeding, GI function should be evaluated. Clinical indicators of GI function, such as bowel sounds and flatus, are nonspecific and do not guarantee the tolerance of enteral feeding. Conversely, the absence of bowel sounds is common in critically ill patients and does not necessarily indicate that the small bowel is incapable of absorbing nutrition or that feedings should be withheld or reduced.[1] Patients should be able to tolerate enteral feeding if the GI output is <500 mL/24 h.

In critically ill patients, some conditions that produce excessively high GI outputs, and therefore preclude the use of enteral nutrition are gastroparesis, intestinal obstruction, paralytic ileus, high-output enteric fistulas, *Clostridium difficile* colitis, severe idiopathic diarrhea, short-bowel syndrome (early stage), and severe GI bleeding. Enteral feeding may buffer gastric acid, reduce mild upper GI bleeding and does not usually exacerbate lower GI bleeding. Therefore, a trial of enteral nutrition should be initiated if enteral nutrition is clinically indicated, and contraindications such as clinical shock and significant GI disease are absent.

ENTERAL FEEDING TECHNIQUES

Once a decision for enteral nutrition is made, the physician must decide on how best to deliver nutrition into the stomach, duodenum, or jejunum. There are multiple approaches to enteral feeding: nasal or oral tube insertion, gastric or postpyloric, placed bedside, endoscopically or fluoroscopically, and tube enterostomy placed endoscopically, fluoroscopically or surgically (Table 7-3). The anticipated duration of enteral feeding, tube preference, patient illness, GI condition (patency and motility), aspiration risk, and the presence of intubation and mechanical ventilation will influence delivery choices. The nasal/oral approach is appropriate for short-term use, while tube enterostomies should be considered if long-term use is

For short-term feeding and in the absence of contraindications, nasal or oral feeding is easy and convenient.

TABLE 7-3

METHODS OF ENTERAL DELIVERY

- Nasal/oral insertion: unguided bedside, endoscopic, or fluoroscopic
  - Naso (Oral[a])gastric
  - Naso (Oral[a])enteric
  - Combined nasogastric-jejunal (fluoroscopic/endoscopic technique)
- Tube enterostomies (some): percutaneous, fluoroscopic, laparoscopic or surgical
  - Gastrostomy
    - Percutaneous endoscopic gastrostomy
    - Percutaneous fluoroscopic gastrostomy
    - Laparoscopic gastrostomy
    - Open gastrostomy (Stamm technique)
  - Jejunostomy
    - Percutaneous endoscopic jejunostomy (PEJ)
    - Laparoscopic jejunostomy
    - Jejunostomy (Witzel technique)
  - Combined (gastric decompression and small bowel feedings)
    - Percutaneous endoscopic gastostomy–jejunostomy
    - Percutaneous fluoroscopic gastrojejunostomy
    - Transgastric jejunal tubes

[a]Oral route preferred for mechanically ventilated patients.
SOURCE: Data from Bankhead and Rolandelli[28] and ASPEN Board of Directors and the Clinical Guidelines Task Force[34]

anticipated. Generally, gastrostomy and jejunostomy are preferred for patients with longer requirements for nutrition (>4 weeks).

NASAL/ORAL ENTERAL FEEDING

As noted above, if short-term enteral tube feeding is anticipated, a nasal or oral route is easy and convenient, assuming there are no specific contraindications. Specific indications and contraindications for insertion of a nasal or oral feeding tube are listed in Table 7-4. The indications for enteric feeding include patients who are intubated and mechanically ventilated, patients with neurologic disorders that prevent adequate oral intake and patients with GI tract disorders that prohibit eating. Nasoenteric tube feedings may also be used as a

TABLE 7-4

INDICATIONS AND CONTRAINDICATIONS TO NASOENTERIC TUBE ROUTE

- Indications
  - Neurologic disorders
  - Oropharyngeal/esophageal disorders
    - Tumors
  - Gastrointestinal disorders
    - Enteric fistulas (selected)
    - Short bowel syndrome
    - Inflammatory bowel disease
  - Pulmonary disorders
    - Intubation and mechanical ventilation
  - Medical treatment/environmental injuries
    - Chemotherapy/radiation therapy
    - Burns
- Contraindications (some)
  - Absolute contraindications
    - Facial/cranial abnormalities or injuries (some)
    - Nasopharyngeal obstruction
    - Esophageal obstruction (stricture or malignancy)
    - Complete gastric or intestinal obstruction
    - Severe ileus
    - Recent GI surgery (i.e., fresh suture lines)
  - Relative contraindications (some):
    - Coagulopathy/thrombocytopenia
    - Esophageal varices
    - Acute GI hemorrhage
    - Inflammatory bowel disease (very active)
    - Partial gastric or intestinal obstruction

supplement to parenteral nutrition in patients with GI fistulas and during transition to oral intake to decrease the risk of parenteral nutrition-associated complications. Nasoenteric tube feeding is contraindicated in patients with bowel ischemia or complete gastric or intestinal obstruction. In partial obstruction, patients typically have nausea, vomiting, and bloating; the use of enteral feeding in this setting is controversial.

Postpyloric Tube Feeding

Postpyloric tube feeding, especially distal to the ligament of Treitz, may theoretically be preferred over gastric feeding due to a reduced risk of regurgitation and aspiration. In 2003, the Canadian Critical Care Practice Guidelines Committee[2] analyzed 11 level-2 randomized trials in a meta-analysis of gastric vs. small bowel feedings and found no significant difference in mortality, though there was a reduction in pneumonia using small bowel feeding. However, it should be noted that one study[5] greatly influenced these results and when eliminated, no difference was observed in the frequency of pneumonia whether the feeding tube had been placed into the small bowel or not. However, the committee routinely recommended small bowel feeding in critically ill patients if small bowel access is easily obtained. If small bowel access is more difficult, it should be considered for patients at high risk for intolerance to enteral nutrition (patients receiving inotropic support, continuous sedation or paralysis, or have high nasogastric drainage) or at increased risk for regurgitation and aspiration.[2] Similarly, factors identified as independent risk factors for aspiration in ICU patients were a Glasgow Coma Scale of <9, GE reflux disease, and one or more vomiting episodes.[6] If small bowel feeding tubes are an option, small bowel feeding should be considered in patients who repeatedly demonstrate high gastric residuals and are not meeting nutritional goals.[2] The consensus statement of the North American Summit on Aspiration is similar and recommends small-bowel feeding tubes if gastric feeding is not tolerated by the patient or they have previously aspirated tube feedings.[7] Recent guidelines jointly issued by the Society of Critical Care (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN) in 2009 recommend either gastric or small bowel tube feeding in the ICU and to place a small bowel feeding tube in those patients with a high risk for aspiration[7] or in those demonstrating gastric feeding intolerance.[1] The guidelines defined factors for increased risk for aspiration based on those identified from the consensus statement from the North American Summit on Aspiration. Some of the factors related to an increased risk for aspiration were mechanically ventilated patients with an endotracheal tube, depressed consciousness, patient positioning, those older than 70 years, those receiving bolus intermittent feedings, ICU transport for tests and procedures, poor oral health, and poor nursing care.[1]

In critically ill patients, feeding tube insertion may result in significant complications. Before a feeding tube is inserted, the physician should carefully assess the patient for an intact GI tract and risk factors for complications during nasal/oral insertion. These factors can be grouped into neurologic, naso-oropharyngeal, and pulmonary-related risk factors (Table 7-5).

Nasally or orally inserted tubes may be placed in gastric or transpyloric (duodenal or jejunal) positions.

In the critically ill, the nasal route is preferred for nonintubated patients and the oral route for intubated and mechanically ventilated patients; this is true for the gastric or more preferable postpyloric duodenal position. Initially a large-bore nasogastric tube is usually inserted for enteral feeding. This allows for regular assessment of stomach content, volume, and evaluation of the absorption of feedings. The large-diameter nasogastric tubes (14 Fr or larger)

TABLE 7-5

RISK FACTORS FOR NASAL/ORAL ENTERAL FEEDING TUBE INSERTION-RELATED COMPLICATIONS

Neurologic
Altered mental status: coma, delirium

Gastroesophageal
Esophageal stricture/web/obstruction
Gastric obstruction

are also used to administer medications and for gastric decompression. These tubes are usually made of stiff polyvinyl chloride (PVC) and are relatively easy to insert. This large-bore tube will later be replaced by a more flexible, smaller-bore (8–12 Fr) soft polyurethane or silicone tube designed to enable transpyloric passage. This type of tube will permit delivery of nutrients into the proximal duodenum and theoretically reduce the risk of aspiration. Softer tubes are generally preferable for more alert patients as they are better tolerated.

Soft, flexible, small-bore (8–12 Fr) tubes are frequently used for patients who require enteral feeding for less than 4 weeks. The nasoenteric small-bore tubes vary in material, diameter, length, stylet-type, lubrication, and the presence of a weighted tip; they are available from a variety of manufacturers. The selection of an appropriate tube is largely dependent on purpose and duration of use. Smaller bore tubes are less traumatic to the nasal mucosa during insertion and while in place.[8] However, smaller diameter tubes are more likely to clog and also displace more easily, especially into the respiratory tract without warning.[9] Although somewhat controversial, smaller tube size does not seem to decrease gastro-esophageal reflux and microaspiration.[6,10] The choice of tube diameter and length depends on its use and placement-goal: gastric; ~33 in.; duodenal, ~43 in.; jejunal, ≥48 in. Weighted tips may help with gastric insertion in the presence of cuffed endotracheal tubes, but probably provide no advantage in attaining transpyloric passage. There are also combination enteral tubes, composed of stiff outer, large-caliber PVC tubing and more pliable inner small-caliber silicone tubing; these may help with insertion or gastric decompression. Otherwise, there are no major differences, and tube choice should be based more on familiarity, ease of use, and cost.

Procedure for Feeding Tube Insertion

The approximate necessary length of a nasal tube can be estimated by placing the tip of the tube on the patient's xiphoid process, and then wrapping the tube around the ear and extending it to the tip of the nose. For oral insertion, the tube is extended from the xiphoid process to the corner of the mouth. A longer tube should be considered for placement beyond the pylorus. After selection of the feeding tube, the tube may be inserted using the following procedures:

Nasal Feeding Tube Insertion

1. Evaluate the size and patency of the nares and check for a deviated septum and other abnormalities. Place the patient in a comfortable, semi-upright position.
2. Put a small amount of water-based lubricant around the nasal vestibule to facilitate passage.
3. Using the larger and more patent nasal passage, start inserting the tube along the inferior aspect and advance it slowly until it is in the posterior pharynx.
4. Request the patient to repeatedly swallow to promote esophageal placement.
5. The tube should be advanced to approximately 40–45 cm for placement into the stomach.
6. The tube is taped to the nose with a 5–10-cm loop of tubing left free to allow for migration into the small intestine. Taping the tube to the nose by anchoring a tube loop to the ipsilateral cheek avoids upward tension and pressure on the anterior nare.
7. The following measures may help to prevent dislodgement of the feeding tube: mark the point where the feeding tube enters the nostril using a black marker. Using tape (8 cm) that adheres well to the skin partially cut the tape lengthwise for approximately 6 cm to form two strips. The uncut section is placed on the nose and the loose strips are wrapped on the tube in a crosshatched pattern. A small piece of tape also can be placed on the uncut section over the bridge of the nose. If the patient has an endotracheal tube, you can place a piece of tape around the feeding tube and then attach it to the ET tube ties.

Oral Feeding Tube Insertion

1. Direct the tube posterior and tilt the head forward slightly to help negotiate the bend in the posterior pharynx into the esophagus.
2. Advance the tube to 40 cm from the incisors.

3. To assess position, approximately 100 mL of air should be instilled while auscultating over the stomach. This will also distend the stomach and promote transpyloric migration.
4. Place the patient on their right side, advance the tube another 15 cm and secure it with tape.
5. An X-ray should be taken after the patient has remained on their right side for 1 h.

Trans-Pyloric Feeding Tube Placement

Spontaneous transpyloric passage of the feeding tube (usually within 8–24 h) in critically ill patients is often unsuccessful due to gastric atony. There are multiple methods reported to increase the placement of feeding tubes in the small bowel[11-14] but individual skill may be more important.[15] To promote the transpyloric placement of feeding tubes, air insufflation techniques,[14] promotility agents, stylets,[14] and guided tube insertion can be used. Promotility agents include metoclopromide 10 mg, or erythromycin, 200–400 mg intravenously,[16] which are administered 20–30 min before tube insertion. However, only using prokinetic agents alone is usually ineffective in critically ill patients and more aggressive methods to guide insertion into the correct position may be needed. If duodenal placement does not occur after several hours, fluoroscopic or endoscopic guidance may be required.

Transpyloric placement of feeding tubes may be aided by promotility agents, stylets, and guided insertion.

Assessing Tube Placement

The methods for assessing tube location (listed in Table 7-6) include physical signs and roentgenography. Physical signs can be helpful during the insertion procedure of a feeding tube. One method to help evaluate tube placement in the gastrointestinal tract is by noting the color and pH of the aspirated material to determine if it is gastric in origin. This method is unable to distinguish between a postpyloric and a respiratory location as pH is more alkaline in these sites[17] and especially if currently being enterally tube fed, since this increases pH. Physical signs such as auscultation during insufflation of air into the tube, observing for cough, and testing the patient's ability to speak are helpful but not reliable in confirming proper tube position. Because the complications of tube misplacement are significant, confirmation of tube placement by abdominal and/or chest imaging is required. If the location of the feeding tube still remains unclear, injection of the tube with a small amount of radiopaque liquid (e.g., meglumine diatrizoate) can confirm its location; this is especially helpful in distinguishing between gastric and proximal duodenal placement.

Physical examination signs of tube placement are helpful but not completely reliable in confirming the appropriate position of the feeding tube.

Enteral tube placement requires confirmation by radiography.

Complications

Enteral feeding tube complications may be divided into insertion and postinsertion related complications (Table 7-7). These complications are related to the tube and the anatomic areas traversed and can be further grouped into nasopharyngeal-otic-sinus, gastrointestinal, pulmonary, and metabolic complications.[18] Complications of tube insertion, especially using small-bore tubes with stiff guide wires, are usually secondary to tube misplacement and include perforation of the esophagus and lung. Mechanically ventilated patients with inflated endotracheal tube cuffs are at increased risk of errant placement into the lung. This occurs because the esophagus can become compressed by an overinflated endotracheal tube cuff and the stiffened feeding catheter is then able to slide into the trachea and puncture the lung.

Postinsertion tube complications include tube obstruction, GI tract erosion, delayed gastric emptying and increased gastric residual volumes, aspiration, and ear and sinus infections.

The complications of enteral feeding tube insertion are usually secondary to tube misplacement; these include perforation of the esophagus and the lung.

Intubated and mechanically ventilated patients are at significant risk for tube misplacement due to cuff compression of the esophagus and the ability of small feeding tubes to pass into the trachea.

TABLE 7-6

ASSESSING NASAL/ORAL FEEDING TUBE PLACEMENT

Physical signs
Aspiration of gastric contents
Air insufflation and abdominal auscultation
Cough/altered phonation
Color and pH testing of aspirates
Roentgenography
Abdominal X-ray
Injection of radiopaque liquid (5–10 mL) if needed

TABLE 7-7

NASAL/ORAL ENTERAL FEEDING TUBE COMPLICATIONS

- Insertion-related complications
  - Upper airway
    - Nasal trauma
    - Pharyngeal irritation-induced vomiting
  - Gastroesophageal
    - Esophageal perforation/hemorrhage
  - Respiratory
    - Feeding tube perforation into lung/pleural space
    - Hemoptysis
    - Hydrothorax/pneumothorax
    - Bronchopleural fistula
    - Pneumomediastinum
    - Subcutaneous emphysema
- Postinsertion-related complications
  - Nasal-oropharyngeal-oto-sinus
    - Ear, nasal/sinus infections
    - Nasopharyngeal stenosis
    - Laryngeal stenosis
    - Pharyngeal/vocal cord paralysis
  - Gastroesophageal
    - Tube dislodgement/migration (especially esophagus)
    - GI mucosal tract erosion (by tube tip)
    - Esophageal stricture
  - Respiratory
    - Enteral feeding aspiration
    - Pneumonia/pleural effusion
    - Empyema
  - Intrinsic tube problems
    - Bursting/breakage
    - Obstruction

Long-term use of oral/nasal feeding tubes may result in nasopharyngeal and laryngeal stenosis, and pharyngeal and vocal cord paralysis.

Prolonged use of nasal tubes may result in nasopharyngeal and laryngeal stenosis as well as pharyngeal and vocal cord paralysis.

Aspiration is a major complication of enteral feeding tubes. To help prevent aspiration, the head-of-bed should be elevated to 45°, if this is not feasible, then it should be elevated as high as possible. Maintaining head-of-bed elevation to 45° resulted in a significant reduction in ventilator-associated pneumonia.[19] After assessment of aspiration risk factors, the SCCM/ASPEN 2009 guidelines have suggested measures to reduce aspiration risk: head-of-bed elevation to a level between 30° and 45°, continuous feeding, starting prokinetic drugs or narcotic antagonists when possible, and consideration of postpyloric tube placement.[1] Prokinetic agents have improved gastric emptying and tolerance but not changed ICU mortality or incidence of pneumonia.[1] However, the treatment with the narcotic antagonist, naloxone, in one placebo-controlled study increased enteral feeding tolerance and lowered mechanical ventilator-associated pneumonia but not mortality.[1,20] Additional measures to reduce aspiration risk were to lower the degree of sedation or analgesia, reduce frequency of ICU transport, and increase the ratio of ICU nurses to patients.[1]

Small bowel feeding can stimulate gastric fluid resulting in large gastric residual volumes, requiring sump tubes for monitoring and gastric decompression. During small-bowel tube feeding, one study suggests that concurrent gastric decompression can markedly reduce the risk of aspiration.[10] Although the use and relationship of gastric residual volumes to aspiration risk is controversial,[21] the North American Summit on Aspiration consensus statement states that clinicians should not depend on gastric residual volumes to determine high or low risk for aspiration; it should be identified by the patients' disease process.[22] The consensus statement also states that the measurement of gastric residual volumes is poorly standardized and that the interpretation and response to residual volume data has led to inappropriate cessation of feeding. The consensus statement recommends the following: Gastric residual volumes should be interpreted along with clinical assessment. Feeding should be stopped for overt regurgitation or aspiration. If gastric residual volumes are >500 mL, then withhold feedings and reassess tolerance. If residual volumes are ≤400–500 mL, this does not indicate

feeding tolerance or normal gastric emptying. Residual volumes between 200–500 mL should initiate a timely bedside evaluation and use of an algorithm to reduce risk for aspiration. At residual volumes <200 mL, there should still be continuing evaluation of risk of aspiration.[22]

If gastric stasis is present as reflected by large gastric residual volumes, the addition of a decompression tube such as a sump nasogastric tube may be needed.[23] The stomach should be intermittently decompressed no less than every 4 h and the nasogastric tube then clamped. The nasogastric tube should not be placed to continuous suction because it may cause irritation of gastric mucosa, alteration of fluid and electrolyte balance, and suction of feedings from the small bowel.[23] If frequent (e.g., hourly or more) decompression is needed, the nasogastric tube should be placed to gravity drainage without suction.[23]

The maintenance of feeding tube patency and resolution of tube obstruction when it occurs is important for continuation of adequate and safe delivery of nutrition. To maintain nasoenteric feeding tube patency, 2–5 mL of a pancreatic enzyme solution should be instilled into the tube every 6 h; if feedings are held, flush the tube with 15–30 mL water about every 4 h. Medications such as elixirs, solutions, suspensions, and syrups should not be delivered via the nasoenteric tube because they may crystallize and form large particles when in contact with the feedings. The likelihood of tube occlusion can also be reduced by delivering medications via a nasogastric tube instead of the nasoenteric tube.[23]

If the nasoenteric tube does become obstructed, and it is not twisted in the mouth or throat, aspirate the residual feeding in the tube, and then using a 5-mL luer slip syringe, repeatedly instill and aspirate 5 mL of water into the tube. If the tube remains obstructed, instilling pancreatic enzyme has a high rate of success[24]; repeat the same procedure as above with 2–5 mL of a pancreatic enzyme solution. If the tube does not clear in 20 min, tightly cap the ports and leave the enzyme in the tube for 1–2 h.[23] If the above procedures do not open the tube, and gastric residuals are low, restart feeding using the nasogastric tube.

TRANSABDOMINAL TUBE ENTEROSTOMIES: GASTRIC, JEJUNAL, AND TRANSGASTRIC JEJUNAL

As noted above, the long-term use of nasal feeding tubes (>4 weeks) may lead to significant complications. Additionally, nasal feeding tubes can become dislodged or obstructed. In patients requiring long-term nutritional support, access in the form of gastrostomy or jejunostomy is required. These tubes have a larger diameter, less tendency to clog, and allow easier and more rapid feeding and medication delivery. They also have less tendency to migrate, which may decrease the aspiration risk, and are more convenient and aesthetically acceptable.

Gastrostomy Tubes

Transabdominal gastrostomy can be placed surgically, laparoscopically, endoscopically, or fluoroscopically. Percutaneous gastrostomy can be placed with endoscopic or fluoroscopic guidance. Usually, surgical gastrostomy is a simple procedure often performed during another abdominal surgical procedure. However, laparotomy exposes the patient to the risk of ileus, wound infection, and dehiscence. Furthermore, major complications are more common (3–15%) when compared to patients undergoing percutaneous gastrostomy. For that reason in acceptable patients, percutaneous endoscopic gastrostomy (PEG) is preferable; it is also technically easier, cheaper, and postoperatively less painful than surgical gastrostomy. Although experience with laparoscopic techniques is limited, laparoscopic gastrostomy may be an alternative if PEG is contraindicated.

If possible, the preferred insertion method for a gastrostomy tube is percutaneous with endoscopic guidance.

The specific indications and contraindications for PEG tube placement are listed in Table 7-8. This procedure can be considered in patients with an inability to eat, normal gastric emptying, a low risk for pulmonary aspiration, and the absence of pharyngeal or esophageal obstruction to allow for performance of endoscopy. Contraindications include patients at risk for aspiration in such conditions as gastric outlet obstruction, gastric atony and prior

A PEG tube should be considered in patients with an inability to eat, normal gastric emptying, a low risk for pulmonary aspiration, and the absence of pharyngeal or esophageal obstruction to allow for the performance of endoscopy.

TABLE 7-8

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY (PEG): INDICATIONS AND CONTRAINDICATIONS

- Indications
  - Prolonged need (usually >4 weeks) for enteral feeding
  - Impaired swallowing or access/obstructive conditions
    - Neurologic conditions
    - Oropharyngeal/esophageal dysphagia
    - Neoplasm (oropharynx, larynx, esophagus)
  - Head/facial trauma
- Contraindications
  - Absolute
    - Functional impairment/obstruction of GI tract
  - Technical (absolute)
    - Uncorrectable coagulation abnormalities
    - Inadequate transillumination
    - Anterior abdominal/gastric walls cannot be approximated
    - Near-total esophageal or oropharyngeal obstruction
    - Subtotal gastrectomy
  - Technical (relative)
    - Gastric wall disease (inflammatory, tumor)
    - Ascites
    - Prior abdominal surgery
    - Extreme obesity

history of aspiration. These patients may be considered for gastrojejunostomy. Other contraindications include large esophageal varices, sepsis, left upper quadrant skin burns, and anterior abdominal or gastric wall malignancy or infection. Technical concerns such as coagulopathy, an inability to pass the endoscope (e.g., upper GI obstruction) or an inability to approximate the anterior abdominal and gastric walls may preclude this procedure. Massive ascites, especially after large-volume paracentesis, obesity, and previous abdominal surgery, are relative contraindications.

There are several variations on the original technique for percutaneous gastrostomy tube placement.[25-27] Although a detailed description of these techniques is beyond the scope of this chapter, the original and most popular of these is performed via a pull technique described in 1980 by Gauderer and others.[25] Briefly, the technique entails insertion of an endoscope through the esophagus and into the stomach. Air is then insufflated, resulting in gastric distension and approximation of the anterior gastric and abdominal walls with displacement of the transverse colon distally. The optimal insertion site, which is identified by maximal transillumination, is along the left lateral rectus muscle and inferior to the left lobe of the liver. After this site is transilluminated and confirmed by palpation, a small incision is made and the catheter needle is inserted through the incision and into the stomach. Under continued endoscopic observation, a heavy suture with a looped distal end is passed through the catheter and snared with a polypectomy loop. Both the endoscope and suture are drawn up the gastrointestinal tract and out the patient's mouth. The PEG catheter is then securely tied to the suture, guided into the esophagus and under endoscopic guidance, through the gastroesophageal junction and juxtaposed to the anterior wall.[28] After stomach decompression and endoscope removal, the inner and outer bumpers are secured.

The overall complication rates for PEG tubes vary from 4 to 24% with major complications comprising 3–4% and minor complications comprising 7–20% of cases.[29] However, based on several studies,[29-32] the procedure-related mortality rate of 0–2% and a 30-day mortality rate of 1.55–2.1% are low.[33] Complications include infection of the cutaneous insertion site, necrotizing fasciitis, peritonitis, septicemia, aspiration, peristomal leak, tube dislodgement, bowel perforation, pneumoperitoneum, gastrocolocutaneous fistula, internal bumper irritation/erosion into the abdominal wall, and GI bleeding (Table 7-9). Pneumoperitoneum due to gastric wall puncture is usually not clinically significant, but if fever and abdominal pain develop, a gastrograffin study should be performed. Excessive tension on the tube may cause gastric wall necrosis, leading to GI bleeding or to separation of the anterior gastric and abdominal walls during feeding, resulting in peritonitis.[28] Use of prophylactic antibiotics may reduce peristomal wound infection; antibiotics are needed only in those patients not receiving appropriate antibiotics for other infections. Excessive tension between the inner and outer bumpers may cause pressure necrosis of the wall and lead to tube dislodgment.

TABLE 7-9

PEG: COMPLICATIONS

- Infection
  - Insertion site wound infection
  - Necrotizing fasciitis
  - Sepsis
  - Peritonitis
- GI hemorrhage
- Gastrocolocutaneous fistula
- Pneumoperitoneum
  - Bowel perforation
- Aspiration
- Peristomal leakage
- Tube dislodgment
- Internal bumper irritation/erosion into the abdominal wall

Replacement of a dislodged gastrostomy tube can only be considered if the fistulous tract is mature; otherwise, this is performed endoscopically.

Jejunostomies and Transgastric Jejunostomies

Jejunostomy tube insertion techniques include percutaneous endoscopic or fluoroscopic, needle-catheter and subserosal, a combination of gastric and jejunal access, and transgastric.

Indications for jejunostomy tube insertion include prevention of aspiration, prior gastric resection, and postoperative gastroparesis.

Jejunal feedings must be continuous as bolus feeding is poorly tolerated.

Jejunal tubes can be placed using endoscopic, fluoroscopic, laparoscopic, or surgical methods. However, for jejunostomy tubes, surgical and fluoroscopic techniques are the best methods. The lumen of the small intestine is narrow, making it difficult to insert a jejunal feeding tube percutaneously and the laparoscopic indications and techniques are still developing. Specific procedures include the surgical jejunostomies: needle-catheter jejunostomy and subserosal tunnel jejunostomy (Witzel procedure), percutaneous endoscopic jejunostomy (PEJ), or a transgastric jejunostomy.[28] Although still controversial, the most common indication for jejunal tube placement is to help prevent repeated feeding-related aspiration, especially in medical conditions with a significant aspiration risk, such as severe GE reflux, gastroparesis, and neurologic disorders. Other indications include patients with prior gastric resection or gastrocutaneous fistula, and also following postoperative abdominal surgery as small intestinal motility is usually restored more quickly than gastric motility (Table 7-10). Contraindications to jejunostomy tube placement include ileus, distal bowel obstruction, radiation and regional enteritis, and anesthetic considerations.[28] Jejunal feedings must be continuous, as opposed to gastric feeding where the stomach can act as a reservoir for bolus feeds. General complications of jejunostomy are included in Table 7-11. Some complications are specific to the type of procedure.

The needle-catheter jejunostomy is the method of choice in many centers and is usually performed at the time of laparotomy for another indication. The procedure does require a proficient and experienced operator. It involves the insertion of a needle into the small intestine, after which a polyethylene catheter is inserted through the needle and then through the anterior abdominal wall. Complications specific to needle-catheter jejunostomy include small bowel ischemia, pneumatosis intestinalis (1%), and small bowel obstruction (<1%).

TABLE 7-10

JEJUNOSTOMY: GENERAL INDICATIONS AND CONTRAINDICATIONS

- Indications
  - Repeated tube feeding-related aspiration
    - Severe GE reflux
    - Gastroparesis
    - Neurologic disorders
  - Gastric resection
  - Gastrocutaneous fistula
  - Postoperative laparotomy
- Contraindications
  - Enteritis
  - Small bowel ischemia
  - Ileus
  - Postjejunal obstruction
  - Short bowel syndrome
  - Intermittent or bolus feedings

TABLE 7-11

JEJUNOSTOMY TUBES: COMPLICATIONS

Wound infection
Proximal/distal tube migration
Intestinal obstruction
Intraabdominal leak
Small intestine ischemia/infarction
Tube malfunction: clogging

SOURCE: Data from Bankhead and Rolandelli[28]

Feedings should be held for patients at risk for bowel ischemia, which include those who are hypotensive and/or receiving vasopressors.

PEJ is a method to obtain access to the stomach and jejunum for decompression and jejunal feeding. The procedure, which is technically difficult, essentially involves the initial placement of a large-bore PEG tube followed by coaxial insertion of a smaller jejunal tube.

The transgastric approach provides better and easier access to the stomach and small intestine than the PEJ and also allows gastric decompression and jejunal feedings. These tubes are especially useful in critically ill patients who undergo laparotomy and require gastric decompression and enteral nutritional support. The transgastric jejunal tube procedure can be performed radiologically or surgically; the endoscopic technique has not yet been perfected.

SUMMARY

Enteral feeding is superior to parenteral nutrition because it is associated with fewer complications and is more cost-effective. In general, enteral feeding should be started in patients who have an intact GI tract, no obstruction, a GI output less than 500 mL/day, and are at risk for malnutrition. Some conditions, such as intestinal obstruction, ileus, enteric fistulas, *Clostridium difficile* colitis syndrome, and severe GI bleeding preclude the use of enteral tube feeding. Accordingly, GI tract function should be carefully evaluated prior to tube placement.

There are two general approaches for delivering enteral tube feeding: nasal/oral feeding tubes and gastrostomy and jejunostomy tube enterostomies; the latter may be inserted under fluoroscopic, laparoscopic, endoscopic, or surgical guidance. Nasal or oral enteric feeding tubes are primarily used for patients requiring short-term feeding while the more invasive procedures are recommended for patients requiring long-term feeding. Fluoroscopic and endoscopic guidance methods have been used for postpyloric placement of nasal and oral feeding tubes. Confirmation of correct tube placement requires interpretation of radiographic plain films. The long-term use of nasal or oral feeding tubes may lead to significant complications.

Gastrostomy should be considered in patients with an inability to eat, normal gastric emptying, low risk for pulmonary aspiration, and absence of bowel obstruction. Other indications for gastrostomy include patients who have access problems, facial trauma, or oral pharyngeal dysphagia. A percutaneous endoscopic technique cannot be performed in the presence of significant pharyngeal or esophageal obstruction. Otherwise, PEG is generally the procedure of choice. Contraindications include patients at risk for aspiration, but these patients may be considered for gastrojejunostomy.

Gastrojejunostomy carries a low complication rate compared to surgical placement. Although still controversial, the most common indication for jejunostomy placement is to help prevent aspiration in patients with high aspiration risk. Other indications include prior gastric resection and postoperative abdominal surgery. The types of feeding jejunostomy tubes include surgical jejunostomies such as needle-catheter jejunostomy or subserosal tunnel (Witzel procedure), PEJ, and transgastric jejunal tubes. Jejunostomy feedings must be continuous as bolus feeding is not well tolerated.

The clinician has a number of techniques and feeding tubes to choose from, each with their own indications, contraindications, and associated risks. Further refinements in tube technology and techniques will continue to expand and improve the options for enteral nutrition.

REVIEW QUESTIONS

Each of the questions below has one best answer.

1. **Which statement regarding enteral feeding is false?**
   - **A.** Should be avoided in patients with paralytic ileus
   - **B.** Should be avoided in all patients with gastrocutaneous fistula
   - **C.** Is cheaper and associated with fewer complications than parenteral nutrition
   - **D.** Helps to prevent intestinal atrophy
   - **E.** May increase gastric pH and improve mild gastrointestinal bleeding

2. **A 60-year-old man with diabetes mellitus and amyotrophic lateral sclerosis develops respiratory failure secondary to pneumonia and requires mechanical ventilation. After 4 weeks of nasoduodenal feeding for persistent gastric atony, the patient develops nasopharyngeal stenosis. Of the following, the most appropriate method to provide nutrition is:**
   - **A.** Total parenteral nutrition (TPN)
   - **B.** Nasogastric tube feeding
   - **C.** Open gastrostomy
   - **D.** Nasojejunal tube
   - **E.** Jejunostomy
   - **F.** Percutaneous endoscopic jejunostomy
   - **G.** Transgastric jejunal

3. **Contraindications to enteral support in any amount include all except:**
   - **A.** Clinical shock
   - **B.** Complete bowel obstruction
   - **C.** Intestinal bowel ischemia
   - **D.** Paralytic ileus
   - **E.** Enterocutaneous fistula (output 700 mL/day)

4. **Complications that can occur during nasal or oral enteral feeding tube insertion/placement include all except which of the following:**
   - **A.** Esophageal perforation
   - **B.** Esophageal variceal rupture
   - **C.** Pericardial effusion
   - **D.** Pneumothorax
   - **E.** Fatal intracranial placement

5. **In assessing the patient for a nasal feeding tube, *known* factors increasing the risk for complications associated with feeding tube insertion include all the following except:**
   - **A.** Delirium
   - **B.** Septal deviation
   - **C.** Esophageal web
   - **D.** Gastric obstruction
   - **E.** Impaired gag reflex
   - **F.** Congestive cardiomyopathy

6. **The most reliable methods to distinguish between gastric and duodenal placement of a enteral feeding tube are:**
   - **A.** Testing pH and color of aspirated fluid
   - **B.** Air insufflation and abdominal auscultation
   - **C.** Plain abdominal roentgenogram
   - **D.** Aspiration of bile

7. **An absolute contraindication to PEG is:**
   - **A.** Ascites
   - **B.** Oropharyngeal dysphagia
   - **C.** Previous abdominal surgery
   - **D.** Partial (25%) esophageal obstruction
   - **E.** Prior subtotal gastrectomy

ANSWERS

1. The answer is B. A nasoenteric tube can be placed more distally to bypass the fistulous tract. Compared to parenteral nutrition, enteral feeding is cheaper, associated with fewer complications, and helps to prevent intestinal mucosal atrophy even with as little as 10 mL/h.
2. The answer is G. At this time, the patient continues to have persistent gastric atony that would preclude oral, nasogastric tube, and open gastrostomy feeding. Although nasal-jejunal tube feedings are suitable for short-term use, the patient has been on nasal tube feeding for 4 weeks and has also developed a complication of prolonged nasal tube feeding. Other jejunal feeding methods would be appropriate, and several can be considered, such as PEJ, jejunostomy (by laparotomy, laparoscopic, or fluoroscopic methods), and transgastric jejunostomy (by surgical or fluoroscopic methods). Jejunostomies are usually indicated for patients with temporary gastric reflux or atony. PEJ can provide simultaneous access to the stomach and jejunum for decompression and jejunal feedings. However, the technique is difficult, the gastric component often provides ineffective decompression, and the jejunal component frequently returns to the stomach. Transgastric jejunostomy has advantages over the PEJ or jejunostomy as it can provide more effective gastric decompression and enteral feeding until gastric dysfunction resolves, and then, if needed, provide for directly administered gastric feeding.
3. The answer is E. Although enteral nutrition can be administered to patients with enterocutaneous fistula, they should be monitored carefully. Enteral feedings during clinical shock may cause bowel ischemia and infarction, especially in those patients with acute risk for bowel ischemia. Intestinal bowel ischemia may result in bowel infarction. Further evaluation would be required to determine if feeding could be given. Complete bowel obstruction is an absolute contraindication. For paralytic ileus due to a wide variety of reversible and nonreversible causes, the physician should evaluate and treat the cause while parenteral nutrition is administered.
4. The answer is C. The insertion of small-bore feeding tubes has less risk for complications than the insertion of central venous lines for parenteral nutrition. Despite improvements in enteral feeding tube technology for more accurate insertion and placement (e.g., better radiopaque tube quality, self-lubrication, and less rigid stylets), a number of misplaced tubes have resulted from increased use of small-bore tubes. Placement of small-bore feeding tubes should be performed carefully, especially in intubated patients on mechanical

ventilation. Pericardial effusion has not been noted as a complication directly associated with nasal or oral tube insertion. To help avoid intracranial placement, exercise more caution in patients with maxillofacial or basilar skull fractures and use oral insertion or endoscopy. In general, if resistance is met during tube insertion, discontinuation of tube placement may help avoid a number of complications such as esophageal perforation, esophagitis, gastrointestinal perforation, and pneumothorax. The risk of esophageal variceal rupture may be reduced by using a smaller, softer tube and caution with guidewires.

5. The answer is F. Congestive cardiomyopathy is not a known risk factor for feeding tube insertion. The other factors have been described in the literature.
6. The answer is C. A plain roentgenogram of the abdomen is very reliable. However, if the location (stomach or proximal duodenum) of the feeding tube is still not clear, injection of a radiopaque liquid can help verify the location. Of the physical signs, testing pH and color of aspirated fluid is more reliable than the other physical signs, but both have some problems.
7. The answer is E. Depending on the amount of residual stomach present, other surgical techniques may be helpful; all the others are relative contraindications. Massive ascites was initially an absolute contraindication, but if the ascites is drained and the bowel is not interposed between the anterior gastric and abdominal walls, the technique can be performed. Previous abdominal surgery may cause technical problems, but the abdomen needs further evaluation including CT scan imaging. For partial (25%) esophageal obstruction, PEG can be performed if the obstruction is less than near total to allow endoscopy to be performed.

SHEILA E. WEAVER

Common Procedures in the Intensive Care Unit: Thoracentesis, Lumbar Puncture, Paracentesis, and Pericardiocentesis

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to do the following:

- Know the general methods of aseptic and local anesthesia techniques in most common ICU procedures.
- Know the most important indications and contraindications for thoracentesis, lumbar puncture, paracentesis, and pericardiocentesis.
- Know how to diagnose and treat complications associated with the described procedures.
- Know the common methods of performing thoracentesis, lumbar puncture, paracentesis, and pericardiocentesis.

Informed consent, patient comfort, and sterile technique are important for any type of procedure.

Several general conditions should be fulfilled before performing any type of invasive procedure. First, the benefits and nature of the procedure and possible complications should be explained in full to the patient and their family members. An informed consent, preferably written, should always be obtained before performing any procedure.

Second, care should be taken to minimize patient discomfort during the performance of any intervention. Reassuring and communicating with the patient before and during the procedure can provide much psychological comfort. A well-organized procedural plan includes the proper number and types of instruments, available monitoring equipment, and intravenous access, all to be prepared beforehand. Proper planning shortens the time of an intervention and provides a sense of comfort to both the patient and the operator.

Third, the correct type and dose of anesthetics have a great value in the conduct of any procedure. In most cases, especially for the procedures discussed in this chapter, local anesthesia, usually with topical infiltration of lidocaine, is suggested. However, in some ICU patients undergoing procedures, the systemic use of analgesic, sedative, or paralytic agents may be employed on occasion to control agitation or discomfort.

Finally, optimal positioning not only facilitates the performance of a procedure but may also help avoid complications. Because infection is a common complication of a variety of procedures, special attention should be devoted to performing procedures with an aseptic, sterile technique. Generally, the skin over the procedural site is carefully and thoroughly cleansed with an antiseptic solution over an area that extends at least 4–6 in. in all directions from the selected site. A sterile drape with the center hole taped around the site of skin entry is required, and the operator is appropriately gowned and gloved to ensure sterile operator technique.

In this chapter, we discuss the diagnostic and therapeutic procedures that are commonly used in ICU patients. Special attention is given to the indications, the technique of performance, and the adverse effects of the procedures most commonly performed.

THORACENTESIS

The pleural cavity is a potential space for the accumulating fluid resulting from different pathophysiological conditions. There is always a small amount of fluid in the pleural space. This thin layer of fluid acts as a lubricant and helps the visceral pleura to move efficiently along the parietal pleura during respiratory excursions. The normal amount of pleural fluid has not been formally established; however, it is agreed that up to 3–5 mL of fluid may normally be present in each pleural space at any given time.

Indications

Indications for thoracentesis can be divided in two major categories: diagnostic and therapeutic. A diagnostic thoracentesis is performed to sample the pleural effusion to evaluate the type and character of the fluid (Table 8-1) and to confirm or exclude certain pathophysiologic states (Table 8-2). A therapeutic thoracentesis serves to remove a sufficient amount of fluid to make a diagnosis and relieve the symptoms caused by the accumulation of fluid in the pleural space.

Contraindications

The main contraindication to thoracentesis is the presence of a coagulopathy or hemorrhagic diathesis. We recommend measuring not only prothrombin time but also partial thromboplastin time and a platelet count before the procedure. Also, blood urea nitrogen and creatinine should be measured in patients with suspected renal insufficiency because patients with

The major contraindication for thoracentesis is coagulopathy.

TABLE 8-1

CRITERIA FOR DIFFERENTIATION OF TRANSUDATE AND EXUDATE

CRITERIA	TRANSUDATE	EXUDATE
Ratio of pleural fluid protein to serum	< 0.5	> 0.5
Ratio of pleural fluid LDH to serum	< 0.6	> 0.6
Pleural fluid LDH	< 2/3 the upper limit of normal for serum	> 2/3 the upper limit of normal for serum

LDH lactate dehydrogenase

TABLE 8-2

COMMON CAUSES OF TRASUDATIVE AND EXUDATIVE PLEURAL EFFUSIONS

VARIABLE	TRANSUDATE	EXUDATE
Common causes	Cirrhosis Nephrotic syndrome Congestive heart failure Pulmonary embolism	Cancer Pneumonia Tuberculosis Trauma Rheumatoid arthritis Systemic lupus erythematosis Pulmonary embolism

azotemia may have serious platelet dysfunction. If necessary, coagulopathy or platelet abnormalities should be corrected or minimized before the procedure. A thoracentesis should be avoided in areas of cutaneous infection. Obviously, if the patient is hemodynamically unstable, stability should be restored before the procedure.

Patient Position

In the intensive care unit, thoracentesis may be performed while the patient lies recumbent with the head of the bed elevated close to 90°. In this case, thoracentesis is performed in the midaxillary line.

Correct positioning of the patient has a significant role in the successful performance of a thoracentesis. Usually, the patient is placed in the sitting position, leaning forward, with the arms outstretched and supported at shoulder height with feet resting on a footstool (Fig. 8-1). It is recommended that the patient be positioned with the back vertical so that the pleural fluid remains more posterior and dependent second to gravitational effects. For an ICU patient too ill to sit erect, a thoracentesis may be performed in the supine position with the head of the bed elevated close to a 90° angle. In this position, thoracentesis is performed in the posterior axillary line after localization by ultrasound.

Site Selection

Physical findings, such as percussion dullness, reduced or absent breath sounds, and loss of tactile fremitus, are all very helpful in the identification and localization of pleural effusions. However, before any attempts at thoracentesis, the amount and location of pleural effusion should be confirmed, at least by chest X-ray imaging. It is important to establish whether the

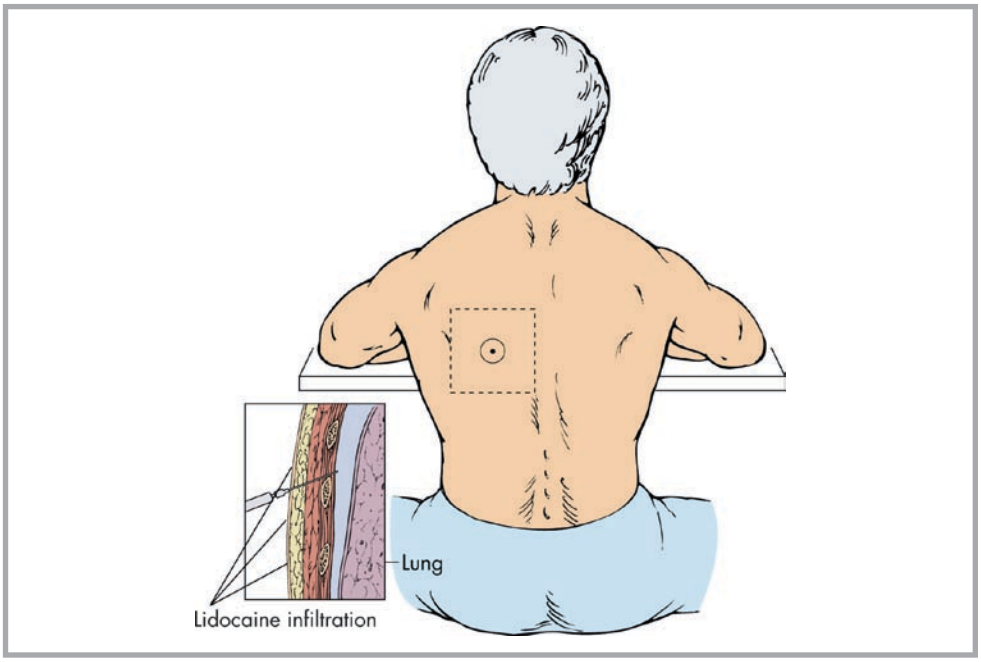

FIGURE 8-1

Positioning for thoracentesis. The sitting position, with the arms supported by the bedside table and feet resting on a footstool, is recommended for thoracentesis (*Inset*). (from www.imagesmd.com. Used with permission)

pleural effusions are free flowing or located. One of the simplest diagnostic tests is a supine and bilateral decubital chest X-ray. If the position of the pleural effusion changes, a free-flowing pleural effusion is most likely present. In addition, ultrasound is a useful bedside tool to help determine the location and depth of an effusion. Generally speaking, pleural effusions have an anechoic appearance. The effusion needs to be visualized with the probe placed in the intercostal space with an established gravitational axis.[1] Ultrasound imaging is especially helpful in cases of smaller or loculated pleural effusions as it allows the operator to locate and measure the collection of pleural fluid more precisely.

Thoracentesis should be performed one interspace below the spot where percussible sounds become dull, and approximately 5–10 cm lateral to the spine, a location where the ribs are wider and more easily palpated. Ultrasound can be helpful in confirming this potential site. The precise location for the penetration of the skin should be just superior to a rib. This location avoids the arteries, veins, and nerves that run just inferior to the rib, thereby minimizing the risk of pleural bleeding and intercostal nerve injury. The needle should not be inserted below the ninth rib to help prevent intraabdominal injury.

Thoracentesis should be performed with the needle advanced into the pleural cavity over the superior aspect of a rib.

Technique

The materials required to perform a thoracentesis (Table 8-3) should be assembled before starting the procedure. Once the thoracentesis puncture site is identified and sterilely prepared, the skin is anesthetized with a 25-gauge needle, connected to a 5-mL syringe, and filled with 1% lidocaine solution, creating a skin wheal (Fig. 8-2). Then, with a 20–22-gauge needle, the operator should anesthetize the deeper subcutaneous tissues, the rib periosteum, and the parietal pleura. The needle, positioned above the rib, may be slowly advanced into the pleural space with continuous aspiration followed by the injection of about 0.2–0.3 mL of lidocaine every 1–2 mm. This technique guarantees anesthesia of the parietal pleura and avoids accidental injection of lidocaine into the intercostal vessels. When pleural fluid is aspirated into the syringe, stop advancing the needle and inject the remaining lidocaine to anesthetize the parietal pleura. Note the depth of the needle prior to withdrawal.

Aspiration of Pleural Fluid

An 18-gauge over-the-needle catheter attached to a syringe should be inserted at the original aspiration site (Fig. 8-3). The needle should be advanced slowly with constant aspiration being applied. Once pleural fluid is seen in the syringe, stop advancing the needle, and carefully guide the catheter over the needle. The needle can then be removed, leaving only the catheter within the pleural cavity. Cover the hub of the catheter with a finger to prevent air

entry. Then attach a 50-mL syringe with a three-way stopcock to the catheter hub. Position the stopcock so that it is open to the patient and syringe. Aspirate 50 cc of pleural fluid for diagnostic analysis and close the stopcock to the patient. Repeat as necessary, not to exceed more than 1,500 mL of pleural fluid. Attach additional tubing and a collection bag to the third port of the stopcock if a therapeutic thoracentesis is desired. Prepackaged thoracentesis kits are commercially available which allow for the tubing to be attached to the third port of the stopcock without having to disconnect the syringe from the catheter or reposition the stopcock.

Once completed, the catheter is removed from the pleural space as the patient exerts a valsava maneuver at the end of expiration. The catheter should be removed with simultaneous gentle pressure over the puncture site with sterile gauze and covered with an occlusive dressing. Close attention should be paid to removing all sharp objects with appropriate disposal. A chest ray is recommended to ensure that there is no evidence of a pneumothorax.[2]

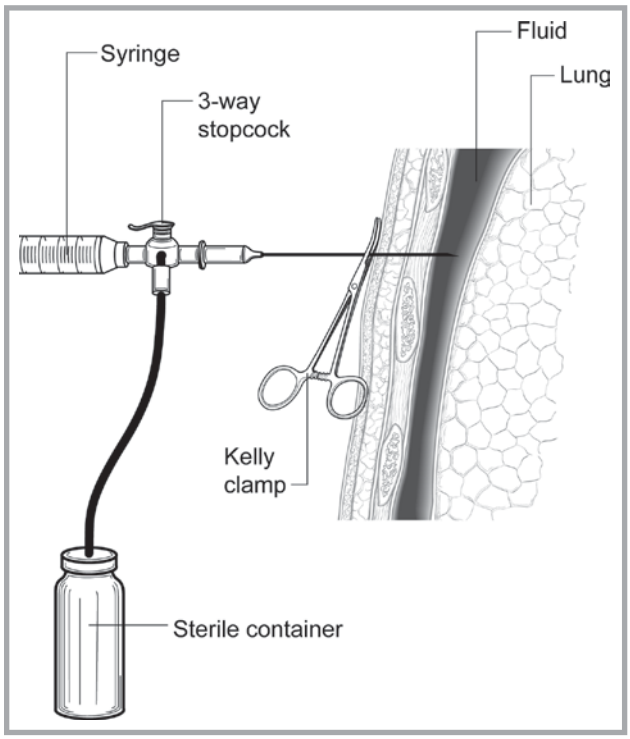

FIGURE 8-3

Final step of thoracentesis. Pleural fluid is withdrawn by a 50-mL syringe connected via a three-way stopcock to the pleural catheter and sampling container (illustration by Alice Chen).

Pleural Fluid Analysis

If thoracentesis is performed for diagnostic reasons, pleural fluid should be collected in special tubes, which are usually provided by almost all types of thoracentesis kits, and sent for chemistry analysis, which includes protein, glucose, and lactate dehydrogenase (LDH). Cytology, bacterial Gram stain, and aerobic and anaerobic cultures should also be done. We recommend sending at least 50–100 mL of pleural fluid for cytologic examination; an amount of fluid that may increase the diagnostic sensitivity for cytologic analysis. A separate specimen may be needed for pleural fluid pH analysis. For pH sampling, we recommend that the pleural fluid be placed in an arterial blood gas syringe with the specimen inserted in ice and delivered to the lab as soon as possible. Delays in pleural fluid processing may significantly alter the pH.

Complications

Pneumothorax is the most common complication of thoracentesis.

The most common complication of thoracentesis is pneumothorax. The incidence of pneumothorax after thoracentesis varies significantly, ranging from 5 to 20%. However, serious pneumothorax requiring chest tube placement occurs relatively rarely and probably occurs in less than 5% of all cases of pneumothorax resulting from thoracentesis.

Another complication of thoracentesis is hemothorax, which usually occurs as a result of injury to the intercostal artery. This complication can usually be avoided if thoracentesis is performed just superior to a rib, as previously described. However, in certain conditions, such as severe pulmonary hypertension or bronchiectasis, or in older patients, the intercostal arteries may be tortuous and hemothorax can result even when proper technique is performed. An infection of the pleural space is a rare complication of thoracentesis. About 2% of all pleural infections are caused by infection of the pleural space during thoracentesis. Strict enforcement of sterile technique during thoracentesis is necessary to help prevent this complication.

Post thoracentesis reexpansion pulmonary edema is a rare, although potentially serious, complication. The etiology and pathogenesis of this complication are complex and not well established. It may occur when the lung is reexpanded too rapidly and stretch lung injury

causes noncardiogenic pulmonary edema. However, this complication is preventable and almost never occurs when the pleural fluid is withdrawn slowly. For this reason, we do not recommend using vacuum bottles for thoracentesis and prefer to aspirate the pleural fluid slowly by manual methods. The amount of fluid that is safe to remove while avoiding reexpansion pulmonary edema is controversial. However, it is generally believed that up to 1,500 mL of pleural fluid can be safely withdrawn without causing reexpansion pulmonary edema.

The patient may also develop a vasovagal episode during thoracentesis, which is characterized by bradycardia, decreased cardiac stroke volume, and a fall in blood pressure. A vasovagal reaction may occur secondary to the stimulation of the parietal pleura if not properly anesthetized. This reaction can be treated and prevented by intramuscular administration of 1 mg atropine. Other rate complications of thoracentesis include splenic and hepatic puncture, soft tissue infection, and adverse reactions to the local anesthetic.

PARACENTESIS

Indications

A diagnostic paracentesis is particularly important in patients with new-onset ascites of uncertain etiology. In addition, a diagnostic paracentesis should also be performed in patients with preexisting abdominal ascites and spontaneous bacterial peritonitis (SBP).[3] SBP is common in patients with ascites due to cirrhosis and can be life-threatening as it can lead to sepsis and shock. Diagnostic paracentesis can also be used to rule out intraabdominal hemorrhage in patients with a rapid increase in ascitic fluid that was previously well controlled by medical therapy. Therapeutic paracentesis is usually performed in patients with respiratory compromise secondary to the restrictive effect of severe, massive ascites.

The major indication of paracentesis is to evaluate the etiology of ascites or remove excessive amounts of fluid.

Contraindications

Patients with ascites due to liver disease frequently have an associated coagulopathy or thrombocytopenia. Paracentesis should be avoided if there is evidence of disseminated intravascular coagulation. There are no data-supported coagulopathy values which preclude a paracentesis. Bleeding complications are reportedly uncommon.[4] Therefore, the potential harm of the prophylactic use of blood products should be weighed against the risk of bleeding. Secondly, patients with associated renal failure may have a higher risk of bleeding complications. Lastly, paracentesis should be avoided in pregnancy, urinary obstruction with bladder distension, and unavoidable abdominal wall infection.

Site Selection

The best site for paracentesis is the left flank of the lower abdomen lateral to the rectus abdominis muscle.

The most important aspect of site selection is choosing an avascular site on the abdominal wall. The usual point for penetration is the lower abdominal wall, just lateral to the rectus abdominis muscle in the left lower abdominal quadrant; other sites can also be used (Fig. 8-4).

Procedure

Prior to the procedure, the indications, risks, and benefits should be explained to the patient and informed consent obtained. Before the procedure, it is very important to ensure that the urinary bladder is well drained to avoid accidental bladder injury. Also, before the procedure, the operator should confirm the presence of ascitic fluid at the site of intended paracentesis, which is usually done by percussion of the anterior abdominal wall. On occasion, ultrasound guidance may be used. In most cases, however, physical examination suffices. The patient is placed in the supine position. The skin in the area of the intended procedure must be cleaned and sterilely draped. Skin anesthesia is achieved by creating a skin wheal with the injection of 1% lidocaine, using a 25-gauge needle. Lidocaine is then injected with

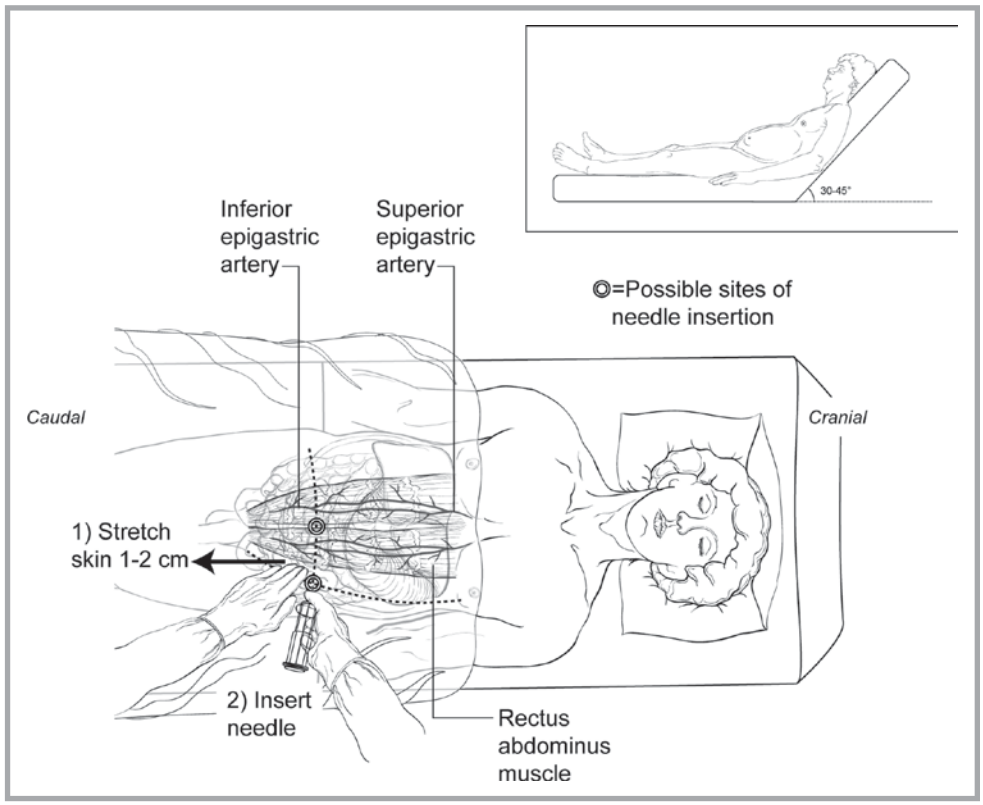

FIGURE 8-4

Positioning of the patient and needle for diagnostic paracentesis using the Z-tract technique (illustration by Alice Chen).

a larger needle (e.g., 20-gauge needle), first through the skin wheal and then through the fascia and peritoneum. When the peritoneal space is entered, a "pop" or loss of tissue resistance is felt.

There are two acceptable techniques for advancing the catheter through the skin, subcutaneous tissues, and parietal peritoneum. The first is the angular technique in which the needle is placed at a 45° angle to the abdominal wall and follows that trajectory into the peritoneal cavity. The second is the Z-tract technique in which the subcutaneous tissues are pulled 2 cm in the caudal direction and the needle is inserted at a 90° angle to the abdominal wall into the peritoneal cavity (Fig. 8-3). When the needle is withdrawn, the cutaneous tissue will retract to their original position creating an overlap of the peritoneal entry in an effort to minimize ascitic fluid leak.

After the skin is anesthetized, a 20-gauge angiocatheter attached to at least a 20-mL syringe is inserted through the anesthetized area into the peritoneal space. Advance the needle carefully through the subcutaneous tissues while intermittently attempting to aspirate. Once the peritoneal cavity is entered, the same loss of resistance will again be felt. When the ascitic fluid appears in the syringe, stop advancing the needle, and carefully guide the catheter over the needle and withdraw the needle. If a diagnostic sample is needed, withdraw approximately 60 mL of fluid. If a therapeutic tap is required, attach the tubing to the catheter hub and then to a negative pressure container. Once the desired amount of fluid is removed, remove the catheter and apply a sterile occlusive dressing.

Peritoneal Fluid Analysis

Ascitic fluid should be placed in appropriate specimen tubes without delay. If the diagnosis of SBP is suspected, culture bottles should be inoculated at the bedside. Initial laboratory values include a cell count and differential, albumin, and total protein. Other studies can be ordered based on pretest probability. If there is a clinical suspicion of pancreatitis, a sample can also be sent for amylase. An elevated carcinoembryonic antigen and alkaline

TABLE 8-4

DIFFERENTIAL DIAGNOSIS ACCORDING TO THE SERUM-ASCITES ALBUMIN GRADIENT (SAAG)

GRADIENT >1.1 g/dl (PORTAL HYPERTENSION)	GRADIENT <1.1 g/dl
Cirrhosis	Peritoneal carcinomatosis
Alcoholic hepatitis	Pancreatic ascites
Cardiac ascites	Tuberculous peritonitis
Budd-Chiari	Biliary ascites
Liver metastasis	Nephrotic syndrome
Portal-vein thrombosis	Serositis

phosphatase are suggestive of a perforated hollow viscus. An elevated triglyceride level may suggest a chylous ascites.[5] The *serum-ascites albumin gradient* (SAAG) is the difference between the serum fluid albumin level and the ascitic albumin. The serum albumin level should be obtained at the time of the paracentesis. Generally, values greater than 1.1 g/dL indicate portal hypertension as the cause of the ascites[6] (Table 8-4).

Complications

Complications of paracentesis, which are uncommon, include bleeding, injection, bowel or bladder perforation, and a persistent leak of ascitic fluid. Hypotension may develop after a large volume paracentesis. This is a risk for the development of hepatorenal syndrome which is a result of extreme arterial underfilling and vasoconstriction of the renal circulation.

LUMBAR PUNCTURE

Indications

The major indication for lumbar puncture of the ICU patient is to obtain spinal fluid for chemical and microbiological analysis, as well as opening pressure measurements, to diagnose or exclude CNS infection, subarachnoid hemorrhage, or increased intracranial pressure states. Occasional indications may include administration of analgesics following surgery or trauma, or for pain relief in conditions such as reflex sympathetic dystrophy. Lumbar puncture can also be used as a route to administer antibiotics.

The major indication for the performance of lumbar puncture is for diagnostic purposes.

Contraindications

Absolute contraindication for lumbar puncture is full anticoagulation or severe coagulopathy, because of the significantly increased risk of epidural hematoma formation with severe neurologic sequelae. Cardiopulmonary compromise may occur in some patients as a result of the position required for the procedure. Patients with some degree of respiratory compromise should avoid a lumbar puncture. Cutaneous infection of the procedure site also represents an absolute contraindication. Lumbar puncture should be avoided if there are any signs or symptoms of increased intracranial pressure as withdrawal of spinal fluid may lead to brainstem herniation. Therefore, if there is any clinical suspicion, a head CT scan should be done prior to the procedure.

Positioning and Landmarks

Before attempting a lumbar puncture, one should clearly identify bony markings and properly position the patient. The operator should remember that the space between the vertebrae varies depending on the patient's position, weight, and height. Occasionally, osteoarthritis and spinal fusion can completely obliterate the space between the vertebrae and make the procedure extremely difficult. Positioning of the patient is absolutely critical for success in performing this procedure. The lateral decubitus position is preferred to obtain an accurate opening pressure and reduce the risk of a postprocedure headache. The patient should assume the fetal position, which is achieved by flexing the knees to the chest and flexing the neck.

The fetal position is optimal for the performance of lumbar puncture in the ICU setting.

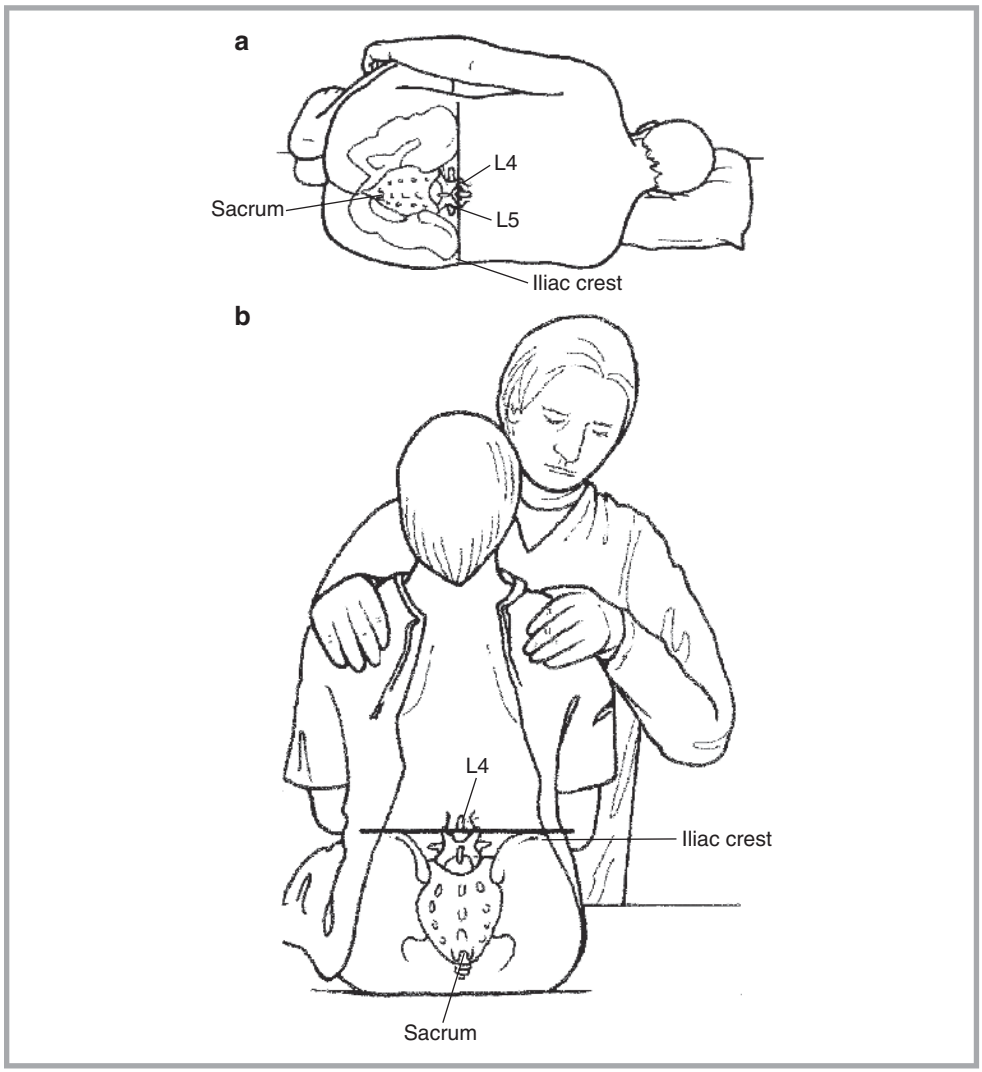

FIGURE 8-5

Positioning for lumbar puncture. (**a**) Lateral decubitus position. (**b**) Sitting position. A line connecting the iliac crests crosses over L4 or the L4–L5 interspace.

This position allows greater separation between the vertebrae, and therefore, facilitates penetration of the intervertebral space (Fig. 8-5a,b).

If the patient is in the flexed lateral decubitus position, a line projected between the iliac crests crosses over the L4 vertebra or L4–L5 interspinal space. In most cases, the spinal cord terminates at the level of L2. Therefore, a lumbar puncture procedure performed at the level of L4–L5 rarely causes any spinal cord injury. These landmarks should be palpated and marked if necessary before preparing the skin or applying anesthetic.

Assistance may be necessary for this procedure, especially in the ICU setting. An assistant facilitates patient positioning and monitors vital signs. Different commercial lumbar puncture kits can be used with care to ensure aseptic technique. The choice of the kit depends on local preference and economics. Any kit used should include the items listed in Table 8-5.

Method

After the skin is cleaned and draped, under sterile technique, it is infiltrated with a few milliliters of a local anesthetic. A topical anesthetic cream can be used prior to infiltration of the skin. Several approaches may be used to perform a lumbar puncture. A midline approach is most commonly used during lumbar puncture and is considered the preferred method. A special needle with an introducer is inserted into the interspinal ligament at the L3–L4 or L4–L5 interspace (Fig. 8-6). The spinal needle is passed through the introducer and carefully

TABLE 8-5

MATERIALS REQUIRED TO PERFORM LUMBAR PUNCTURE

MATERIALS FOR LOCAL ANESTHESIA AND STERILE TECHNIQUE	MATERIALS FOR OBTAINING SPINAL FLUID
Aseptic solution	Spinal needle with stylet
Sterile gloves	Spinal fluid collection tubes ($n=4$)
Sterile gauze pads	Manometer tubing
Sterile drape with center hole	
Sterile gauze pads	
Lidocaine, 1% solution	
25-gauge needle ($n=1$)	
10-mL syringe ($n=1$)	
Bandage	

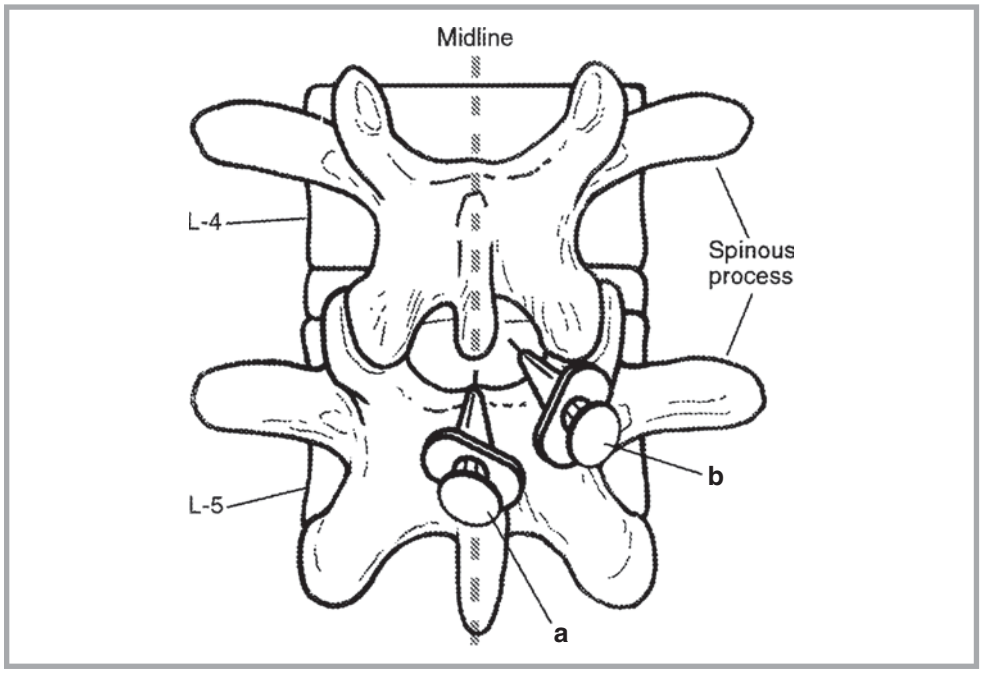

FIGURE 8-6

Lumbar puncture approaches. (**a**) Midline approach. (**b**) Paramedian approach. A midline approach is recommended.

and slowly advanced in a slightly cephalad direction. A typical decrease in resistance occurs as the needle traverses the ligamentum flavum and approaches the subarachnoid space. At this point, withdraw the stylet in 2 mm intervals to assess for cerebrospinal fluid (CSF) flow. Normal spinal fluid is "tear-clear" in gross appearance. When spinal fluid is seen in the needle hub, a manometer should initially be attached to measure spinal fluid pressure. If the tap is traumatic, the CSF may be tinged with blood but should clear as additional CSF is collected unless there is a subarachnoid hemorrhage. If the flow is poor, the needle can be rotated by 90° as a nerve root may be obstructing the flow.[7] After measuring the opening pressure, collect the CSF into specimen tubes as it drips out of the spinal needle. The volume collected should be as little as needed, approximately 3–4 mL. After the collection is complete, replace the stylet and remove the needle. The point of entry is covered with a sterile bandage and the patient is placed in the supine position. Spinal fluid is collected for cytology and cell count, protein and glucose determinations, serology, and microbiology at the end of the procedure.

Complications

Headache is probably the most common complication of lumbar puncture and is believed to be due to persistent CSF leak. The onset of headache may not occur until several hours after

the procedure and worsens if the patient does not maintain the supine position. Headache usually resolves with bed rest, fluids, and analgesics. However, in severe cases of headache, an epidural block patch can be applied. (The description of this technique is beyond the scope of this chapter.) The occurrence of headache after a lumbar puncture is prevented in most cases by 6–8 h of bed rest.

Headache is the most common complication following a lumbar puncture. It can be prevented by maintaining the patient in the supine posture several hours after the performance of the procedure.

The most common cause of neurologic damage following lumbar puncture is needle trauma, which usually affects a single spinal nerve. The risk of trauma to the spinal cord is very remote, especially if the lumbar puncture is performed below the level of the conus medullaris. Any complaints of pain from the patient during the insertion of the lumbar puncture needle must be taken seriously and evaluated immediately. Any suspicion of spinal cord injury should lead to immediate termination of the procedure.

Epidural hematoma in most cases follows anticoagulant therapy. The main symptom is severe backache with progressive paraplegia. This complication is a surgical emergency. The treatment of choice is surgical decompression. Epidural abscess is also a life-threatening complication and surgical emergency. The usual presentation is fever, leukocytosis, pain, and paraplegia. The diagnosis requires a high level of clinical suspicion and CT or MRI confirmation. Adhesive arachnoiditis is a serious but rare complication that can lead to severe disability. The symptoms are pain, paralysis, and impairment of bowel function. The abscess rarely occurs with a simple lumbar puncture; it usually follows accidental injection of an irritant solution into the arachnoid space. The disorder is characterized by fibrosis and distortion of the arachnoid space. Unfortunately, clinical symptoms and signs may not be evident for weeks after the procedure. There is no definite treatment for this complication.

PERICARDIOCENTESIS

Normally, as much as 50 mL of fluid can be contained in the pericardial space. The composition of the fluid is very similar to serum. An accumulation of fluid in the pericardial sac may be caused by a variety of reasons, including trauma, inflammation, neoplasms, and renal failure. Pericardial tamponade is caused by the restriction in ventricular diastolic filling secondary to a significant accumulation of fluid, which leads to a reduction in cardiac ejection fraction and mean arterial blood pressure. Pericardial tamponade is a life-threatening condition, requiring immediate intervention.

Pericardial tamponade is the major indication for emergent pericardiocentesis.

Indications

Pericardiocentesis is indicated for the treatment of cardiac tamponade or for the etiologic diagnosis of pericardial effusion.

Contraindications

There are no absolute contraindications for an emergent therapeutic pericardiocentesis. Coagulopathy and skin infection are considered to be the two major contraindications for a diagnostic pericardiocentesis.

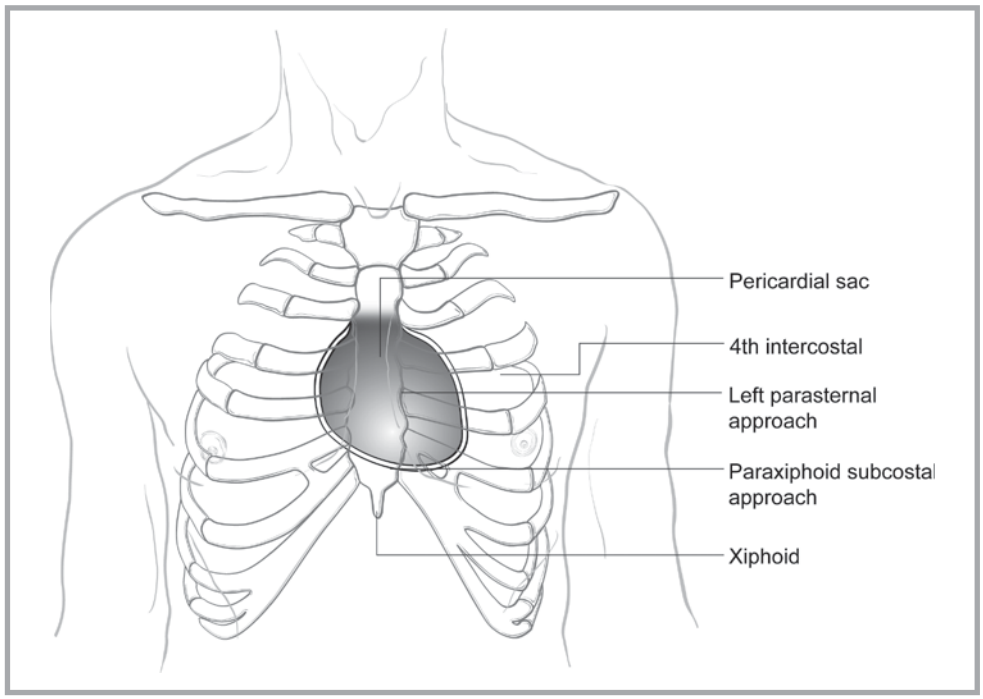
Technique

The patient is placed in the supine position with the chest and shoulders elevated at least 30°. Routine sterile precautions are followed. One percent lidocaine is used as the local anesthetic. Figure 8-7 demonstrates two approaches to perform pericardiocentesis: the paraxiphoid subcostal approach and the left parasternal approach. We describe here only the paraxiphoid subcostal approach. It is the most commonly performed technique because it is relatively simple and avoids both the pleura and major vessels.

For this approach, a long, large-bore (~18 cm, 18 gauge) cardiac needle, connected to a syringe and the V lead of the EKG (Fig. 8-8), penetrates the skin just underneath the costal

FIGURE 8-7

Two approaches to perform pericardiocentesis: the paraxiphoid subcostal approach and the left parasternal approach (Illustration by Alice Chen).



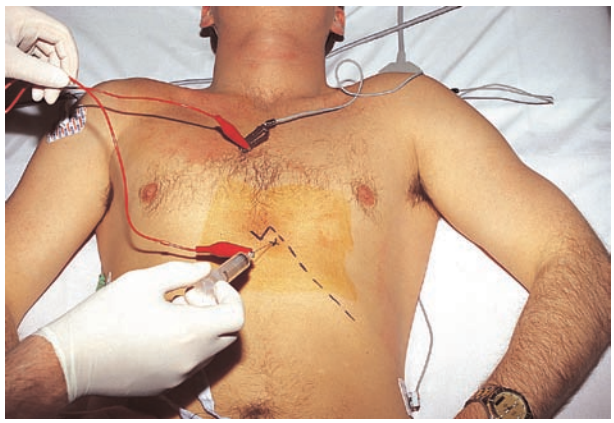


FIGURE 8-8

Pericardiocentesis technique. A cardiac needle is connected to the V lead of the EKG to monitor for a cardiac injury current (from www.imagesmd.com. Used with permission).

Monitoring should be provided while performing pericardiocentesis to exclude the development of a cardiac injury current.

margin next to the xiphoid and is advanced carefully at a 45° angle, beneath the ribs toward the midpoint of the left clavicle. Suction is continuously applied to the syringe as the needle is advanced while monitoring for a cardiac injury current. ST segment elevation is seen with ventricular epicardial contact, and atrial epicardial injury is manifested by PR segment elevation. If any of these are noted on the EKG, the needle should be slightly withdrawn and redirected. When the fluid is returned, the needle is secured to prevent accidental overpenetration by attaching a hemostat at the skin level or taping the needle to the skin. Removal of even a small amount of fluid may bring a rapid improvement in hemodynamic status if the procedure is performed for pericardial tamponade.

Complications

Cardiac arrhythmias and coronary artery laceration, as well as hydrothorax and pneumothorax are potential complications of pericardiocentesis.. However, both coronary artery laceration and pleural space injury seldom occur with the paraxiphoid subcostal approach. Ventricular

tachycardia may occur during the procedure as a result of ventricular puncture. If ventricular puncture occurs, the patient should be watched for possible intrapericardial bleeding.

SUMMARY

The procedures of thoracentesis, paracentesis, lumbar puncture, and pericardiocentesis can often be performed safely at the bedside using standard sterile techniques. It is imperative that the physician understands the indications and contraindications for each procedure to minimize the risk of adverse events.

REVIEW QUESTIONS

1. **Which of the following is the major reason for performing thoracentesis above the rib?**
   - **A.** It is easier to perform
   - **B.** It is more comfortable for the patient
   - **C.** It is safer

2. **The most important factor for choosing a site for paracentesis is:**
   - **A.** The least amount of adipose tissue
   - **B.** Proximity to umbilicus
   - **C.** Finding an avascular site

3. **A patient developed fever, leukocytosis, pain, and paraplegia 12 h after lumbar puncture. The most likely diagnosis is:**
   - **A.** Epidural abscess
   - **B.** Epidural hematoma
   - **C.** Arachnoiditis

4. **During pericardiocentesis, the patient developed PR segment elevation in the V lead on the EKG. What is the most likely reason for this observation?**
   - **A.** Ventricular epicardial injury
   - **B.** Ischemia
   - **C.** Atrial epicardial injury

ANSWERS

1. The answer is C. A neurovascular bundle is located on the inferior surface of the rib; therefore, approach above the rib is associated with less chance of an injury to this structure.
2. The answer is C. Paracentesis has a relatively low incidence of complications. One of these is bleeding from the site of needle insertion, because many patients with ascites have coagulopathy. Therefore, finding an avascular site is very important. An area on the left flank of the lower abdomen, adjacent to the rectus abdominis, meets this criterion.
3. The answer is A. Epidural abscess is a complication secondary to the introduction of infection into the epidural space. It usually has hematogenic origin, but occasionally may occur as a result of lumbar puncture. It has typical symptoms of infection (fever and leukocytosis) as well as severe neurologic deficit and pain.
4. The answer is C. ST segment elevation would be characteristic for ventricular epicardial injury. PR segment elevation during pericardiocentesis is typical for atrial epicardial injury and not for ischemia.

CHAPTER 9

FRANCIS C. CORDOVA AND NATHANIEL MARCHETTI

Noninvasive Monitoring in the Intensive Care Unit

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to do the following:

- Know the different noninvasive monitoring techniques commonly used in the intensive care unit (ICU) setting.
- Know the advantages and limitations of the different noninvasive monitoring methods.
- Know the different technologies used in noninvasive monitoring.
- Correlate the findings observed during noninvasive monitoring with the patient's changing physiology.

INTRODUCTION

The modern paradigm of critical care medicine is not only to effectively treat the patient's underlying life-threatening illness, but also to recognize, as early as possible, any potential complications that may occur because of the underlying disease or as a result of therapy. Indeed, the modern coronary care unit in the early 1960s was born from the need to monitor the development of cardiac arrhythmias in patients who suffered acute myocardial infarction. Similarly, the impetus for the creation of the specialized respiratory care unit was also brought about by the need to care for patients who developed respiratory failure during polio epidemics.

Today, intensive care monitoring is widely practiced in most modern intensive care units (ICUs) across the country. In the context of ICU care, monitoring has been defined as making repeated or continuous observations or measurements of physiologic functions, the functions of the life support equipment, and to guide management decisions, including when to make therapeutic interventions and assessing those interventions. Using this definition, intensive care monitoring can be as simple as frequent bedside assessment by an experienced clinician or the use of a noninvasive monitoring device, such as pulse oximetry, to assess the adequacy of oxygenation. Alternatively, ICU monitoring may use sophisticated medical technology that requires skilled physicians and health care workers to operate the equipment and maintain it. The use of the pulmonary artery catheter in the ICU to continuously monitor hemodynamics and the use of an esophageal balloon to monitor auto-PEEP during mechanical ventilation are examples of invasive monitoring techniques. Regardless of the type of monitoring methods used in a particular clinical scenario, the success of any monitoring algorithm hinges on appropriate responses from physicians, nurses, and respiratory therapists. The type (invasive or noninvasive) and frequency (continuous inline or specified timed interval) of monitoring should be tailored to an individual patient's clinical condition. Thus, a patient in septic shock who requires multiple vasoactive drugs will often require invasive hemodynamic monitoring with pulmonary artery and peripheral artery indwelling catheters. In contrast, patients who are admitted to the ICU in status epilepticus often require only continuous electroencephalographic monitoring.

Invasive monitoring techniques are typified by the use of pulmonary and arterial catheters and invariably require a highly skilled physician not only to obtain accurate physiologic measurements, but also to troubleshoot problems. By its nature, invasive monitoring often contributes to pain and suffering and may potentially result in increased morbidity (infection, bleeding, and pneumothorax), and even mortality. In contrast, noninvasive monitoring techniques are easier to use and maintain, and are not associated with the complications inherent with invasive monitoring methods.

In this chapter, we discuss the noninvasive monitoring methods commonly used in ICUs throughout North America. Specifically, we discuss the different types of noninvasive methods used in respiratory and cardiac monitoring and also their advantages and disadvantages.

GOALS OF MONITORING

In general, the goal of intensive care monitoring is to decrease the morbidity and mortality resulting from life-threatening diseases or from complications that may arise during diagnostic and therapeutic interventions. Specifically, the goals of monitoring are to assess vital organ function, to detect early life-threatening complications, to determine the need for interventions such as mechanical ventilation or airway intubation, and to assess the effects of a particular therapeutic intervention. More importantly, monitoring should not cause undue pain and discomfort to the patient. Also, it should not be so cumbersome as to interfere with direct patient care.

The type of monitoring device or technique should be tailored to the particular disease process and to the need of individual patients. Thus, patients who are admitted to the ICU for gastrointestinal hemorrhage need frequent assessment of their vital signs. Patients who are admitted for an exacerbation of chronic obstructive lung disease (COPD) may benefit from continuous monitoring of oxygen hemoglobin saturation in addition to routine vital signs. In certain situations, ICU monitoring is necessary in patients receiving therapy that may lead to fatal complications. For example, patients with stroke who are candidates for thrombolytic therapy require frequent neurologic monitoring in an ICU setting.

CASE STUDY: PART 1

A 55-year-old man was brought to the emergency room after being found unconscious on his living room floor by fire rescue personnel. The paramedics removed him from a room filled with thick smoke. He was spontaneously breathing with a palpable radial pulse and a blood pressure of 160/96 mmHg. On arrival to the emergency room, the patient was drowsy, intermittently agitated, and confused. He complained of mild dyspnea and vague anterior chest pain. He also complained of a severe headache, located mostly over both temporal areas. He had nausea and vomited 3 times while in the ER. His past medical history was significant for hypertension and a "touch of asthma." He has a 25 pack-year history of smoking. On presentation, his vital signs were as follows: T=98.6°F, P=110 mm, BP=156/88 mmHg, RR=32 breaths/min, and SpO_2=100% while breathing from a face mask with 40% inspired oxygen. On physical exam, the patient had singed facial sideburns but without obvious signs of facial burns. Carbonaceous deposits were found in the nares, throat, and posterior pharynx. He appeared anxious and tachypneic but was not using the accessory muscles of respiration. His eyebrows and nasal hairs were singed. His lung exam revealed a few mild end-expiratory wheezes. Cardiac exam revealed regular tachycardia without any murmurs or gallops. The physical exam was otherwise completely unremarkable.

RESPIRATORY MONITORING

Oxygenation

Pulse Oximetry

Noninvasive measurement of tissue oxygen saturation using an oximeter is based on the principle of differential light absorption characteristics of the different species of hemoglobin (oxyhemoglobin, deoxyhemoglobin, methemoglobin, carboxyhemoglobin, and sulfhemoglobin). Modern pulse oximetry uses two wavelengths of light, red (660 nm) and infrared (900–940 nm), to discriminate between oxyhemoglobin and deoxyhemoglobin. The absorption spectra for oxygenated and deoxygenated hemoglobins are shown in Fig. 9-1. The reason why oxygenated hemoglobin appears to be redder compared to deoxygenated blood is that the oxygenated hemoglobin reflects red light better than other hemoglobin species. Earlier models of ear oximeters were large and cumbersome and required frequent calibration. Because the peripheral circulation contains a mixture of blood from arterial, venous, and capillary sources with different levels of oxygen saturation, the skin surface where the oximeter was applied had to be warmed or "arterialized" to increase arterial blood flow.

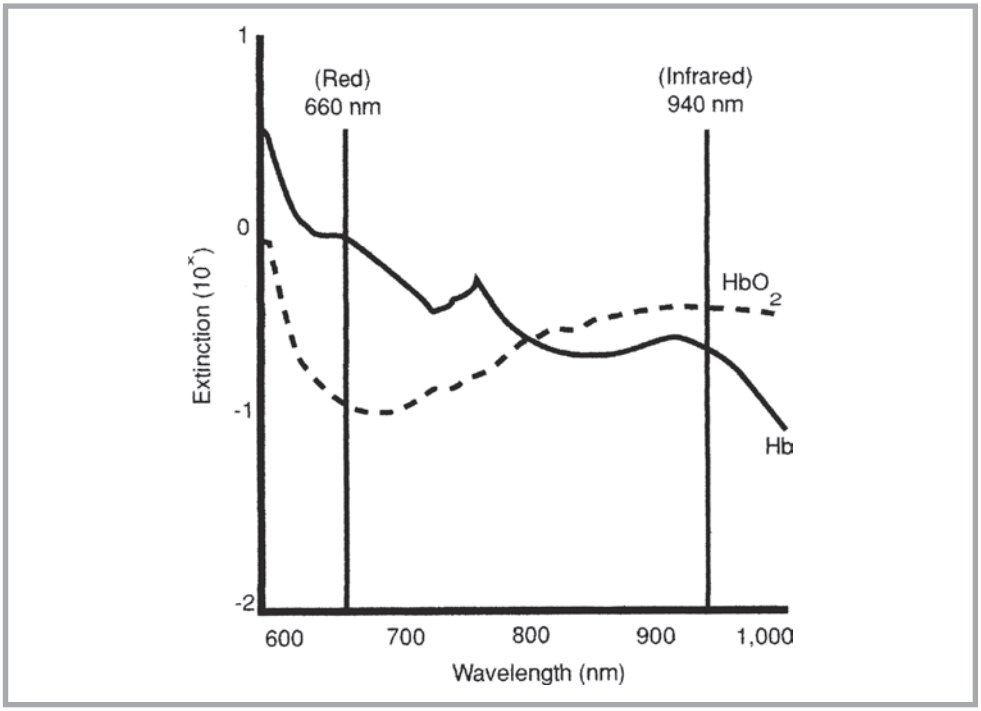

FIGURE 9-1

Modern pulse oximetry uses two wavelengths of light, red (660 nm) and infrared (940 nm), to differentiate oxyhemoglobin (HbO_2) from deoxyhemoglobin (Hb) (adapted from [38]).

The widespread use of noninvasive measurements of oxyhemoglobin did not come about until the development of pulse oximetry. Pulse oximetry obviated the need for skin warming by assuming that the changes in light absorbance are mainly the result of the pulsatile flow of arterial blood. Oxygen saturation is calculated using an algorithm with a predetermined calibration curve stored in a microprocessor. The calibration curve is derived from healthy normal volunteers with oxygen saturations ranging from 70 to 100%. The accuracy of different pulse oximeters in measuring oxyhemoglobin saturation is excellent, with 95% confidence limits of 2–4% when the oxygen saturation is above 70%. The accuracy of SpO_2 measurements substantially declines at lower oxyhemoglobin saturations; the error increases from ±4% at SpO_2 of 70% to as much as ±15% with SpO_2 levels below 50%. The accuracy of SpO_2 measurements at the lower range of values is further magnified by the presence of hypoperfusion states commonly encountered in ICU patients. If the heart rate recorded by the pulse oximeter does not closely match the patient's true heart rate, the pulse oximeter reading is likely to be inaccurate.

The accuracy of SpO_2 measurement by pulse oximetry is ±4% and becomes inaccurate with $SaO_2 \leq 60\%$.

Although pulse oximetry is useful in different clinical situations requiring respiratory monitoring, it is not a substitute for arterial blood gas determination. Pulse oximetry does not provide any information on the adequacy of ventilation nor does it provide any information on the acid–base status of the patient. In addition, because of the sigmoidal shape of the oxygen hemoglobin dissociation curve, a given SaO_2 estimation by pulse oximetry represents a wide range of PaO_2 values (Fig. 9-2). For example, a SpO_2 of 95%, assuming a measurement margin of error of ±4%, represents PaO_2 values between 60 and 160 mmHg.

Pulse oximetry measures only oxygenation function of the lung, and not the adequacy of ventilation.

Other factors that may affect the accuracy of SpO_2 measurements are listed in Table 9-1. Exogenous factors such as artificial finger nails[1] and nail polish[2,3] can also affect the

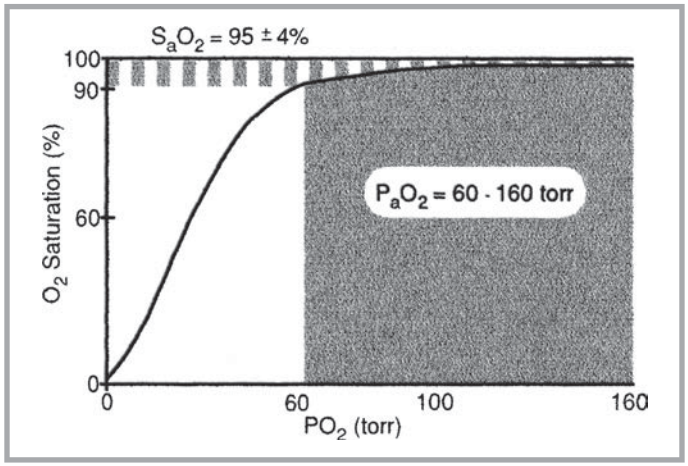

FIGURE 9-2

The oxygen hemoglobin dissociation curve is sigmoidal. On the upper portion of the oxygen hemoglobin dissociation curve, a given oxygen hemoglobin saturation represents a wide range of PaO_2 (adapted with permission from [39]. ©American Thoracic Society).

TABLE 9-1

CAUSES OF INACCURATE PULSE OXIMETER READINGS OF OXYHEMOGLOBIN SATURATION

CONDITION	CAUSE	EFFECTS ON PULSE OXIMETER
Dyshemoglobinemia		
Carbon monoxide	Smoke inhalation	Falsely elevated
Methemoglobin	Local anesthetics (lidocaine, benzocaine), nitrates, sulfa drugs, EDTA	Initially decreased, but falsely elevated at higher levels of methemoglobinemia
Dyes and pigments		
Methylene blue	Antidote for methemoglobinemia	Falsely low
Bilirubin	Hyperbilirubinemia from various causes	Inaccurate reading
Low perfusion	Hypothermia Hypovolemia Peripheral vascular disease Vasopressors	Inadequate pulse signal
Anemia	Bleeding, hemolysis	Inaccurate at hemoglobin <5 g/dL
Increased venous pulsation	Right heart failure, tricuspid regurgitation	Any pulsatile flow is interpreted as arterial
External light source	Excessive light interference	Inaccurate reading

accuracy of the pulse oximetry reading. Because pulse oximetry uses only two wavelengths, other forms of dyshemoglobinemia will not be detected by conventional pulse oximetry. For example, patients with methemoglobinemia (e.g., hemoglobin oxidized to its ferric state) may initially show a decrease in pulse oximetry readings but plateau at 80–85% even with increasing methemoglobin levels. This inconsistent SpO_2 reading results from the absorbance characteristic of methemoglobin, which absorbs equally well at 660 nm (red) and 940 nm (infrared) (Fig. 9-3). As methemoglobinemia worsens, both red and infrared light absorption increases and approaches an R (the ratio of pulsatile and baseline absorbance of red and infrared wavelengths) value of 1, which equates to a SpO_2 of 85%. In contrast, methylene blue, which is used in the treatment of methemoglobinemia, leads to falsely low SaO_2 values. Similarly, carboxyhemoglobin, which mimics the light absorbance pattern of oxyhemoglobin, also results in falsely elevated oxyhemoglobin saturation determinations by pulse oximetry. If a dyshemoglobinemia is suspected, the SaO_2 should be measured directly from the blood utilizing a cooximeter. Recent development in technology paved way for the development of multiwavelength pulse oximeter (Rainbow technology, Masimo Corp). The Rad-57 pulse oximeter uses eight wavelengths of light to measure SpO_2, SpCO (pulse oximeter estimate of COHb%), and SpMet (estimate of MetHb%). This multiwavelength pulse oximetry addresses the major limitation of the current two wavelength pulse oximetry in recognizing abnormal hemoglobin species.[4]

Both methemoglobinemia and carboxyhemoglobinemia result in false SpO_2 readings.

Hemoglobin F (fetal hemoglobin) behaves similar to hemoglobin A (normal Hb) spectrophotometrically. Therefore, pulse oximetry can be accurately used in neonates and infants. The presence of hemoglobin S, the predominant Hb in sickle cell disease, can lead to inaccurate or inconsistent pulse oximetry readings. The abnormal geometry of the sickle cells alters the scatter of the light, thereby interfering with the measurements made based on light absorption characteristics alone. Moreover, sickle cell disease shifts the oxygen–hemoglobin dissociation curve to the right, resulting in lower SaO_2 saturations for any given PaO_2 value. Finally, in sickle cell disease, significant hemolysis during painful crises can modestly increase carboxyhemoglobin concentration, thereby leading to falsely increased measurements of oxygen saturation.

The oxygen–hemoglobin dissociation curve in sickle cell disease is shifted to the right, resulting in a lower SaO_2 for a given PaO_2.

Although pulse oximetry is widely used in the ICU, in perioperative settings, and during outpatient procedures requiring conscious sedation, its effect on patient morbidity and mortality is unclear. Recently, a Cochrane review showed that pulse oximetry monitoring significantly reduced the extent of perioperative hypoxemia through the detection and treatment of hypoxemia and related respiratory events. Pulse oximetry monitoring, however, did not significantly decrease postoperative complications.[5,6]

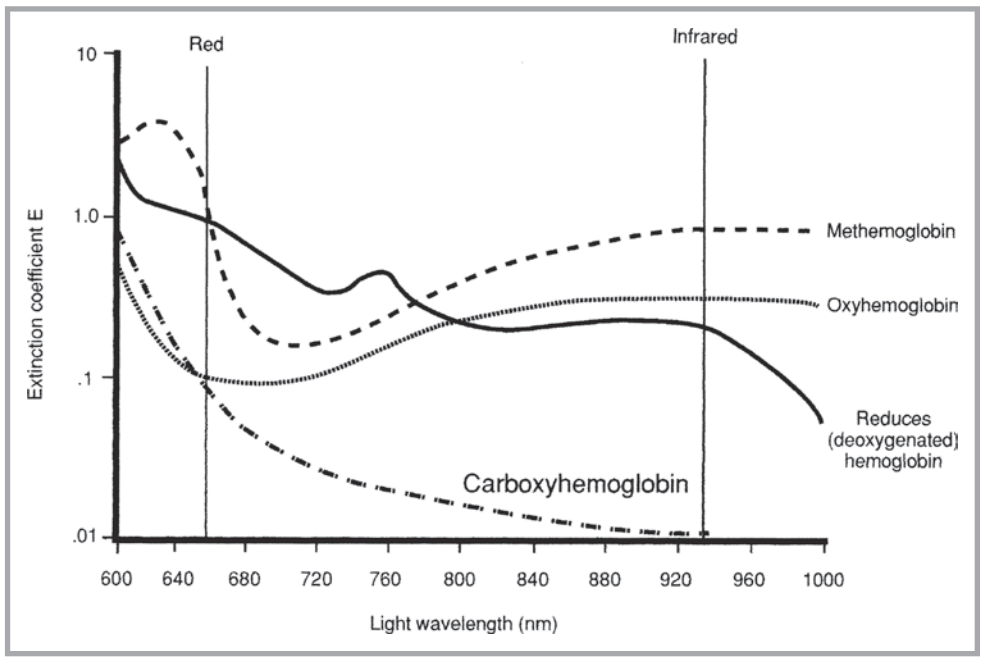

FIGURE 9-3

Different forms of dyshemoglobinemia, in particular methemoglobinemia and carboxyhemoglobin, mimic the light absorbance characteristics of oxyhemoglobin, resulting in false pulse oximetry reading of the true oxyhemoglobin saturation (adapted from [40]).

CASE STUDY: PART 2

A portable chest X-ray of the patient was normal. An arterial blood gas sample was sent to the laboratory, with results as follows: pH=7.43, $PaCO_2$=25 mmHg, PaO_2=225 mmHg, HCO_3=16 mEq/L, CoHb=34%, and oxyhemoglobin saturation by cooximeter=82%. The patient was immediately given 100% supplemental oxygen via a nonrebreather mask. Six hours later, the patient was feeling much better and a repeat ABG revealed that the carboxyhemoglobin level decreased to less than 5%, with an improvement in oxyhemoglobin saturation as measured by cooximeter.

Transcutaneous Oxygen Measurement

The measurement of transcutaneous PO_2 ($tcPO_2$) using a modified Clark electrode depends on the oxygen concentration gradient across the skin. It assumes minimal cutaneous metabolism. Local heat (to about 43°C) is applied to the electrode contact site to ensure adequate skin perfusion to produce a $tcPO_2$ approximating the PaO_2. The electrode site is changed every 4–6 h to prevent skin burn. In neonates or young infants, whom have a thin epidermis and low metabolism for a given blood flow, the $tcPO_2$ closely approximates the PaO_2 value. Previous studies have shown that the oxygen tension gradient across the skin can be as low as 5%. In stable adult patients, the $tcPO_2$ is only approximately 80% of the simultaneously measured PaO_2, because adults have thicker skin with a decreased skin capillary density. The discrepancy between the measured PaO_2 and $tcPO_2$ is further magnified by the changes in cardiac output and skin perfusion abnormalities that are commonly encountered in critically ill patients.

Factors affecting $tcPO_2$ value:
Skin thickness and capillary density.
Cutaneous metabolism.
Cardiac output.

Because of the limitations previously mentioned, $tcPO_2$ monitoring is mostly used in neonates and young infants to obviate the need for frequent arterial blood gas sampling and to avoid hypoxemia and hyperoxia. In these pediatric patients, the direction and percentage change in $tcPO_2$ correlates well with the PaO_2. In adult specialty care units, pulse oximetry has largely supplanted the use of PaO_2 measurement by arterial blood sampling. However, it is important to remember that $tcPO_2$ measures tissue oxygenation and not arterial oxygenation. In sepsis, tissue hypoxia may be present due to abnormal microvascular circulation even in the presence of adequate arterial oxygenation. In critically ill trauma patients who were monitored with a battery of noninvasive parameters, $tcPO_2$ was one of the hemodynamic values that were able to discriminate survivors from nonsurvivors.[7]

Because the $tcPO_2$ measurement in part depends on skin perfusion and thus reflects the adequacy of oxygen delivery, it has been used to monitor the results of vascular surgery in patients with peripheral vascular disease. Different threshold values of $tcPO_2$ have been associated with impaired wound healing. Thus for wound healing to occur, $tcPO_2$ should be >40 mmHg; impaired wound healing occurs with $tcPO_2$ between 20 and 40 mmHg, and failure of wound healing is demonstrated with $tcPaO_2$ of <20 mmHg.[8,9] Similarly, $tcPO_2$<34 mmHg measured at the dorsum of the ischemic foot predicts the need for revascularization in diabetic patients with critical limb ischemia; $tcPO_2$ levels of 40 mmHg suggest that revascularization is optional, depending on the severity of ulcer and possible morbidity due to the procedure.[10] The differences between transcutaneous and pulse oximetry are shown in Table 9-2.

TABLE 9-2

DIFFERENCES BETWEEN TRANSCUTANEOUS AND PULSE OXIMETRY

FACTOR	TRANSCUTANEOUS	PULSE OXIMETRY
Accuracy in adults	No	Yes
Detection of high PaO_2	Yes	No
Setup time	Minutes	Seconds
Time response	Minutes	Seconds
Measures pulse	No	Yes
Heated skin burns	Yes	No
Stability at one site	2–4 h	Yes
Motion artifact	Minimal	Yes
Sensitivity to perfusion	Yes	Yes

Transcutaneous Carbon Dioxide Monitoring

Carbon dioxide gas easily diffuses through body tissues and can be detected on the surface of the skin. Severinghaus first described the measurement of PCO_2 on the human skin in 1960. The use of local heating through the sensor, first described in the development of $tcPO_2$, was the breakthrough allowing the continuous measurement of blood gases for prolonged periods of time. The first commercially available $tcPCO_2$ sensors were introduced in 1980 and the combined $tcPO_2$–PCO_2 in 1985. The transcutaneous electrode for the measurement of carbon dioxide tensions can either be measured on the skin surface using a Stowe–Severinghaus electrode or an infrared sensor. Most of the commercially available capnographs use the Stowe–Severinghaus electrodes. The modern Stowe–Severinghaus electrodes consist of a small pH sensitive electrode, a silver/silver chloride reference electrode, and a heater. The electrodes are bathed in a bicarbonate buffer solution and covered by a gas permeable membrane. The heater warms the skin to a temperature of 42–44°C to promote local vasodilatation and to soften the keratin layer to promote diffusion of CO_2 gas. As the CO_2 diffuses from the skin and into the membrane, it reacts with water to form carbonic acid (H_2CO_3), which dissociates into hydrogen ion (H^+) and bicarbonate ($HCO3^-$). The H^+ production modifies the pH in the electrolyte solution producing voltage difference between the pH electrode and the silver/silver chloride reference electrode. The $tcPCO_2$ is calculated from the changes in pH detected by the sensor using the Henderson-Hasselbach equation. The $tcPCO_2$ reported by the sensor reflect the correction factors used by the system software to compensate for both the patient and sensor temperature. The measured $tcPCO_2$ is always higher than $PaCO_2$ obtained from the arterial blood gas, because the increased temperature at which the transcutaneous $tcPCO_2$ operates not only increases capillary blood flow and CO_2 diffusion, but also increases skin metabolism, and consequently, CO_2 production. Because CO_2 tissue solubility is temperature dependent, excessive skin heating or a poorly calibrated electrode results in spuriously high $tcPCO_2$ values. For every degree centigrade rise in temperature, the $tcPCO_2$ increases by 4.5%, resulting in an overestimation of $PaCO_2$ by a factor of 1.31–1.61 when skin heating is used.

Factors causing inaccurate $tcPCO_2$ measurement:
- Excessive skin heating.
- Low cardiac output.
- Thick skin.

To avoid skin burns, the probe has to be removed and rotated to another skin site every 4 h. The suggested locations for transcutaneous monitor sites are the forearm, chest, and abdomen. Another limitation of the transcutaneous probe is the need for frequent calibration whenever the probe has been turned off or after 4 h of use. The standard method of calibration is the two-point dry gas calibration. Carbon dioxide concentrations of 5 and 10% are commonly used. This method of calibration usually produces higher $tcPCO_2$ than the actual $PaCO_2$ that is largely due to a higher temperature in the electrode. Alternatively, the transcutaneous sensor can be calibrated using the patient's own $PaCO_2$ from either the arterial blood or arterialized ear lobe capillary blood sample. This method of calibration is thought to be more accurate since it accounts for each patient's skin characteristics.

Another transcutaneous capnometer has a small (50-μL) collection chamber that analyzes CO_2 from the skin with an infrared sensor. The relatively large gas collection chamber of the transcutaneous capnometer system, compared to the volume of the bicarbonate buffer surrounding the pH electrode, results in the slower response time of the infrared based system to changing CO_2 levels. In studies of stable ICU patients using an infrared sensor, the measured $tcPCO_2$ showed excellent correlation with $PaCO_2$ with *r-values* as high as 0.98; the mean difference between $tcPCO_2$ and $PaCO_2$ was 4–5 mmHg.[11,12]

Because CO_2 has high tissue solubility several fold higher than oxygen, the measured $tcPCO_2$ is affected less by tissue metabolism. In a study of 26 hemodynamically stable patients who were treated with noninvasive positive pressure ventilation (NPPV), the $tcPCO_2$ showed excellent agreement with arterial measurements over a wide range of PCO_2 values (e.g., 26–71 mmHg $PaCO_2$) ($r = 0.968$, $p < 0.0001$). There was no significant drift of $tcPCO_2$ as compared to $PaCO_2$ over 4 h. Changes in $tcPCO_2$ with initiation or interruption of NPPV was <60 s showing an excellent responsiveness to changing clinical conditions. Low-dose dopamine and body mass index did not affect the accuracy of the $tcPCO_2$ measurement.[13,14] Storre and colleagues also reported an excellent correlation between $tcPCO_2$ and $PaCO_2$ in a cohort of patients with acute chronic hypercapneic respiratory failure who were treated with

NPPV ($r=0.916$, $p<0.001$). The mean difference between the $tcPCO_2$ and $PaCO_2$ was 4.6 mmHg. This study also showed a lag time of approximately 2 min in $tcPCO_2$ values to reliably predict dynamic changes in $PaCO_2$. Similarly, good correlations between $tcPCO_2$ and $PaCO_2$ measurements have been reported in patients with a variety of respiratory diseases[15] and in critically ill adult patients who required vasopressor and ventilatory support.[16] In critically ill trauma patients, $tcPCO_2$ in the first 5 days after presentation was significantly higher in nonsurvivors compared to survivors.[7] However, the accuracy of $tcPCO_2$ degrades with low cardiac output states and profound skin vasoconstriction. In ICU and surgical patients with cardiac index >1.5 L/min, the $tcPCO_2$ is 23 ± 11 mmHg above the simultaneously measured $PaCO_2$ ($r=0.8$). When the cardiac index is <1.5 L/min, the accuracy of the $tcPCO_2$ degrades significantly suggesting that even the use of electrode heating or vasoactive medications may not enhance skin perfusion in shock or low flow state.[16-18]

Newer $tcPCO_2$ sensor designs include integration of the oxyhemoglobin saturation, lower sensor temperature to minimize repositioning of the sensor (42°C), increased sensor stability and reliability, and miniaturization of the sensor.[19] Janssens and others reported the continuous use of $tcPCO_2$ monitoring for up to 8 h without a significant drift in $tcPCO_2$ signal or a decrease in electrode performance.[20]

Capnometry

Uses of capnometry in the ICU:
- Verifying endotracheal tube placement.
- Monitoring ventilation adequacy.
- Noninvasively estimating $PaCO_2$.

Capnometry is the measurement of carbon dioxide concentrations in respiratory gases. The measurement of carbon dioxide concentration in expired respiratory gas was first used in the intraoperative setting to confirm endotracheal intubation and to aid in the quantitative assessment of ventilation during general anesthesia. Currently, capnometry in the ICU and other emergent settings is used mainly to confirm the endotracheal tube placement during intubation, because of the inaccuracy of capnometry in the presence of significant intrinsic lung disease.

The capnometer is a device that quantitatively measures the amount of exhaled carbon dioxide; a capnograph has the added capability to display and track changes in end-tidal carbon dioxide over time. The principle of bedside capnometry is based on infrared spectroscopy, or calorimetry. Similar to pulse oximetry, capnometry utilizes the unique light absorption quality of carbon dioxide. In this case, carbon dioxide is measured in vitro by quantifying the absorption of infrared light at a wavelength of 4.3 μm as it passes through the sample gas. Because only carbon dioxide absorbs infrared light, the presence of oxygen, helium, or nitrogen in the expired gas does not interfere with its measurement. However, the presence of nitrous oxide may interfere with the capnometer reading because nitrous oxide also absorbs infrared light, resulting in an artifactual increase in the measured carbon dioxide concentration. In addition, nitrous oxide reduces the optical density of carbon dioxide, resulting in artificially low readings in less sophisticated capnometers.

Capnometers can be further categorized as mainstream or sidestream on the basis of the gas sampling method. The mainstream capnometer is attached inline to the endotracheal tube, resulting in rapid breath-by-breath gas analysis. The sensor used in the mainstream capnometer is typically heavy and bulky and therefore cumbersome to use. In contrast, the sidestream capnometer continuously withdraws gas from the breathing circuit into a gas sampling line. The gas sampling circuit, however, introduces a delay in overall carbon dioxide (CO_2) analyzer response time. The advantage of this system is that it can be used in an unintubated patient by holding the capnometer close to the patient's face.

In clinical practice, capnometry has three important uses: (1) to verify endotracheal tube placement, as previously mentioned, (2) to noninvasively estimate the arterial partial pressure of carbon dioxide ($PaCO_2$), and (3) to monitor the respiratory rate.

Confirmation of Endotracheal Tube Placement

Rapid confirmation of the endotracheal tube position following intubation in patients with an unstable respiratory status is crucial. In most circumstances, an experienced physician can confirm tracheal intubation initially by listening for equal breath sounds, visually inspecting

for symmetric chest expansion with each assisted inspiration, and by observing rising oxyhemoglobin saturation. However, none of these clinical methods is foolproof. The use of capnometry following intubation can further rapidly confirm successful tracheal intubation, especially in unstable patients or during a difficult airway intubation. Following airway intubation, a capnometer is connected to the tracheal tube. The colorimetric membrane inside the capnometer changes color when exposed to expired CO_2.

This method provides a rapid and accurate assessment of endotracheal tube placement within minutes. However, there are a few situations that may cause inaccuracy when using this technique. Normally, there is no appreciable amount of CO_2 in the gastrointestinal tract, but ingestion of carbonated beverages before intubation may result in high carbon dioxide readings; this is known as the "cola effect." In certain situations, cardiogenic shock and low flow states may lead to erroneous capnometer readings as a result of low exhaled carbon dioxide levels outside the range of the colorimetric assay.

Recent ingestion of carbonated drinks before intubation may lead to a high carbon dioxide reading.

Estimation of Arterial CO_2 with End-Tidal CO_2

The $P_{ET}CO_2$ is 1–3 mmHg lower than $PaCO_2$.

In healthy individuals, the end-tidal carbon dioxide ($P_{ET}CO_2$) value is generally 1–3 mmHg lower compared to the arterial carbon dioxide level ($PaCO_2$). This difference between $P_{ET}CO_2$ and $PaCO_2$ is mainly caused by minimal physiologic ventilation/perfusion imbalance found in the upper lobes, because ventilation is greater than perfusion as a result of the gravitational effects influencing the blood flow to more dependent lung regions. Thus, the measured $P_{ET}CO_2$ does not always reflect the $PaCO_2$, especially in the presence of ventilation/perfusion (V_A/Q) inequalities (Fig. 9-4). When the V_A/Q ratio approaches 1.0, then $P_{ET}CO_2$ correlates well with $PaCO_2$. If the V_A/Q ratio is higher than 1.0, as in dead space ventilation, then $P_{ET}CO_2$ will be lower than $PaCO_2$. An increase in dead space ventilation is commonly seen in patients with acute pulmonary embolism. When the V_A/Q ratio is less than 1.0, then $P_{ET}CO_2$ will be lower than $PaCO_2$. A variety of clinical conditions are associated with the changes in $P_{ET}CO_2$ (Table 9-3).

The accuracy of $P_{ET}CO_2$ in estimating $PaCO_2$ is affected by ventilation–perfusion inequality.

Interpretation of the Capnogram

A visual inspection of a capnogram may provide some clues to changes in the patient's ventilatory status. A normal capnograph has four phases: an inspiratory baseline (I), an expiratory upstroke (II), an expiratory plateau (III), and the inspiratory downstroke (IV) (Fig. 9-5). The inspiratory baseline is normally at zero, indicating the absence of carbon dioxide in the inhaled gas. Phase II or the expiratory upstroke corresponds with the beginning of expiration. The curve is normally steep due to the rapid emptying of the gas from the anatomic dead space followed immediately by mixed alveolar gas. The expiratory plateau, or phase III, results from good mixing of alveolar gas. $P_{ET}CO_2$ is measured at the end of the expiratory plateau phase. During the next respiratory cycle, the inspiration of fresh gas leads to a steep drop in CO_2 toward zero during phase IV. The cycle then repeats itself with each breath.

An abnormal capnograph suggests a change in the patient's condition, or malfunction of the breathing circuit such as an incompetent exhalation valve. An inspiratory baseline above zero suggests partial rebreathing of exhaled gas from breathing circuit malfunction. An up-sloping expiratory plateau can be seen in patients with airflow obstruction resulting from poor mixing of alveolar gas. Similarly, ventilated patients with a partially obstructed endotracheal tube have capnograph readings showing a gradual rise in the expired CO_2, as opposed to the brisk increase that normally occurs during the expiratory phase. A dip in the expiratory plateau phase, sometimes called curare clefts, is caused by small inspiratory efforts during expiration that could be due to hiccups, inadequate depth of anesthesia or muscle relaxation, or manipulation of the thoracoabdominal contents. Cardiac oscillations may be seen as sawtooth irregularities on the expiratory plateau (Fig. 9-6).

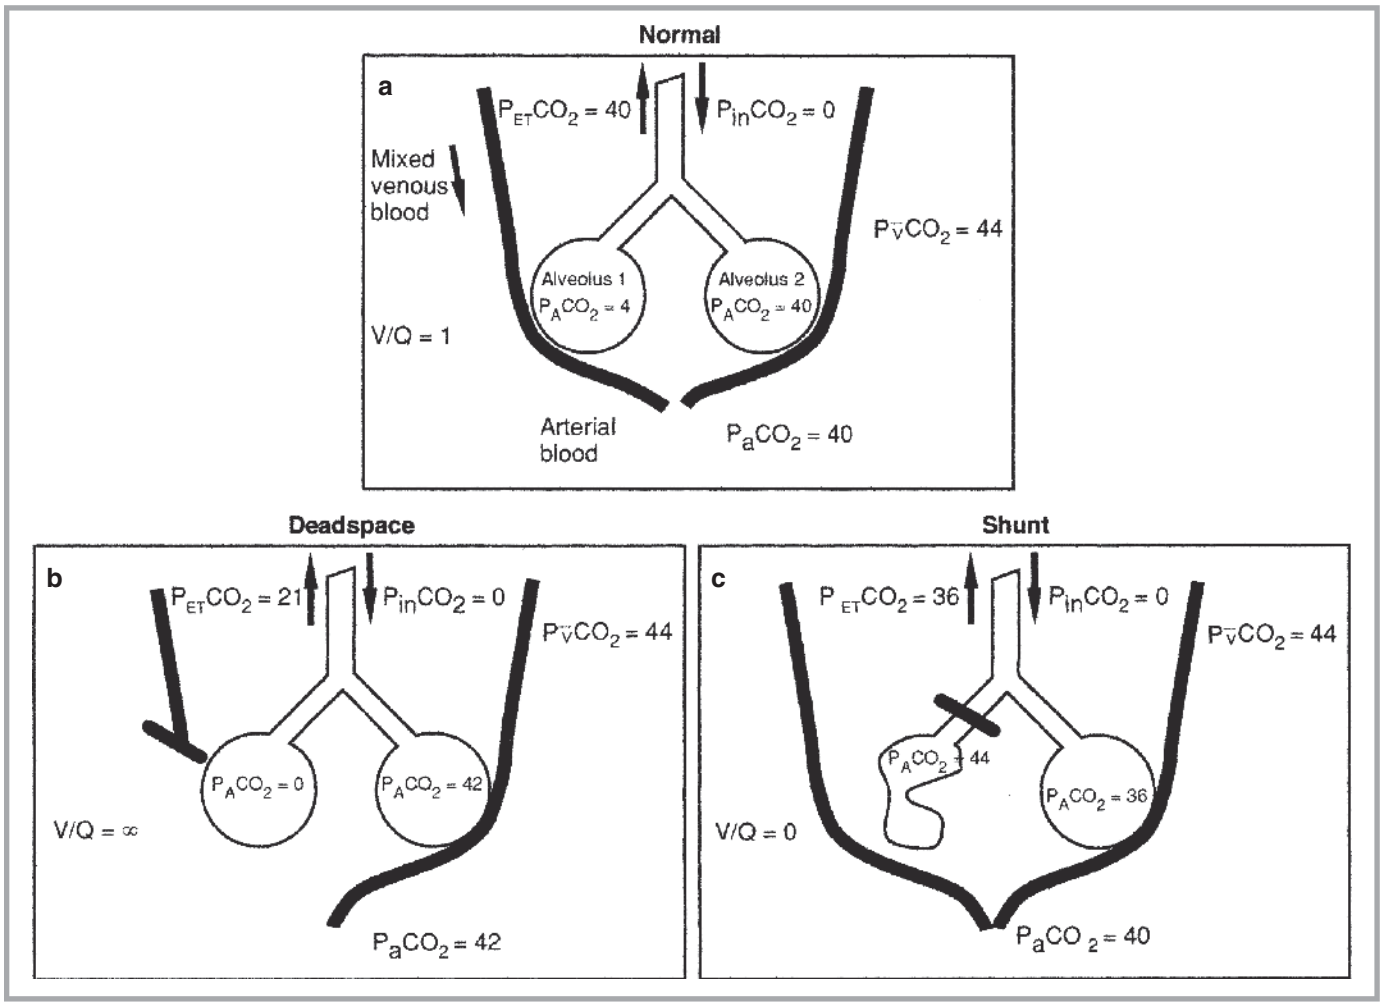

FIGURE 9-4

(**a–c**) The relationship between end-tidal carbon dioxide ($P_{ET}CO_2$) and arterial carbon dioxide level ($PaCO_2$) is affected by the presence of ventilation perfusion inequalities. In normal individuals, $P_{ET}CO_2$ is usually 1–3 mmHg lower than simultaneously measured $PaCO_2$ (**a**). The discrepancy between $P_{ET}CO_2$ and $PaCO_2$ becomes marked in the presence of dead space (**b**) and shunt physiology (**c**) (adapted with permission from [41]).

TABLE 9-3

CLINICAL CONDITIONS THAT MAY LEAD TO CHANGES IN END-TIDAL PCO_2

CONDITION	RESULT
Impaired central respiratory drive	Inadequate alveolar ventilation
	Apnea or hypopnea
Airway problems	Misplaced endotracheal tube
	Bronchial intubation
	Partial inadvertent extubation
	Presence of airflow obstruction
	Bronchospasm
	Mucous plug
Parenchymal disease	Massive pulmonary embolism
	Pneumothorax
	Aspiration
	Pneumonia
	Acute respiratory distress syndrome
Ventilator malfunction	Rebreathing of exhaled gas
	Ventilator circuit leak

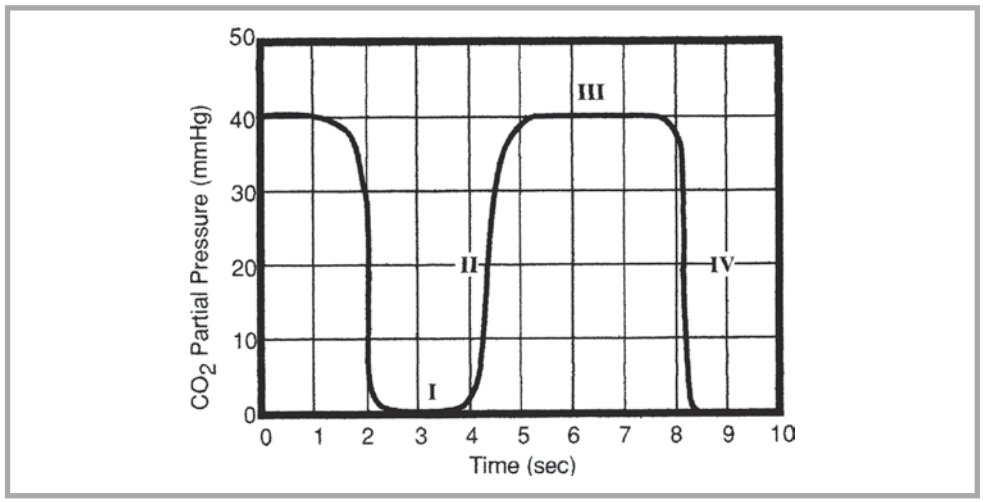

FIGURE 9-5

The four phases of a normal capnogram: *I,* inspiratory baseline; *II,* expiratory upstroke; *III,* expiratory plateau; *IV,* inspiratory downstroke (adapted with permission from [41]).

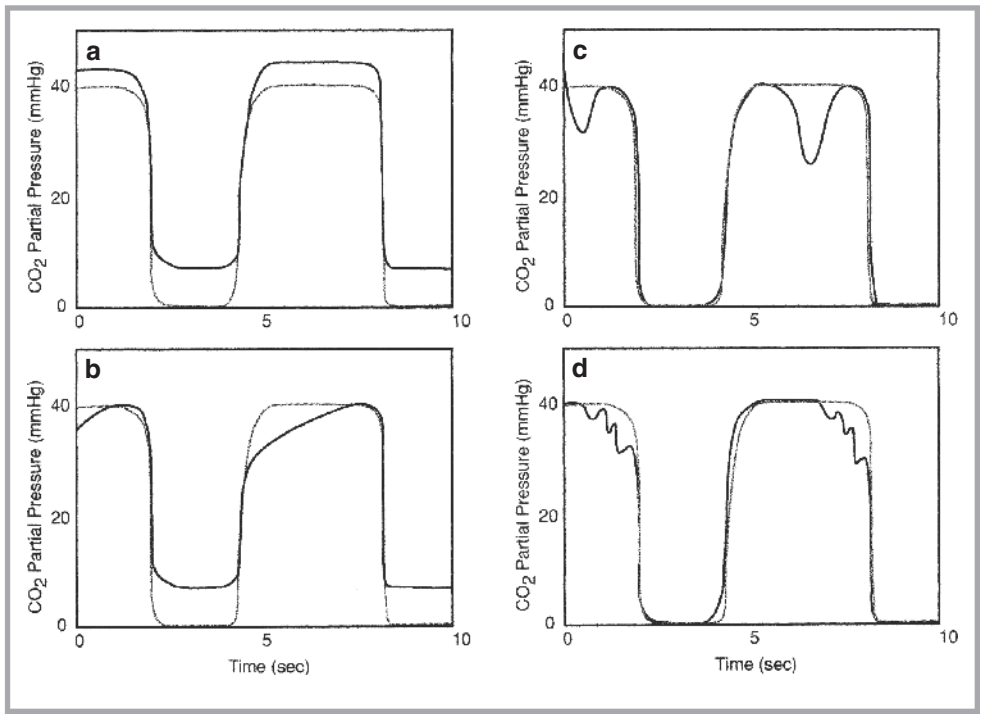

FIGURE 9-6

Changes in the shape of the phases of the capnogram may suggest the cause of ventilation abnormalities in a particular patient. An elevated baseline suggests elevated inspired carbon dioxide (CO_2) (**a**). Sloping of the expiratory plateau is commonly seen in patients with chronic airflow obstruction (**b**). A dip on the expiratory plateau indicates a superimposed breath during controlled ventilation (**c**). A sawtooth pattern during periods of low expiratory flow is caused by cardiac oscillations (**d**).

RESPIRATORY MECHANICS

The integrity of the respiratory pump can also be assessed at the bedside just as we are able to assess the gas exchange function of the lung. In the ICU setting, the clinical conditions that may benefit from frequent assessment of lung mechanics are those patients with acute or chronic airflow obstruction or acute progressive neuromuscular disease, and those who are being weaned from mechanical ventilation. In patients with acute asthma, a peak flowmeter is useful in following the response to treatment. Serial measurements of the forced expiratory volume in 1 s (FEV_1), and forced vital capacity (FVC) can be performed with a portable spirometer. FEV_1 is less dependent on patient effort and therefore may be more accurate in measuring airflow compared to the PEF rate. Additionally, serial measurements of FVC are useful in timing the need for ventilatory support in patients with acute progressive neuromuscular diseases, such as the Guillain–Barré syndrome. Perhaps the most common indication for bedside spirometry in the ICU is the measurement of commonly used weaning parameters: V_T, $\dot{V}_E$, FVC, MVV, NIF, and the tidal volume/respiratory rate ratio. Finally, the pattern

CASE STUDY: PART 3

The patient was admitted to the Burn Unit with a diagnosis of smoke inhalation injury and carbon monoxide poisoning. The next morning, his nurse reported that Mr. Jones' pulse oximeter reading was 88% despite increasing his supplemental oxygen back to 50% FiO_2. His other vital signs were HR=124/min (sinus tachycardia on the monitor), RR=28 mm, BP=100/60 mmHg, and *T*=102°F. Physical exam revealed the patient to be in moderate respiratory distress, using his accessory muscles of respiration and complaining of shortness of breath. His jugular venous pressure was less than 6 cm. Lung exam revealed diffuse scattered bronchi with some bronchial breath sounds bilaterally. Heart exam was regular, tachycardic, and without murmurs or gallops. The remainder of his exam was normal. A stat portable chest X-ray showed diffuse bilateral fluffy infiltrates consistent with noncardiogenic pulmonary edema. An arterial blood gas showed pH=7.47, $PaCO_2$=30 mmHg, PaO_2=60 mmHg, and HCO_3=20 mEq/L. Despite titrating the FiO_2 to 100%, the patient's SpO_2 remained at 88%, and he began to exhibit an abdominal paradoxical breathing pattern suggestive of incipient respiratory muscle fatigue. He was intubated and placed on mechanical ventilation. Proper placement of the ETT was confirmed with a colorimetric capnometer. His initial ventilator setting was assisted control with a rate of 14 breaths/min, V_T=600 mL, FiO_2=100%, and PEEP=5 cmH_2O. The positive end-expiratory pressure (PEEP) was titrated up to 12.5 cmH_2O and the FiO_2 was decreased to 60%. He was started on broad-spectrum IV antibiotics after all appropriate cultures were collected.

of breathing can be assessed by measuring changes in both rib cage and abdomen expansion during tidal breathing with elastic bands placed over the rib cage and abdomen that measure changes in electrical impedance (e.g., impedance plethysmography).

Bedside Spirometry

A portable flowmeter can be used in the ICU to assess the presence and severity of airflow obstruction and its response to therapy. Depending on the sophistication of the device being used, different expiratory flow and lung volume measurements can be performed to evaluate the overall respiratory status of critically ill patients. The commonly measured weaning parameters such as FVC, V_T, RR, $\dot{V}_E$, MVV, PEF, and NIF can be easily and repeatedly measured with a portable spirometer.

Commonly measured bedside respiratory mechanics in the ICU are FVC, tidal volume (V_T), respiratory frequency or rate (RR), minute ventilation ($\dot{V}_E$), maximum voluntary ventilation (MVV), peak expiratory flow (PEF), and negative inspiratory force (NIF).

The two most commonly used flowmeter technologies are the Wright's respirometer and the pneumotachograph. The Wright's respirometer utilizes a rotating-vane technology that estimates the flow based on the spinning rate of the turbine when exposed to gas flow. The volume of the expired gas is estimated from the velocity of the rotating turbine, which is directly proportional to the flow rate of the expired gas. The Wright's respirometer is small in size, lightweight, simple to operate, and reasonably accurate except with very low flow rates (<3 L/min). The pneumotachograph estimates the flow indirectly by measuring the differential pressure generated across the flow resistor placed in the gas stream. The pneumotachograph is more accurate in measuring the flow and in detecting changing flow rates. The volume of the expired gas can also be measured indirectly by integrating flow. A modern pneumotachograph attached to a portable computer is shown in Fig. 9-7.

Two commonly used bedside spirometers are Wright's respirometer and a pneumotachograph.

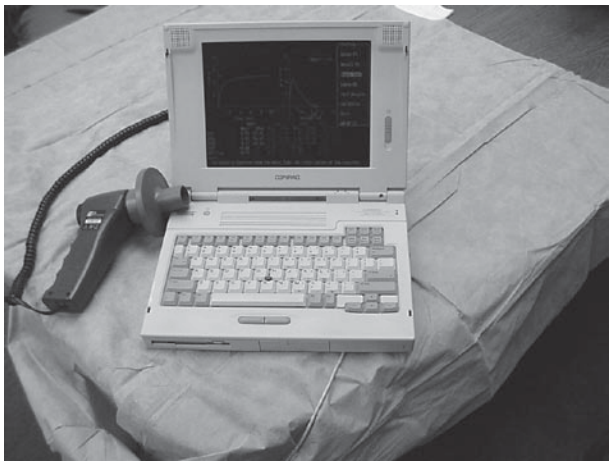

FIGURE 9-7

An example of a modern portable spirometer using a pneumotach connected to a laptop computer.

Interpretation of Spirometry

Serial forced vital capacity (FVC) measurement is useful in timing the need for ventilatory support in patients with progressive neuromuscular weakness.

Serial measurements of forced expiratory flow (FVC, FEV_1, and PEF) are useful to assess the response to therapy and to detect early deterioration in a patient's clinical condition after intensive therapy for acute asthma exacerbation. In patients with neuromuscular dysfunction, serial measurements of FVC are helpful in evaluating the need for partial or full ventilatory support. A decreasing FVC in patients with neuromuscular dysfunction usually suggests progressive respiratory weakness and is a harbinger of impending respiratory failure. At FVC less than 10 mL/kg, coughing becomes ineffective in clearing airway secretions, thereby increasing the risk for the development of atelectasis and pneumonia. Alternatively, the FVC can also be used as one of the criteria for the initiation of weaning trials and liberation from mechanical ventilation.

In patients with progressive neuromuscular weakness, FVC ≤ 10 mL/kg is an indication for assisted ventilation.

FVC ≤ 10 mL/kg is associated with impaired cough, retained secretions, and atelectasis.

Causes of high minute ventilation are intrinsic lung disease, pain, anxiety, fever, and central nervous system disorders.

The minute ventilation is the amount of air that is inhaled and exhaled by an individual in 1 min. Therefore, minute ventilation is equal to the respiratory rate multiplied by V_T. Minute ventilation is composed of dead space ventilation and alveolar ventilation. In healthy subjects, the normal minute ventilation is 5–6 L/min. Because minute ventilation is inversely proportional to $PaCO_2$, high minute ventilation in the presence of hypercapnia suggests the presence of increased dead space ventilation. Apart from intrinsic lung disease, high minute ventilation may also result from pain, fever, or central nervous system disorders. Excessively high minute ventilation is not sustainable for prolonged periods of time, especially in critically ill patients. The majority of these patients often require ventilatory assistance if the cause of high minute ventilation cannot be easily reversed. For the same reason, a minute ventilation of less than 10 L is preferred in patients who are being weaned from mechanical ventilation. Conversely, low minute ventilation may indicate decreased central respiratory drive as seen in conditions of oversedation, hypothyroidism, obesity hypoventilation syndrome, and respiratory muscle dysfunction. The ventilatory reserve of the respiratory system can be estimated by measuring the maximum minute ventilation (MVV), which is the maximum volume of gas that can be breathed over a specified period of time. Normal MVV values range from 50 to 250 L/min. The MVV is best interpreted in relation to the resting minute ventilation. If high minute ventilation is required to maintain a normal $PaCO_2$ in relation to the MVV (≥60%), the risk for the development of respiratory muscle fatigue increases during weaning trials.

An excessively high minute ventilation requirement may lead to respiratory muscle fatigue and acute respiratory failure.

Causes of low minute ventilation are hypothyroidism, oversedation, respiratory muscle dysfunction, and obesity hypoventilation syndrome.

A simple peak flowmeter can be used to measure airflow obstruction in highly motivated patients. It is a simple handheld device that is portable and easy to use. Serial measurements using the peak flowmeter give more useful clinical information than a single absolute reading. Peak flow readings are affected by the volitional effort of the patient, the strength of the respiratory muscles, the recoil of the lungs and chest wall, and the degree of airway resistance. In patients with reversible airflow obstruction, the peak flow reading can be compared to their previously recorded personal best reading. Patients with chronic respiratory diseases such as asthma and COPD, have their own optimal peak flows.

Factors affecting peak flow measurements are volitional effort, respiratory muscle strength, recoil of the lung and chest wall, and airway resistance.

Serial measurement of respiratory muscle strength with a simple aneroid meter is important in patients with neuromuscular dysfunction. Maximum static mouth pressures, measured at the airway opening during a voluntary contraction against an occluded airway, are the most sensitive to assess respiratory muscle dysfunction in routine clinical practice. The extent of respiratory muscle weakness can be quantified by measuring the maximum inspiratory (Pl_{max}) and expiratory pressures (PE_{max}) that can be generated by the respiratory muscles. It should be remembered that measurement of static mouth pressures is affected by the lung volume at which they are measured. Thus, Pl_{max} is measured near residual volume where the inspiratory muscles are lengthened to their optimum precontraction length; $PE_{max,}$ conversely, is measured near total lung capacity where expiratory muscles are lengthened to their optimum precontraction length. When respiratory muscle strength decreases to less than 30% of the predicted value, hypercapnic respiratory failure usually ensues.

PI_{max} is measured at residual volume; PE_{max} is measured at total lung capacity.

Inductive Plethysmography

Changes in breathing pattern herald the onset of respiratory muscle fatigue and ventilatory failure. In patients with respiratory muscle fatigue caused by high resistive loads

CASE STUDY: PART 4

Reassessment of this patient's vital signs revealed that the automated blood pressure cuff was unable to record any blood pressure. His blood pressure could not be adequately ascertained manually with a bedside sphygmomanometer because of faint Korotkoff sounds. The systolic blood pressure on palpation was estimated at 80 mmHg, which was subsequently confirmed by a doppler-enhanced stethoscope; 1 L normal saline was rapidly infused and dopamine was initiated at 5 μg/kg/min. A radial arterial line was inserted for more accurate blood pressure monitoring.

(e.g., patients with chronic airflow obstruction) or high elastic loads (e.g., morbidly obese patients), the breathing pattern is characterized as rapid and shallow. This rapid and shallow breathing pattern can be expressed as the ratio of V_T to respiratory rate, which is commonly referred to as the rapid shallow breathing index V_T/RR. In ventilator-dependent patients who are undergoing weaning trials, a rapid shallow breathing index less than 100 is highly predictive of weaning failure. Similarly, during breathing, thoracoabdominal rib cage paradox in the absence of upper airway obstruction also suggests respiratory muscle weakness or fatigue.

The breathing pattern in patients with ventilatory insufficiency can be followed qualitatively using inductive plethysmography. In inductive plethysmography, an elastic band that contains electrical wires or magnets is wrapped around the patient's rib cage and abdomen. The wires are then connected to an oscillator module. Changes in the compartmental volume of the rib cage or abdomen create proportional changes in the cross-sectional areas of the electrical inductance loops. This resultant change in volume displacement is compared to the calibration curve obtained from lung function data measured while performing spirometry. Using this technique, V_T can then be qualitatively estimated and followed serially during weaning trials.

Inductive plethysmography measures the qualitative compartment volume changes of the thorax in relation to the abdomen during inspiration and expiration.

CARDIAC MONITORING

Blood Pressure Monitoring

Arterial blood pressure can be monitored either directly via an intra-arterial catheter or indirectly using a traditional sphygmomanometer and a stethoscope. Although intra-arterial blood pressure monitoring is more accurate, especially in the presence of shock, noninvasive blood pressure monitoring is easy to set up and not subject to the complications commonly associated with intravascular catheters such as pain, infection, bleeding, and thrombosis. Several indirect blood pressure monitoring techniques have been developed that surpass the accuracy and convenience of the auscultory method.

In the presence of shock, direct intra-arterial blood pressure measurement is more accurate than noninvasive indirect blood pressure measurement.

Indirect Blood Pressure Measurement

Although several techniques are currently available for the indirect measurement of blood pressure, the basic method remains the same: the application of external pressure via an appropriately sized cuff when flow is observed in the artery distal to the occlusion. It is important to note that what is actually detected is blood flow, not the intra-arterial pressure itself. The accuracy of the blood pressure measurement is affected by the cuff size. An inadequate cuff size will result in a falsely elevated blood pressure reading. In contrast, an inordinately large cuff size will lead to a falsely low reading.

In the indirect blood pressure monitoring method, a small cuff size falsely elevates blood pressure and a big cuff size results in falsely low blood pressure readings.

Manual Methods

Manual blood pressure measurement can be obtained by auscultatory, oscillation, or palpation methods. The auscultatory method of blood pressure measurement involves inflating mercury or an aneroid sphygmomanometer cuff around an extremity and auscultating for the disappearance of blood flow in the distal artery. The resumption of blood flow when the cuff is released

The oscillation or palpation methods are useful in rapidly estimating systolic blood pressure in the presence of shock.

causes distinctive thumping sounds (Korotkoff sounds) due to the vibrations of the artery under pressure. The level at which the Korotkoff sounds reappear, and the level at which these disappear or diminish in volume, are taken as the systolic and diastolic blood pressures, respectively. In most clinical conditions, the auscultatory method is more than adequate in estimating clinically relevant blood pressure readings. However, in shock states, the Korotkoff sounds become faint, making accurate readings difficult. In this circumstance, the oscillation or the palpation methods may help identify the systolic blood pressure in emergency situations. With the oscillation method, the resumption of blood flow as the cuff pressure is released is indicated by the pulsatile movement of the mercury column or the needle of the aneroid manometer, representing the systolic blood pressure. In the palpation method, the detection of the radial pulse as the cuff pressure is slowly released is the palpatory blood pressure. With oscillation or palpation methods, the diastolic blood pressure cannot be measured. Overall, these noninvasive blood pressure techniques correlate poorly with the directly measured blood pressure value.

Automated Methods

The automated indirect blood pressure measurement devices obviate the need to manually inflate and deflate the sphygnomanometer cuff. The automated blood pressure measurement is widely used in critical care units and offers the ability to repetitively measure the blood pressure with ease, convenience, and without the associated morbidity of intra-arterial blood pressure monitoring. The most commonly used principles in automated blood pressure system include Doppler flow, infrasound, oscillometry, volume clamp, and arterial tonometry. With the Doppler flow system, the changes in the reflected echo signal in the distal artery during cuff inflation and deflation (Doppler shift) is used to estimate the blood pressure. In an uncompressed artery, the small amount of wall motion does change the frequency of the reflected signal. The first appearance of flow in the distal artery is the systolic pressure, and the disappearance of the Doppler shift represents the diastolic blood pressure. In the infrasound system, a microphone is used to detect low-frequency sound waves associated with the vibration of the arterial wall during cuff deflation. In the oscillometric method of blood pressure monitoring, oscillations of the arterial vessel wall due to pulsatile blood flow are detected by a sensor in the cuff. Systolic and diastolic blood pressures are estimated from the magnitude of the pressure fluctuation. The volume clamp technique is unique because a finger cuff applied over the proximal or middle phalanx is used instead of the arm cuff. A servo-control unit, strapped to the wrist, which keeps the artery at a constant size, regulates the pressure on the finger cuff. The pressure needed to maintain the artery at a constant size is equal to the intra-arterial pressure.

Overall, these automated blood pressure devices are adequate in frequent blood pressure monitoring, especially in patients who are essentially stable, or during transport when arterial lines cannot be easily used, or for burned patients in whom intra-arterial blood pressure monitoring may lead to infections. The limitations of the automated indirect blood pressure measurement are similar to other noninvasive methods of blood pressure determination.

ELECTROCARDIOGRAPHIC MONITORING

The preferred leads for monitoring myocardial ischemia are V_1, aVf, and V_5.

Monitoring of cardiac rhythm using the principles of electrocardiography to detect life-threatening cardiac arrhythmia has been shown to improve prognosis in patients with acute myocardial infarction. The impact of routine cardiac rhythm monitoring in the ICU is unclear. However, because most patients who are admitted to the ICU are older, have multiple organ dysfunctions, and have concomitant ischemic heart disease, continuous electrocardiographic monitoring should be used in all patients regardless of the admitting diagnosis. Common causes of cardiac arrhythmia in the ICU setting are shown in Table 9-4.

The ECG leads commonly selected are either for monitor display leads V_1 or lead II. The American Heart Association Task Force recommends using at least two and preferably three leads for patient monitoring. The use of multiple leads enhances recognition of abnormal ECG patterns and artifact detection. If the patient is at a high risk for myocardial ischemia,

CASE STUDY: PART 5

On the fourth day in the hospital, this patient was noted to have a heart rate of 171 beats/min. The rhythm appeared to be a narrow complex tachycardia on the patient's cardiac monitor. His blood pressure was 110/58 mmHg while receiving dopamine infused at 6 μg/kg/min. A 12-lead ECG showed a regular and narrow complex tachycardia with a consistent AV nodal reentrant tachycardia. Right carotid massage was attempted but without success. The patient was given 12 mg IV of adenosine with spontaneous conversion to sinus tachycardia at a rate of 110 beats/min. A stat electrolyte determination revealed potassium of 3 mEq/L and a low serum magnesium level. A bedside echocardiogram revealed normal left ventricular function with an ejection fraction of 55%. His left atrial size was normal. He had no further recurrence of cardiac arrhythmia after adequate correction of his hypokalemia. The patient had a prolonged course in the ICU complicated by sepsis associated with multiorgan failure. On the seventh day in the hospital, he was weaned from dopamine, and his blood pressure remained stable. He was slowly weaned from the ventilator following a tracheostomy. He was subsequently transferred to the ventilator rehabilitation unit for further care.

TABLE 9-4

COMMON CAUSES OF CARDIAC ARRHYTHMIA IN THE INTENSIVE CARE UNIT (ICU)

CONDITION	RESULT
Cardiac	Myocardial ischemia
	Myocardial infarction
	Congestive heart failure
	Sick sinus syndrome
	Atrioventricular bypass tract
	Postcardiac surgery arrhythmias
	Hypotension
	Dehydration
	Gastrointestinal bleeding
	Sepsis
Noncardiac	
Metabolic	Electrolyte abnormalities
	Hypokalemia
	Hypomagnesemia
	High-catecholamine state
	Pain
	Sepsis
	Alcohol withdrawal syndrome
	Hyperthyroid state
Respiratory	Respiratory distress due to airflow obstruction or parenchymal lung disease
	Acute pulmonary embolism
Drugs	Vasopressors
	Dopamine
	Dobutamine
	Epinephrine
	Norepinephrine
	Theophylline
	Antiarrhythmic drugs

a basic system using leads V_1, aVf, and V_5 is preferred for monitoring. Lead V_5 has been reported to have the greatest sensitivity for detecting myocardial ischemia. To enhance the recognition and interpretation of a wide QRS complex tachycardia, bipolar precordial leads, MCL1 and MCL6, are used to simulate leads V_1 and V_6, respectively.

Lead V_5 is most sensitive in detecting myocardial ischemia.

Apart from choosing the optimal lead system, it is important to remember to clean the skin with alcohol and to remove the hair on the electrode site to decrease skin electrical resistance and to prevent artifacts. By properly following these techniques, the skin electrical resistance can be reduced from 200 to approximately 10 Ω in most patients. Other electromagnetic devices used in other monitoring systems can interfere with ECG monitoring. A common type of interference is caused by nearby 60-Hz power lines. This type of interference can be minimized by (1) using shielded electrodes and ensuring that the electrode cables are properly attached, (2) preparing the skin properly, (3) using an amplifier with common-mode rejection, and (4) using only monitors with built-in filtering systems.

Current continuous ECG monitoring system not only can detect cardiac arrhythmia but also can monitor ST segment morphology that may indicate ongoing myocardial ischemia. This added capability is important because (1) patients with coronary artery disease with ST segment changes may have no symptoms (silent myocardial ischemia), (2) patients with unstable angina with ischemic ST-T wave changes at rest or during pain have a poorer prognosis, and (3) patients in the ICU are often intubated or heavily sedated and may not be able to communicate their symptoms properly.

The modern ECG monitoring system includes analysis of the ST segment 60–80 MS after the J point.

In most ST segment monitoring systems, the computer analyzes the ECG pattern and stores a normal QRS template. The computer algorithm used in the detection of ST segment changes compares the isoelectric points just before the QRS and the ST segment 60–80 ms after the J point. The computer uses the stored QRS template to differentiate a normal QRS from an ectopic beat that makes the ST segment changes void. The use of a multiple lead system enhances the sensitivity and accuracy of ST segment monitoring.

Causes of ST segment elevation are acute myocardial infarction, acute pericarditis, ventricular aneurysm, coronary artery spasm, benign early repolarization, and a change in body position.

Changes in the ST segment (e.g., elevation or depression) on the ECG monitoring leads need to be confirmed by a 12-lead ECG and interpreted in light of other clinical findings. In patients with known history of coronary artery disease, ST segment elevation or depression usually suggests ongoing myocardial injury or ischemia. Other causes of ST segment elevation include acute pericarditis, ventricular aneurysm, coronary artery spasm (Prinzmetal angina), change in body position, and benign early repolarization. In acute pericarditis, chest pain is worse when the patient leans forward, and a pericardial rub may be heard on cardiac auscultation. Moreover, ST segment elevation is often present diffusely on the ECG and is frequently accompanied by PR segment depression. In the presence of a ventricular aneurysm, the ST segment remains persistently elevated. These patients often have a history of prior anterior myocardial infarction. ST segment elevation in coronary artery spasm usually correlates with the patient's symptoms. It is important to remember that changes in body position can lead to artifactual ST segment elevation.

BIOIMPEDANCE CARDIOGRAPHY

Thoracic electrical bioimpedance (TEB), also known as impedance cardiography, is based on the measurement of changes in thoracic impedance (or resistance) to the transmission of small electrical current in the chest. In essence, the technology is based on the differences in impedance characteristics of the body tissues that act as electrical conduits. In the thorax, an electrical current passes through conduits of high (cardiac muscle, lungs, fat, and air) and low impedance (blood, plasma). Thus, over time, changes in the body's resistance to electrical current flow are reflective of the changes in blood volume. During cardiac systole, the impedance to electrical current flow is decreased as the blood is rapidly ejected into the aorta and its arterial branches. During diastole, the impedance to electrical flow is back to baseline. Since the blood flow in the venous circulation is nonpulsatile, it does not contribute to dynamic changes in thoracic impedance. Therefore, changes in thoracic impedance reflect changes in aortic pressure during systole (Fig. 9-8). With thoracic impedance cardiography, hemodynamic parameters, such as stroke volume and cardiac output, can be measured noninvasively and continuously without the morbidity and mortality associated with a pulmonary artery catheter.

The first reported application of the TEB was the measurement of cardiac output during space flights in the 1960s. Since then, with an improvement in technology and development of better predictive algorithms, TEB has been shown to be accurate in patients following cardiac surgery, chronic heart failure, in patients receiving mechanical ventilation, and in critically ill patients following severe trauma. In addition, TEB is increasingly used in the clinical setting in the diagnosis and management of heart failure.

Most early studies comparing cardiac output measurements with dye dilution, thermodilution, or the Fick equation showed reasonable correlation coefficients ($r = 0.65–0.9$) depending on the population studied and the impedance algorithm used. The accuracy of the impedance cardiography is also influenced by the technique and placement of the electrodes. Currently, there are three basic types of impedance cardiography, namely, thoracic,

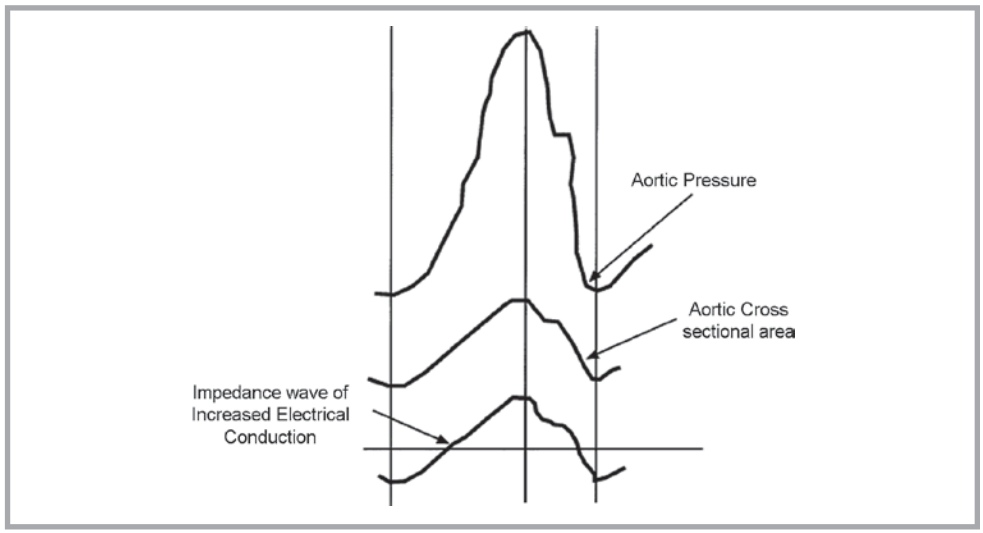

FIGURE 9-8

Relationship between impedance during cardiac systole and diastole. During cardiac systole, thoracic impedance decreases as blood is ejected into the aorta (reprinted with permission from Djordjevich, Sadove,[42] published by ASME International).

whole body, and regional impedance cardiography. In thoracic impedance cardiography, the electrodes are placed on the root of the neck and the lower part of the chest. In whole body cardiography, the electrodes are placed on each limb, whereas in regional impedance cardiography the electrodes are placed only on the wrist and contralateral ankle. In patients with cardiac dysfunction, cardiac output measurement using thoracic impedance cardiography showed 44% disparity compared to thermodilution technique, upper and lower limits of agreement of two standard deviation of approximately ± 2.21 L/min. Using the regional lead placement, the disparity between the impedance cardiography was reduced to 20%.[21] The improved accuracy with peripheral lead placement is the result of improved capture of the peripheral impedance signal, which is mainly due to systolic blood volume pulsation of the arterial vasculature. As the technology of bioimpedance continue to evolve, cardiac output measurement becomes more reliable. In a prospective observational study involving 74 patients who underwent coronary artery bypass surgery, paired measurement of cardiac output using both thoracic bioimpedance and thermodilution techniques were significantly correlated ($r = 0.83$), and showed clinically acceptable agreement and precision even in hemodynamically unstable patients.[22] The differences between the two techniques were within 15% in more than 90% of the patients. It has been used in optimal treatment of resistant hypertension,[23] in fine tuning atrioventricular pacing in patients with refractory heart failure, in hemodynamic monitoring during acute and chronic management of heart failure,[24,25] and critically ill trauma patients.[7] Shoemaker and others simultaneously measured cardiac index of 262 trauma patients using both thoracic bioelectric impedance technique and conventional pulmonary artery. In 907 simultaneous measurements of cardiac index in these trauma patients, the cardiac index measurement by thermodilution was highly correlated with bioimpedance method ($r = 0.915$). The bias and precision of these simultaneous measurements was -0.070 ± 0.47 L/min. The average percentage error between two consecutive thermodilution measurements was 9.5%, and the average difference between simultaneous thermodilution and bioimpedance measurements was 9.7%. The authors concluded that there is a satisfactory agreement between thermodilution and cardiac output measured by bioimpedance technique in the emergency condition of trauma patients.

There are several limitations to the clinical application of thoracic impedance cardiography. It does not provide any data about cardiac filling pressures and systemic oxygenation parameters that are important in the management of hemodynamically unstable patients. In addition, certain clinical conditions such as cardiac arrhythmias, aortic regurgitation, bradycardia (<40 beats/min), tachycardia (>140 beats/min), late stage liver cirrhosis, and poor skin contact may interfere with the accuracy of thoracic impedance cardiography.[26,27]

ELECTROENCEPHALOGRAPHIC MONITORING

Secondary brain injury often complicates recovery in critically ill patients. Digital video continuous electroencephalography (cEEG) provides prolonged monitoring of brain activity in critically ill patients with altered mental status and patients who are at risk for ischemia after acute brain injury. The increased use of cEEG monitoring in ICU showed that nonconvulsive seizures are more common than previously recognized. In a study of 570 hospitalized patients who underwent cEEG monitoring, 19% of the patients had seizures, 95% of which were nonconvulsive seizures.[28] In neurointensive care unit setting, 34% of the patients had seizures, majority of which were nonconvulsive seizures (76%).[29] Nonconvulsive seizures or status epilepticus are associated with increased morbidity and mortality regardless of the underlying etiology.[30,31] The duration and time for the diagnosis of seizures are important predictors of outcome in nonconvulsive seizures. The reported mortality after 30 min of seizure was 36%, and increased to 75% if the seizure is sustained for 24 h.[32] Thus, the early diagnosis and successful termination of seizures with appropriate treatment is crucial to improving outcome. The indication of cEEG include: (1) detection of nonconvulsive seizures or status epilepticus in patients with unexplained fluctuating mental status and after convulsive status epilepticus; (2) evaluation of abnormal motor activities such as posturing, rigidity, tremors, chewing, twitching, nystagmus, eye deviation, and agitation; (3) assessment of the level of consciousness during sedation and paralysis, including the management of burst suppression in anesthetic coma; (4) detection of ischemia after subarachnoid hemorrhage or during neurosurgical and neuroendovascular procedures, and (5) for providing prognostic information following acute brain injury. Multiple factors can affect the fidelity of cEEG monitoring in the ICU (Table 9-5). Common EEG patterns of encephalopathy and coma are encountered in the ICU and their clinical significance is shown in Table 9-6. Most of the EEG patterns seen in toxic and metabolic encephalopathy are nonspecific and tend to

TABLE 9-5

COMMON CAUSES OF EEG ARTIFACT IN THE ICU (MODIFIED WITH PERMISSION FROM KAPLAN [43])

60 Hz electromagnetic source artifact
Respirator and EKG artifact
Telephone and other electronic devices
Sweat, muscle, movement artifact
Health care provider touching the patient

TABLE 9-6

EEG PATTERNS AND THEIR CLINICAL SIGNIFICANCE

EEG PATTERNS	CLINICAL SIGNIFICANCE
Intermittent rhythmic delta activity	Structural brain disease, bihemispheric disease, encephalopathies, nonspecific in elderly
Triphasic waves	Encephalopathies (hepatic coma, uremia, lithium intoxication, ifosfamide, tricyclic overdose, neuroleptic malignant syndrome, serotonin syndrome)
Periodic discharges	
Periodic lateralized epileptiform discharges (PLEDs)	Structural or focal lesions (ischemic strokes, abscesses, intracranial hemorrhages, brain tumors)
Bilateral independent periodic lateralized epileptiform discharges (BIPLEDs)	Anoxic encephalopathy, CNS infections, seizures, associated with high mortality (61%)
Generalized periodic epileptiform discharges (GPEDs)	Anoxic-ischemic coma, metabolic encephalopathy, Creutzfeldt-Jakob disease, herpes encephalities
Burst suppression	Anoxic encephalopathy, toxic CNS drugs, hypothermia, anesthesia
EEG patterns in coma	
Electrocerebral inactive (ECI)	No EEG activity exceeds 2 mV, poor prognosis
Alpha coma	Anoxia following cardiac arrest, poor prognosis
Spindle coma	Head injury, good prognosis
Beta coma	Benzodiazepines or barbiturates overdose, good prognosis

show slow background rhythms with variable degrees of intrusion of slower theta-delta frequencies. Some EEG patterns are suggestive of drug/alcohol intoxications: high voltage beta activity is associated with benzodiazepine or barbiturate intoxication; low voltage fast patterns are associated with alcohol withdrawal; burst of high voltage slow activity interspersed with mixed frequencies with phencyclidine (PCP) intoxication.

MONITORING OF SEDATION

Sedation in the ICU setting is an essential aspect of providing safe, effective, and humane care, but oversedation leads to excessive morbidity and mortality. Daily assessment of patients after holding sedation in the ICU setting has been shown to reduce the ICU length of stay and the duration of mechanical ventilation.[33] Current societal guidelines suggest that the level of sedation and the presence of delirium be assessed concurrently in the ICU.[34] Numerical scales are available for assessing the levels of sedation, but not many of them have been prospectively studied. The Ramsey sedation scale was the first published scale and it is commonly used to this day.[35] The Ramsay sedation scale uses three different levels of wakefulness and sleep (Table 9-7). The typical goal is to achieve a level of 3 or 4, but one critique of this scale is that there is not a way to fine-tune the level of sedation. Recently, the Richmond Agitation and Sedation Scale (RASS) has been shown to have a high reliability and validity among medical and surgical ICU patients.[36] The RASS uses a ten-point scale that assesses the level of sedation in response to verbal and physical stimuli ranging from unarousable (−5), to calm (0), to combative (+4) (Table 9-7). The RASS had excellent inter rater reliability among five different individuals who performed 1,100 RASS evaluations in nearly 300 patients.[36] One of the unique aspects of RASS is that it was successfully validated on patients in surgical, medical, coronary, cardiothoracic, and neurological ICUs.

Delirium is very common in the ICU and has been associated with longer ICU stays and worsened outcomes. The risks for delirium include age, presence of multisystem illness, and the use of psychoactive medications. Because the treatment of delirium differs from that of agitation, early recognition is important in the ICU setting. Recognizing delirium may be difficult due to the presence of multisystem disease and because many critical care physicians are not familiar with the DSM-IV diagnostic criteria for delirium. The Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) was developed to screen for

TABLE 9-7

SEDATION SCALES USED FOR ASSESSMENT IN THE ICU PATIENT

RAMSAY SCALE		RICHMOND AGITATION AND SEDATION SCALE (RASS)	
Level of sedation	score	Level of sedation	score
Patient anxious or agitated	1	Combative, danger to self and staff	+4
Patient cooperative and tranquil	2	Very agitated, pulls on catheters	+3
Patient responds to commands only	3	Agitated, nonpurposeful movement	+2
Brisk response to light glabellar tap	4	Restless, anxious but movements are not aggressive or vigorous	+1
Sluggish response to glabellar tap	5	Alert and calm	0
No response	6	Drowsy, sustained eye contact for 10 s to voice	−1
		Light sedation, briefly awakens (<10 s) to voice contact	−2
		Moderate sedation, any movement but no eye contact to voice	−3
		Deep sedation, no response to voice but moves to physical stimuli	−4
		Unarousable, no response to voice or physical stimulation	−5

delirium in the ICU where many patients are nonverbal and the time that clinicians can devote to assessment is limited. The four features of the CAM-ICU include: (1) an acute onset of mental status change or a fluctuating mental status (2) inattention (3) disorganized thinking and (4) altered level of consciousness. Patients must have both features one and two and then either feature three or four in order to have delirium. Nonverbal patients can be evaluated for inattentiveness by showing them five pictures and then showing the same pictures along with five that they have not seen. The patient is then asked to nod yes or no if they have seen the picture previously.[37] Patients with poor vision are read a series of ten letters slowly and then are asked to squeeze the interviewer's hand whenever they hear the letter "A". The CAM-ICU tool has excellent interrater variability, sensitivity, and specificity for recognizing delirium.[37]

LIMITATION AND SIDE EFFECTS OF MONITORING

Although noninvasive monitoring in the ICU can alert the physicians, nurses, and respiratory therapists to potential life-threatening events, the limitations of the different ICU monitoring techniques must be remembered and applied in the right clinical setting. For example, pulse oximetry should not be used or relied upon as a measure of adequate oxygenation in patients who are suspected of methemoglobin poisoning. It is incumbent on the health care practitioner to recognize artifactual as well as factitious data. A common cause of monitoring artifacts in the ICU is patient movement that causes dislodgement of the monitoring electrodes or probes. Electrical interference among different monitoring devices can also lead to artifactual results. This type of interference is commonly referred to as 60-Hz interference. Artifactual and factitious recordings may result in false alarms that may prompt less experienced health care providers to order unnecessary tests. In some studies, the incidence of false alarms generated by the multiple monitoring devices commonly used in the ICU can be as high as 50–90%.

Apart from the measurement problems of the various monitoring devices, the alarms triggered by the different commonly used monitoring techniques contributes to noise pollution in the ICU environment, which may lead to sleep disruption in some patients. In one study, the noise level in a medium-sized ICU during the day and night exceeded the exposure threshold by the U.S. Environmental Protection Agency (>45 dB in 24 h).

Another emerging problem in ICU care is overreliance of health care givers on data from monitoring devices to the exclusion of the patient's physical examination. All too often work rounds in the ICU consist of discussion of the patient's monitoring data, rather than careful observation and physical examination of the patient. It is sometimes difficult to remember, amidst all the technologically advanced monitoring equipment in the ICU that critically ill patients are more than the sum of their physiologic data.

SUMMARY

Noninvasive monitoring is widely used in the management of critically ill patients. It is safe, relatively easy to use, and does not have complications associated with invasive monitoring techniques. Its main use is to detect early changes in the patient's physiology so that appropriate interventions can be performed promptly. As long as the capabilities and limitations of the monitoring devices are understood by physicians, nurses, and other health care workers, noninvasive monitoring is valuable, provides useful information, and helps prevent complications.

REVIEW QUESTIONS

1. **A 12-year-old boy was rescued by a firefighter from a smoke-filled room of a burning 12-story apartment building. The following procedures are appropriate, except which of the following:**
   - **A.** A careful inspection of the upper airway passages to detect signs of inhalational injury
   - **B.** A chest radiograph on admission to look for inhalation lung injury
   - **C.** A 24-h hospital observation
   - **D.** Normal oxygen hemoglobin saturation by pulse oximetry to exclude the presence of carbon monoxide poisoning

2. **Factors that may affect the accuracy of thoracic bioimpedance cardiography except**
   - **A.** Cardiac arrhythmia
   - **B.** Pleural effusion
   - **C.** Aortic regurgitation
   - **D.** Coronary artery disease

3. **The following statements about pulse oximetry are true except which of the following:**
   - **A.** Modern pulse oximetry uses two wavelength of light, red and infrared, to discriminate between oxygenated and deoxygenated blood
   - **B.** Unlike transcutaneous oxygen measurement, pulse oximetry is not affected by low cardiac output state
   - **C.** Different forms of dyshemoglobinemia can affect the accuracy of oxyhemoglobin measurement by pulse oximetry
   - **D.** The accuracy of pulse oximetry degrades with oxygen saturation ≤ 65%

4. **The following statements about capnometry and endotracheal tube placement are true except which of the following:**
   - **A.** Capnometry provides a rapid and accurate confirmation of a successful tracheal intubation in critically ill patients
   - **B.** By looking at the end-tidal PCO_2 level, capnometry may also be able to discriminate right and left mainstem intubation
   - **C.** Recent ingestion of carbonated drinks before attempted intubation may lead to positive CO_2 detection despite esophageal intubation
   - **D.** Bedside proper endotracheal tube placement can also be assessed by listening for bilateral breath sounds, symmetric chest expansion, and absence of gastric sound following a positive inspiratory breath

5. **ST segment elevation in the ICU may be seen in the following clinical scenario except which of the following:**
   - **A.** A 22-year-old man with cocaine overdose
   - **B.** A 48-year-old executive presenting to the emergency room with chest discomfort and jaw pain radiating to the left arm
   - **C.** A 70-year-old man with history of multiple anterior myocardial infarction and four-vessel coronary artery bypass surgery who now presents to the emergency room with symptoms and signs of congestive heart failure
   - **D.** A 24-year-old man who complains of chest pain and shortness of breath 4 days after knee surgery

ANSWERS

1. The answer is D. Normal oxygen hemoglobin saturation by pulse oximetry in patients with a history of smoke exposure does not exclude the presence of a significant carbon monoxide poisoning. Because the absorption characteristics of carboxyhemoglobin mimic the light absorbance pattern of oxyhemoglobin, falsely elevated oxyhemoglobin saturation is invariably seen by pulse oximetry. The oxygen saturation should be measured directly in the blood samples by cooximetry technique.
2. The answer is D. Coronary artery disease does not affect the accuracy of cardiac index determination by thoracic bioimpedance cardiography. Most studies showed very good correlation in cardiac index measurement between thoracic impedance cardiography and thermodilution in patients with heart disease, and in patients who underwent coronary artery bypass surgery. Factors that can affect the accuracy of cardiac output measurement by thoracic bioimpedance cardiography include lead placement, bioimpedance algorithm use, aortic regurgitation, pleural effusion, extreme bradycardia (HR < 40/min) and tachycardia (HR > 140 beats/min), liver cirrhosis, and poor skin contact.
3. The answer is B. Pulse oximetry is unreliable in the low cardiac output state. Similarly, oxygen hemoglobin measurement by pulse oximetry becomes unreliable in the presence of dyshemoglobinemia, severe anemia, and severe hypoxemia.
4. The answer is B. Capnometry is increasingly used to confirm successful endotracheal intubation by the qualitative detection of expired CO_2. It will not differentiate an inadvertent bronchial intubation from tracheal intubation. Careful bedside examination for equal breath sounds and symmetric chest expansion, and listening for gastric sound on inspiration, is helpful in the detection of bronchial intubation. Capnometry may detect CO_2 release from carbonated drinks despite esophageal intubation.
5. The answer is D. In a small percentage of patients with acute pulmonary embolism, 12-lead electrocardiogram may show an S_1-Q_3-T_3 pattern, that is, an S wave in lead I and Q-wave and T-wave inversion in lead III. The cardiac toxicity of cocaine may be associated with either ST segment depression or elevation suggestive of myocardial ischemia or coronary vasospasm, respectively. Choice B is a classic presentation of acute myocardial infarction. Choice C is a patient with left ventricular aneurysm due to multiple episodes of myocardial infarction in the past. The typical 12-lead electrocardiographic finding is persistent ST segment elevation in the precordial leads.

CHAPTER 10

HARVEY M. LICHT, FREDRIC JAFFE, AND GILBERT E. D'ALONZO

Endoscopy in the Intensive Care Unit

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to do the following:

- Understand the indications for both respiratory and gastrointestinal (GI) endoscopy in critically ill patients.
- Describe the contraindications and potential complications that are associated with endoscopy and endosurgery.

During the past three decades, the technology of endoscopy has led to the development of sophisticated optics and simple-to-use devices that are practical for use in critically ill patients. The upper airway, lung, and gastrointestinal (GI) passageways are accessible by endoscopy. In the intensive care unit, endoscopy is commonly performed for therapeutic reasons and diagnostic purposes. This chapter reviews the indications, contraindications, techniques, and complications of laryngoscopy, bronchoscopy, and GI endoscopy in critically ill patients.

LARYNGOSCOPY

The upper airway can be inspected by both rigid and flexible laryngoscopy techniques.

The larynx can be examined directly with a laryngoscope or a bronchoscope. The traditional rigid laryngoscope is a lighted metal instrument that displaces the tongue and permits the observation of the glottis, including the epiglottis and vocal cords. It consists of a handle containing batteries and a detachable blade, either straight (Miller) or curved (McIntosh), which comes in a variety of sizes, and a bulb to illuminate the tip of the blade. The straight blade bypasses and lifts the epiglottis, while the curved blade tip fits into the vallecula (Fig. 10-1).

Fiberoptic laryngoscopy has enhanced the ease and comfort of visualizing the oronasopharynx and larynx. The flexible fiberscope, inserted via the nose, is considered as the

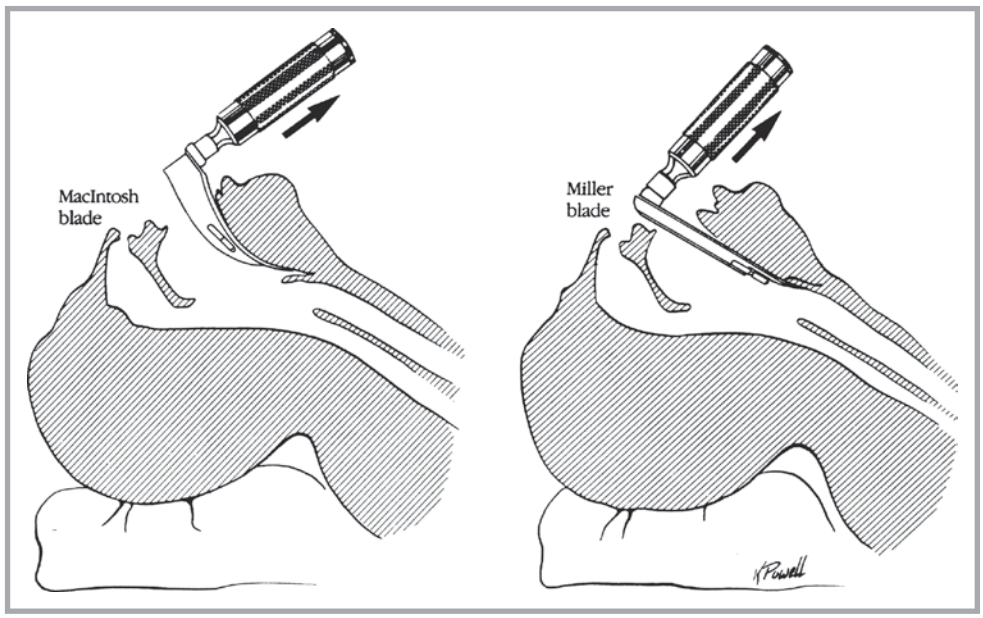

FIGURE 10-1

There are two basic types of laryngoscope blades, the MacIntosh (left) and the Miller (right) blades. The MacIntosh blade is curved and its use differs from that of the Miller blade. The MacIntosh blade tip is placed in the vallecula, and the handle of the laryngoscope is pulled forward at a 45° angle. This technique allows visualization of the epiglottis. With the Miller blade, which is straight, the tip is placed posterior to the epiglottis, and therefore, the epiglottis is pinned between the base of the tongue and the straight laryngoscope blade. The motion on the laryngoscope handle is the same as that used with the MacIntosh blade.

simplest method of visualizing the upper airway and an excellent way to monitor the epiglottic swelling to evaluate the need to intubate or perform a tracheostomy. Rigid laryngoscopy should be performed for upper airway inspection, particularly in patients who are suspected of having upper airway obstruction (Table 10-1). The major indication for rigid laryngoscopy is endotracheal intubation.

Rigid laryngoscopy facilitates endotracheal intubation.

Endotracheal intubation with a flexible fiberoptic laryngoscope or bronchoscope requires training. First, the larynx must be localized by visualization. Second, the tip of the scope is advanced into the trachea. Excessive secretions and tissue edema can hamper visualization of the larynx. Although the maneuver may sound simple, it can be difficult.

BRONCHOSCOPY

Bronchoscopy is the endoscopic examination of the larynx and tracheobronchial tree. In the intensive care unit, it can be performed with a rigid or flexible bronchoscope. It is rarely performed using a rigid instrument, but is predominately performed using a flexible bronchoscope.

Flexible fiberoptic bronchoscopy can be performed through an endotracheal tube while a patient is mechanically ventilated.

Flexible fiberoptic bronchoscopy allows the most complete inspection of the large airways.

Rigid bronchoscopy is most helpful in massive hemoptysis and the removal of a foreign body.

With the presence of bronchopulmonary disease in the intensive care unit and the use of mechanical ventilation with endotracheal tubes, bronchoscopy has become an important tool in the management of ICU patients. Fiberoptic bronchoscopy can be easily performed and is rarely associated with complications. With proper attention to patient sedation, it can be performed without significant patient discomfort. It has surpassed rigid bronchoscopy as the instrument of choice for evaluating the tracheobronchial tree. Further, as compared to rigid bronchoscopy, flexible bronchoscopy allows for more complete exploration of the airways. There is access to the upper lobes that rigid bronchoscopy does not allow. The procedure can easily be performed at the bedside, with minimal technical assistance.

Despite the ease of use of flexible fiberoptic bronchoscopy, the rigid bronchoscope still has advantages in certain clinical situations. Two such instances are massive hemoptysis and the removal of large foreign bodies. Although laser surgery can be performed using a flexible fiberoptic bronchoscope, the rigid bronchoscope has distinct advantages for this intervention. It also has an advantage in certain dilation procedures of the tracheobronchial tree involving airway stricture and tumors, and in particular, the placement of airway stents. Nonetheless, flexible fiberoptic bronchoscopy can also be used for these procedures.

Diagnostic Indications

Bronchoscopy is often used to evaluate hemoptysis and to culture airway secretions and lung washings in critically ill patients.

The diagnostic indications for bronchoscopy are numerous (Table 10-2). However, the most commonly encountered diagnostic indications in the ICU include the evaluation of hemoptysis, atelectasis, diffuse parenchymal disease, inspection of the airways following an inhalation injury or blunt trauma, assessment of the large airways following intubation, and for culturing airway secretions or washings, including bronchoalveolar lavage.

Bronchoscopy can be employed to identify the site of bleeding when a patient has hemoptysis. Hemoptysis can be caused by a variety of tracheobronchial lesions, cardiovascular and hematologic conditions as well as localized and diffuse parenchymal lung disorders. The clinician must decide when bronchoscopy is indicated in the patient with hemoptysis.

For example, the patient who has hemoptysis as a complication of pulmonary embolism does not likely require bronchoscopy. However, a respiratory failure patient with a localized lung infiltrate on chest X-ray and hemoptysis does require bronchoscopy to determine if there is an airway lesion. Diseases such as carcinoma can be responsible for the latter clinical

TABLE 10-2

INDICATIONS FOR BRONCHOSCOPY

DIAGNOSTIC INDICATIONS	THERAPEUTIC INDICATIONS
Acute inhalation injury	Airway stent placement
Assessment of intubation trauma	Bedside tracheostomy
Atelectasis	Brachytherapy for central airway neoplasms
Blunt chest trauma	Closure of bronchopleural fistula
Chest radiograph consistent with neoplasia	Endotracheal intubation
Cough	Excessive secretions and atelectasis
Cultures	Foreign bodies
Diaphragmatic paralysis	Hemoptysis
Diffuse parenchymal disease and/or bilateral hilar adenopathy	Laser resection for central airway neoplasms
Hemoptysis	Lung abscess
Laryngeal abnormalities	Preoperative assessment of resectability
Localized wheeze	Pulmonary alveolar proteinosis lavage
Lung abscess	
Metastatic disease with unknown primary site	
Pleural effusion of unknown etiology	
Positive cytology and normal chest radiograph	
Recurrent laryngeal nerve paralysis	
Recurrent pneumonia	
Symptoms after resection surgery	
Unresolving infiltrate	

presentation. In intubated patients, hemoptysis should always be evaluated to determine if tracheal damage has occurred at the time of or during intubation. The bronchoscopist should carefully inspect the airways and attempt to find the source of bleeding, when possible. The use of the fiberoptic bronchoscope allows the bronchoscopist to evaluate the areas to the segmental, and even subsegmental, bronchial level.

Hemoptysis following intubation should always be evaluated by bronchoscopy.

Many chest X-ray abnormalities can be evaluated by bronchoscopy. However, *not all* chest X-ray abnormalities require diagnostic bronchoscopy. Not even all intensive care patients with pneumonia require bronchoscopy. Some situations such as, when the patient is immunocompromised and/or special cultures are necessary can be clear indications for diagnostic bronchoscopy to obtain specimens that may be recovered only with the use of a bronchoscope. Certain chest X-ray abnormalities may indicate a need for diagnostic bronchoscopy (see Table 10-2). These abnormalities include atelectasis (of an entire lung, lobe, or segment), an enlarging or suspicious pulmonary parenchymal mass, cavitating pulmonary lesions, as well as diffuse parenchymal processes that do not have an established diagnosis.

Atelectasis often requires fiberoptic bronchoscopy to attempt to rule out endobronchial obstruction by carcinoma or a foreign body. Mucous plugging of the airway many times causes atelectasis. When atelectasis occurs in a critically ill patient who has had a normal chest X-ray on admission, mucous plugging is a common cause.[1] In patients who are intubated, the position of the endotracheal tube can be responsible for the atelectasis. Endotracheal tubes can slip down a mainstem bronchus, generally the right main stem, and obstruct the right upper lobe creating right upper lobe atelectasis. Additionally, the left lung may not have been aerated during this process, and complete left lung atelectasis may occur.

Lung atelectasis often necessitates bronchoscopy to rule out an endobronchial lesion, a foreign body, or mucous plugging.

Bronchoscopy can be helpful in the diagnosis of both bacterial and nonbacterial pulmonary infections in critically ill patients.[1] Lung secretions can be obtained by several different ways, including bronchial washings, bronchoalveolar lavage, protected-catheter brushings, and in select patients, transbronchial lung biopsy. Certain factors must be considered when choosing a certain bronchoscopy procedure in a critically ill patient with diffuse lung infiltrates. They include physician expertise, the patient's condition, and the potential for diagnostic success of a particular procedure in a select patient.

Bronchoscopy can help diagnose a variety of pulmonary infections.

The two major bronchoscopic procedures used in the diagnosis of diffuse lung disease are bronchoalveolar lavage and transbronchial lung biopsy. Often, the protected-brush catheter (Fig. 10-2) is employed with bronchoalveolar lavage in the diagnosis of lung infection. Quantitative culturing using these techniques has improved the diagnosis of infection of the lung. Cultures obtained from the protected-brush catheter that provides 10^3 or more colony-forming units (CFU) per milliliter indicate active infection.[2] This brush catheter technique is equivalent to needle aspiration biopsying of the lung in the identification of the etiology of bacterial pneumonia.[2] The protected-brush catheter technique is limited by the fact that it only samples a very small area. Cultures obtained from this area may not alter the antibiotic therapy that is being used at that time because of the use of broad-spectrum antibiotics that treat most of the common bacterial infections. Bronchoalveolar lavage, performed through the flexible bronchoscope when wedged peripherally in an airway of the lung, allows for the recovery of both cellular and noncellular components of the lower respiratory tract. Bronchoalveolar lavage has been used to diagnose certain interstitial lung diseases, malignancies, and infections. Quantitative cultures obtained from the bronchoalveolar lavage that provides 10^4 or more CFU per milliliter indicate active infection.[3] Unfortunately, bronchoalveolar lavage is not the preferred method to make a definitive diagnosis for most interstitial lung diseases, and tissue biopsy is the diagnostic procedure of choice for that set of diseases. Bronchoalveolar lavage has been very successful in the diagnosis of *Pneumocystis carinii* pneumonia and other causes of diffuse pulmonary infiltrates in immunocompromised hosts.[4] Its greatest efficacy is in the diagnosis of opportunistic

Protected-brush catheter and bronchoalveolar lavage techniques are useful in the diagnosis of pneumonia.

Bronchoalveolar lavage is the diagnostic procedural choice for *Pneumocystis carinii* pneumonia.

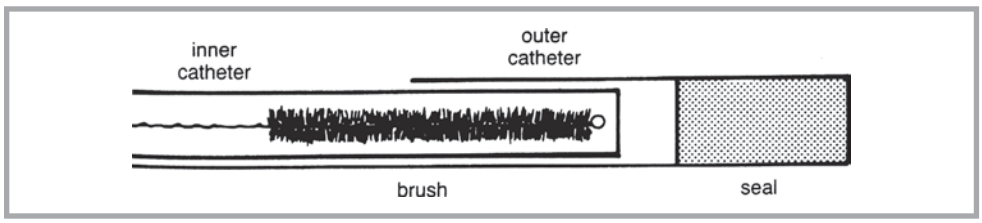

FIGURE 10-2

The plugged telescoping catheter brush is used to obtain selective samples from the lower airways and to keep the brush sterile until it is pushed out of the catheter at the time of culturing.

infections, including *Pneumocystis carinii,* cytomegalovirus, a variety of fungi, and mycobacterium.[5] The detection of hemosiderin-laden macrophages can be helpful in the diagnosis of pulmonary hemorrhage. Occasionally, it may be helpful in the diagnosis of pulmonary malignancy, particularly in those patients who have lymphangitic metastasis.[6]

Following blunt chest trauma, bronchoscopic inspection can determine airway fracture and laryngeal injury.

Critically ill patients who require fiberoptic bronchoscopy for airway inspection include those who have sustained serious inhalation injuries or blunt chest trauma and those patients suspected of having intubation damage. For patients who have sustained an inhalation injury, the presence of serious mucosal injury can be identified during fiberoptic bronchoscopy. A decision for prophylactic intubation can be better addressed with this information available. Fiberoptic bronchoscopy allows the trauma surgeon to evaluate the airways following blunt chest trauma to determine if the patient has sustained a fractured airway. This is suspected if atelectasis, pneumomediastinum, or pneumothorax is determined during the evaluation. Fiberoptic bronchoscopy can be used to determine whether laryngeal or tracheal complications have occurred during an intubation. If serious injury has occurred, then a tracheostomy should be considered. Fiberoptic bronchoscopy can be performed in patients who are intubated and have an endotracheal tube in place that is 7.5 mm or larger in internal diameter. Therefore, it is important for most of our adult patients to use an endotracheal tube at least 8 mm in internal diameter during intubation in case bronchoscopy is needed. A complete airway inspection can be done with a fiberoptic bronchoscope. With the endoscope inserted through the endotracheal tube, the balloon can be deflated and the tube withdrawn over the bronchoscope to look for subglottic damage. The tube can be carefully withdrawn up through the vocal cords over the fiberoptic bronchoscope for glottic and supraglottic assessment. The presence of serious mucosal ulceration, necrosis, or edema indicates the need for a tracheostomy. Tracheostomy lessens the likelihood of the consequences of tracheomalacia, tracheal stenosis, and laryngeal stenosis.

Therapeutic Indications

Airway secretion management can be facilitated by bronchoscopy in intubated patients.

Many bronchoscopies in the intensive care unit are performed for airway secretion management. It is common to perform bronchoscopy for both diagnostic and therapeutic reasons in patients who are intubated and are critically ill. The therapeutic uses of fiberoptic bronchoscopy (see Table 10-2) are as important as its diagnostic indications.

Bronchoscopy can remove retained secretions, mucous plugs, blood clots, and foreign bodies.

When aggressive pulmonary toilet, including physical therapy, incentive spirometry, and sustained maximum inspiration with cough, fails to clear the airways of excessive secretions or reexpand significant lung atelectasis, then fiberoptic bronchoscopy can be considered. Retention of secretions and mucous plugging of the airways are common clinical complications in those patients with an altered level of consciousness and impaired cough. Poor pulmonary function often results from weakness, recurrent aspiration, ventilator dependence, or pain following thoracoabdominal surgery. Following thoracic surgery, blood clots often accumulate in the lung airways and can induce atelectasis. Patients with airway mucosal injury are more likely to have serious secretion and mucous plugging problems. In these situations, fiberoptic bronchoscopy may enhance pulmonary toilet and can be lifesaving.

For airway secretion management, it is better to use a flexible bronchoscope with large-channel suctioning capabilities. The airway secretions can be thick and tenacious making it difficult to remove. In an intubated patient, the fiberoptic bronchoscope can be introduced to enhance secretion removal. Occasionally, the installation of *N*-acetylcysteine or pulmozyme through the bronchoscope may be necessary to help liquify thick, tenacious inspissated mucus from the airways. The use of acetylcysteine may trigger bronchospasm, but patients who experience this complication generally respond well to a bronchodilator nebulizer treatment.[7] Dornase alfa inhalation may cause less bronchospasm.

Bronchoscopy can facilitate endo- or nasotracheal intubation.

Fiberoptic bronchoscopy can be used to retrieve a foreign body lodged in an airway. Various techniques can be used either to grasp or net the object and to pull it out of the airway with the bronchoscope when it is withdrawn. Fiberoptic bronchoscopy can be used for endotracheal intubation. The bronchoscope acts as an obturator for endotracheal intubation in patients for whom intubation is difficult. In select patients with neck or head trauma or certain disease states such as ankylosing spondylitis or in those who have had laryngeal trauma or have vocal cord dysfunction, this technique can be particularly helpful. With the endotracheal tube over the bronchoscope, the bronchoscope is advanced either through the

nose or orally to the vocal cords under direct visualization. After placing the endoscope through the cords, the endotracheal tube can be slipped over the bronchoscope into the airway. This technique can be helpful in individuals with massive facial injuries.

Fiberoptic bronchoscopy can assist in the treatment of massive hemoptysis. Bronchial tamponade can be accomplished with a transbronchoscopic endobronchial balloon occlusion technique after the bronchoscope has been placed in an airway that is hemorrhaging. Bronchial tamponade can be used for either bronchial or pulmonary hemorrhage, as well as for refractory pneumothorax secondary to persistent air leaks following thoracotomy.

Bronchoscopy helps locate the area of hemoptysis, and it can assist in tamponade.

Sometimes a bronchopleural fistula can develop between a bronchial tree and a pleural space. After chest tube placement, bronchoscopy can identify which airway is part of this phenomenon and then be used to distally occlude the bronchopleural fistula. A variety of materials have been injected through the bronchoscope to seal the fistula.[8]

Central airway-obstructing lesions involving the larynx, trachea, or a major bronchus can be treated using a variety of bronchoscopic techniques including photoresection using laser technology or airway stenting.[9] Airway stenting can be used in malignant or benign disease with severe airway narrowing from intrinsic or extrinsic processes. The trachea and main stem bronchi can be stented, but the technique is not suitable for lobar and distal bronchial stenosis. Many types of tracheobronchial stents are available, such as expandable metal wire (Fig. 10-3), molded silicon stents, or a combination of these. After the area of stenosis has

Airway stenting can open stenotic segments of large airways.

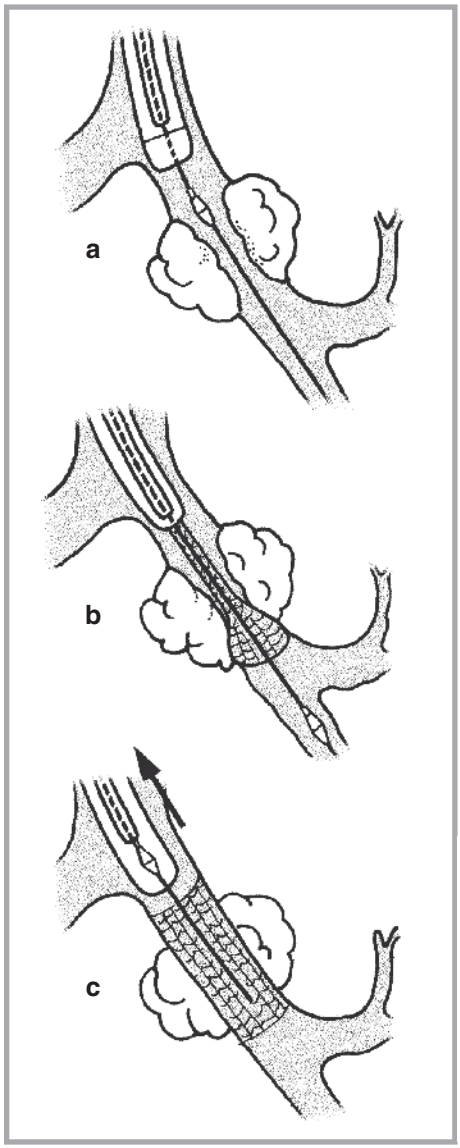

FIGURE 10-3

(**a**–**c**) Wire stent dilation of airway. (**a**) A guidewire is placed into the distal end of the delivery catheter. Under direct visualization with the bronchoscope, the catheter is threaded over the guidewire into the stricture. (**b**) The wire stent is expanded under fluoroscopic guidance to dilate the airway stricture. (**c**) The catheter and bronchoscope are withdrawn after the airway is dilated open.

been identified and balloon dilatation is used, then a stent is placed in that area and distended, expanding the airway lumen and relieving the critical stenosis. Complications can occur with balloon dilation and stenting, such as airway rupture, stent migration, increased mucosal secretions, and a granulomatous mucosal reaction.

Complications

Serious complications are rare with bronchoscopy.

When performed by a trained physician, flexible fiberoptic bronchoscopy has a very low morbidity and mortality incidence. Mortality does not exceed 0.1%, and overall complications should not exceed 10%.[10] The complications may be related to the use of procedure premedications including sedatives or topical anesthetics, and vagal-mediated reactions or complications from the bronchoscopy itself or its related procedures. Absolute contraindications to performing bronchoscopy include an unstable cardiovascular status including life-threatening cardiac arrhythmias, severe hypoxemia that is likely to worsen during the procedure, and an inexperienced bronchoscopist and bronchoscopy team. Coagulation problems are not an absolute contraindication to bronchoscopy when a tracheobronchial inspection is needed or only bronchoalveolar lavage is to be performed. However, more invasive procedures including biopsy and needle aspiration techniques should not be performed until the coagulopathy has been corrected.

Premedication with sedatives may lead to respiratory depression, hypoventilation, hypotension, and syncope. Topical anesthetics can cause laryngospasm, bronchospasm, and if given excessively, seizures. The bronchoscopy itself or its associated procedures such as brushing, biopsy, and bronchoalveolar lavage may also induce laryngospasm, bronchospasm, hypoxemia, and cardiac arrhythmias or cause fever, pneumothorax, and hemorrhage. Patients on mechanical ventilation who are receiving high positive end-expiratory pressure (PEEP) are at increased risk for barotrauma. Although fever is a relatively common complication, it is generally transient and not associated with sustained bacteremia. Perforation of the airway is exceedingly uncommon, but pneumothorax has been reported.

Procedure for Patient Preparation

Although each institution is different, certain guidelines should and do exist. As in all medical procedures, patient preparation prior to the procedure can help to enhance the success and minimize any complications and adverse outcomes (Table 10-3). Understanding of the patient's history and current condition is paramount to successful bronchoscopy.

TABLE 10-3

PATIENT PREPARATION FOR FIBEROPTIC BRONCHOSCOPY (FOB)

1. Obtain a list of all current medications and verify if the patient has held:
   - **(a)** Aspirin for 5 days.
   - **(b)** Plavix (clopidogrel) for 5 days.
   - **(c)** Aggrenox for 5 days.
   - **(d)** Ticlid (ticlopidine) for 5 days.
   - **(e)** Coumadin (warfarin) for a minimum of 3 days. Prior to procedure an INR of <1.3 must be documented.
   - **(f)** Heparin stopped for 24 h. Prior to procedure a normal PTT must be documented.
   - **(g)** Low molecular weight heparin stopped for 24 h.
2. Document a normal PT/INR, PTT, and platelet count within 7 days of the procedure. If the patient is on Coumadin (warfarin) or heparin, a normal coagulation profile (INR<1.6) must be documented off these anticoagulants prior to the procedure.
3. Document that the patient has held NPO at least 4 and preferably 6 h prior to the procedure. Hypoglycemic medications are generally held prior to the procedure, as the patient is NPO.
4. Verify FOB indication and procedural plan.
5. Document the patient's known allergy history.
6. Verify that the patient or responsible party has been explained about the procedure and informed consent has been appropriately filled out, signed, and witnessed.

Procedure

Generally, before bronchoscopy, an anxiolytic, antisialagogue, and topical anesthetic are administered. Either the oral or nasal route can be used for flexible fiberoptic bronchoscopy. In the intensive care unit, the procedure is generally done through the endotracheal tube while the patient is on the mechanical ventilator. This procedure is done with the use of a swivel adapter with a rubber diaphragm through which the bronchoscope can be inserted safely without disconnecting the patient from the ventilator. The procedure should be done when the patient is as stable as possible. For critically ill patients, careful monitoring, including the use of oximetry and electrocardiography are necessary.

When bronchoscopy is performed through an endotracheal tube, the tube should have a lumen of at least 8 mm in internal diameter to help ensure that the patient receives an adequate tidal volume and that excessive airway resistance and pressure do not develop. While the procedure is being done, the patient generally receives 100% oxygen to optimize the chances of keeping the arterial oxygen saturation greater than 90%. The procedure should be done as quickly as possible but without compromising thoroughness. It is best to perform the procedure in patients who have fasted or at least after the stomach has been emptied of its contents by gastric tube suctioning. In mechanically ventilated patients, after the procedure has been completed, it is best to return the ventilator settings to the preprocedure settings and to obtain a chest X-ray to look for a postprocedure pneumothorax. Although postbronchoscopy fever develops in approximately 15% of patients, it usually lasts less than 24 h and does not require antibiotic therapy. However, if the fever does last more than 24 h, then postprocedure pneumonia should be considered.[11]

GASTROINTESTINAL ENDOSCOPY

At the present time, GI endoscopes are capable of visualizing nearly 100% of the upper GI tract, including the esophagus, stomach, and duodenum. Enteroscopes allow examination of the proximal small intestine, and the colon and terminal ileum are also accessible to examination with video-colonoscopes. The portability of these scopes allows these procedures to be performed on critically ill patients in the intensive care unit. The scopes are thin and flexible and are usually well tolerated with conscious sedation, even in critically ill patients. However, as with all interventions, the potential benefits for diagnosis and therapy must be weighed against the risks for each individual patient. This section reviews the indications, contraindications, and complications of GI endoscopy in critically ill patients.

GI endoscopy is done for both diagnostic and therapeutic reasons.

Indications

The indications for GI endoscopy in the intensive care unit are found in Table 10-4. If the clinician believes that the patient is too critically ill to be taken to the GI endoscopy suite, then gastroscopy and colonoscopy may be done with careful monitoring in the intensive care unit. The most frequent indication for emergency gastroscopy is upper GI bleeding. This can occur in two settings. The first is the patient who is admitted to the hospital for the primary

GI endoscopy is commonly done for acute upper GI bleeding in critically ill patients.

TABLE 10-4

INDICATIONS FOR GASTROINTESTINAL (GI) ENDOSCOPY

Endoscopic retrograde cholangiopancreatography (ERCP)
Severe gallstone pancreatitis
Severe cholangitis
Lower GI endoscopy
GI bleeding
Acute colonic ileus

diagnosis of GI bleeding. Initial assessment determines whether the patient is admitted for treatment to a general medical floor or to the intensive care unit. This decision is based on several risk factors in the patient with GI bleeding that are recognized to be associated with increased morbidity and mortality such as increased age, shock, comorbid illness, and the active passage of red blood per mouth or per rectum.

The second situation in which upper GI bleeding is evaluated and treated in the intensive care unit is when bleeding develops in a patient already being treated in the intensive care unit for other medical or surgical reasons. The in-hospital mortality rate for patients in the latter situation is much greater than for patients admitted to the hospital for GI bleeding. The overall mortality for patients hospitalized for upper GI bleeding is 10%. However, newer evidence shows mortality rates for patients with upper GI bleeding complicating hospitalization for treatment of other illnesses. The in-hospital mortality in these two studies ranged from 42 to 77%. Both the studies found that the cause of death was usually from multisystem organ failure or sepsis related to the initial illness and not from blood loss. Endoscopic intervention frequently achieved hemostasis;however, rebleeding occurred in 30% of patients and repeat endoscopy was often needed.[12]

In some studies, peptic ulcer accounted for greater than 50% and stress gastritis or erosions caused approximately 20% of the bleeding episodes that arose during the treatment of other medical or surgical illnesses. One study found that 45% of patients had been treated during the hospitalization with aspirin or nonsteroidal antiinflammatory drugs prior to the onset of bleeding and 42% had been receiving corticosteroids.[13] Aspirin and nonsteroidal antiinflammatory drugs have been proven to be the causative factors in the formation of ulcers and erosions in the stomach and duodenum and are associated with bleeding. The role of corticosteroids is more controversial. One study found that 44% of the patients were treated with mechanical ventilation and over 60% had a coagulopathy with an elevated prothrombin time or thrombocytopenia before the onset of bleeding.[13] The latter finding highlights another observation that has been found in several studies that the risk of bleeding from stress ulceration or gastritis has been shown to be most closely associated with two risk factors; mechanical ventilation and coagulopathy. The presence of renal insufficiency in patients with either of these risk factors further increases the risk of bleeding.[14] Patients with burns and acute central nervous system diseases are also at increased risk of bleeding from stress ulceration. Four percent of intensive care patients who require mechanical ventilation or have coagulopathy develop clinically important bleeding resulting in a decrease in hemoglobin greater than 2 g and associated with a fall in blood pressure. In contrast, only 0.1% of patients without these risk factors develop significant bleeding. This underscores the need for pharmacologic prophylaxis of stress gastritis in this group of patients. A proton pump inhibitor is most commonly used. General medical support to maintain adequate blood pressure and perfusion and the use of enteral nutritional support also probably reduces the risk of significant bleeding from stress ulceration, but no controlled trials of this nature exist.

In the same way that upper GI bleeding can be the primary reason for admission of the patient to the intensive care unit or a complication of a patient hospitalized for other reasons, the same is true for lower GI bleeding. The two most common causes of significant lower GI bleeding requiring admission to the hospital and treatment in the intensive care unit are colonic diverticulosis and colon angiodysplasia. However, the etiology of lower GI bleeding that complicates the treatment of other medical or surgical illness is unlikely to be either diverticulosis or angiodysplasia. In a study from Taiwan, it was found that, in this setting, lower GI bleeding was more commonly secondary to ischemic colitis, rectal ulcer, or pseudomembranous colitis.[15] These complications are often seen in critically ill patients being treated in an intensive care unit since many were being treated for respiratory failure, sepsis, stroke, or circulatory compromise secondary to cardiac disease, and even some required therapy with antibiotics or vasopressor agents before the bleeding episode. In many instances, the underlying illness or its treatment predisposes to these complications. The in-hospital mortality rate of patients with lower GI bleeding as a complication of other medical illnesses is high, and in this study, was found to be greater than 50%.[15] This is similar to the findings in upper GI bleeding complicating other illnesses where the cause of death is rarely secondary to hemorrhage. Other factors such as sepsis, respiratory failure, and multiorgan failure are the common causes of death.

Colonoscopy is difficult to perform during an episode of acute lower GI bleeding. Unlike gastroscopy, which can be successful in defining the site of blood loss during an episode of upper GI bleeding, colonoscopy is frequently a suboptimal exam and more often fails to determine the cause of bleeding. It can be difficult to adequately purge the colon in preparation for colonoscopy and residual blood and stool interferes with the passage of the scope and compromises the examination of the mucosa. The poor visualization during the exam can also increase the risk of complications during the procedure. In one study, colonoscopy was aborted in 20% of the cases because of an inadequate prep and too much blood in the lumen of the colon. The ability to perform a complete exam with the passage of the scope to the cecum was successful in only 60% of patients.[15] This is in contrast to greater than 95% of elective colonoscopies. However, the cause of bleeding was frequently found in the left colon enabling a diagnosis to be established in two thirds of the cases. This study concluded that colonoscopy should be considered as a modality, in addition to angiography, to be used in the evaluation of lower GI bleeding.

Colonoscopy is done to locate the site of lower GI bleeding and is also used to decompress a markedly dilated colon.

Another indication for colonoscopy in the intensive care setting is for decompression of a dilated colon secondary to an ileus. Ileus is a common complication seen in patients critically ill with intraabdominal processes and in patients with systemic disease. It can be secondary to electrolyte abnormalities, such as hypokalemia, hypercalcemia and sodium disturbances. It can also be caused by medications such as narcotics or drugs with anticholinergic effects. Ileus may also develop in patients with neurologic disorders such as stroke or intracranial bleed or infection, and also occurs in patients with sepsis. Although ileus usually affects both the small intestine and colon, it can sometimes affect only the colon. This is also referred to as colonic pseudo-obstruction because the colon is dilated without concomitant distention of the small intestine, a radiographic finding that is seen with distal colonic obstruction. Colonic ileus can lead to significant dilation of the colon that can result in ischemia and perforation, most commonly in the cecum. Colonic ileus is diagnosed when the transverse colon is greater than 5 cm or the cecum is greater than 8 cm in diameter on an abdominal X-ray and distal colonic obstruction must be excluded. If the cecum dilates to greater than 10–12 cm, the risk of perforation significantly increases. Predisposing factors, such as electrolyte abnormalities or medications or infection, should be addressed and corrected if possible and decompression with naso-gastric and rectal tubes should be attempted. If not successful, a trial of intravenous neostigmine, a cholinesterase inhibitor, can be attempted after colonic obstruction is excluded. If successful, a response with the passage of gas and fecal residue and improvement of distention is usually seen within minutes.[16] If colonic dilation persists, then colonoscopy for decompression can be attempted at the bedside. Although colonoscopy may successfully decompress the colon, until the etiology of the colonic ileus is corrected, there remains a likelihood of recurrent colonic distention. Therefore, a drainage tube can be passed with the colonoscope and left in place in the proximal colon for continued decompression to try to reduce recurrent dilation. Because no prep is possible before the colonoscopy in this clinical situation, the procedure is difficult and carries an increased risk of complications.

Similar to the varied indications for colonoscopy, in addition to the diagnosis and treatment of GI bleeding, there are other indications for gastroscopy in the intensive care patient. These include the removal of foreign bodies, evaluation of caustic ingestion, and endoscopic placement of percutaneous gastrostomy feeding tubes.

The endoscopic placement of a percutaneous gastrostomy feeding tube affords a route for enteral nutrition that reduces these risks and provides access to the GI tract for feeding and for medications. After initiating enteral feeds through the gastrostomy tube, residual gastric contents must be checked to assess gastric emptying and minimize the risk of aspiration.

A gastrostomy tube can be placed percutaneously by an endoscopic technique at the bedside.

ERCP occasionally is necessary in an ICU patient. ERCP should be considered in a patient who has severe gallstone pancreatitis or in a patient with cholangitis unresponsive to medical therapy. ERCP combined with sphincterotomy and gallstone extraction reduces the complications that can occur in patients who have gallstone pancreatitis and cholangitis. For the patient with cholangitis, biliary stents can be placed if common duct stones cannot be removed during the procedure.

Endoscopic retrograde cholangiopancreatography (ERCP) is indicated for the patient with cholangitis that is unresponsive to medical therapy.

Complications

Major risks of colonoscopy are bleeding and perforation.

Bleeding and perforation are the major risks of GI endoscopy (Table 10-5). Bleeding can occur as a complication of endoscopic intervention with thermal coagulation. Perforation of the bowel wall may result from direct pressure of the endoscope against the wall or by the inadvertent puncture of the wall by an endoscopic instrument. Perforation may also complicate the use of thermal coagulation used to stop bleeding. Aspiration of gastric contents during gastroscopy is always a concern and this risk is increased during active upper GI bleeding. Elective endotracheal intubation may be done prior to endoscopy to protect the airway when the risk of aspiration is felt to be high. There may also be complications related to sedation such as respiratory depression and hypotension. The best way to avoid serious procedural complications is to avoid the patient who has certain contraindications to the procedure (Table 10-6).

In addition to these general complications of endoscopic procedures, individual procedures are associated with specific risks. ERCP and sphincterotomy carries an increased risk of perforation or bleeding during sphincterotomy and also may cause pancreatitis. ERCP that is done to decompress an obstructed biliary tree, if unsuccessful, can worsen cholangitis and cause bacteremia and septicemia. Percutaneous endoscopic gastrostomy tube placement can be complicated by inadequate formation of the feeding tube tract between the abdominal wall and the stomach. This can result in peritonitis. This risk is the greatest in patients who are severely malnourished with low serum albumin and in patients receiving corticosteroids. Wound infection at the gastrostomy tube site and leakage of gastric contents through the site are other complications that are also increased in critically ill patients, especially those who are malnourished. Unique complications can also occur during the treatment of esophageal varices (Table 10-7). Sclerosis of esophageal varices is associated with complications including chest pain, fever, esophageal ulceration, bleeding, stricture, and perforation.

TABLE 10-5

COMPLICATIONS OF GI ENDOSCOPY

Bleeding
Perforation of the GI tract lumen by endoscope, catheters, or guidewires
Aspiration
Reaction to sedative medication

TABLE 10-6

CONTRAINDICATIONS TO GI ENDOSCOPY

Perforated viscus suspected/impending
Hemodynamic and respiratory gas exchange instability
Severe diverticulitis
Severe inflammatory bowel disease
Severe coagulopathy
Uncooperative patient
Unprotected airway in a confused or stuporous patient with acute upper GI bleeding

TABLE 10-7

COMPLICATIONS OF ENDOSCOPIC COAGULATION AND INJECTION SCLEROTHERAPY

Esophageal complications
Ulceration
Stricture formation
Perforation (early or delayed)
Dysmotility
Pulmonary complications
Pleural effusions and pleuritis
Pulmonary infiltrates
Aspiration
Mediastinitis
Adult respiratory distress syndrome
Septic complications
Bacteremia
Sepsis
"Spontaneous" bacterial peritonitis

Pleuro-pulmonary complications may develop and mediastinitis can rarely occur. Variceal banding can cause superficial esophageal ulceration, but these ulcers usually do not bleed, nor do they result in the other complications that are seen with sclerosis.

Procedures

During episodes of bleeding, upper and lower GI endoscopy should be done following fluid resuscitation. Naso-gastric lavage with large-bore tube irrigation should be performed to empty the stomach of blood before gastroscopy. The endoscopy team should consist of an experienced endoscopist, and an assistant skilled in monitoring the patients who are undergoing endoscopy.

A variety of endoscopic techniques can be used to control bleeding. These include laser photocoagulation, thermal electrocoagulation, injection therapy, hemoclipping, and ligation. Laser equipment is expensive and not easily portable and is rarely used at the bedside. In contrast, the other techniques are readily available and can be done in the intensive care unit. Directed injection to the bleeding site using a catheter with a needle tip that is passed through the endoscope offers the ability to give injection therapy and control bleeding. Sclerosing agents can be injected into varices to control bleeding. For other bleeding lesions, such as ulcers or Mallory Weiss tears, epinephrine can be injected as a temporizing technique to constrict the bleeding vessel. This reduces or stops bleeding and facilitates more definitive endoscopic treatment such as thermal coagulation. Multipolar probes or heater probes can be passed through the endoscope to stanch bleeding by coagulating the bleeding vessel. Endoscopic clips can also be applied to compress the bleeding vessel to control bleeding. Because of the complication profile, variceal sclerosis has been replaced by band ligation as the favored approach of most endoscopists in the treatment of bleeding esophageal varices. However, sclerosis is still utilized for bleeding gastric varices and by some endoscopists as an alternative to banding for esophageal varices. It is also used if banding ligation fails to stop variceal bleeding.

SUMMARY

Endoscopy has substantially broadened our diagnostic and therapeutic powers in the intensive care unit. Laryngoscopy, bronchoscopy, and GI endoscopy are rarely contraindicated and often simplify the care of patients who are seriously ill.

REVIEW QUESTIONS

1. **All the following statements are true concerning bronchoscopy, except:**
   - **A.** Flexible bronchoscopy is commonly done in the ICU
   - **B.** Rigid bronchoscopy does not have any advantages over flexible bronchoscopy
   - **C.** Bronchoscopy is safely done often with minimal additional sedation in mechanically ventilated patients
   - **D.** The most common use of bronchoscopy in the ICU is for secretion management

2. **The fiberoptic bronchoscopy is helpful in the ICU for all of the following conditions, except:**
   - **A.** Location of bleeding
   - **B.** Diagnosis of hospital-acquired pneumonia
   - **C.** Removal of an airway mucous plug
   - **D.** Diagnosis of inflammatory lung diseases

3. **All the following statements are true concerning GI endoscopy in the ICU, except:**
   - **A.** Nearly the entire GI tract can be evaluated
   - **B.** All GI problems should be considered for endoscopy evaluation
   - **C.** The most common cause for using endoscopy is bleeding
   - **D.** Bleeding and bowel perforation are the major risks of GI endoscopy

ANSWERS

1. The answer is B. Massive hemoptysis, the removal of a foreign body, and the placement of an airway stent are often best approached with a rigid bronchoscope.
2. The answer is D. The bronchoscopic approach to the diagnosis of diffuse inflammatory noninfectious lung diseases is often unrewarding and is better approached by an open-lung biopsy, either by thoroscopy or thoracotomy.
3. The answer is B. Clinically insignificant GI problems should not be evaluated endoscopically. All the patients who require endoscopy should be as stable as possible.

CHAPTER 11

PHILLIP M. BOISELLE, CHANDRA DASS, AND ROBERT M. STEINER

Radiologic Imaging in the Critically Ill Patient

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to do the following:

- Develop a systematic approach for the interpretation of ICU chest radiographs.
- Be aware of the most common causes of abnormal pulmonary opacities and air collections on ICU chest radiographs.
- Know when to obtain a portable chest radiograph (PCR), thoracic computed tomography (CT), sonography, and ventilation–perfusion (VP) scans in ICU patients.
- Be familiar with the roles of abdominal and pelvic imaging procedures, including plain film examinations, barium contrast studies, US, MRI, and CT in the assessment of the ICU patient with acute abdominal and pelvic disease.
- Be aware of the relative merits of CT and MR imaging in the evaluation of the ICU patient with suspected acute neurologic abnormalities.

INTRODUCTION

Radiology plays an important role in the care of the critically ill patient. The most commonly ordered imaging procedure is the portable chest radiograph (PCR), obtained on a frequent basis for many critically ill patients. In spite of its limitations, the PCR often demonstrates abnormalities not ascertainable by clinical examination alone. Other imaging procedures, such as abdominal radiographs, computed tomography (CT), ultrasound (US), magnetic resonance (MR) imaging, ventilation–perfusion (VQ) imaging, and angiography, are selectively ordered and may assist the intensivist in diagnosis and intervention. In this chapter, we discuss the fundamentals of radiologic imaging of the critically ill patient.

THORACIC IMAGING

Thoracic Radiography

The PCR is the most frequently requested imaging examination in critically ill patient. In fact, at least 200 portable chest studies are performed each day in our critical care units (ICU) and emergency department (ED). Several studies have documented the value of this procedure in the critically ill patient population by showing that abnormalities identified on the daily chest radiograph result in a change in patient management in up to two-thirds of cases. Findings on PCR that result in alterations in patient care range from a change in the position of a vascular catheter, endotracheal tube, nasogastric tube, or other support devices to the diagnosis of new conditions such as pneumothorax, pneumonia, or pulmonary edema. As a result, the PCR is a vital addition to the physical examination providing information that would otherwise not be available to the attending physician

PCRs are the mainstay of radiologic imaging of critically ill patients.

In critically ill patients, daily chest radiographs result in a change in patient management in as many as two-thirds of cases.

Daily rounds with both the ICU team and a thoracic radiologist promote optimal integration of clinical data with radiographic findings and ensure timely communication of radiographic abnormalities.

Digital (DR) and computerized radiography (CR) and picture archiving communications systems (PACS) allow for simultaneous transmission and review of imaging studies in both the radiology department and the ICU.

Important cardiovascular parameters to assess on chest radiographs include heart size, vascular pedicle width, and pulmonary vascularity.

However, recent data challenge the dogma of the usefulness of the daily PCR in the care of the ICU patient.[1] In a paper by Grant et al, over a 5-month period, 2,457 daily routine PCR were performed in 754 consecutive patients.[2] In only 5.8% of the studies were new and/or unexpected abnormalities encountered. These included atelectasis (<2%), areas of parenchymal opacity (<2%), pulmonary edema (2%), and pneumothorax in 1%. In only 2.2% did the findings on the routine portable radiograph result in a change in therapy.[2] More studies are required to determine the usefulness of the daily PCR in the care of the ICU patient.

To maximize the value of the PCR in the ICU setting, it is important to optimize the quality of both the radiograph and its interpretation. A high-quality PCR is the product of a number of important factors, including a well-trained technologist, up-to-date equipment, and a cooperative relationship between the technologist, nursing staff, and respiratory therapist. Radiographic interpretation can be enhanced by daily rounds between the ICU clinical physicians and a radiologist who is familiar with the interpretation of ICU radiographs. Interaction between the clinicians and the radiologist promote optimal integration of the clinical history with the radiologic findings and ensure timely communication of radiographic findings. In lieu of daily rounds, providing a pertinent history and specific indications for the PCR is essential for the adequate interpretation of the images.

In recent years, conventional film-based portable radiographs have been replaced by portable digital radiographs (DR) in many hospitals. The most widely used digital system employs a storage phosphor cassette and an image processing system that converts an electronic image to a digital image. The final products of this process are images displayed on high resolution monitors that can be displayed simultaneously at different locations throughout the hospital by using a picture archiving and communication system (PACS).

There are three major advantages of digital imaging over conventional radiography: These are: (1) the ability to transmit an image simultaneously to both the radiology department and the ICU; (2) the ability to electronically manipulate the image to produce consistent diagnostic quality radiographs; and (3) the opportunity to manipulate images by adjusting window levels and other settings to overcome a variety of exposure problems.[3,4]

Chest Radiographs: Technical Issues

PCR quality may be highly variable, ranging from good to unreadable images. Obtaining diagnostic quality studies on unstable uncooperative patients, or patients who have numerous support devices presents unique challenges to the technologist and is not always possible. There are limitations when attempting to obtain quality PCR, including lack of patient cooperation, difficulty in controlling scatter radiation in obese patients, poor image clarity due to a myriad of lines, catheters, and other appliances obscuring the image as well as wide differences in film exposure times. Patient rotation, incomplete coverage of the thorax, and artifacts may further compromise technique.

To avoid these pitfalls and to standardize the technique, PCR with the patient in a supine position and with the cassette in the vertical dimension is optimal, so that the upper airway and upper abdomen are included, allowing evaluation of the position of endotracheal tubes, feeding tubes, pneumothorax, and pneumoperitoneum, among other

important findings. A tube to patient distance of 50 in. should be maintained to minimize anatomic magnification and facilitate comparison of anatomic structures such as the vascular pedicle, heart, and pulmonary vessels. The radiograph should be obtained at peak inspiration using 80–100 kVp and short exposure times should be used to minimize respiratory artifact. As much as possible, EKG clips, telemetry wires, and other external objects should be removed from the field to better identify the position of lines, tubes, and the subtle findings of pneumothorax and areas of consolidation.

Interpreting Chest Radiographs in the ICU Patient

When interpreting ICU chest radiographs, it is important to have a systematic approach (Table 11-1). First, carefully evaluate the location of all catheters and support devices. Second, assess the cardiovascular status of the patient. Look for cardiac enlargement, increase in the diameter of the azygos vein, cephalization of the upper lobe vessels in an erect portable film, and enlargement of the central pulmonary vasculature. Third, look for areas of abnormally increased lung opacification suggesting pneumonia or atelectasis (Fig. 11-1). Fourth, assess the film for the amount and distribution of pleural fluid. Finally, observe carefully for any abnormal air collections, including pneumothorax, subcutaneous emphysema, pneumomediastinum, or pneumopericardium (Fig. 11-2). It is important to appreciate that the chest examination differs in the supine and the erect projection. The supine AP film will magnify the cardiovascular structures and may erroneously suggest vascular cephalization. It may also over-accentuate the vascular pedicle mimicking the diagnosis of congestive heart failure in the patient with normal cardiovascular status. In the following sections, we review the fundamentals of each of the steps taken in a systematic approach to the analysis of the PCR.

TABLE 11-1

SYSTEMATIC APPROACH TO INTERPRETING ICU CHEST RADIOGRAPHS

Evaluate the locations of all catheters, tubes, and support devices
Assess the cardiovascular status of the patient
Look for areas of abnormally increased or decreased lung opacification
Assess for pleural fluid
Look carefully for abnormal air collections (subdiaphagmatic air and pneumothorax)
Note the position of the patient (AP, RAD, LAO, loardotic)
Assess the technique as part of a quality control program
Compare with previous studies

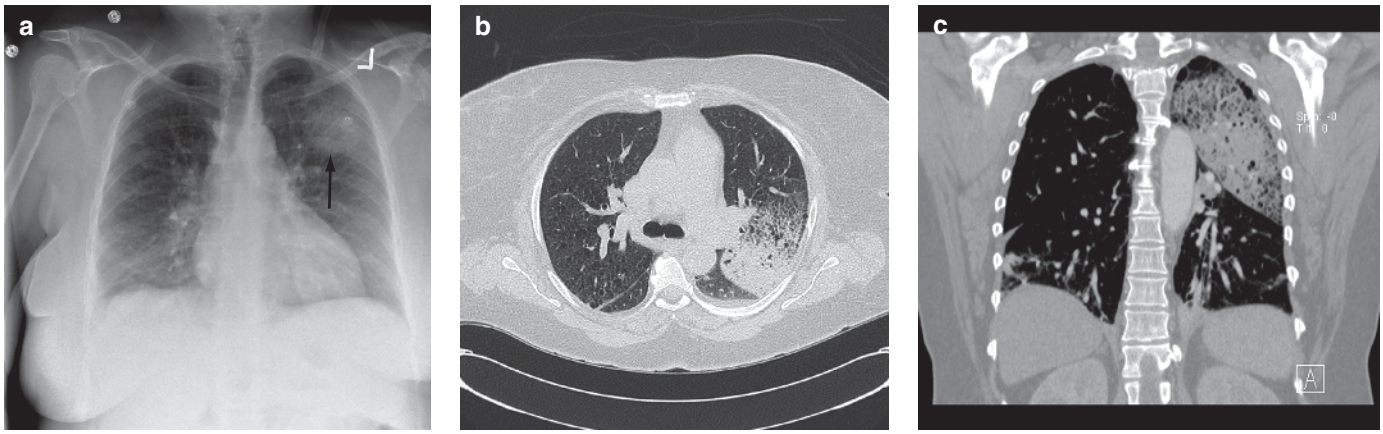

FIGURE 11-1

PA chest radiographs (**a**) demonstrated airspace opacity in the left upper lobe in this patient with fever (↑). Nonenhanced computed tomography (CT) (**b**, **c**) confirmed the location of the abnormality. A diagnosis of Streptococcal pneumonia was established at bronchoscopy.

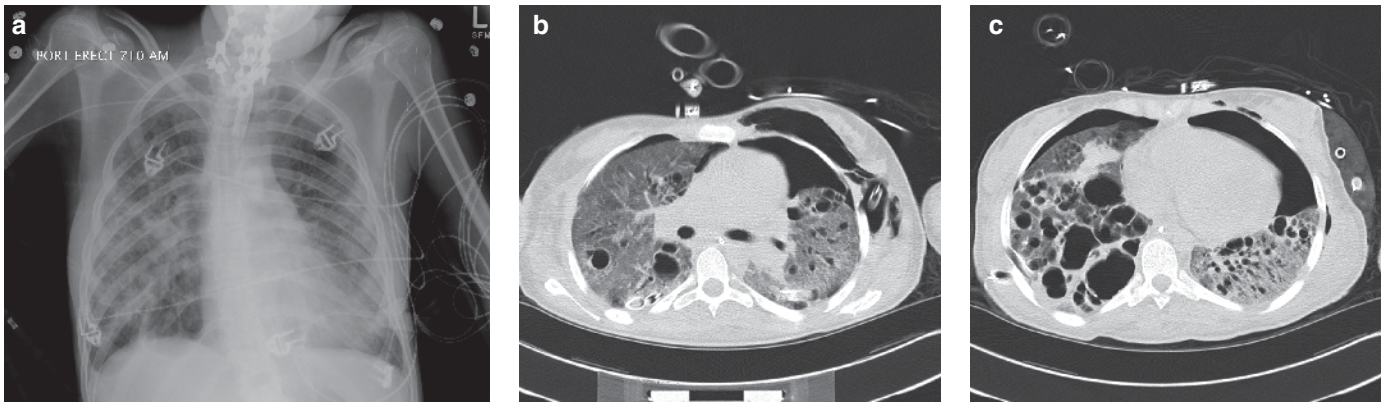

FIGURE 11-2

AP chest radiograph (**a**) axial CT (**b**, **c**) confirms the presence of subcutaneous emphysema and bilateral pneumothorax in this ICU patient who developed barotrauma secondary to high levels of PEEP. There is evidence of acute respiratory distress syndrome (ARDS).

Evaluating Catheters, Tubes, and Support Devices

Several studies have shown that approximately one-half of ICU PCRs reveal unexpected findings. Such findings frequently relate to malpositioning of vascular catheters, endotracheal and nasogastric tubes, and cardiopulmonary support devices (Figs. 11-3 and 11-4). Table 11-2 lists a variety of devices that are employed in the ICU setting, including their ideal positions and possible complications.

Assessing Cardiovascular Status

The PCR provides a noninvasive means for assessing the cardiovascular status of the critically ill patient. Important parameters to access include heart size, vascular pedicle width, and pulmonary vascularity (Figs. 11-5 and 11-6). When assessing these cardiovascular parameters on chest radiographs, it is extremely important to consider how the radiograph was obtained. For example, almost all ICU radiographs are performed using portable equipment in the anterior-posterior projection, and most are obtained with the patient in the supine

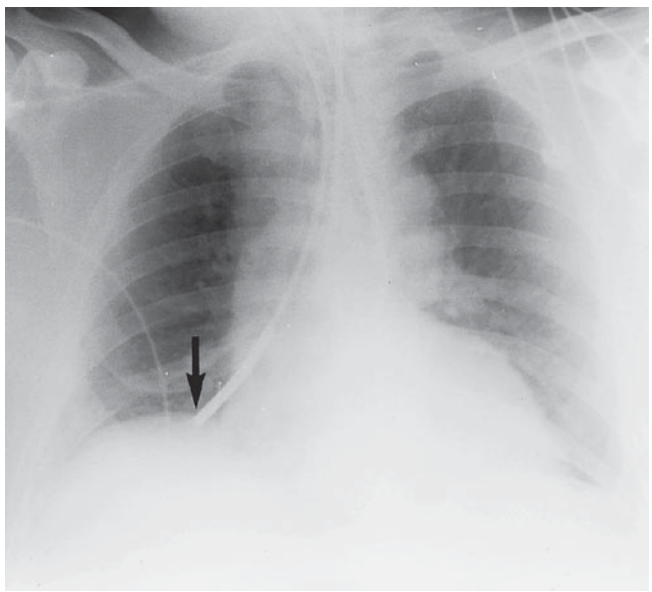

FIGURE 11-3

Portable supine chest radiograph reveals an unexpected finding: a feeding tube has been inadvertently passed into the airway, with its tip terminating in the right lower lobe (*arrow*). Note the expected midline position of a nasogastric tube within the esophagus (*arrowheads*).

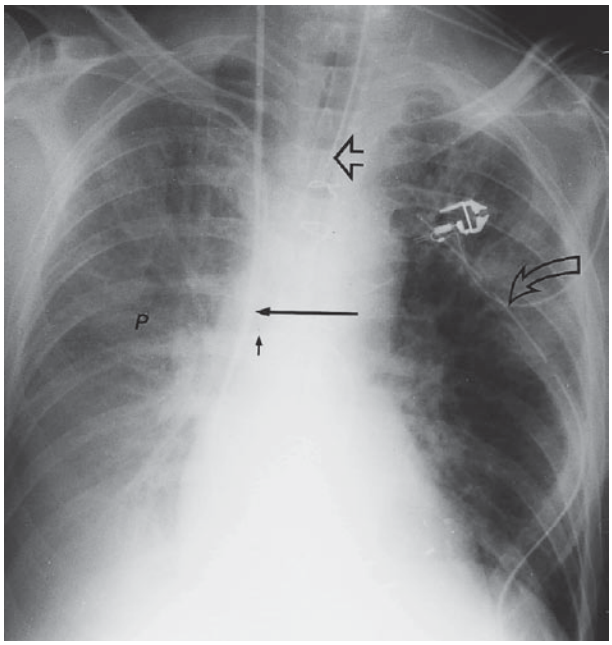

FIGURE 11-4

Portable supine chest radiograph demonstrates appropriate placement of endotracheal tube (tip 5 cm above carina; *straight open arrow*), central venous catheter (tip in superior vena cava; *long closed arrow*), Swan-Ganz catheter (tip in distal right main pulmonary artery; *short closed arrow*), and left-sided chest tube (*open curved arrow*). Also note diffuse haziness of the right hemithorax compared to the left side, corresponding to the presence of a layering right pleural effusion (*P*).

position. These technical factors result in magnification of the cardiac silhouette compared to an upright, posteroanterior chest radiograph. Radiographs performed during end-expiration also result in accentuation of the heart size and pulmonary vasculature.

Heart Size

The most common method of assessing heart size on a chest radiograph is the analysis of the cardiothoracic ratio, which is obtained by dividing the widest transverse diameter of the heart by the widest transverse diameter of the thorax above the diaphragm. On a standard posteroanterior, erect chest radiograph, a cardiothoracic ratio of greater than 0.5 is considered abnormal. Because portable, supine radiographs magnify the cardiac silhouette, it has been suggested that a correction factor of approximately 12% be applied to this equation for evaluation of the cardiothoracic ratio.

Vascular Pedicle

The vascular pedicle refers to a group of vascular structures that are located between the thoracic inlet and the top of the cardiac silhouette. The vessels that comprise the vascular pedicle include the right brachiocephalic vein, superior vena cava, and left subclavian artery. These distensible vessels increase in size in response to an increase in the circulating blood volume (Fig. 11-5).

It is important to keep in mind that the vascular pedicle width, similar to the cardiac silhouette, is dependent on technical factors. For example, the pedicle is magnified by the use of the portable AP film and by supine positioning, and the pedicle will optically increase with patient rotation. Because of the wide range of normal values (38–58 mm on an upright, posteroanterior chest radiograph), a comparison of vascular pedicle widths on serial radiographs of an individual patient is usually more useful than an absolute measurement (Fig. 11-5).

Pulmonary Vasculature

The radiographic appearance of the pulmonary vasculature is largely dependent on the effect of gravity. For example, in the erect position, gravity results in increased blood flow to the dependent, lower lobes of the lungs. As a result, in the erect position, the pulmonary vascular diameters are greater in the lower lobes than the upper lobes. In the supine position, however, gravitational changes result in an equalization of pulmonary blood flow to the upper

TABLE 11-2

EVALUATION OF LINES, TUBES, AND SUPPORT DEVICES PLACEMENT

TUBE/LINE	IDEAL LOCATION	COMPLICATIONS
Endotracheal tube placement	5–7 cm above the carina in the adult patient or half-way between the thoracic inlet and the carina when the head is in a neutral position. Extension or flexion of the head can move the tip of the tube 2–4 cm from its neutral position	Malposition (15%) Too low: endobronchial intubation and potential lung collapse Too high: vocal cord damage, increased dead space overinflated cuff: tracheal stenosis, tracheomalacia, or tracheal rupture Esophageal intubation
Central venous catheters	Superior vena cava just above the right atrium directed from the jugular or subclavian veins and placed centrally and beyond the venous valves	Malposition (15–40%) Pneumothorax (5%) Extrapleural hematoma Hemothorax Mediastinal hemorrhage Cardiac or vascular perforation Arrythmias (right atrial placement) Catheter fragmentation Septic emboli Mycotic aneurysm
Swan-Ganz catheter	Central pulmonary arteries (within 2 cm of hilum)	Pneumothorax Malposition Coiling in a RA or RV may result in arrhythymias Too distal location may result in pulmonary infarction, hemorrhage, infarction, or pulmonary artery pseudoaneurysm
Intra-aortic balloon pump	Tip just below the superior aortic knob	Malposition If the tip is too high, it may occlude the left subclavian artery If the tip is too low, it may occlude the bronchial abdominal or renal arteries Aortic dissection
Cardiac pacemaker placement	Right ventricular lead should project over the cardiac apex on PA view and lie anteriorly on the lateral view. Right atrial appendix lead is anterior on the lateral view	Pneumothorax Lead fracture Cardiac perforation Lead malposition Generator pocket inflammation
Automatic implantable cardiac defibrillator device (AICD)	Proximal lead, superior vena cava; distal lead, right ventricle Biventricular lead in coronary sinus or draining coronary vein	Fracture of lead Retraction of lead
Nasogastric tube	Side port and tip below the left hemidiaphragm	Esophageal or gastric perforation Aspiration pneumonia Pneumothorax
Pleural drainage tubes	For pneumothorax, directed anteriorly and superiorly; for pleural effusion, posteriorly and inferiorly	Bleeding (laceration of vessel) Diaphragmatic perforation Lung contusion and/or laceration

SOURCE: From Trotman-Dickerson B. Radiography in the critical care patient. In: McLoud TC(ed) Thoracic Radiology: The Requisites. St. Louis: Mosby, 1998. p 152

The radiographic appearance of the pulmonary vasculature is gravity dependent.

A balanced pattern of pulmonary blood flow is associated with hydrostatic pulmonary edema from renal failure or fluid overload. A cephalization pattern is associated with hydrostatic pulmonary edema from congestive heart failure.

and lower lobes. In the supine position, the caliber of the upper lobe and lower lobe vessels are similar.

An increase in pulmonary vascularity can be detected on upright chest radiographs when the upper lobe pulmonary vessels appear similar (balanced blood flow pattern) or greater in size (cephalization or redistribution pulmonary blood flow pattern) than the lower lobe vessels. A balanced pattern is typically encountered in patients with hydrostatic edema from renal failure or volume overload, whereas a redistribution or cephalization pattern is associated with elevated pulmonary venous pressure and left-sided heart failure (Fig. 11-7).

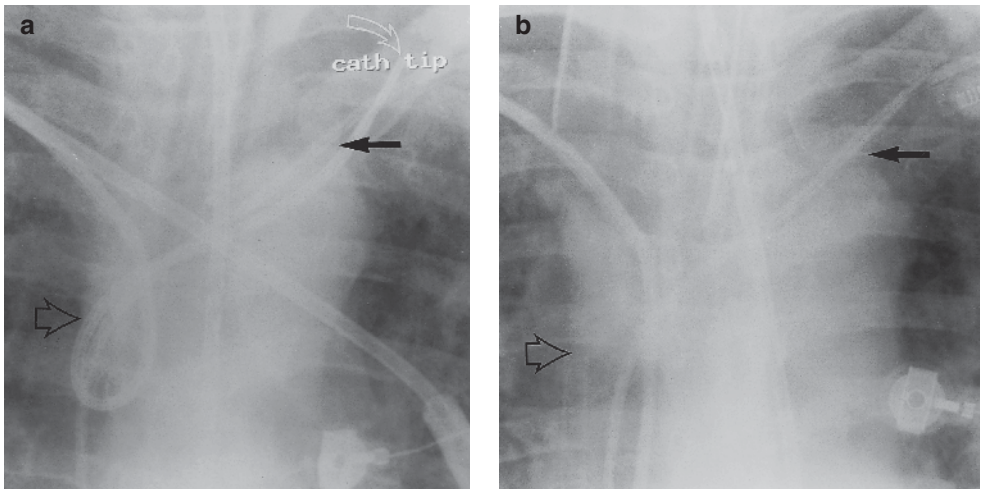

FIGURE 11-5

(**a**) Coned-down image of the mediastinum reveals a normal vascular pedicle width of 46 mm. The pedicle is measured from where the *right* main bronchus crosses the superior vena cava (*open black arrow*) to a perpendicular dropped from where the left subclavian artery originates from the aorta (*closed black arrow*). Also note the malpositioned right subclavian catheter, which has crossed over into the left subclavian vein (*open white arrow,* catheter tip). (**b**) Coned-down image of the mediastinum of the same patient during an episode of fluid overload demonstrates interval widening of the vascular pedicle to a width of 65 mm (*arrows*). The right subclavian catheter has been successfully repositioned.

FIGURE 11-6

Frontal chest radiograph reveals typical features of pulmonary interstitial edema in a patient with congestive heart failure, manifested by peribronchial cuffing, indistinctness of the pulmonary vessels, and Kerley B lines. Note the cephalization or redistribution of the pulmonary vasculature and mild cardiomegaly.

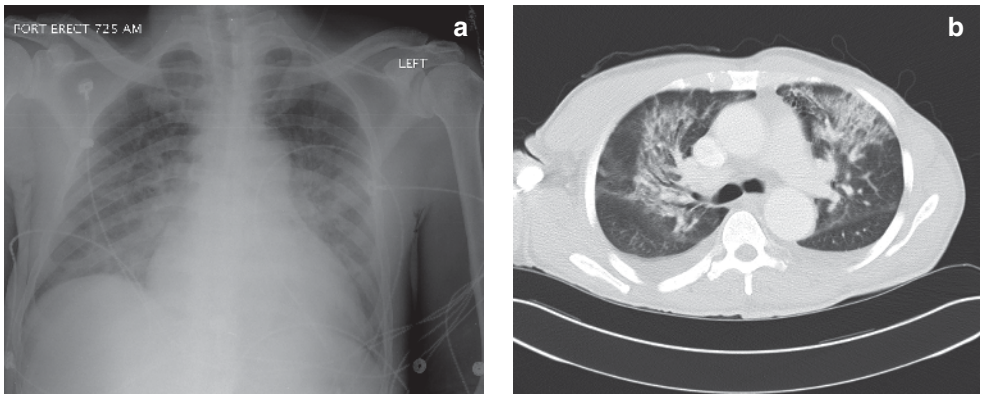

FIGURE 11-7

Portable supine chest radiograph (**a**) and CT (**b**) of an ICU patient with fluid overload and end-stage renal disease demonstrates a bilateral pattern of alveolar consolidation with a central, perihilar distribution.

Common causes of lung opacification in the ICU setting include pulmonary edema, pneumonia, atelectasis, and aspiration.

There are two main forms of pulmonary edema: hydrostatic and increased capillary permeability edema.

Hydrostatic pulmonary edema occurs secondary to congestive heart failure, renal failure, or fluid overload.

Hydrostatic pulmonary edema involves first the interstitial compartment of the lung, followed by the alveolar compartment.

Although the appearance of pulmonary edema may vary among different patients, there is often a strikingly similar pattern in an individual patient from episode to episode.

Hydrostatic pulmonary edema is frequently associated with cardiac enlargement, increased vascular pedicle width, and pleural effusions.

Because the upper and lower lobe vessels normally are of similar caliber on supine radiographs, recognition of increased pulmonary vascularity is more difficult than on erect radiographs. Increased pulmonary blood flow can reliably be identified on ICU radiographs by comparing the caliber of the upper lobe vessels to the adjacent bronchi, both of which are normally seen end-on adjacent to the pulmonary hila. Normally, the artery and bronchus have a 1:1 size ratio. In the setting of increased pulmonary blood flow, the caliber of the artery will appear larger than the adjacent bronchus. Redistribution of flow to the upper lungs characteristic of elevated pulmonary venous pressure is best appreciated on erect portable films (Figs. 11-5 and 11-6).

Assessing Areas of Increased Lung Opacification

There are a variety of causes for increased lung opacification, but only a few entities are frequently identified in the ICU setting. These entities include pulmonary edema, pneumonia, atelectasis, and aspiration (Table 11-3). The characteristic imaging features of these entities are reviewed in the following paragraphs.

Pulmonary Edema

Pulmonary edema is a common cause of diffuse parenchymal opacification in the ICU patient. It is important to attempt to differentiate hydrostatic pulmonary edema from increased capillary permeability edema. Several features can aid in this distinction. Remember, however, that it is not always possible on the basis of radiographic findings alone to separate hydrostatic from increased permeability pulmonary edema. Moreover, both forms of edema – hydrostatic and increased permeability pulmonary edema – may coexist in the same patient.

Hydrostatic Pulmonary Edema

Hydrostatic pulmonary edema secondary to congestive heart failure or volume overload usually follows a typical course. Increased pulmonary vascularity is followed by the sequential development of fluid within the interstitial compartments of the lung, and subsequently by air space or alveolar pulmonary edema.

The interstitial compartment of the lung contains two major components: the peribronchovascular sheath and the interlobular septa. Fluid within the peribronchovascular sheath results in indistinctness of the pulmonary vessels ("hilar haze") and peribronchial cuffing. This occurs with pulmonary venous pressures above the normal range of 8–12 mmHg. Fluid within the interlobular septa results in the presence of Kerley B or septal lines, a term that refers to linear opacities that are best visualized in the lung periphery (Fig. 11-6). As interstitial edema progresses in severity, fluid may also accumulate within the subpleural space of the interlobar fissures; this is referred to as a subpleural stripe or subpleural edema seen as thickening of the interlobar fissures on chest radiographs.

TABLE 11-3

DIFFERENTIATING AIRSPACE OPACITIES ON PCR

ASPIRATION	PNEUMONIA	ATELECTASIS	PLEURAL EFFUSION
Dependent location	Dependent or nondependent	Volume loss	Homogeneous increased density
Rapid onset and clearing	Slowly resolves	Appears or resolves rapidly	Changes with position (if not loculated)
May have associated volume loss	Bronchopneumonia is more likely to exhibit volume loss than lobar pneumonia	Linear or band-like (if segmental or subsegmental)	Blunted costosphrenic angle
		Lobar-triangular or wedge-shaped	Apical cap

SOURCE: Rubinowitz A, et al. Critical care clinics 2007 23:539

As pulmonary venous pressure rises further, there is extension of fluid into the alveolar spaces of the lung. Airspace involvement can be detected by the presence of poorly defined lung opacities that coalesce to produce airspace consolidation and may demonstrate air bronchograms. Air space consolidation is characterized by the presence of confluent, cloudlike lung opacities. Airspace consolidation from hydrostatic pulmonary edema is usually bilateral and symmetric and often has a central, perihilar predominance (Fig. 11-7). In some patients, alveolar pulmonary edema may be asymmetric or atypical in distribution. Although the appearance of pulmonary edema may vary among different patients, there is often a strikingly similar pattern in an individual patient from episode to episode. Thus, it is helpful to compare the current radiograph to the one obtained during a prior episode of pulmonary edema, particularly for patients who present with an asymmetric or atypical distribution.

In addition to the features just described, patients with hydrostatic pulmonary edema frequently demonstrate an enlarged heart, an increased vascular pedicle width, and pleural effusions. Right-sided pleural effusions predominate in patients with congestive heart failure.

Capillary Permeability Pulmonary Edema

Capillary permeability pulmonary edema is most closely associated with the acute respiratory distress syndrome (ARDS). This syndrome refers to a heterogeneous group of conditions in which patients develop acute respiratory failure, characterized by profound hypoxia, with associated diffuse lung opacification on chest radiography. There are a variety of risk factors for developing ARDS, including trauma, blood transfusions, sepsis, drug effect, severe pneumonia, hypoxia, circulatory shock, aspiration, inhaled toxins, and drug overdose(Fig. 11-8).

In contrast to patients with hydrostatic pulmonary edema, the heart size and vascular pedicle width are normal in patients with increased permeability pulmonary edema. Moreover, pleural effusions, septal lines, and peribronchial cuffing are not usually evident in patients with increased permeability pulmonary edema. Although both forms of pulmonary edema may be associated with diffuse airspace opacification, the distribution of lung opacities often differs between these entities. In patients with increased permeability pulmonary edema, the opacities are often patchy and peripheral in distribution, whereas in patients with hydrostatic pulmonary edema, lung opacities are often confluent, and they are usually central and perihilar in distribution. Pleural effusions are not a predominant feature of increased permeability pulmonary edema. Finally, in comparison to hydrostatic pulmonary edema, lung opacities associated with ARDS are more often associated with air bronchograms.

Because of decreased lung compliance and the need for prolonged mechanical ventilation, patients with ARDS frequently develop barotrauma, including subcutaneous emphysema, pneumothorax (Fig. 11-2), pneumomediastinum, and pulmonary interstitial emphysema

Although both increased capillary permeability edema and hydrostatic edema are associated with alveolar consolidation, the pattern is frequently different. The former is usually patchy and somewhat peripheral in distribution, and the latter is usually confluent, central, and perihilar.

ARDS is frequently complicated by barotrauma, including subcutaneous emphysema, pneumothorax, pneumomediastinum, and pulmonary interstitial edema.

When a focal area of alveolar consolidation develops in conjunction with the onset of fever and leukocytosis, a confident diagnosis of pneumonia can usually be rendered.

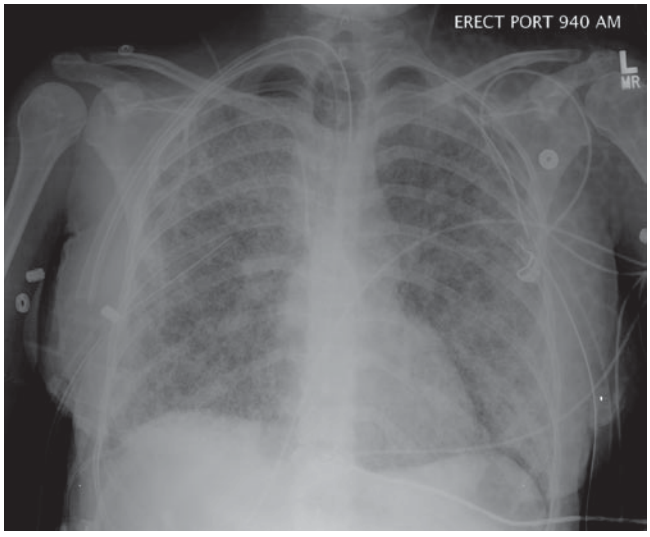

FIGURE 11-8

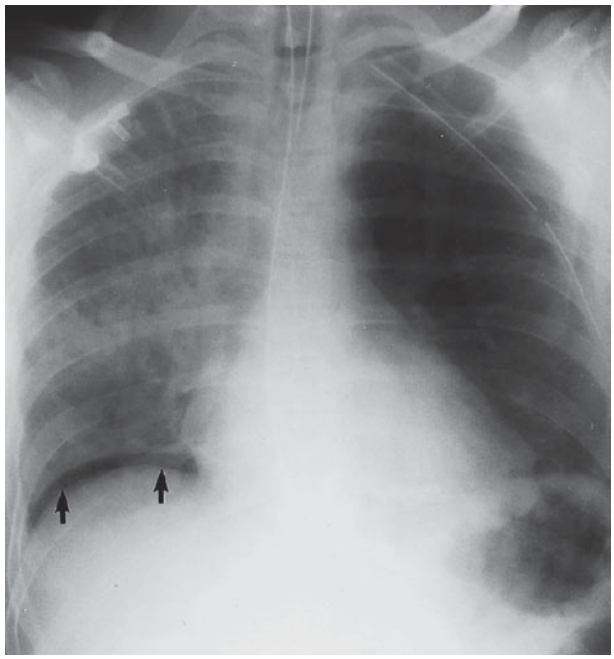
Portable supine chest radiograph of a patient with end-stage ARDS demonstrates diffuse bilateral ground glass air space opacities. Note the patchy areas of normally aerated lung that are spared by this process. The heart size cannot be assessed because the cardiac silhouette is obscured by the adjacent areas of consolidation. Bilateral pneumothorax is present.

FIGURE 11-9

A portable supine chest radiograph reveals diffuse consolidation in the right lung, corresponding to diffuse pneumonia. The time course of development and the corresponding clinical features allowed accurate differentiation between pneumonia and other causes of alveolar consolidation such as aspiration. Despite the presence of right lower lobe consolidation, the right hemidiaphragm is sharply demarcated (*arrows*), indicative of a subpulmonic pneumothorax.



(PIE). As ARDS progresses, areas of lung consolidation are replaced by areas of fibrosis and cyst formation.

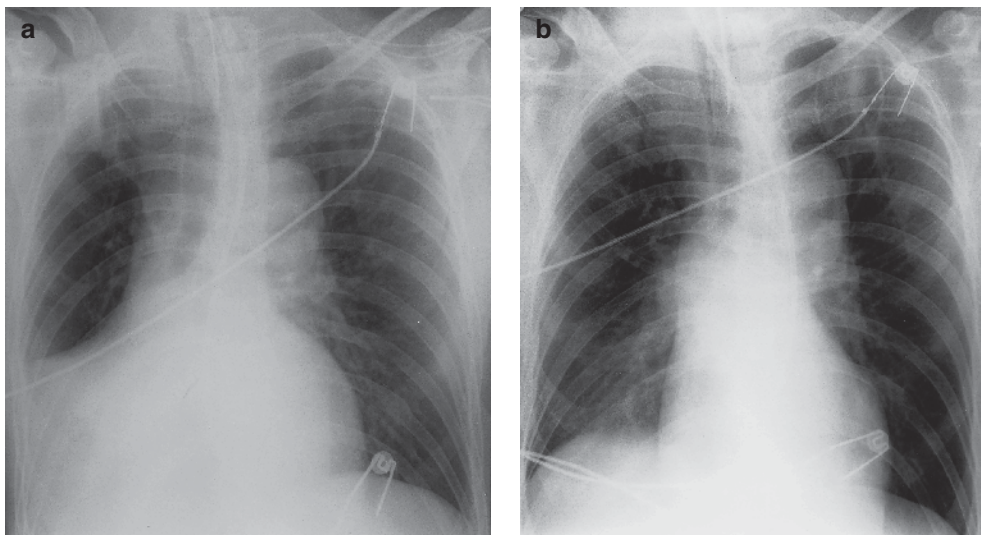
Pneumonia

Pneumonia is a relatively common diagnosis in the ICU setting (Figs. 11-1 and 11-9). For some patients, a severe pneumonia is a reason for admission to the ICU. For others, nosocomial pneumonia complicates another cause of respiratory failure such as ARDS.

Because nosocomial pneumonia is associated with a high mortality rate, a prompt and accurate diagnosis is extremely important. Unfortunately, nosocomial pneumonia is often difficult to diagnose both clinically and radiographically in the ICU setting. When a focal area of alveolar consolidation develops in conjunction with the onset of fever and leukocytosis, a diagnosis of pneumonia can usually be confidently rendered. In many cases, however, lung opacification from pneumonia may be difficult to distinguish from other causes of opacification, including pulmonary edema, atelectasis, and aspiration (Table 11-3) (Figs. 11-9 and 11-10).

FIGURE 11-10

(**a**) A portable supine chest radiograph demonstrates increased opacity in the right lower lung zone that obliterates the right heart border and right hemidiaphragm, corresponding to right middle and right lower lobe collapse. Note the inferior displacement of the right hilum, indicative of volume loss. (**b**) A subsequent radiograph obtained several hours later demonstrates improved aeration of the *right* middle and *lower* lobes, with some remaining atelectasis at the *right* base medially. Note the improved visualization of the right heart border and part of the right hemidiaphragm.



Diffuse bilateral pneumonia may occasionally be difficult to distinguish radiographically from asymmetric patterns of hydrostatic pulmonary edema (Fig. 11-9). Findings that favor asymmetric pulmonary edema include a rapid onset of lung opacities; a change in the distribution of opacities with changes in patient positioning; a rapid improvement in response to diuretic therapy; and ancillary findings of congestive heart failure (e.g., enlarged heart, increased vascular pedicle width, and increased pulmonary vascularity).

Pneumonia in the Immuocompromised Patient

Cancer patients account for a large proportion of the critically ill patients. Chemotherapeutic and immunosuppressive agents, used for the bone marrow and solid organ transplant patients, create vulnerability to opportunistic or fungal infections. Patients with AIDS, and patients who have autoimmune or collagen vascular disease are also at risk for opportunistic infections. In any immunocompromised patient, the presence of new lung nodules, peribronchovascular consolidation, or pleural-based wedge-shaped areas of consolidation should raise concern for septic emboli and fungal infections, such as invasive aspergillosis. The CT halo sign, which is a nodule or mass-like area of consolidation with surrounding ground glass opacity, is highly suggestive, but not specific for invasive aspergillosis. The same finding may be seen in septic emboli. The ground glass opacity is thought to reflect hemorrhage, as invasive aspergillosis is angio-invasive. If this sign is seen in an immunocompromised patient who has severe neutropenia, antifungal therapy should be instituted rapidly.

Atelectasis

Atelectasis, which refers to areas of pulmonary parenchymal volume loss, is a common cause of lung opacification in the ICU patient (Fig. 11-10). The degree of atelectasis may vary from minimal linear opacities, referred to as subsegmental or discoid atelectasis, to collapse of an entire lobe or lung. At these extremes of the spectrum, the radiographic diagnosis of atelectasis is relatively straightforward; intermediate degrees of atelectasis are often difficult to distinguish from pneumonia.

An important feature that favors the diagnosis of atelectasis over pneumonia is the presence of volume loss.

Atelectasis is most common in the lung bases, and the left lower lobe is commonly affected following cardiac surgery. Important features on the CXR that favor atelectasis over pneumonia include: displaced fissures, displaced hila, elevated hemidiaphragms, and shift of mediastinal structures. The time course of the radiographic presentation and resolution of the opacity may also be helpful in this distinction, as atelectasis typically develops and resolves more quickly than pneumonia.

When there is opacification of an entire hemithorax, the differential diagnosis includes complete atelectasis of a lung and a large pleural effusion. The presence of mediastinal shift can help distinguish between these two possibilities. If the mediastinal structures are shifted toward the side of opacification, the predominant abnormality may be lung collapse, usually secondary to a mucous plug. If the mediastinum is shifted to the opposite direction, the predominant abnormality is a large pleural effusion, with associated passive atelectasis of the underlying lung secondary to the effusion.

Aspiration

The radiographic appearance of aspiration is dependent on the nature and volume of the aspirated material and the position of the patient.

Aspiration is a common complication in the ICU setting. The radiographic appearance of aspiration depends on a number of factors, including the nature and volume of the aspirated material and the position of the patient. For example, the aspiration of small amounts of water or blood may not result in clinical symptoms or detectable radiographic abnormalities. On the other hand, the aspiration of acidic gastric contents produces a chemical pneumonitis that resembles pulmonary edema, and the aspiration of food or oral pathogens frequently results in aspiration pneumonia.

A characteristic radiographic feature of aspiration is the presence of lung opacities in dependent distribution.

A characteristic radiographic feature of aspiration is the presence of lung opacities in dependent portions of the lungs. If a patient aspirates in the upright position, the basal segments of the lower lobes are usually affected. In the supine position, the posterior segments of the upper lobes and the superior segments of the lower lobes are most often affected.

The time course can be helpful in distinguishing aspiration from other causes of lung opacification such as pneumonia. Aspiration typically has a rapid onset and often clears rapidly, unless it is complicated by the development of pneumonia or ARDS. Alveolar infiltrates caused by pulmonary hemorrhage are also characterized by rapid onset and subsequent clearance.

Assessment of Pleural Fluid

The radiographic appearance of a pleural effusion is dependent on the size of the effusion and the position of the patient.

Loculated pleural effusions suggest the presence of empyema or hemothorax.

Pleural effusions are a common finding in imaging studies of ICU patients and may occur secondary to a variety of conditions. These include heart failure, infection, hepatic- related hydrothorax, pancreatitis, malignancy, and uremia. The appearance of a pleural effusion on radiographs is dependent on the size of the effusion and the position of the patient.

On an upright PCR, an effusion may be caused by blunting of the costophrenic sulcus, which results in the appearance of a meniscus. It requires approximately 200 mL fluid to produce this appearance on a frontal, upright radiograph. On supine radiographs, a unilateral, layering pleural effusion is suggested by a diffuse, hazy, increased opacity throughout the affected hemithorax. Such opacity does not usually obscure the pulmonary vessels because the vessels are surrounded by air. Moderate-sized effusions may result in a lateral or apical pleural opacity (apical cap) on supine radiographs.

Loculated pleural fluid collections suggest the presence of empyema or hemothorax. Hemothorax should also be considered when a large effusion develops rapidly and when an effusion develops following an invasive procedure such as catheter placement.

Abnormal air collections include:
- Subcutaneous emphysema.
- Pneumomediastinum.
- Pneumothorax.
- PIE.
- Subdiaphragmatic free air.

Abnormal Air Collections/Barotrauma

Abnormal air collections in the thorax include subcutaneous emphysema, pneumothorax, pneumomediastinum, and PIE. Such collections are often related to barotrauma from prolonged or high-pressure mechanical ventilation (Fig. 11-2).

Subcutaneous Emphysema

The presence of subcutaneous emphysema is often one of the earliest signs of barotrauma.

Pneumothorax resulting from barotrauma is a life-threatening condition that requires prompt and accurate diagnosis.

In the supine position, air collects preferentially in the anteromedial and subpulmonic portions of the chest.

Only when a large amount of pleural air is present can an apicolateral pleural line be visualized on a supine chest radiograph.

Flattening of the heart border and adjacent vascular structures is considered a relatively specific sign of tension pneumothorax.

When the diagnosis of pneumothorax is uncertain on the basis of a supine radiograph, additional views such as an upright or lateral decubitus radiograph may be helpful.

The presence of air within the soft tissues of the chest wall is often one of the earliest signs of barotrauma. Subcutaneous emphysema may or may not be associated with pneumomediastinum and pneumothorax, which may be obscured radiographically because of the overlying streaky pattern of the subcutaneous air. Thus, the identification of subcutaneous emphysema should prompt a careful search for pneumothorax or pneumomediastinum.

Although subcutaneous emphysema is dramatic in appearance, it is a benign condition that resolves as pneumomediastinum and pneumothorax improve. It is important to recognize that extensive subcutaneous emphysema limits the diagnostic accuracy of the portable radiograph in the assessment of the pleura and lung parenchyma. CT of the thorax can be helpful in identifying pneumothorax and lung parenchymal disease in such cases (Fig. 11-2).

Pneumothorax

Pneumothorax resulting from barotrauma is a life-threatening condition that requires prompt and accurate diagnosis. A pneumothorax is usually readily identifiable on an upright chest radiograph as an apicolateral white line (the visceral pleural line) with an absence of vessels beyond it. However, a pneumothorax is much more difficult to detect on a supine radiograph. In the supine position, the apicolateral portion of the lung is no longer the least dependent portion of the lung. Rather, air collects preferentially in the anteromedial and subpulmonic portions of the pleural space. Only when a large volume of air is present in the pleural space will an apicolateral pleural line be visualized on a supine radiograph (Fig. 11-11). The radiographic signs of pneumothorax on the supine radiograph (Table 11-4) are described in the following paragraphs.

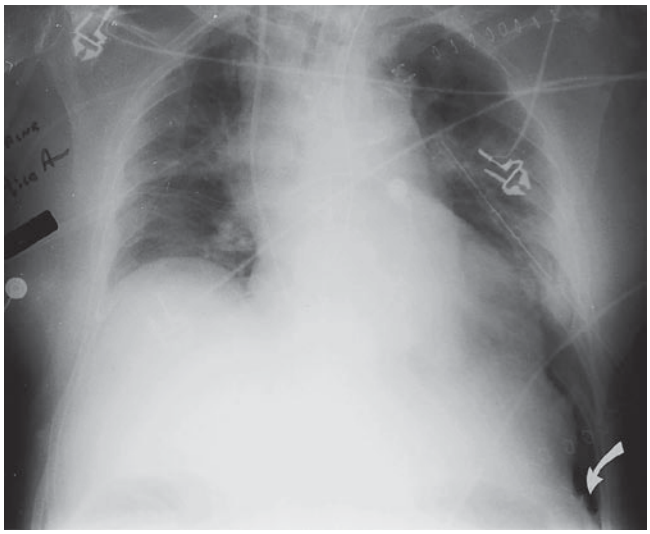


FIGURE 11-11

A supine portable chest radiograph (PCR) demonstrates a deep left costophrenic sulcus (*curved arrow*), indicative of a subpulmonic pneumothorax. Note the absence of a visible apicolateral visceral pleural line.

TABLE 11-4

SIGNS OF PNEUMOTHORAX ON SUPINE RADIOGRAPHS

Anterior-medial pneumothorax
Sharp outline of mediastinal vascular structures, heart border, and cardiophrenic angles
Subpulmonic pneumothorax
Hyperlucent upper quadrant of the abdomen
Deep costophrenic sulcus
Sharp hemidiaphragm despite lung opacification in lower lobe
Visualization of the inferior surface of the consolidated lung in lower lobe

Anteromedial pneumothorax is characterized by an unusually sharp outline of the mediastinal vascular structures, heart border, and cardiophrenic sulcus. A subpulmonic pneumothorax is identified by a hyperlucent appearance of the upper quadrant of the abdomen, a deep costophrenic sulcus (Figs. 11-9 and 11-11), a sharp hemidiaphragm despite lung opacification in the lower lobe, and visualization of the inferior surface of the consolidated lung.

Radiographic signs suggesting the presence of a tension pneumothorax include mediastinal shift, diaphragmatic inversion, and flattening of the heart border and adjacent vascular structures, such as the superior and inferior vena cava. Flattening of these structures is considered as a characteristic sign of tension pneumothorax, reflecting impairment of venous return to the right side of the heart.

When the diagnosis of pneumothorax is uncertain on the basis of a supine radiograph, additional views such as an upright or decubitus radiograph may be helpful for confirmation. CT is the most sensitive method for detecting pneumothorax and may also help in guiding the placement of chest tubes.

Pneumomediastinum

Pneumomediastinum is usually a benign and self-limited condition. Although there are a variety of causes, the majority of cases that arise in the ICU setting are the result of barotrauma. It is important to recognize that pneumomediastinum frequently precedes the development of pneumothorax in patients with ARDS.

Pneumomediastinum presents radiographically as lucent streaks of air that outline the mediastinal contours, elevate the mediastinal pleura, and frequently extend into the soft tissues of the neck (Fig. 11-12). Thus, when you observe subcutaneous air in the neck, you should look carefully for the presence of pneumomediastinum.

Pulmonary Interstitial Emphysema

PIE is a form of barotrauma that occurs when the pressure in the airspaces of the lungs exceeds the tension in the adjacent perivascular connective tissues and interlobular septa.

Pneumomediastinum frequently precedes the development of pneumothorax in ARDS.

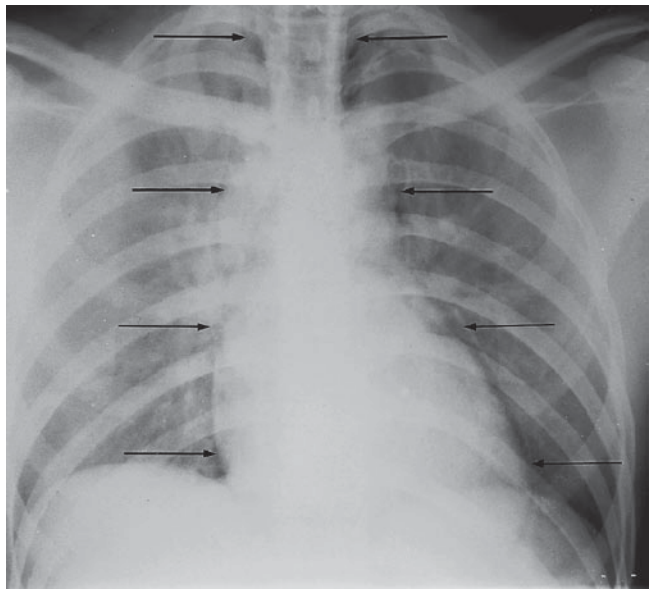
When subcutaneous emphysema is observed in the neck, the patient should be carefully assessed for the presence of pneumomediastinum.

PIE occurs when pressure in the lung airspaces exceeds the tension in the adjacent perivascular connective tissue and interlobular septa.

In patients with PIE, the rupture of small subpleural lung cysts may result in pneumothorax.

FIGURE 11-12

A supine PCR reveals lucent streaks of air surrounding the mediastinal structures (*arrows*), consistent with pneumomediastinum.



Rupture of alveoli results in the dissection of air into the interstitium of the lung, producing interstitial emphysema.

The radiologic signs of PIE include small, mottled, and streaky lucencies, some of which radiate from the hilum to the lung periphery. These lucencies are best visualized when superimposed on diffuse consolidative changes, such as those seen in ARDS. A radiolucent collar surrounding vessels seen on end is a frequent sign of PIE. Small lung cysts may also develop, and the rupture of subpleural lung cysts may result in pneumothorax.

Thoracic CT

Although chest radiography is the mainstay of thoracic imaging of the ICU patient, it clearly has limitations in the detection and differentiation of various acute cardiopulmonary abnormalities. Immediate multiplanar reconstructions are possible, with the use of PACS, and are especially valuable for CT pulmonary angiographs. Thoracic CT is superior to radiography in the assessment of the pleura, lung parenchyma, mediastinum, and the pulmonary vasculature. In certain clinical settings, the additional information provided by thoracic CT can substantially aid in the diagnosis and management of the ICU patient. Miller et al in a study of 103 consecutive ICU patients with thoracic CT scans found that 30% ($n=32$) had at least one new significant clinical finding of which 22% ($n=24$) required a change in clinical management. These included abscesses, postoperative fluid collections, unexpected pneumonias, malignancies, and pleural effusions requiring intervention.[5]

The detection, localization, and characterization of pleural fluid collections are common clinical indications for obtaining a thoracic CT in the ICU setting.

Pleural Effusions and CT

The detection, localization, and characterization of pleural fluid collections are common clinical indications for obtaining thoracic CT in the ICU setting. CT can help to distinguish simple, dependent effusions from complex, exudative effusions such as empyema. An assessment of the Hounsfield units (a Hounsfield unit is an X-ray attenuation unit that is used in CT scan characterization that characterizes the relative density of a unit of lung image in a defined area) of the fluid can also aid in the diagnosis of a hemothorax (Table 11-5).

Alveolar consolidation in the nondependent portions of the lungs in ARDS patients suggests pneumonia.

In patients with PIE, the rupture of small subpleural lung cysts may result in pneumothorax.

CT can readily differentiate among various causes of mediastinal widening, including mediastinal hemorrhage, lymph node enlargement, and mediastinal lipomatosis.

As mentioned earlier in the discussion on abnormal air collections, CT is superior to radiography in the detection and localization of pneumothorax. CT can also be used to guide the placement of drainage tubes for loculated pneumothoraces and pleural fluid collections. CT is valuable for the most accurate assessment of the pleural surface and the characterization of disease processes that occur in the lung parenchyma from those arising in the pleural space.

TABLE 11-5

ADVANTAGES OF THORACIC CT

Pleura
Detecting and characterizing pleural fluid collections
Detecting pneumothorax
Guiding drainage procedures
Lung parenchyma
Accessing ARDS patients with suspected pneumonia
Identifying and characterizing complications of pneumonia such as abscess formation, and parapneumonic effusion
Mediastinum
Assessing patients with mediastinal widening
Evaluating mediastinal vascular disorders such as aortic dissection
Identifying calcified structures such as the aorta, pericardium, and myocardium
Pulmonary vasculature
Assessing the presence or absence of acute pulmonary embolus
Evaluating the complications of Swan-Ganz catheters such as pseudoaneurysm

Lung Parenchyma and Thoracic CT

Chest CT may be helpful in identifying nosocomial pneumonia in patients with diffuse lung disease such as ARDS. On chest CT, the parenchymal opacities from ARDS are usually dependent in distribution, with sparing of the anterior portions of the lungs. Thus, the identification of alveolar consolidation in nondependent portions of the lungs on chest CT scans in ARDS patients suggests pneumonia.

Chest CT also aids in the assessment of the complications of pneumonia, such as lung abscess, empyema, and bronchopleural fistula. Although lung abscess and located pleural collections may appear similar radiographically, CT features usually allow an accurate distinction between these entities.

Mediastinum and Chest CT

CT can readily differentiate among various causes of mediastinal widening, such as mediastinal hemorrhage and hematoma, lymph node enlargement, and mediastinal lipomatosis (Fig. 11-13). CT can also be helpful for the diagnosis of postoperative mediastinitis.

With regard to mediastinal vascular structures, contrast-enhanced CT is an excellent method for assessing the diseases of the thoracic aorta, such as aortic dissection and aortic aneurysm, as well as abnormalities of the superior vena cava such as superior vena cava obstruction.

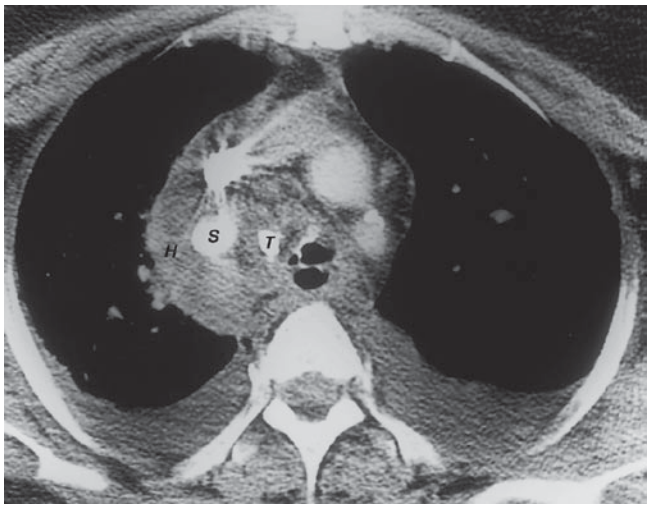


FIGURE 11-13

CT scan of a patient with mediastinal widening demonstrates high-attenuation opacity within the mediastinum, consistent with mediastinal hematoma (*H*). The hemorrhage occurred secondary to vascular perforation by a central venous catheter. Note that the catheter tip (*T*) is extravascular, located medial to the superior vena cava (*S*).

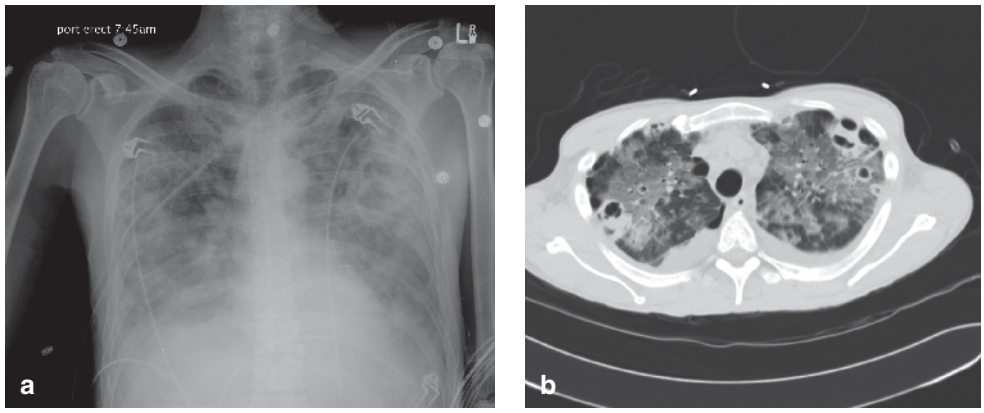

FIGURE 11-14

(**a**) Chest radiograph demonstrates multiple rounded air space opacities in this patient with a cardiac murmur and a high fever (**b**) CT shows the same opacities to be peripheral in location compatible with septic emboli due to staphylococcal sepsis.

Pulmonary Emboli and CT

Patients in the ICU are at increased risk for thromboembolic disease. In any patient who experiences acute unexplained decompensation, including the development of shock or worsening oxygenation, the diagnosis of pulmonary embolism (PE) should be considered. Other causes of pulmonary emboli include septic emboli and tumor emboli (Fig. 11-14). Most pulmonary emboli originate as thrombi in the deep veins of the lower extremity. If a deep vein thrombosis (DVT) is suspected, lower extremity color-flow Doppler ultrasound can be useful in diagnosis prior to a thoracic CT.

Pulmonary Vascularity/Pulmonary Embolism

Both venous thromboembolism and PE share the same risk factors and treatment, as PE is a complication of DVT. Untreated PE is potentially fatal, and its treatment also carries significant potential risks. So the need for an accurate diagnosis of PE is critical.

In recent years, chest CT angiography (CTA) has largely replaced nuclear perfusion scintigraphy studies (V/Q scan) for the diagnosis of pulmonary vascular disorders. Currently, chest CTA is the study of choice for the identification of PE with a high sensitivity and specificity for the detection of both central and segmental pulmonary emboli.[6] CT with angiography obtained for assessing pulmonary emboli should be performed using protocols that optimize visualization of the pulmonary vasculature. When contrast media is contraindicated, or the CT is indeterminate, a V/Q scan is indicated. At our hospital, about 5% of the diagnostic studies for PE are performed with nuclear perfusion scintigraphy studies because the patients have high serum creatinine levels are at risk for pregnancy, or have a history of contrast media allergies.[7] CT may also be helpful to detect iatrogenic pulmonary vascular complications, such as pulmonary artery pseudoaneurysms related to complications that occurred with the use of Swan-Ganz catheters (Figs. 11-15 and 11-16).

The primary roles of thoracic ultrasound in the ICU setting are to assess for the presence of pleural fluid and to guide thoracentesis procedures.

Thoracic Ultrasound

The primary roles of thoracic ultrasound in the ICU setting are to assess for the presence of pleural fluid and to guide thoracentesis procedures. Advantages of ultrasound over CT include its portability, lower cost, and lack of ionizing radiation.

VP imaging is a nuclear medicine study that uses indirect evidence (a VP mismatch) to diagnose acute PE.

A normal VQ scan reliably excludes acute PE, and a high-probability VQ scan is a sufficient evidence to treat a patient for acute PE.

Ventilation–Perfusion Imaging

The primary role of VP imaging (VQ scan) in the ICU setting is to assess for the presence of acute pulmonary embolus. A V/Q scan does not permit direct visualization of a PE. Rather, it relies on the indirect evidence of a VP mismatch. Although there are several interpretative schemes for diagnosing acute pulmonary embolus with V/Q imaging, the most common criteria are those determined from the prospective investigation of pulmonary embolism

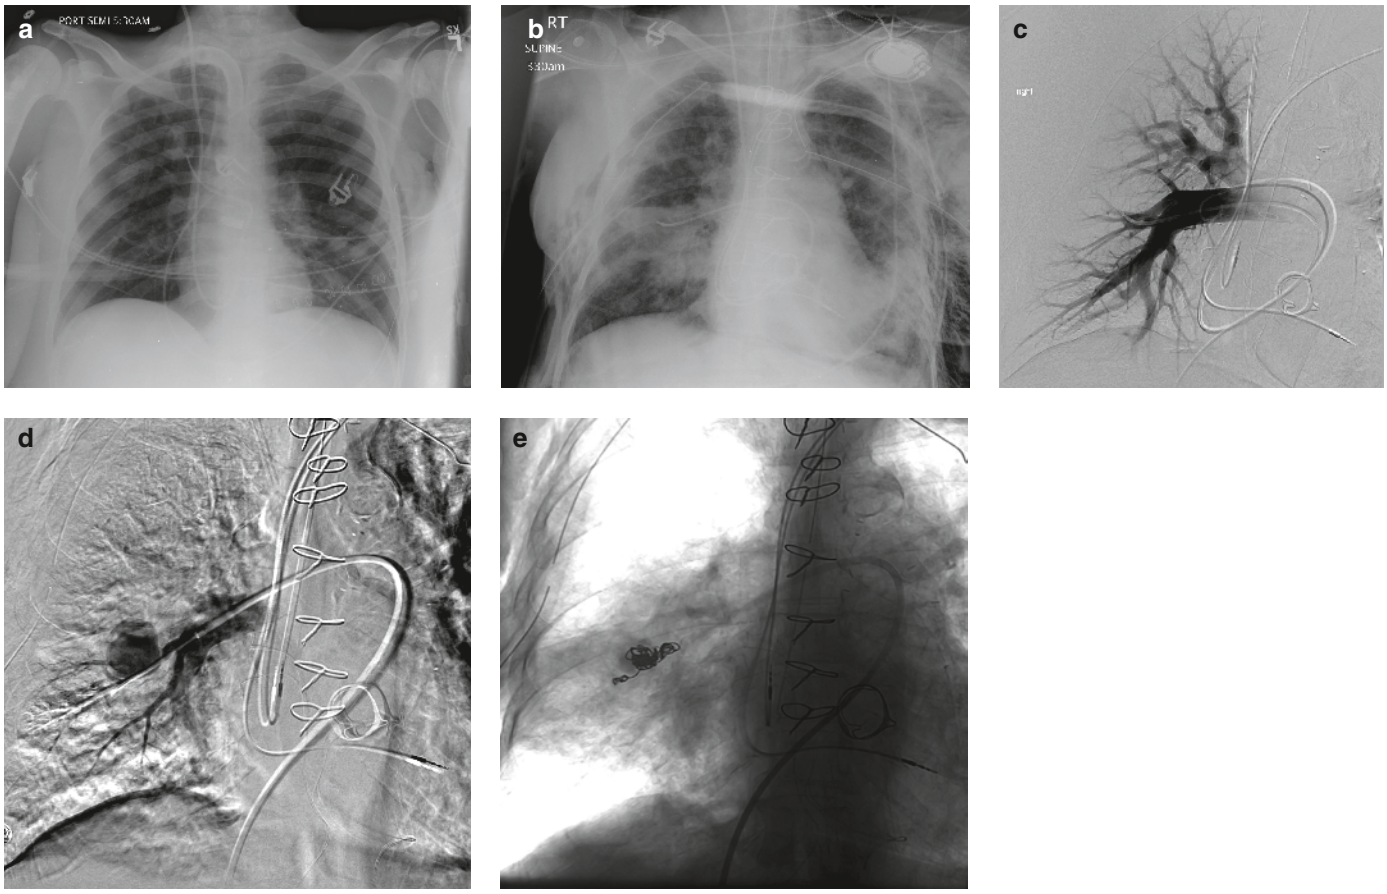

FIGURE 11-15

PCR (**a**) shows a peripheral placement of the Swan-Ganz catheter in the RUL pulmonary artery (*arrow*). A follow-up film (**b**) shows surrounding zone of consolidation representing hemorrhage following rupture of the pulmonary artery branch and formation of a pseudoaneurysm. (**c–d**) Pulmonary angiography shows the position of the catheter tip and the pseudoaneurysm. Coils were introduced (**e**).

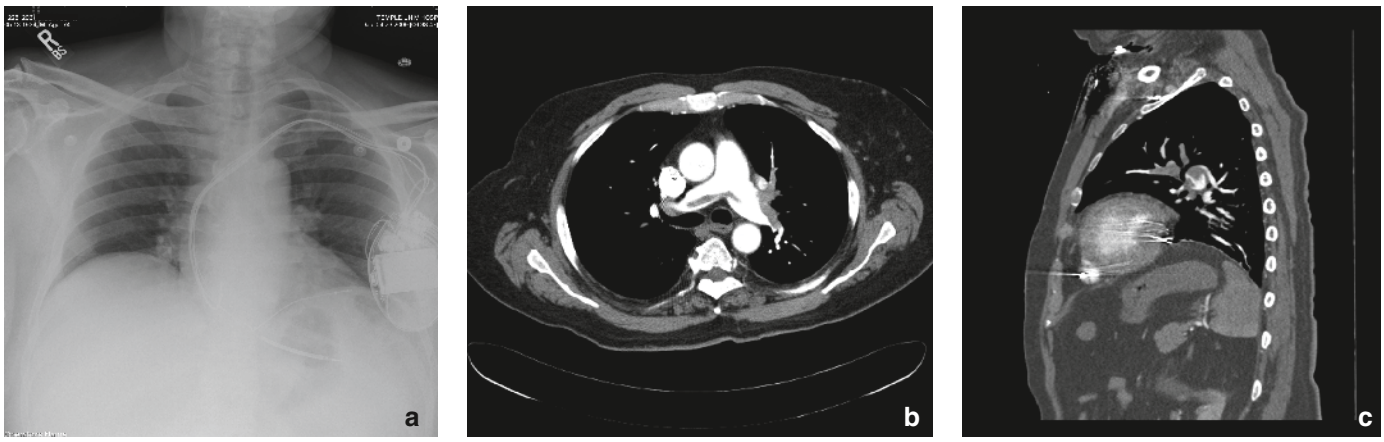

FIGURE 11-16

(**a**) AP portable chest film in an ICU patient with chest pain. Relative hyperlucency of the left upper lobe. This pattern of hyperlucency has been described as the Westermark sign. CT Angiography (CTA) (**b–c**) demonstrates large central emboli in both left and right main pulmonary arteries, manifested by large filling defects in the contrast column.

diagnosis (PIOPED) study. This study was a landmark prospective multiinstitutional investigation that assessed the value of the V/Q scan in diagnosing acute PE. Using the PIOPED interpretative scheme, a V/Q scan is categorized as normal, low probability, intermediate probability, or high-probability for pulmonary embolus. The recent PIOPED II study emphasized the value of chest CT as the study of choice for the diagnosis of acute PE[6].

In general, a normal V/Q scan reliably excludes the diagnosis of acute PE, and a high-probability VQ scan is considered as sufficient evidence to treat a patient for acute PE. Unfortunately, however, the majority of VQ scan interpretations do not fall into these two categories. Because ICU patients frequently demonstrate pleural and parenchymal opacities on chest radiography, V/Q scans are very often indeterminate for PE in this patient population. Based on their results, the PIOPED II investigators recommend that patients with a high clinical suspicion for PE undergo thoracic CT if the lower extremity Doppler study is negative The use of comprehensive algorithms based on the PIOPED II study suggest the use of D-Dimer ELISA first with low or moderate clinical probability assessment. If the D-dimer study is negative, no further workup for PE is suggested. If the D-Dimer study is positive, a color-flow lower extremity Doppler examination is performed first, and if negative, a CT is performed. If there is a high probability based on clinical evaluation, then chest CTA is the study of choice.[6] Because of the high cost, invasiveness, and limited availability of pulmonary arteriography, it is rarely used based on the current diagnostic algorithm. However, if a hemodynamically unstable patient has a high likelihood of a massive PE, angiographers may provide both a diagnosis and immediate therapeutic intervention with thrombolytic therapy.

ABDOMINAL AND PELVIC IMAGING

Abdominal radiographs, abdominal and pelvic sonograms, and CT scans of the abdomen and pelvis are commonly used in the evaluation of critically ill patients. Suspected sepsis, bowel perforation, bowel obstruction, bowel ischemia-infarction, and internal bleeding are some of the common indications for requesting imaging studies. The role of body MRI is limited due to the longer scanning time and repeated breath holding that may be required. MRI of the abdomen may be used as an alternative imaging modality in patients allergic to iodine contrast that obviates the performance of contrast-enhanced CT imaging.

FIGURE 11-17

Free intraperitoneal air from perforated duodenal ulcer. Erect abdominal radiograph demonstrates crescent-shaped lucency (*arrows*) beneath both diaphragmatic domes.

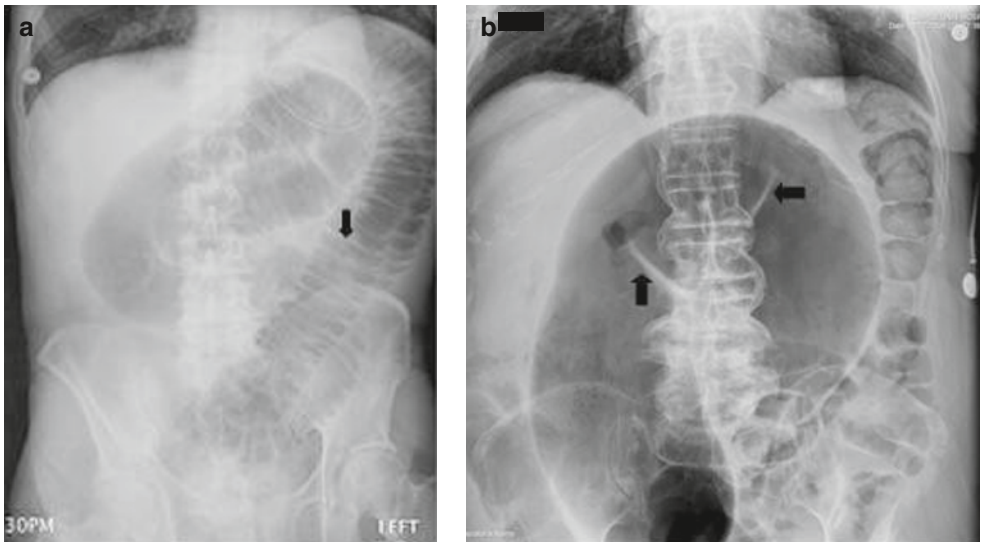

FIGURE 11-18

Mucosal pattern of the dilated bowel loops. (**a**) Valvulae conniventes pattern (*arrow*) suggests small bowel dilatation. (**b**) Sigmoid volvulus, a closed loop obstruction. Haustral markings (*arrow*) suggest colonic dilatation.

Abdominal and Pelvic Radiography

Suspected bowel perforation or obstruction is initially evaluated with bed side radiographs. A curvilinear lucency under the diaphragm in erect chest or abdomen radiographs suggests free intraperitoneal air (Fig. 11-17). The left lateral decubitus view is used in patients unable to sit upright and will demonstrate air between the right margin of liver and body wall. Multiple air-fluid levels in upright radiographs suggest intestinal ileus or bowel obstruction. Generalized bowel distension favors ileus. On distal small bowel obstruction localized ileus (sentinel loop) may be a manifestation of focal inflammation. Mechanical obstruction presents as proximal dilatation and distal decompression depending on the severity, location, and the duration of obstruction. The pattern of the mucosal folds (thin circumferential *valvulae conniventes* in the small bowel vs. thick noncircumferential colonic haustral markings) helps in the identification of the level of obstruction (Fig. 11-18).

A partial small bowel obstruction should be distinguished from complete obstruction and closed loop obstruction because of the tendency of the latter to progress to bowel ischemia. Though this may be difficult to identify in the early stages of the disease process, close clinical and radiographic follow-up, and the response to nasogastric decompression help in the differentiation. Also barium follow-through studies may help to identify the level of obstruction. It is worth remembering that normal radiographs do not rule out bowel obstruction and an abdominal and pelvic CT scan should be ordered when clinically indicated.

Normal radiographs do not rule out bowel obstruction; a CT scan should be ordered when clinically indicated.

Occasionally, abdominal radiography reveals other findings that point to the cause of acute clinical deterioration. Such findings may include bubbly, extra luminal lucencies, corresponding to an abscess collection; mass effect from internal bleeding, and radio-opaque calculi in the biliary and urinary system. Serial abdominal radiographs are used for the localization of nasogastic and feeding tubes, intravascular catheters, as well as to assess the progression of bowel dilatation due to intestinal ileus or obstruction.

Abdominal and Pelvic Sonography

Because of its portability, ultrasound is the preferred modality for the assessment of critically ill patients not believed to be stable enough for transportation to the radiology department. Unlike CT scans, serial follow-up studies pose no radiation risks. In general, ultrasound provides excellent visualization of the solid organs (liver, kidneys, spleen, pancreas, uterus, and ovaries) and fluid containing viscus (gall bladder, and urinary bladder). It is also used for reliable identification of free fluid in the abdomen or pelvis. Sonographic Doppler techniques (color, spectral and power Doppler) provide a quick overview of vascular flow and organ perfusion at the bedside. However, ultrasound is an operator-dependent modality and technical difficulties may exist in obese patients, patients with distended bowel loops, or when an optimal acoustic window is not available.

Though ultrasound is the preferred modality for the assessment of critically ill patients not believed to be stable enough for transportation to the radiology department, it is an operator-dependent modality and technical difficulties may exist in obese patients, patients with distended bowel loops, or when an optimal acoustic window is not available.

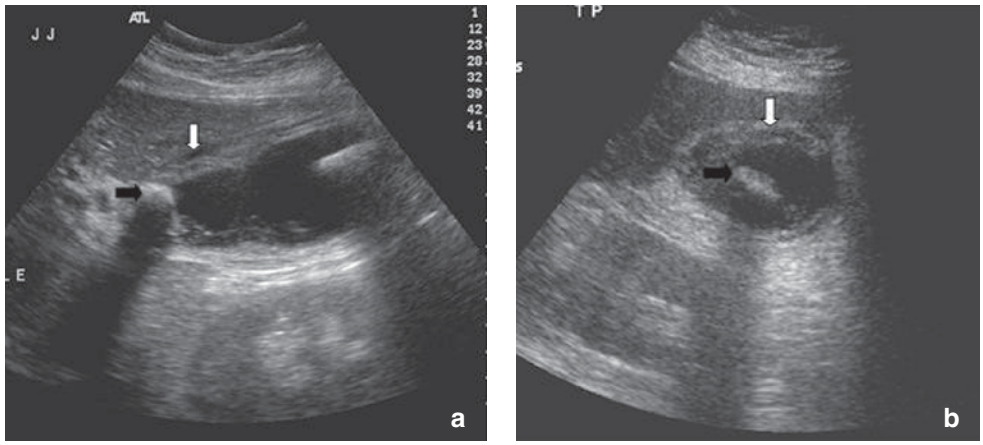

FIGURE 11-19

Acute cholecystitis. Longitudinal (**a**) and transverse (**b**) images of the gall bladder shows diffuse wall thickening due to edema and pericholecystic fluid (*white arrow*). Calculus impacted in the neck of the gall bladder is also seen (*black arrow*).

The best sonographic results are usually achieved when used for the evaluation of a specific clinical finding, such as suspected acute cholecystitis (Fig. 11-19). Ultrasound fares less well than CT as a general screening examination for the patient with suspected sepsis of unknown origin, because abscesses may be obscured by overlying bowel gas on ultrasound examinations. Ultrasound is the only modality available for bed side image-guided procedures such as diagnostic aspiration, needle biopsy, drainage of fluid collections, and catheter placement.

Abdominal and Pelvic CT

Some of the common indications for abdominal and pelvic CT scans in critically ill patients are suspected inflammation and sepsis, bowel perforation, bowel obstruction, bowel ischemia, internal bleeding, trauma surveys, and evaluation of postoperative and postorgan transplant patients (Figs. 11-20 and 11-21). CT is the best screening modality available for evaluating critically ill patients with nonspecific or poorly localized symptoms and signs. CT is also used for further evaluation and confirmation of the findings identified in radiographs or sonograms. With the ever increasing scanner speed available with multidetector CT (MDCT), diagnostic quality images are obtained even on uncooperative patients or patients with cardiac or respiratory compromise. CT is excellent for the identification of even small quantities of free air, and loculated as well as free fluid collections (Fig. 11-22). However, it is important to appreciate that free air in the abdominal cavity is a normal finding after laparotomy and laparoscopy, but decreases with time and is usually completely absorbed in 7–10 days. Also free air could be a manifestation of barotrauma in patients on ventilatory support.

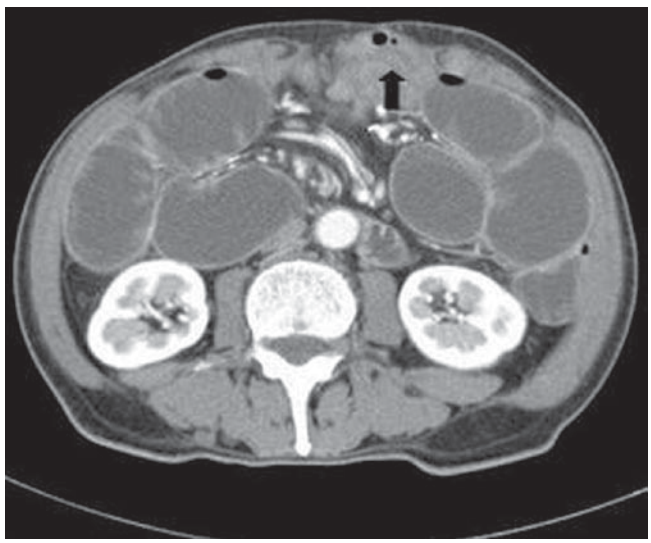

FIGURE 11-20

Abdominal CT demonstrates multiple dilated small bowel loops secondary to adhesion from prior surgery. The point of obstruction (transition point) identified beneath the anterior abdominal wall scar (*arrow*).

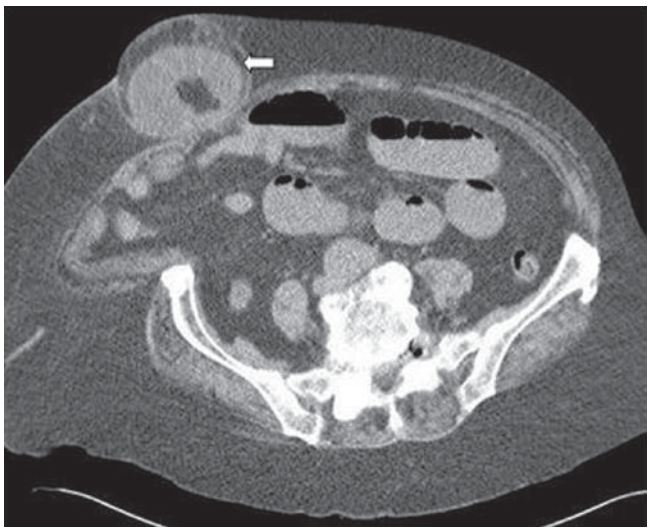

FIGURE 11-21

Closed loop small bowel obstruction. Strangulated right Spigelian hernia (*arrow*).

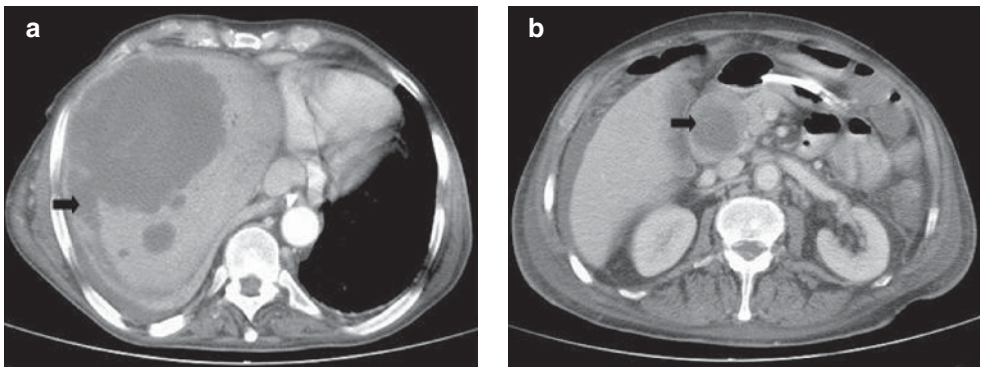

FIGURE 11-22

Multiple intra-abdominal abscesses. CT abdomen demonstrates large pyogenic liver abscess that ruptured (*arrow*) into the peritoneal cavity (**a**). Also there is abscess (*arrow*) in the head of the pancreas (**b**).

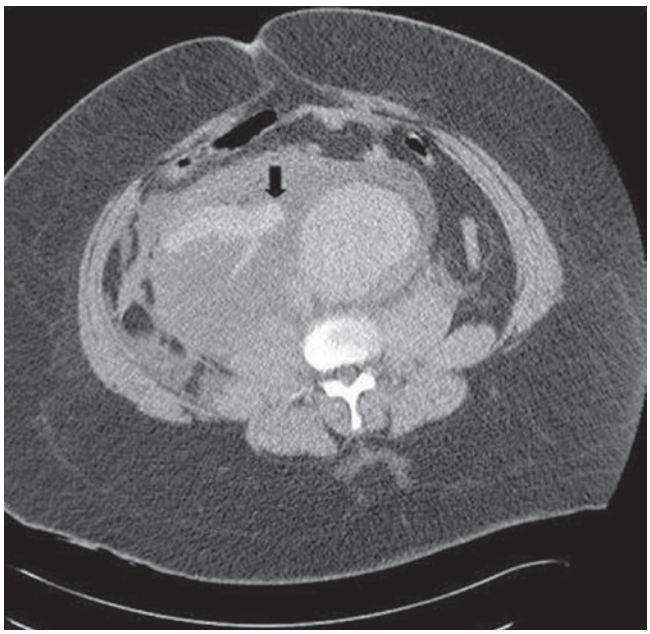

FIGURE 11-23

Postcontrast CT demonstrates large retroperitoneal hematoma from actively leaking (*arrow*) abdominal aortic aneurysm.

CT is the best screening modality available for evaluating critically ill patients with nonspecific or poorly localized symptoms and signs. CT is also used for further evaluation and confirmation of the findings identified in radiographs or sonograms.

CT angiognam (CTA) with advanced postprocessing capabilities (multiplanar reconstruction (MPR) and maximum intensity projection (MIP)) have for the most part replaced catheter angiography for diagnostic vascular imaging (Fig. 11-23) and the assessment of organ perfusion. Like ultrasound, CT is also commonly used for image-guided procedures. In contrast to ultrasound, CT results in exposure to ionizing radiation, and involves patient preparation and transportation to the radiology department. In addition, administration of intravenous iodinated contrast may be necessary.

Though dilute barium is administered in the CT imaging suite for routine bowel opacification, water-soluble iodine contrast is utilized in critically ill preoperative patients as well as those with suspected bowel perforation; critically ill patients usually receive bowel preparation prior to transportation to the CT suite. Whenever possible, patients should undergo a CT examination prior to any type of barium study as the residual barium present within the GI tract may render the CT study nondiagnostic. Rectal contrast administration may also be needed when the region of interest is the colon or pelvis. Though 3 h of NPO status is required in routine patients prior to intravenous contrast administration, it is not crucial in critically ill patients. Patients with a history of atopy or anaphylactoid reaction to iodine must be premedicated with steroids and antihistamines following departmental or institutional protocols. These patients should be monitored vigilantly during and after the procedure.

CENTRAL NERVOUS SYSTEM IMAGING

Neurological imaging studies are commonly performed either for the primary neuromuscular disorder that leads to ICU admission or for the evaluation of new-onset neurological symptoms. Some of the common indications are stroke, trauma, seizure, an acute change in mental status, and acute spinal cord compression symptoms. The documented efficacy of intravenous tissue-plasminogen activator (tPA) for the treatment of acute stroke (within 3 h of the onset of symptoms) highlights the need for rapid diagnostic evaluation of stroke patients. Both CT and MRI enable us to achieve this goal in the critical care setting.

Brain CT

Noncontrast CT remains the modality of choice in unstable patients to exclude hemorrhagic stroke before the initiation of thrombolytic therapy (Fig. 11-24). In trauma patients, CT can

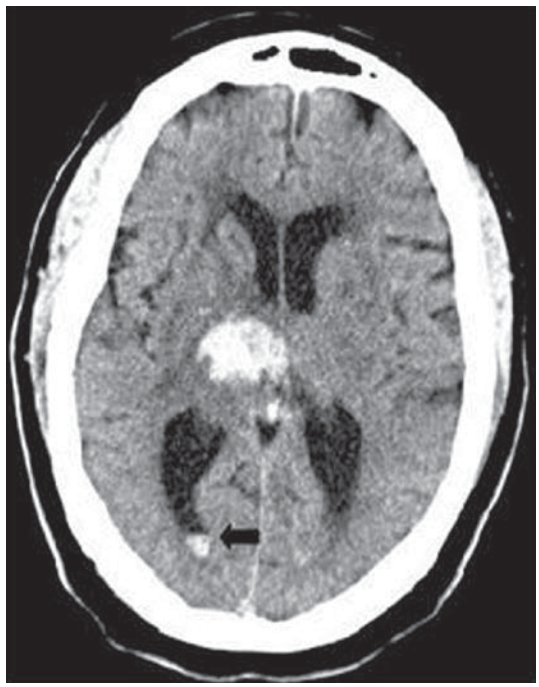

FIGURE 11-24

Hemorrhagic stroke, an exclusion criterion for thrombolytic therapy. Acute right thalamic hypertensive hemorrhage with minimal midline shift and minimal extension into ipsilateral occipital horn (*arrow*).

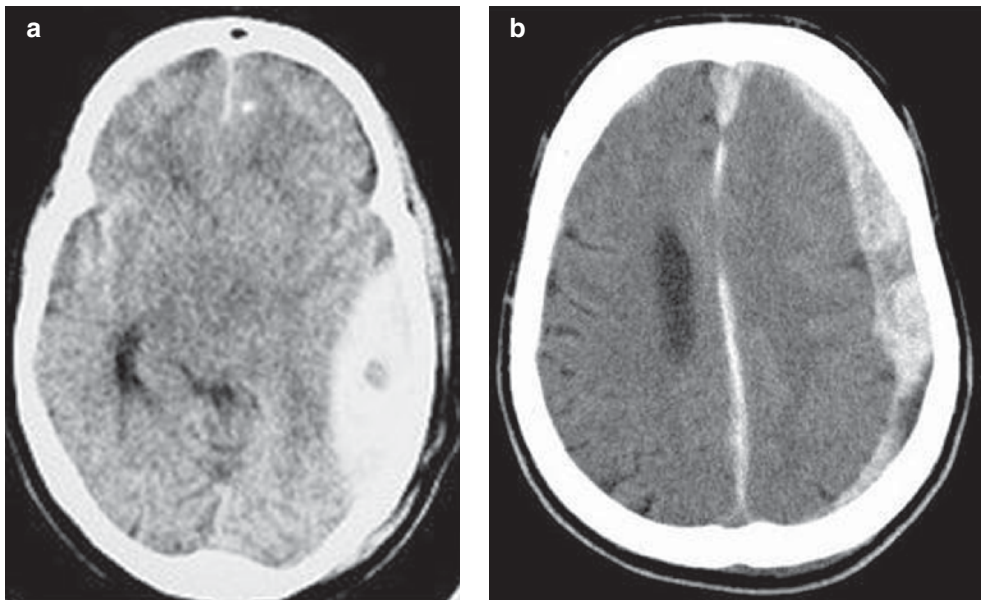

FIGURE 11-25

Typical CT appearance of posttraumatic extraaxial hematoma in two different patients. (**a**) Lentiform acute epidural hematoma on the *left* side (**b**) Crescent-shaped acute subdural hematoma on the *left* side.

FIGURE 11-26

readily identify the site of intracranial bleeding (Fig. 11-25). CT is also used for the assessment of suspected subarachnoid hemorrhage (Fig. 11-26). In the absence of trauma, subarachnoid hemorrhage is usually secondary to a ruptured cerebral aneurysm and CTA is helpful to identify and localize the source of bleeding. Neurovascular interventional procedures (i.e., placement of coils) are now widely used for the management of these patients.

The most common CT findings in ischemic stroke are related to cytotoxic edema that presents as ill-defined hypodense areas and poor gray–white matter differentiation. This leads to obscuration of the definition of structures such as basal ganglion and the insular cortex (insular ribbon sign). Various hyperdense vessel signs may appear before the typical manifestations of cytotoxic edema and are less sensitive but more specific (Fig. 11-27). Though some of these findings may be demonstrated within the first 6 h after the stroke, the CT study may be normal for as long as 24 h, and for this reason MRI is now increasingly used for the positive identification of ischemic areas.

Most stroke intervention strategies rely on the identification of the site of proximal arterial occlusion and the extent of the associated ischemic penumbra, which is sustained by

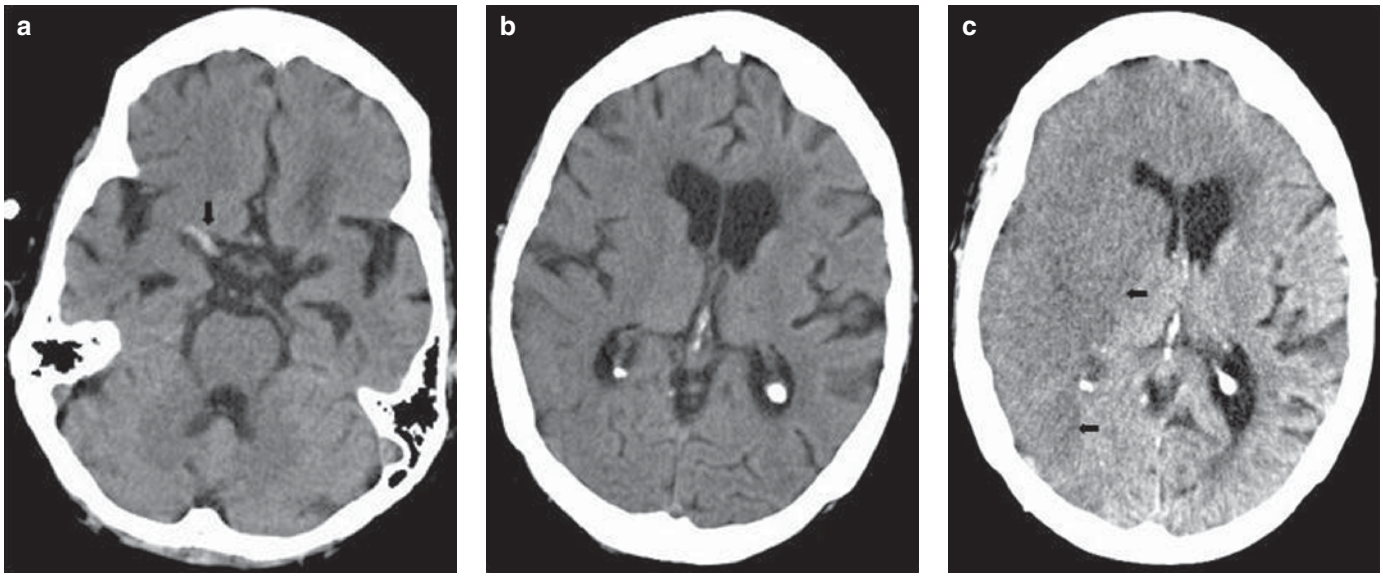

FIGURE 11-27

Hyperdense vessel sign, an early finding in ischemic stroke. (**a**, **b**) Noncontrast CT within an hour of onset of acute stroke symptoms. Linear hyperdensity in the right proximal MCA in the Sylvian fissure due to acute thrombosis (*arrow*). The study is otherwise normal. (**c**) Repeat study after 6 hours reveals extensive right MCA infarct with edema and mass effect (*arrows*).

CT remains the modality of choice for the evaluation of head trauma and unstable stroke patients. MR is increasingly used in stroke patients because of its higher sensitivity for the early positive identification of ischemic areas. MR is also more sensitive than CT in detecting subtle hemorrhage.

collateral circulation. This information can be obtained from CTA and CT perfusion (CTP) techniques with intravenous contrast administration. Cerebrovascular anatomy can be exquisitely defined with CTA to identify large vessel occlusion. CTP images the influx of iodine contrast-labeled arterial blood in the brain in a dynamic fashion; "time-density curves" are created from this data. Various perfusion parameters such as mean transit time (rMTT), cerebral blood volume (rCBV), cerebral blood flow (rCBF), and time to peak (TTP) are derived and help in assessing what portion of the ischemic penumbra may be salvaged. This patient-specific criterion is useful in planning thrombolytic therapy. The advantages of CT imaging are its wide availability and the ease and rapidity of imaging. Recent availability of portable head and neck CT scanners permits bedside CT imaging and mitigates the risk and discomfort of transporting patients to the radiology department.

Brain and Spine MRI

Both CT and MR angiograms and perfusion images provide information about proximal arterial occlusion and the extent of salvageable ischemic penumbra or zone of involvement, thus creating additional patient-specific criteria for thrombolytic therapy.

MR is more sensitive than CT in the detection of acute ischemic strokes, and is frequently positive within the first few hours after the event. This is because MR is extremely sensitive for detecting increased water content (cerebral edema) which appears as bright signal intensity on T_2-weighted images. Early positive diagnosis of cerebral ischemia (within an hour of symptom onset) has been principally advanced by the development of a diffusion weighted imaging (DWI) technique and has a very high sensitivity. The specificity of this technique to estimate infarct age is improved by correlating DWI with apparent diffusion coefficient (ADC) maps (Fig. 11-28). Magnetic resonance angiography (MRA) and the perfusion-weighted imaging (PWI) obtained after the administration of gadolinium (DSA-dynamic susceptibility contrast) provide information analogous to the CTA and CTP techniques mentioned previously. PWI is also obtained using arterial spin-labeling (ASL) techniques. Several DWI-PWI mismatch models are used to identify the salvageable ischemic penumbra. MRI using gradient refocused echo (GRE) sequences is better than CT to detect subtle microhemorrhage (Fig. 11-29).

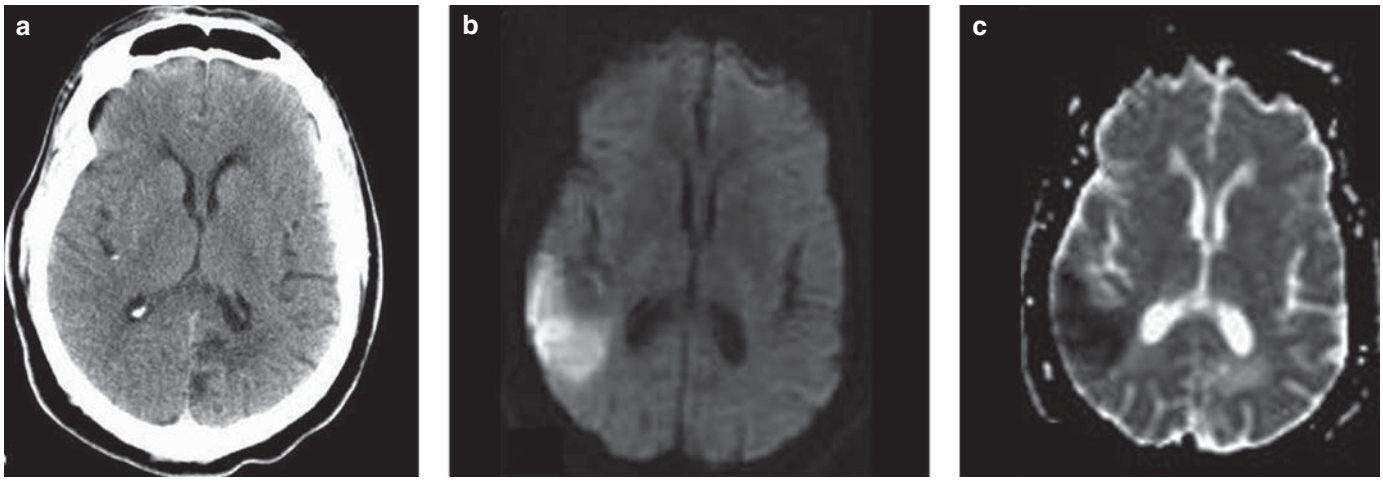

FIGURE 11-28

Hyperacute infarct. (**a**) Negative noncontrast CT in a stroke patient. (**b**, **c**) are obtained within an hour after the CT. (**b**) Diffusion weighted imaging (DWI) showing high signal (*bright*) area in the right posterior MCA territory. (**c**) Apparent diffusion coefficient (ADC) map showing low signal (*dark*) corresponding to the area of high signal in DWI.

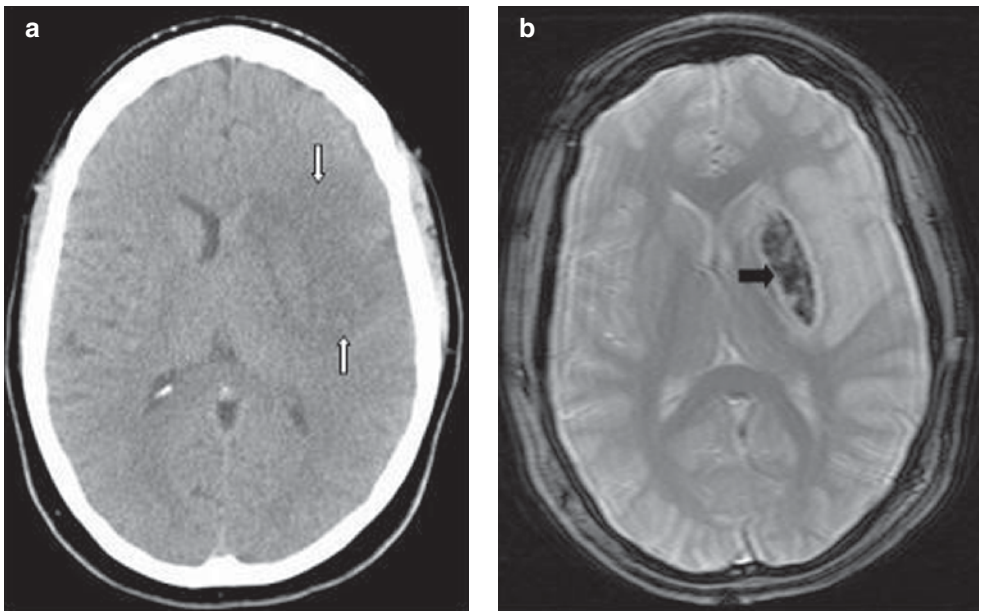

FIGURE 11-29

Hemorrhagic infarct. (**a**) Noncontrast CT showing an area of ill-defined hypodensity (*white arrows*) suggesting acute infarct in the left anterior MCA territory. (**b**) MR image with gradient sequence (GRE) showing an area (*dark area*) of hemorrhagic conversion (*dark arrow*) in the medial aspect of the infarct (*bright area*).

Though new-onset seizures in ICU patients are commonly secondary to nonneurological causes, imaging studies are performed to rule out unsuspected intracranial lesions. MR is more sensitive than CT in the early evaluation of intracranial or spinal infection. In patients with acute spinal cord compression, CT (for bone details) and MR (for soft tissue detail) provide complementary information (Fig 11.30). Radionuclide brain perfusion studies and CT angiograms are among the battery of tests used in establishing the diagnosis of brain death. The role of functional imaging (PET/fMRI) for the evaluation of vegetative state has not yet been established.

CT and MR provide complementary information in the evaluation of patients with spinal cord compression symptoms.

SUMMARY

The advancing science of medical imaging provides opportunities as well as challenges for the appropriate selection and interpretation of complex diagnostic studies, all of which are intended to assist in the management of critically ill patients. The basic principles as discussed in this chapter should provide the reader with the background knowledge that helps in the appropriate selection and interpretation of commonly used imaging studies.

Like any other area of medicine, risk-benefit ratios and cost-benefit analyses must be considered. Close cooperation between critical care physicians and radiologists is essential in providing state-of-the-art care to critically ill patients.

REVIEW QUESTIONS

1. **Which one of the following radiographic findings is present in both hydrostatic and increased permeability pulmonary edema?**
   - **A.** Cardiomegaly.
   - **B.** Widened vascular pedicle.
   - **C.** Increased pulmonary vascularity.
   - **D.** Kerley lines.
   - **E.** Airspace consolidation.

2. **Which one of the following causes of lung opacification is most closely associated with volume loss?**
   - **A.** Pneumonia
   - **B.** Pulmonary edema
   - **C.** Atelectasis
   - **D.** Aspiration

3. **Which one of the following is a radiographic sign of pneumomediastinum?**
   - **A.** Hyperlucent upper quadrant of the abdomen
   - **B.** Deep costophrenic sulcus
   - **C.** Lucent streaks of air that outline the mediastinal contours
   - **D.** Sharp hemidiaphragm despite lung opacification in lower lobe
   - **E.** Visualization of the inferior surface of the consolidated lung in lower lobe.

4. **Which one of the following is the most sensitive imaging modality for the detection of intra-abdominal abscesses?**
   - **A.** Abdominal CT scan
   - **B.** Abdominal ultrasound
   - **C.** Abdominal radiograph
   - **D.** Abdominal MR exam

5. **With regard to neurologic imaging of the ICU patient, which one of the following is true?**
   - **A.** MR is the preferred imaging modality in the evaluation of major cranial trauma
   - **B.** MR is more sensitive than CT for detecting acute ischemic strokes
   - **C.** CT with intravenous contrast is the best for assessing patients with subarachnoid hemorrhage
   - **D.** MR is the preferable modality for imaging the clinically unstable patient

ANSWERS

1. The answer is E. Both hydrostatic and increased permeability pulmonary edema are characterized by the presence of airspace consolidation. The other features listed (A–D) are typical of hydrostatic pulmonary edema, but they are not associated with increased permeability pulmonary edema.
2. The answer is C. Atelectasis, which refers to areas of nonaerated lung, is a very common cause of lung opacification in the ICU setting. An important feature that favors atelectasis over other causes of lung opacification such as pneumonia is the presence of associated volume loss. Radiographic signs of volume loss include displaced fissures, displaced hila, elevated hemidiaphragms, and shift of mediastinal structures.
3. The answer is C. Pneumomediastinum manifests radiographically as lucent streaks of air that outline the mediastinal contours, elevate the mediastinal pleura, and frequently extend into the soft tissues of the neck. The other listed features (A, B, D, E) are signs of a subpulmonic pneumothorax.
4. The answer is A. CT is the most sensitive imaging modality for the detection of intraabdominal abscesses. Whenever possible, it is important that abdominal CT be performed with adequate oral and intravenous contrast to optimize sensitivity and specificity for diagnosing abscess collections.
5. The answer is B. MR is more sensitive than CT for detecting acute ischemic strokes. MR is frequently positive within the first few hours of an acute ischemic stroke, because MR is extremely sensitive at detecting increased water (edema), which appears as bright signal intensity on T_2-weighted images.

CHAPTER 12

MICHAEL R. JACOBS

Critical Care Research and Regulatory Compliance

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Discuss the concept of research intent.
- Identify the regulatory authorities who are responsible for research conducted in the United States.
- Describe the responsibilities of the institutional review board (IRB).
- List the categories available to the IRB for review of research.
- Give examples of the materials the IRB will need to adequately review a research proposal.
- Describe the informed consent process.
- Discuss how the exception from informed consent (EFIC) impacts emergency and critical care research.

INTRODUCTION

Conducting medical research activities in compliance with Good Clinical Practice guidelines is challenging for experienced investigators and may be overwhelming for the individual making a first attempt to perform a clinical study. Research regulations are extensive and many have resulted in the issuance of guidance documents to facilitate appropriate interpretation and compliance by all members of the research enterprise. The potential for noncompliance with regulations is high, although the actual prevalence is difficult to estimate. While not addressing the issue of the extent of regulatory noncompliance, an analysis of warning letters from the Food and Drug Administration (FDA) to investigators[6] and institutional review boards (IRBs)[7] shows that serious violations of the regulations do occur. Investigators have been cited for deviating from the investigational plan, failing to obtain legally effective informed consent, and not reporting adverse events in a timely manner. IRBs have been cited for not having (or not following) adequate written procedures for reviewing research, poor documentation of meeting activities, and inadequate continuing review procedures.

CASE STUDY: THE PAD TRIAL

The Public Access Defibrillation trial prospectively compared the effectiveness and safety of cardiopulmonary resuscitation (CPR) only to CPR plus the use of an automated external defibrillator (AED) in patients experiencing an outpatient cardiac arrest when treated by trained community lay volunteers.[1] The primary outcome parameter was survival until hospital discharge. The study design and regulatory considerations of this trial go well beyond what many investigators will need to deal with in their own research endeavors. Even so, it can serve as a model for developing a study design,[2,3] accurately defining important study parameters,[4] and developing an approach for conducting exceptions from informed consent trials.[5]

The critical care setting presents unique circumstances that may further strain the clinical and ethical standards for performing research. Among these are patient populations at high risk for morbidity or mortality, narrow time frames for initiating an intervention to maximize effectiveness, and difficulties in obtaining informed consent from patients or their surrogates.[8] These issues are infrequently encountered in most other human research situations. Even so, the conduct of critical care research is essential to the development, evaluation, and effective use of new therapeutic approaches in the critically ill patients and should be encouraged. The objectives of this chapter are to provide a general overview of the regulatory requirements of human subjects' research in the ICU and to assist clinicians in writing research protocols that measure up to IRB standards.

The conduct of critical care research is essential to the development, evaluation, and effective use of new therapeutic approaches in the critically ill patients.

RESEARCH INTENT

Human research must be conducted in compliance with governmental regulations. Long before the initiation of data collection, or even the writing of the protocol, the question should be asked, "Is this human research?" Many hospital processes and procedures are scrutinized for the purposes of quality improvement or resource utilization. They frequently rely on the use of medical records and may collect information prospectively. Yet, these activities are generally not considered research.

The Code of Federal Regulations defines research as "a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge."[9] There are problems when this definition is used by itself to decide if a project is a research. A report of a single case could hardly be considered "a systematic investigation." Conversely, a randomized controlled trial would be considered research even if there was no plan to "contribute to general knowledge" by publishing the results. Amdur and Speers provide excellent guidance for determining if a project meets the criteria for research.[10] In short, they explain that research is a function of what is being done and what is ultimately motivating the investigator to conduct the research, what they term *research intent.* They suggest that investigators and IRB members ask the question, "Would the project be conducted as proposed if the project investigators knew they would never receive any form of academic recognition for the project, including publication of results in a medical journal or presentation of the project at an academic meeting?"[10] If the answer to this question is no, the proposed activity is research and should be submitted for IRB approval. Increasingly, medical journals require evidence of IRB approval as a precondition for publication of research results. Furthermore, there are no regulatory provisions that permit retroactive review and approval of research that has already been conducted. Therefore, having appropriate IRB approval is an important first step in regulatory compliance and facilitates publication of important research results.

IRB approval is an important first step in regulatory compliance and facilitates publication of important research results.

ETHICAL CONDUCT OF RESEARCH AND RESEARCH REGULATIONS

Individuals who participate in human medical research are special; even those who participate in the least invasive, most minimal risk study imaginable. Why? Because each took the time to provide information or engage in a procedure that could lead to better care for

Human research participants and the information they provide receive additional protections established in internationally accepted codes for research conduct, laws enacted at the federal and state levels, and regulations promulgated by a variety of governmental agencies.

someone they have no knowledge of; often without compensation. As such, human research participants and the information they provide appropriately receive additional protections established in internationally accepted codes for research conduct, laws enacted at the federal and state levels, and regulations promulgated by a variety of governmental agencies. The Department of Health and Human Services (DHHS) maintains oversight of human subject research through three separate units. The FDA oversees clinical trials of drugs, devices, vaccines, and other products to be marketed for the diagnosis and treatment of disease. Its authority comes from Title 21 Parts 50 and 56 of the Code of Federal Regulations. The Office for Human Research Protections (OHRP) enforces similar regulations from Title 45 Part 46 for research supported by 18 federal agencies (thus being known as the Common Rule). The Office for Civil Rights (OCR) is responsible for enforcing Health Insurance Portability and Accountability Act (HIPAA) regulations. The history of and relationships among these programs are well described in a Library of Congress report.[11]

"IRB mission creep" can include:
- Evaluation of the scientific merit of the research
- Assessment of research methodology
- Use of appropriate statistical and analytical procedures
- Evaluation of plans to protect the integrity of the data collected
- Adherence to HIPAA regulations
- Determining if conflicts of interest exist

IRB RESPONSIBILITIES

Once it is decided that the activity being pursued is a research, plans should be made for submitting a proposal to the IRB for review. The primary mission of an IRB is to protect the rights and welfare of human research subjects. Over the years, review boards have assumed many more responsibilities as the meaning of "rights and welfare" has evolved, resulting in "IRB mission creep."[12] This means that the IRB work often extends beyond just the protection of human subjects; there is a commitment to the investigator and the institution. Examples of the extended mission of the IRB at many institutions include the evaluation of the scientific merit of the research, assessment of research methodology and use of appropriate statistical and analytical procedures, evaluation of plans to protect the integrity of the data collected, adherence to HIPAA regulations, and determining if investigator or institutional conflicts of interest exist.

Given these complexities, it is essential that the investigator determine the policies of their local IRB and follow the correct submission procedures. Each IRB has its own submission guidelines. Investigators should check with their IRB office or website frequently to make sure that the most current submission requirements are being followed.

CATEGORIES OF REVIEW

Categories of research defined in 45 CFR 46: (1) exempt, (2) expedited, and (3) full board review.

There are three major categories of research defined in 45 CFR 46; exempt, expedited, and full board review, which relate to the type of research being conducted and the level of risk. While the FDA regulations permit expedited review, there is no provision for exempt research in these regulations. While most IRBs provide investigators some guidance as to how their research will be categorized, the IRB remains the final authority for making this determination. Some IRBs require that all studies be submitted for full board review. While this requirement avoids the potential problem of inappropriate use of exempt or expedited review procedures for the IRB, it may result in delays in getting a project started. It can be frustrating for the investigator who is certain that the proposed project qualifies for an exemption, yet IRB policies call for full committee approval. From the IRB perspective, however, not applying these regulations correctly may result in the institution receiving a "letter of determination" and possible sanctions. Despite years of experience with these regulations, questions about their use continue to occur.[13,14]

The two most common exemption categories in medical research are the use of anonymous surveys (exemption two) and the use of existing data or specimens (exemption four). Investigators often err, however, in assuming that all surveys are exempt.

Research Exempted from IRB Review

Table 12-1 lists the categories of research in the 45 CFR 46 that qualify for exemption from IRB review. In medical research, the two most common exemption categories are the use of anonymous surveys (exemption two) and the use of existing data or specimens (exemption four). Investigators often err in assuming that all surveys are exempt.

TABLE 12-1

EXEMPT RESEARCH CATEGORIES

Research conducted in established or commonly accepted educational settings, involving normal educational practices, such as (1) research on regular and special education instructional strategies, or (2) research on the effectiveness of or the comparison among instructional techniques, curricula, or classroom management methods
Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures, or observation of public behavior, unless: (1) Information obtained is recorded in such a manner that human subjects can be identified, directly or through identifiers linked to the subjects; and (2) any disclosure of the human subjects' responses outside the research could reasonably place the subjects at risk of criminal or civil liability or be damaging to the subjects' financial standing, employability, or reputation
Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures, or observation of public behavior that is not exempt under paragraph (b)(2) of this section, if: (1) The human subjects are elected or appointed public officials or candidates for public office; or (2) federal statute(s) require(s) without exception that the confidentiality of the personally identifiable information will be maintained throughout the research and thereafter
Research, involving the collection or study of existing data, documents, records, pathological specimens, or diagnostic specimens, if these sources are publicly available or if the information is recorded by the investigator in such a manner that subjects cannot be identified, directly or through identifiers linked to the subjects
Research and demonstration projects which are conducted by or subject to the approval of department or agency heads, and which are designed to study, evaluate, or otherwise examine: (1) Public benefit or service programs; (2) procedures for obtaining benefits or services under those programs; (3) possible changes in or alternatives to those programs or procedures; or (4) possible changes in the methods or levels of payment for benefits or services under those programs
Taste and food quality evaluation and consumer acceptance studies, (1) if wholesome foods without additives are consumed or (2) if a food is consumed that contains a food ingredient at or below the level and for a use found to be safe, or agricultural chemical or environmental contaminant at or below the level found to be safe, by the Food and Drug Administration (FDA) or approved by the Environmental Protection Agency or the Food Safety and Inspection Service of the U.S. Department of Agriculture

Adapted from Title 45 on Public Welfare. Code of Federal Regulations, Part 46.101(b)

This can occur if survey responses are collected in a way where they can be linked to individual patients or to their medical information. With the use of existing data, problems typically arise in one of two areas. The first relates to the information being collected and how it will be handled. The regulations require that the investigators maintain confidentiality of the information they collect. This is further complicated by HIPAA regulations that insist that the data de-identified. The second problem that often develops is if most of the information of interest is available in the medical record, and the investigator needs to get some additional information that might not be routinely collected, such as the patient's hair color or whether they are left or right handed. If there is a need to contact the patient to obtain this information, obviously not all data exists at the time of IRB approval. Therefore, this study would no longer qualify for an exemption.

Expedited Review

Table 12-2 describes the types of research that may qualify for expedited IRB review. Expedited review is appropriate only for studies that present no more than minimal risk or for ongoing research undergoing continuing review. Research submitted for expedited review is typically evaluated by the IRB chairperson or delegated to an IRB member who is familiar with the application of these regulations. The reviewer can require modifications of the research in order to obtain approval under expedited review regulations, but cannot reject or disapprove a proposed study. These cases would be referred to a convened meeting of the IRB. The studies reviewed under this provision of the regulations are all prospective. Given this, investigators should expect, and the regulations require, that informed consent be obtained

The IRB reviewer can require modifications of the research in order to obtain approval under expedited review regulations, but cannot reject or disapprove a proposed study.

TABLE 12-2

STUDIES THAT MAY QUALIFY FOR EXPEDITED REVIEW

RESEARCH ACTIVITIES THAT PRESENT NO MORE THAN MINIMAL RISK AND FALL INTO ONE OF THE FOLLOWING CATEGORIES ARE ELIGIBLE FOR REVIEW EXPEDITED BY THE INSTITUTIONAL REVIEW BOARD (IRB) THROUGH THE EXPEDITED REVIEW PROCEDURE

Clinical studies of drugs and medical devices only when condition (a) or (b) is met
- Research on drugs for which an investigational new drug application (21 CFR Part 312) is not required (note: research on marketed drugs that significantly increases the risks or decreases the acceptability of the risks associated with the use of the product is not eligible for expedited review)
- Research on medical devices for which (1) an investigational device exemption application (21 CFR Part 812) is not required; or (2) the medical device is cleared/approved for marketing and the medical device is being used in accordance with its cleared/approved labeling

Collection of blood samples by finger stick, heel stick, ear stick, or venipuncture as follows:
- From healthy, nonpregnant adults who weigh at least 110 pounds. For these subjects, the amounts drawn may not exceed 550 mL in an 8 week period and collection may not occur more frequently than 2 times/week
- From other adults and children, considering the age, weight, and health of the subjects, the collection procedure, the amount of blood to be collected, and the frequency with which it will be collected. For these subjects, the amount drawn may not exceed the lesser of 50 or 3 mL/kg in an 8 week period and collection may not occur more frequently than 2 times/week

Prospective collection of biological specimens for research purposes by noninvasive means

Collection of data through noninvasive procedures (not involving general anesthesia or sedation) routinely employed in clinical practice, excluding procedures involving X-rays or microwaves. Where medical devices are employed, they must be cleared/approved for marketing (studies intended to evaluate the safety and effectiveness of the medical device are not generally eligible for expedited review, including studies of cleared medical devices for new indications)

Research involving materials (data, documents, records, or specimens) that have been collected or will be collected solely for nonresearch purposes (such as medical treatment or diagnosis)

Collection of data from voice, video, digital, or image recordings made for research purposes

Research on individual or group characteristics or behavior (including, but not limited to, research on perception, cognition, motivation, identity, language, communication, cultural beliefs or practices, and social behavior) or research employing survey, interview, oral history, focus group, program evaluation, human factors evaluation, or quality assurance methodologies

Continuing review of research previously approved by the convened IRB as follows:
- Where (1) the research is permanently closed to the enrollment of new subjects; (2) all subjects have completed all research-related interventions; and (3) the research remains active only for the long-term follow-up of subjects
- Where no subjects have been enrolled and no additional risks have been identified
- Where the remaining research activities are limited to data analysis

Continuing review of research, not conducted under an investigational new drug application or investigational device exemption where categories two (2) through eight (8) do not apply, the IRB has determined and documented at a convened meeting that the research involves no greater than minimal risk and no additional risks have been identified

Adapted from Title 45 on Public Welfare. Code of Federal Regulations, Part 46.110

from the research participants. There are provisions in the regulations to waive informed consent under certain circumstances. Investigators should consult with their local IRB for guidance in this area.

Full Board Review

Any study that is greater than minimal risk must be reviewed at a convened meeting of the full IRB.

Any study that is greater than minimal risk must be reviewed at a convened meeting of the full IRB.

The composition and functions of the board are detailed in the Code of Federal Regulations. The reader is again directed to the Library of Congress report for an overview of these requirements.[11] The materials that must be provided by the investigator are discussed in the section below. In addition to the written materials, the IRB may invite the principal investigator to the meeting to provide an overview of the research activity and how it will be conducted. Investigators should take full advantage of this opportunity, if offered. However, the investigator should be well prepared to answer the questions posed by IRB members.

WHAT TO SUBMIT FOR IRB REVIEW

Once it is determined that a project is human research, it needs to be submitted to the IRB for review. It makes no difference if the project is a randomized controlled trial, or a retrospective chart review; all human research must be approved by the IRB. If the IRB is responsible for compliance with the HIPAA regulations as related to research, this will influence the materials that must be supplied for review.

IRB decisions are based on the materials provided by the investigator. On the surface, having to state this fact seems unnecessary. Yet it is not unusual for questions to arise in the committee due to deficiencies in the background materials provided, unclear study procedures, or omission of essential information. It is not the responsibility of the IRB to figure out the investigator's intent. The goal should be to provide all of the needed information in the initial submission. This information falls into four general areas: (a) an institution-specific submission form, (b) the research protocol, (c) informed consent document, and HIPAA authorization, (d) other materials. The amount of information required by the IRB is usually a function of the category of research being conducted and the associated risks. No human research project is free from risks. Even a retrospective chart review may result in the loss of confidentiality of patient data. Given this, it is important for the investigator to provide the details necessary to fully evaluate research risks and thus avoid IRB requests for additional information.[15] Providing guidance for developing a research protocol is beyond the scope of this chapter. The reader is directed to three excellent texts that can assist in this process.[16-19] The following four sections provide an overview of typical IRB requirements for each of the four groups of materials mentioned above.

No human research project is free from risks.

Institution-Specific Submission Form

There is very little standardization in the amount and types of information the local IRB requires in submitting a research proposal. To further confuse things, some IRBs have multiple submission forms depending on the type of research being proposed. The rule of thumb is, "if you know how to make a submission to one IRB, you know how to submit to one IRB." Before putting the materials together for any study, visit the IRB website or office to make sure that the correct submission procedures and the most up-to-date forms are being used.

Before putting the materials together for any study, visit the IRB website or office to make sure that the correct submission procedures and the most up-to-date forms are being used.

Once the correct forms have been obtained, investigators will be faced with a simple two-page form, or forms of over twenty pages filled with dozens of mind-numbing questions. In either case, carefully provide all of the required information. From the IRB perspective, there are no unimportant questions. Investigators tend to focus on the protocol, which is also a major concern of the IRB. However, the IRB also needs to make sure that the investigative team is properly qualified and adequately staffed, the research facilities can accommodate the demands of the study, if vulnerable groups of participants will be included, the amount and timing of compensation for participating in the trial, and provisions for the acute care of the study participants are available if necessary. For sponsored trials, information about the sponsor, the clinical research organization or site management organization, and even the study monitor may be requested. Most IRBs will also request conflict of interest statements from principal and subinvestigators.

The Research Protocol

The objective of the protocol is to provide a document that describes in adequate detail what is known about the condition being studied; what questions remain unanswered and the clinical relevance of this information; a testable hypothesis; eligibility criteria; study methodology; an assessment of risks and benefits; a sample size estimate and how data will be analyzed; and supporting references. The information provided in the study protocol needs to follow a logical progression with sufficient attention to detail. The IRB members reviewing the protocol are not likely to be experienced in the condition being studied or the

procedures being utilized. It is always better to err on the side of providing too much information, rather than too little. Table 12-3 lists the elements of a clinical research protocol and offers suggestions for the content of each.

TABLE 12-3

COMPONENTS OF A RESEARCH PROTOCOL

PROTOCOL COMPONENT	COMMENTS
Title of the research	The title of the research project appears on many other documents such as the initial review form and consent form. Make sure that the title is the same on each document
Research objectives	Describe the major goals or aims of the research in a few sentences. What will be learned from this study?
Background	What is the current state of knowledge related to the condition being studied? What is unknown? How will the information derived from this study improve patient care?
Research hypothesis	What is being tested? Identify the primary outcome parameter
Study methodology	Briefly state the study methodology (randomized, double blind, placebo controlled)
Eligibility criteria	Define the patient population that will qualify for participation in the trial. Provide specific information. A term like normal renal function is of little meaning to the IRB or the investigator. Does it mean a serum creatinine of less than 1.5 mg/dL or is it an estimated creatinine clearance of greater than 80 mL/min? Also exclude patients based on contraindications to drugs or procedures required by the study
Study procedures	Describe the methods for identifying and recruiting study participants, how and when informed consent will be obtained, and the sequence of events that will be followed as the study is executed. Remember to include a description of randomization procedures, if appropriate, and inform the committee if this is an inpatient or outpatient study. Identify those study procedures that are part of standard of care and those that are being done solely for the purpose of research. For studies that are longer or more complex, it is useful to provide a flow diagram for the committee to review. Describe how the test article (drug or device) or procedure being evaluated will be used, and the monitoring parameters that will be followed. Identify when the participants' involvement in the study will end
Risks	Identify all risks. Most investigators easily identify risks associated with drugs, devices, and medical procedures, but other risks and inconveniences may exist. These may include the time required for office visits or to complete survey instruments; withdrawal of other therapies to meet eligibility criteria; risks of device failure; radiation exposure; extra blood sampling; psychological or emotional harm; and the potential loss of confidentiality. Investigators should state the specific measures that have been instituted to minimize risks. Do not understate risks
Benefits	Identify the benefits that could reasonably accrue to the participant. If there are no direct benefits, just say so. Remember, financial compensation is not a benefit, and someone must benefit (other than the investigator) from the results of the project
Alternative treatments	Describe reasonably available treatment alternatives. If the treatment being offered is available outside of the study, participants should be informed of this. Stating that other treatments are available and instructing the participants to ask the investigator about these, is generally not acceptable. Specific examples of alternative therapies should be provided
Data collection and statistics	Identify the primary end point and provide a sample size calculation. Remember, the sample size calculation provides the number of study participants required to achieve statistical significance at the desired power. Investigators need to factor in screen failure rates and dropout rates to ask the IRB for an adequate number of participants to enroll
Costs	IRBs are concerned with the cost of research to the participant. The investigator should differentiate those costs that are part of clinical care and are the responsibility of the participant (or their insurer) from those that are borne by the study
Bibliography	Provide literature citations that support the need for the research and the interventions and procedures required by the study

Informed Consent Document and HIPAA Authorization

Regulations require documentation of informed consent using a written consent form. Table 12-4 lists the elements from the Code of Federal Regulations that must be included in the informed consent and optional elements that may be required in certain situations.[20] The process of informed consent and the particular challenges of obtaining consent in the critical

TABLE 12-4

ELEMENTS OF INFORMED CONSENT

BASIC ELEMENTS OF INFORMED CONSENT	COMMENTS
A statement that the study involves research, an explanation of the purposes of the research and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures which are experimental	Investigators should consider expanding the purposes of the research as explained to the participant to include the rationale for the study. For example, the purpose of the study might be to compare a new drug with a standard-of-care treatment for lowering blood pressure. The rationale for the study might state that while there are many drugs that can be used to lower blood pressure, they are not always effective and cause side effects in some patients. There is a need to study new drugs for lowering blood pressure
A description of any reasonably foreseeable risks or discomforts to the subject	Include all potential risks associated with participation in the study. These may result from study-related procedures (whether experimental or standard of care), the intervention being investigated, inconvenience and time required for study visits, and possible risks from loss of confidentiality. If surveys are being used, there is the time required to complete the survey and the possibility of embarrassment in answering certain questions. Avoid the temptation to include generalized methods to minimize risks such as, "you will be carefully monitored"; or "the investigators are qualified to conduct this study"
A description of any benefits to the subject or to others which may reasonably be expected from the research	If there are no benefits, just say so. At a minimum, there should be a benefit for patients with similar conditions and to society. Compensation for participation and access to new treatments are not benefits
A disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject	A statement that alternatives are available and instructions to ask the physician or study personnel are generally inadequate. Alternative treatments should be presented in some detail. If a drug or procedure is available without having to participate in the study, this should also be explained to the participant. Health Insurance Portability and Accountability Act (HIPAA) language may be included here or provided as a separate document
A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained	This section should include the individuals and entities that will have access to the records as well as methods used to protect unauthorized access to the records. This will almost always include the local IRB and Office for Human Research Protections (OHRP). The sponsor should be included for sponsored trials and the FDA for studies that they regulate
For research involving more than minimal risk, an explanation as to whether any compensation and medical treatments are available if injury occurs, and if so, what they consist of, or where further information may be obtained	Consult with the IRB regarding this language and make sure that the language in the consent form matches the language in the contract with the sponsor, if one exists. One of three procedures is typically offered. (1) Sponsor provides coverage for research-related injury; (2) institution provides coverage for research-related injury; (3) treatment for research-related injuries is the responsibility of the participant (usually the participant's insurance carrier). Avoid language that places, or appears to place, undue responsibility on the participant such as, "if you follow all of the doctor's instructions"; or "if you use the device as instructed"

(*continued*)

TABLE 12-4

(CONTINUED)

BASIC ELEMENTS OF INFORMED CONSENT	COMMENTS
An explanation of whom to contact for answers to pertinent questions about the research and research subjects' rights, and whom to contact in the event of a research-related injury to the subject	Most often research subjects' rights questions are handled by the IRB, although some institutions might refer these questions to the research subject advocate. In either case, the individual should be identified by name and should not be affiliated with the study. The contact person for research-related injury is usually they physician responsible for the medical care of the study participant. The telephone number should be operational on a 24/7 basis
A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled	Many consent forms include this exact language from the regulations. There are ethical concerns that might arise in the conduct of critical care research. Consider the situation where the participant's life is being supported by an investigational device and the participant requests to be withdrawn from the study
Additional elements of informed consent	
A statement that the particular treatment or procedure may involve risks to the subject (or to the embryo or fetus, if the subject is or may become pregnant) which are currently unforeseeable	Although an additional element, the unforeseeable risk statement is usually included in the consent form when investigational drugs and devices are being studied
Anticipated circumstances under which the subject's participation may be terminated by the investigator without regard to the subject's consent	This statement should provide the likely reasons that a participant would be removed from the study, such as failure to adhere to study procedures; inability to take a medication, or failure to meet certain screening criteria
Any additional costs to the subject that may result from participation in the research	Many IRBs have refined this to address more specifically the costs that will be covered as part of the research and those that will be billed to the participant (or their insurer) as part of routine clinical care
The consequences of a subject's decision to withdraw from the research and procedures for orderly termination of participation by the subject	Many times participants can withdraw from research with minimal problems. In other situations, additional tests, study procedures, or recovery of a device may be required. These situations should be addressed in detail here
A statement that significant new findings developed during the course of the research which may relate to the subject's willingness to continue participation will be provided to the subject	Most often seen in the course of new product development as experience is gained and additional side effects are identified. Depending on the findings, the IRB may require changes to the informed consent document and that participants already enrolled in the study be reconsented
The approximate number of subjects involved in the study	Another additional element that is often included in the consent document. Some IRBs will require the disclosure of the number of subjects in the entire study and the number at their institution

Adapted from Title 45 on Public Welfare. Code of Federal Regulations, Part 46.116

care setting are discussed below. Sponsors, IRBs, and investigators focus heavily on the consent form itself. It is more important to consider informed consent as a process.[21] Nonetheless, the informed consent document remains the centerpiece around which the consent process revolves and care should be taken in its preparation. Silverman et al. provide some additional examples of the content of each required section of informed consent documents used in critical care research.[22]

Like the format required for protocol submissions, most IRBs also provide a template that should be followed in the construction of the consent document. Investigators are strongly encouraged to follow this template. The second most important aspect of the consent form is readability. The usual goal is to develop a document that reads at an eighth grade level or lower. Commonly used word processing programs have the ability to determine the reading level of the document in the spell checking options. Other approaches that may facilitate the ease of using the form are the use of headings, tables, pictures, and flow diagrams. Care should be taken to use a font size and type that is easy to read, and to maintain adequate margins, even though both of these maneuvers may make the consent form longer.

Institutions manage HIPAA authorizations for research in one of two ways. The first is to incorporate the necessary language into the consent form itself. This will make the consent longer, but ensures that the HIPAA authorization is obtained when the participant signs the informed consent. The second way is to present the HIPAA authorization as a separate document that can be modified to include specific recipients. This method ensures that all of the required elements in wording approved by the institution are included in the authorization. It also makes it clear to the participants that not only are they agreeing to take part in the research study, but that they are also agreeing to the release of their protected health information.

Supplemental Materials

Other information required by the IRB from the investigator often depends on the characteristics of the study and the mechanism of funding. For industry-sponsored research, the IRB will require a copy of the company protocol, investigators' brochure, as well as any other materials (such as diaries) that will be provided to participants when they enter the study. NIH-sponsored studies should be accompanied by a complete copy of the grant application. Patient recruitment materials are usually not an issue with research being conducted in the critical care unit. If any of them are to be used, they must be approved by the IRB. Any surveys or quality-of-life measures that are part of the research should be provided for review. Some of these materials are copyrighted, so permission from the copyright holder to use the materials or a receipt documenting the purchase of the materials may be requested. This is one way in which the IRB protects the investigator and the institution.

REQUIREMENTS OF IRB APPROVAL OF RESEARCH

The criteria that the IRB must follow in making its determination that the proposed research is approvable are found in Table 12-5. Investigators are strongly encouraged to consider these criteria in the development of their IRB submission. For example, because the IRB is required to determine that risks to subjects are minimized, it is helpful for the investigator to comprehensively identify all of the associated risks and the specific steps taken to minimize them.

The IRB is required to determine that risks to subjects are minimized, so investigators should comprehensively identify all of the associated risks and the specific steps taken to minimize them.

Risk minimization is typically accomplished by defining how subjects will be recruited, specific eligibility criteria, coordinating blood draws or office visits with those required as standard-of-care, providing a detailed description of follow-up and monitoring procedures, establishing criteria for the removal of the subject based on safety concerns and for some studies outlining the conditions that would result in the study being stopped for reasons of safety or futility. Some studies might require a data safety monitoring board (DSMB) that will periodically review study data to ensure subject safety and the continued need to proceed with the investigation.

Some studies also require that the DSMB periodically review study data to ensure subject safety and continued need to proceed with the investigation.

TABLE 12-5

IRB CRITERIA FOR APPROVAL OF RESEARCH

CRITERIA	COMMENTS
Risks to subjects are minimized	First, identify all of the risks and inconveniences. These may result from drugs, devices, or procedures that are required by the study, even if standard of care. Data collected could be accessed by individuals not involved in the research resulting in loss of confidentiality. Even surveys, depending on the information collected, could cause emotional stress or embarrassment. Once identified, explain how the risks have been minimized (timing of research procedures to coincide with clinical care; describing how data will be protected; permission for subjects not to answer questions they find embarrassing; adding study visits for safety monitoring)
Risks to subjects are reasonable in relation to anticipated benefits	The IRB will make this determination for the investigator. The investigator should provide specifics as to how the research might benefit the subject, or individuals with the same condition
Selection of subjects is equitable	Describe the population that subjects will be drawn from. Do all patients with the condition being studied have an equal chance to participate in the research?
Informed consent will be sought	As mentioned in the text, informed consent is more than the consent form itself. Investigators should describe the process that will be used, as well as the circumstances under which consent will be obtained. Importantly, subjects should be given adequate time to make their decisions
Informed consent will be documented	The informed consent form typically provides the documentation that consent was sought and given. An entry should be made into the medical record that describes how this process occurred, and that the subject was given the opportunity to ask questions
Where appropriate, adequate provisions for data monitoring to ensure subject safety	Depending on the research and the outcomes of interest, it may be necessary to develop rules for stopping the study where continued enrollment would be unethical because of superiority or inferiority of one of the treatments. The study might be stopped due to futility (the inability to show a difference between treatments)
Where appropriate, adequate provisions to protect subject privacy and confidentiality	Describe the methods for protecting data such as limiting access, using password-protected electronic files, and storing paper records in locked cabinets or files
Adequate safeguards to protect the rights and welfare of vulnerable subjects	Describe the steps taken to protect vulnerable groups, if they will be considered for enrollment

Adapted from Title 45 on Public Welfare. Code of Federal Regulations, Part 46.111

THE INFORMED CONSENT PROCESS

Perhaps the greatest challenge to the conduct of critical care research is the problem of obtaining legally effective informed consent. The content of the informed consent document was discussed above. This section deals with the process of informed consent. Critically ill patients are considered a vulnerable population.[23] As such they are afforded enhanced protection under research regulations. The National Bioethics Advisory Commission describes the circumstances that may result in the potential for vulnerability.[20] FDA regulations and the Common Rule define vulnerable groups. They include those individuals "vulnerable to coercion or undue influence, such as children, prisoners, pregnant women, mentally disabled persons, or economically or educationally disadvantaged persons." The Common Rule also provides specific requirements for the review and conduct of research that involves fetuses, pregnant women, human in-vitro fertilization, prisoners, and children. As discussed by Baren and Fish, consent issues surrounding emergency and critical care research can be categorized into those of exploitability and those of capacity.[24]

Consent issues surrounding emergency and critical care research can be categorized into those of exploitability and those of capacity.

Individuals might be exploited (taken advantage of) because of social or economic situations such as incarceration or poverty. Others might be in a subordinate position as could exist in student–teacher, resident-attending, or employee–employer relationships.

When conditions that result in real or potential vulnerability exist, the IRB is required to provide special protections for these individuals. A common approach to limiting the possibility of exploitation is for the investigator (or the IRB) to establish recruitment procedures that prohibit enrollment of certain individuals who might be exploited. For example, investigators could be restricted from enrolling medical residents, students, and support staff members who they directly supervise. The type and amount of compensation provided for participation in a trial might also be limited to avoid coercion of economically disadvantaged individuals.

The IRB is required to provide special protection to individuals when conditions that result in real or potential vulnerability exist.

The Four Requirements of Informed Consent

Managing issues surrounding the capacity of an individual to make an informed choice to participate in research can be much more difficult. Iltis identifies four requirements that must be met for legally effective informed consent to be obtained.[26] These are: (1) disclosure of all study-related elements including procedures, risks, benefits, and alternative treatments; (2) comprehension of the information presented; (3) obtaining consent from competent individuals; and (4) ensuring that participation is voluntary. While seemingly straight forward, she goes on to point out that adhering to these requirements is often impossible because most competent adults cannot make a reasonable prospective evaluation of risk. For life in general, it is only through hindsight that most individuals are able to assess if the option chosen provided a satisfactory balance of risks and benefits. Prospective assessment of medical research risks, benefits, and alternative treatments would be expected to be much more difficult for the average individual.

Four requirements before legally effective informed consent may be obtained: (1) disclosure of all study-related elements including procedures, risks, benefits, and alternative treatments; (2) comprehension of the information presented; (3) obtaining consent from competent individuals; and (4) ensuring that participation is voluntary.

Special Issues Regarding Informed Consent in Critical Care Research

In the critical care setting, many potential research participants may not have the capacity to provide informed consent, and investigators may want to obtain consent from the subject's legally authorized representative. In this case, the investigator should describe how this will be incorporated into the consent process in the materials submitted to the IRB. This process must meet regulatory and institutional requirements, the first of which is to identify the appropriate legally authorized representative. The regulatory definition of legally authorized representative is "an individual or judicial or other body authorized under applicable law to consent on behalf of a prospective subject to the subject's participation in the procedures involved in the research." The "authorized under applicable law" wording refers to state laws, which identify, prioritize, and possibly restrict those who can serve as a legally authorized representative for medical research. It is the investigator's responsibility to comply with applicable state regulations.

A legally authorized representative is "an individual or judicial or other body authorized under applicable law to consent on behalf of a prospective subject to the subject's participation in the procedures involved in the research."

If consent is being obtained from a subject's legally authorized representative, the investigator must meet the same requirements as if the subject was providing consent directly. Basically, this means that the subject's representative should have sufficient opportunity to consider whether or not to participate; there is no coercion; the consent is in a language understandable to the representative; and no language is used that appears to restrict the subject's rights or releases the investigator or the institution from their responsibilities. Documentation of informed consent still means the use of an IRB-approved written consent form. Unlike the situation of clinical care where telephone consent alone can be obtained for medical treatments, research informed consent requires this written documentation. The usual approach followed if the legally authorized representative is not physically present is to fax a copy of the consent form to the subject's representative and to conduct the informed consent process over the telephone after which the subject's representative would sign the consent and return it by fax to the investigator.

Unlike clinical care, research informed consent requires this written documentation.

However, there are situations in critical care research where there is insufficient time to find a subject's legally authorized representative before the potential benefits of an

Although a deferred consent process can be used in certain types of research conducted outside of the United States,[28,29] this approach is not available to researchers in the US.

intervention are lost. In the late 1980s, the process of "deferred consent" was used in the conduct of emergency care research.[27] The deferred consent process allowed the subjects to be enrolled into a trial and receive the study intervention without obtaining the consent of the subject (because of being incapacitated) or the legally authorized representative (because they cannot be contacted in the limited time available). Once the subject's legally authorized representative was available, consent would be obtained. This process created the curious situation where permission was granted for interventions that had already been performed (as if they could be undone). Although a deferred consent process can be used in certain types of research conducted outside of the United States,[28,29] this approach is not available to researchers in the US. Instead, emergency critical care research conducted here must follow the procedures for exception from informed consent (EFIC) as described regulations promulgated by the FDA and OHRP in 1996.

Research conducted under the EFIC regulations must meet specific requirements.[30] These requirements are summarized in Table 12-6. The IRB is given the ultimate responsibility for assuring that all of the conditions and requirements for an EFIC study are met. However, like nonemergency research, the protocol, consent form, obtaining an IND or IDE, as well as the description of procedures required by the study are the responsibility of the investigator and the sponsor. Upon review of these materials, the IRB first needs to determine if the study meets the criteria for EFIC. If these criteria are not met, the IRB must inform the investigator and the sponsor. The sponsor must promptly notify the FDA, and other investigators and IRBs that have reviewed or have been asked to review the trial or one that is essentially equivalent. If the study meets EFIC criteria, the committee will consider the processes offered by the investigator or sponsor for community consultation (asking community stakeholders of the best way to inform individuals who might become study subjects). Based on this input, a community notification plan will be developed and reviewed by the IRB. The plan should outline the steps taken before the start of the study to increase community

A community notification should outline the steps taken before the start of the study to increase community awareness of the study and to offer a mechanism to "opt out" as well as the plan for disseminating research results.

TABLE 12-6

EXCEPTION FROM INFORMED CONSENT (EFIC) REQUIREMENTS FOR EMERGENCY RESEARCH

Research characteristics
The human subjects are in a life-threatening situation and available treatments are unproven or unsatisfactory, and the collection of valid scientific evidence is necessary to determine the safety and effectiveness of particular interventions
Obtaining informed consent is not feasible
Participation in the research holds out the prospect of direct benefit to the subjects
The clinical investigation could not practicably be carried out without the waiver
The proposed investigational plan defines the length of the potential therapeutic window
Investigator and sponsor obligations
The investigator has committed to attempting to contact a legally authorized representative for each subject within the therapeutic window to obtain consent. Efforts to obtain consent from a legally authorized representative will be documented and provided to the IRB at the time of continuing review
A consent procedure and an informed consent document are developed for those situations where obtaining informed consent from the subject or the subject's legally authorized representative is feasible
If a subject's legally authorized representative is not available, develop procedures whereby attempts will be made to contact a family member during the therapeutic window, to ask if they object to the subject's participation in the study. The investigator must summarize these efforts and make this information available at the time of continuing review
Develop a procedure for community consultation that may include consultation by the IRB
Develop a procedure for community disclosure prior to the initiation of the trial and at the completion of the trial that provides demographics of the study population and research results
Establish an independent data safety monitoring committee to oversee the conduct of the trial
Develop procedures for informing the subject (if the subject's condition improves), the subject's legally authorized representative, or a family member (if a legally authorized representative is not available), at the earliest possible time, details of the investigation contained in the informed consent document, that the subject can discontinue participation at any time without penalty
Obtain a separate IND or IDE for a drug or device for protocols where EFIC is requested

Adapted from Title 21 on Food and Drugs. Code of Federal Regulations, Part 50.23

awareness of the study and to offer a mechanism to "opt out" as well as the plan for disseminating research results.

Studies suggest that the effort required to conduct EFIC research has adversely impacted the number of critical care trials performed in the United States.[31-33] However, this process is currently the only viable option available to US investigators wanting to conduct emergency or critical research where obtaining legally valid informed consent is impractical. The reader is referred to the article by Mosesso, and others that describes these requirements in detail and discusses how this process was used in the conduct of the Public Access Defibrillation Trial.[5]

Informed Consent for the Use of Biological Samples

It is becoming increasingly common for the investigators to collect human biological samples in attempts to correlate clinical phenotypes with candidate genes or the expression of certain proteins. This type of research has the potential to significantly impact the selection

TABLE 12-7

IRB CONCERNS IN THE COLLECTION OF HUMAN BIOLOGICAL SAMPLES

CONCERN	COMMENTS
Purpose	The purpose driving the sample collection should be defined as completely as possible. The aims of some projects are very specific, limited to known genetic polymorphisms or biomarkers, and specific disease states. At the other end of the spectrum are protocols to establish a tissue bank. The tissue bank might collect samples that are used to study a variety of disease states and investigate genes or biomarkers that were unknown at the time the sample was collected
Donor eligibility	Biological samples are most often collected from patients who meet certain diagnostic criteria; it may be desirable to be able to compare with "normal" individuals. Will normal individuals be asked to provide samples? Will samples be accepted from outside investigators?
Method of collection	For blood samples, this process is pretty straight forward. For tissue samples, investigators should describe how these will be obtained and if there will be a departure from the standard of care procedure. For example, will the duration of a procedure be extended in order to obtain samples? Will tissue samples be obtained from areas that would not normally be biopsied?
Types of testing	Will samples be screened for concurrent disease states, such as HIV, hepatitis B, or hepatitis C?
Sample access	Will samples be available only to members of the study team or will they be released to others within or outside of the collecting center?
Clinical data	Describe the demographic and clinical information that will be associated with the sample
Donor compensation	Will donors be compensated for the materials they provide? Are there any plans for the distribution of royalties should a commercially viable product become available?
Sharing of results	Research results may have important clinical implications. Will patients and/or their physicians be given access to this information? Findings generated from a research laboratory should not be used to make treatment decisions. Can results be confirmed by a CLIA-certified lab?
Confidentiality	Describe the procedures that will be utilized to protect donor confidentiality. In addition to an informed consent document a HIPAA waiver may be necessary. Materials and data should be sent outside of the institution only when signed data use and/or material transfer agreements are in place. Methods for coding samples should be described. For certain types of research, it might be necessary to obtain a certificate of confidentiality
Benefits	Most donors cannot expect to derive any benefit from their participation. There may be societal benefits, or benefits to patients who suffer from a similar condition
Risks	Investigators should consider the risks due to alterations in standard procedural techniques. Some or the entire collected sample might bypass examination by a pathologist leading to an inaccurate diagnosis. Another possible risk is loss of confidentiality. This could theoretically affect the donor's insurability, cause embarrassment, or result in discrimination

of drug therapy by differentiating "responders" from "nonresponders," or those who are most likely to experience severe drug toxicity. Investigators wanting to conduct this type of research should be prepared to provide additional information to the IRB related to the selection of sample donors, the manner in which the samples are obtained, where the samples will be stored, and who has access to them. The IRB may require a separate protocol and consent form when the intent is to establish a tissue bank for research that has not yet been completely defined because the genes or proteins of interest are not yet known. Investigators should also consider what needs to be communicated to the sample donors. Examples of IRB issues that might need to be addressed by the investigator are presented in Table 12-7. Regulations and institutional policies related to this area of research change rapidly, so investigators are encouraged to speak with the IRB staff members for guidance.

SUMMARY

Successful researchers should understand the principles of study design, statistical analysis, and adherence to regulatory and ethical standards related to human research.

Conducting clinical research in the critical care environment is essential to improving the care and clinical outcomes in a population of patients at high risk for morbidity and mortality. All successful researchers need to develop and maintain skills outside of those required of a competent practitioner including understanding the principles of study design, statistical analysis, and adherence to regulatory and ethical standards related to human research.

This chapter was written to provide clinicians with an overview of regulations that affect human research. The reality is that entire textbooks and numerous publications exist for topics that were presented in a few short paragraphs. Like clinical skills, research skills are acquired and refined through practice. Unfortunately, the opportunities for formal training and skill development in conducting human research frequently are not part of the professional curriculum or residency training. Fellowship programs usually include a research component; but these may vary widely in quality and intensity. While these factors may make initiating a research project difficult for new investigators, local support is usually available. Support may come through interactions with colleagues or identifying an individual who can become a research mentor, even if his or her specialty lies outside of your own. More and more hospitals and universities are providing formal assistance to clinical researchers. Finally, discussing your research with the IRB chairperson or manager can ensure that the project is moving in the right direction.

REVIEW QUESTIONS

1. **Scientific principles are used in a variety of evaluation activities, but not all qualify as human research. "Research intent" helps to identify activities that qualify as research and can be determined by:**
   - **A.** Identifying the use of a systematic approach to determining the cause and effect of a particular problem
   - **B.** Recognizing that an investigator is collecting and organizing data about the daily activities of certain groups
   - **C.** Asking the question "Would this activity be performed if there wasn't an opportunity to publish the results?"
   - **D.** Asking the question "Why ask why?"

2. **A pulmonary fellow wants to collect anonymized data through a retrospective chart review of patients admitted to the intensive care unit to identify risk factors that are associated with prolonged mechanical ventilation. What are the investigator obligations to the IRB?**
   - **A.** None. The study is retrospective and is therefore exempt from IRB review
   - **B.** None. However, the fellow should develop a data collection form if the journal editors want to see what data was actually collected
   - **C.** The fellow is required to inform the IRB prior to submitting the completed manuscript to the journal for peer review
   - **D.** The fellow should follow local IRB procedures and submit the proposed research to the IRB for a determination of exemption and compliance with HIPAA regulations

3. **An investigator receives a communication from his local IRB stating that the research protocol he submitted has been deferred because of an inadequate sample size and other methodological problems. Which of the following is the most appropriate action?**
   - **A.** Resubmit the unchanged protocol to be reviewed again, explaining that funding is limited and that the methods being used make it easier on the investigative team
   - **B.** Modify the protocol and sample size according to the IRB's suggestions. If the sample size required is too large, consider changing the primary outcome parameter. Then submit the updated protocol for IRB reconsideration
   - **C.** Meet with the hospital CEO to determine how the research can be conducted without IRB approval. Include a statement in the consent form that the protocol has not been approved by the IRB
   - **D.** Do nothing. If the IRB defers a protocol, it means that the project cannot be conducted at that specific institution

4. **Which of the following *would not* be a required element of informed consent?**
   - **A.** An explanation of the type and amount of insurance the study sponsor has to cover research-related injuries
   - **B.** A statement that research participation is voluntary
   - **C.** An explanation of the research-related procedures
   - **D.** An explanation of foreseeable risks and benefits

5. **The difference between "benefits" and "compensation" as related to research activities is:**
   - **A.** Benefits happen when the patient has a good outcome and compensation is something that happens when the patient has a bad outcome
   - **B.** Benefits means everything that is not financial and compensation is always related to money paid to the subject
   - **C.** Benefits relates to improvements in the patient's condition or global improvements to society that might be found, whereas compensation is what is offered to the patient for the time spent in study-related activities
   - **D.** None of the above adequately describes the differences between benefits and compensation

6. **Determining the appropriate sample size is:**
   - **A.** An important part of the design of a study, but not related to an assessment of the risk-benefit ratio
   - **B.** Important for study design and risk assessment
   - **C.** Often impossible to do and not a requirement for any study other than government-funded, multicenter studies
   - **D.** Only necessary for pilot studies involving ten or fewer participants

7. **Which of the following are appropriate for the IRB to consider when asked to approve a research study?**
   - **A.** The availability of alternative treatments not being evaluated as part of the study
   - **B.** The qualifications of the investigators
   - **C.** The method by which subjects will be identified and recruited
   - **D.** All of the above
   - **E.** B and C only

ANSWERS

1. C. Asking the question "Would this activity be performed if there was not an opportunity to publish the results?"
2. D. The fellow should follow local IRB procedures and submit the proposed research to the IRB for a determination of exemption and compliance with HIPAA regulations.
3. B. Modify the protocol and sample size according to the IRB's suggestions. If the sample size required is too large, consider changing the primary outcome parameter. Then submit the updated protocol for IRB reconsideration.
4. A. An explanation of the type and amount of insurance the study sponsor has to cover research-related injuries.
5. C. Benefits relates to improvements in the patient's condition or global improvements to society that might be found, whereas compensation is what is offered to the patient for the time spent in study-related activities.
6. B. Important for study design and risk assessment.
7. D. All of the above.

CHAPTER 13

GWENDOLYN VANCE, DEBRA KOCZEN-DOYLE, DEBORAH MCGEE-MCCULLOUGH, ANNE MARIE KUZMA, AND MARIANNE BUTLER-LEBAIR

Nursing Care in the Intensive Care Unit Setting: The Role of the Nurse in the ICU

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Identify the role the critical care nurse (CCN) plays as an advocate for the critically ill patients and their family.
- Recognize the contribution of the CCN to the critical care team through collaboration and communication.
- Describe the role of the CCN in patient assessment and subsequent formulation of the plan-of-care.
- Categorize the critical nursing interventions that can prevent or mitigate nosocomial infections and common complications seen in the critically ill patient.

CASE STUDY

A 55-year-old male with a past medical history of leukemia, status post bone marrow transplant two times, and status post renal transplant with BOOP was transferred to the intensive care unit (ICU) following admission for ventilator-dependent respiratory failure at a local hospital. During his ICU stay, the patient had an open lung biopsy which revealed interstitial lung disease with fibrosis. The patient had a prolonged hospital course complicated by shock, Klebsiella pneumonia, and tracheomalacia requiring placement of a customized tracheostomy, critical illness polyneuropathy, and a pulmonary nontuberculosis mycobacterial infection. He was stabilized and transferred to the ventilator rehabilitation unit for reconditioning and weaning from the ventilator. He was able to gradually regain the ability to speak, swallow, eat with additional enteral feeding via gastrostomy tube, and stand and ambulate with assistance; however, despite aggressive reconditioning, the patient was unable to be weaned from the ventilator. He requested to be discharged to home on mechanical ventilation instead of a long-term care facility.

The initial nursing evaluation of suitability for home mechanical ventilation included assessing:

- Medical stability on chronic ventilator settings
- Home accessibility
- Safety
- Psychosocial health and adequacy of social support
- Cognitive ability
- Compliance
- Access to insurance and or finances for homecare/medical equipment
- Readiness for learning

Once the patient was deemed an appropriate candidate for home mechanical ventilation by the multidisciplinary team, patient and family education included:

- Airway care and clearance – tracheostomy care, suctioning, and inner cannula cleaning.
- Ventilator care – cleaning equipment, power options, assembly of tubing.
- Alarm troubleshooting.
- Infection control – hand washing, sterile technique, proper equipment handling, and general health maintenance such as flu and pneumonia immunizations.
- Emergency techniques – manual breathing, loss of airway, power failure.
- Gastrostomy tube feeding, pump function.
- Patient transfers and mobilization – specialty or adaptive equipment education, general home safety.
- Oxygen use and safety.
- Medication administration.

After the patient and his wife demonstrated safe and appropriate management of the tracheostomy, mechanical ventilator, and medication administration, a final safety check of the home by the durable medical equipment company was completed. This included electrical safety, cleanliness, and accessibility. Final preparation for discharge included:

- Written medication schedule including aerosolized medication treatments.
- Written troubleshooting guide with emergency information.
- Phone numbers for homecare agencies, durable medical equipment providers, and primary care and specialty physician offices.
- Follow-up appointments with specialty and primary physicians.
- Notification of utility companies of life-support equipment at home.
- Notification of emergency fire rescue department that ventilator-dependent person may require assistance in household and may be nonverbal.

The specialty nurse continued with daily phone calls to the patient, home care, and durable medical equipment providers to monitor patient progress, troubleshoot problems, and provide emotional support and additional resources or social service contact information as needed. During outpatient visits with specialty physician, the specialty nurse also meets with patient in the outpatient clinic for ongoing management and monitoring of progress.

INTRODUCTION

The most visible member of the ICU healthcare team is the critical care nurse (CCN). The CCN provides highly skilled nursing care for the patient in the ICU and often facilitates communication between the various practitioners involved in the care of the patient. The nurse's expertise and ongoing presence promote early recognition of subtle, but often significant changes in the patient's condition, thereby helping to minimize the complications of critical illness.[1]

The CCN's primary role in the ICU setting is early recognition of changes, early intervention, evaluation, and communication with healthcare team member.

CCNs practice in settings where patients require complex assessment, high-intensity therapies and interventions, and continuous monitoring. CCNs rely upon a specialized body of knowledge, skills, and experience to provide care to patients and families and create environments that are healing and humane. In the past, nursing practice was traditional and ritualistic.[2] Changes in the healthcare community have lead to evidence-based nursing practice. Nursing care must be efficient and cost effective; cognizant of patient satisfaction and quality-of-life issues, and based on demonstrated effectiveness-of-practice.

Foremost, the CCN is a patient advocate. The American Association of Critical Care Nurses (AACN) defines advocacy as respecting and supporting the basic values, rights, and beliefs of the critically ill patient.

The Roles of the Critical Care Nurse

CCNs work in varied settings, fulfilling multiple roles that include bedside nurses, clinical nurse specialists (CNS), nurse practitioners, nurse educators, nurse managers, and nurse researchers. With the onset of managed care and the resulting migration of patients to alternative settings, CCNs are caring for patients who are sicker than ever before.[3] Managed care has also fueled a growing demand for advanced practice nurses in the acute care setting.

Rapid changes in healthcare administration, laws on limits to physicians working hours, and length of stay concerns have necessitated implementation of diverse nursing models in the ICU setting.

Advanced practice nurses are those who have received advanced education at the master's or doctoral level. In the critical care setting, they are most frequently CNS or acute care nurse practitioners (ACNP). A CNS is an expert clinician in a particular specialty – critical care in this case. The CNS is responsible for the identification, intervention, and management of clinical problems to improve care for patients and families. They provide direct patient care, including assessing, diagnosing, planning, and prescribing pharmacological and nonpharmacological treatment of health problems. ACNPs in the critical care setting focus on making clinical decisions related to complex patient care. Their activities include risk appraisal, interpretation of diagnostic tests, and providing treatment, which may include prescribing medication.[4]

Educational Preparation for Critical Care Nurses

A registered nurse (RN) is a person who has successfully completed a nursing program and passes a national licensing exam. Entry level education for a RN may be either through earning a diploma in nursing, an associate's degree in nursing (ADN), or a bachelor's degree in nursing (BSN). Requirements vary as dictated by each state's Board of Nursing.

Hospital Orientation

Although it is typical for nursing curriculums to offer students clinical rotations in critical care, the CCNs specialty education and orientation is provided by the employer. Course work over several weeks to months is both didactic and clinical. Most employers utilize a

preceptor or mentor program to facilitate the clinical orientation. The critical care nursing curriculum focuses on the management of complex patients with emphasis on analytic thinking, decision making, hemodynamic monitoring, pharmacology, nutrition support, and psychosocial education for the critically ill. The nurse is eligible to sit for the certification examination in critical care after working in the ICU for more than 2 years and demonstrating proficiency in the care of the acutely or critically ill patient.[4]

Certification

Critical care certification for ICU nurses (CCRN) validates that the nurse has current and ongoing clinical expertise in the general care and management of the critically ill person.

Although certification is not mandatory for practice in a specialty like critical care, many nurses chose to become certified. Some employers prefer to hire critical care certified nurses as the certification demonstrates acquisition of a specific high level of knowledge through successful completion of a rigorous, psychometrically valid, job-related examination. In order to be eligible, for example for the CCRN certification examination offered by AACN, a CCN must care for critically ill patients for a minimum of 2 years.[4] Continuing education and ongoing clinical experience are commonly required for the certified CCN to renew certification. This practice assures that certified nurses validate their knowledge of current practices in acute/critical care nursing.

Because of the availability of Medicare and managed care reimbursement to clinical nurse specialists, a growing number of employers are requiring advanced practice certification. Additionally, as state boards of nursing attain statutory authority to issue advanced practice nursing licenses, nurses are often being required to pass a nationally recognized certification examination. Certified nurses validate their continuing knowledge of current practices in acute/critical care nursing through a renewal process that includes meeting continuing education and clinical experience requirements.

CRITICAL CARE NURSE: SCOPE OF PRACTICE

Patient Advocacy

The primary role of all nurses is to function as the patients advocate. In the ICU, this role is heightened due to the intensity of stressors, complexity of medical interventions, and the decreased ability of the patient to protect his or her rights secondary to sensory overload.

The CCN is responsible for continuous bedside management of the critically ill patient. The nurse in ICU setting has emerged as the patient's advocate and works toward realistic outcomes that are in accordance with the best practices and the patient's wishes. In the ICU, the very nature of patients' life–threatening illnesses and the heightened urgency can create crisis within the patient and family, which makes the CCNs "holistic" approach to healthcare integral to the patients overall outcome.[5]

The most essential skill the CCN utilizes is the ability to assess quickly and anticipate patient responses to a variety of physical and psychological changes. The nurse utilizes evidence-based knowledge and his or her own experience in dealing with patients' responses to external and internal stressors. The goal is to create an environment which promotes healing or if necessary allows a peaceful, dignified death The American Nursing Association defines the role of all nurses in the 2003 Social Policy Statement as:

The protection, *promotion*, *and optimization of health and abilities*, *prevention of illness and injury*, *alleviation of suffering through the diagnosis and treatment of human response*, *and advocacy in the care of individuals*, *families*, *communities*, *and populations*.

For the CCN, the role is magnified because of the fast-paced nature of critical care medicine. The patient and the family often require a consistently available presence to assist them in understanding and interpreting an ever changing clinical picture. In order to assure a trusting, beneficial relationship, the nurse must first become the patient's advocate.

Vulnerable patients who may be too sick or confused to convey their wishes depend on nurses to protect their autonomy and individual rights with regard to receiving or refusing treatment. Because of the close physical proximity of nurses to the patient and the holistic approach to care, nurses are well suited for this role. CCNs strive to create a safe, healing atmosphere primarily through effective communication with physicians, allied healthcare members, family members, and the patient.[5] In a complex, multifaceted environment such as

the ICU, nurses must function as the "air traffic controllers" of patient care. In consultation with the multidisciplinary ICU team, nurses assess the practicality of interventions such as physical therapy, the timing of transportation off the unit for diagnostic testing and the patient's readiness to endure stressors such as weaning from the ventilator. The paramount concern is always patient safety and how to best meet the demands of delivering highly technical, invasive, and advanced care to an anxious patient and how to communicate this to family members in a way which minimizes stress.

Equally important is that the patient or his surrogate receives accurate and understandable information, which will allow them to give informed consent for procedures and invasive therapies. Consent to treat and especially informed consent for clinical research trials include assuring that the patient not only hears what the procedure is but also understands the implications and risks versus benefits associated with the procedure and any other alternative treatments or diagnostic tests available. Patients are often queried after their discussions with the medical team and asked to repeat back their understanding of what has been communicated to them.

Communication with the patient and family must be conveyed in clear concise language such that the patient and family are able to accurately reiterate the essential concepts.

Collaboration and Communication

For the entire multidisciplinary team, daily rounds are the primary tool used to share information, assess patient's status, evaluate clinical interventions, and formulate a daily care plan. Collaborative discussions, which allow each discipline's perspective to be voiced, will enhance patient outcomes.[6] CCNs advocate for the patient during daily rounds by communicating to the team patient information that may impact decision making. For example, if an intubated patient has been displaying signs of delirium, such as thrashing in bed and consistently triggering high pressure alarms on the ventilator, the nurse may inquire regarding the need for pharmacologic intervention. Nurses understand that they are not to prescribe medications, but they can relate to the managing intensivist the behaviors of distressed patients and suggest evidence-based strategies to the team.

Since nurses have a uniquely close proximity to the patient during direct care, they develop relationships in which the patient may convey information that would not be given during their interactions with other team members. Frequently, patients are anxious, forgetful, or intimidated by physicians during rounds and may underreport or minimize symptoms or pain. Family members or surrogates can also become stressed and may not disclose details that could impact overall medical care or discharge planning. Nurses often obtain crucial information gathered during the time spent performing routine patient care and then relay this information to the team. Nurses may also have to intercede with families to assure that the patient's directives are implemented. They achieve this through establishing trust with the family, listening to their concerns, and relaying what the patient has conveyed to them. Educating family on the equipment being used, rationales for therapies, or lack of certain therapies may also assist the adjustment to illness. Families, during crisis, are typically very anxious, struggle with feelings of helplessness, and may cope by displaying anger. Some refuse to cooperate with the team or create distractions that have the potential to impair the team's ability to provide focused patient care. The nurse can mitigate some of these problems by empowering the family through education and keeping them informed of changes. Nurses are often viewed as a "safe" person to whom concerns can be directed; they can also help facilitate access to the patient and medical staff. Most critical care units have flexible visitation policies that can be adjusted considerably, based on the medical condition of the patient. Initiating contact with daily phone calls, and providing phone access on night shifts, alleviates some of the anxiety and powerlessness that families experience. Ultimately, caring for the patient means caring for the family as well.

Patients may underreport or omit critical information to the team on rounds secondary to feelings of intimidation or becoming overwhelmed with information. Patients may be more forthcoming during routine nursing care because of the close, extended personal contact required for such care. Therefore it is important that rounds are attended by the CCN to impart that information to the team.

Nurses and other medical professionals must also strive to avoid becoming too rigid and inflexible, in their roles, and entrenched in their perceptions of care management. Respectful discussions benefit the patient and promote team-building. Again, the multidisciplinary team approach best integrates all members into the decision-making process and results in improved patient outcome.[3]

Patient Education

Most patients and families are neophytes to the highly complex critical care environment. Many have rarely been in a hospital and may have never experienced a highly technical ICU. The most frightening element upon entering the ICU is most certainly the monitors, alarms, and specialized equipment. All patients will have EKG, oxygen saturation, and blood pressure monitoring. Some may have more advanced hemodynamic monitoring such as arterial, central venous, or PA catheters or intracranial pressure monitoring. All technical equipment (infusion pumps, mechanical ventilators, continuous renal replacement, intra-aortic balloon pumps, ventricular assist devices, and specialty beds) have monitors and alarm systems, which can appear both terrifying and confusing to families. These emotions can be moderated by explaining in layman's terms the basic rationale for each piece of equipment or monitoring device. Orientation to the members of the unit staff and their roles should occur, and the written names of the staff nurse and nurse manager, should be distributed.

Uncertainty, due to a sudden illness for which the patient and family were unprepared, will be lessened by basic explanations regarding the disease process and the treatment plan. Education techniques should be tailored to the patient's educational level and communication style. Many patients want a detailed and highly technical overview of their condition, while others become overwhelmed by too much information. Documenting the patient's learning needs assessment, and evidence of learning is essential in communicating to the members of the team. Whatever the method, nurses are responsible for assuring that patients comprehend what is happening and have the knowledge to give an informed consent to treatment.

Identifying impediments to learning and interpreting the patients' level of understanding are the initial assessments required to initiate patient education.

In the broader public arena, CCNs work in conjunction with public health practitioners to educate the public regarding disease prevention, disease management, and end-of-life issues.

Patient Assessment and the Development of the Interdisciplinary Care Plan

The CCN caring for acutely and critically ill patients has a responsibility to assess and analyze the level of care needed by the patient. This assessment is an organized, systemized approach to the ICU patient and incorporates both:

- An understanding of the pathology of the disease processes affecting the patient allows for areas of assessment on which to focus.
- A thorough head-to-toe approach to assessment includes a systematic physical examination, review of patient's history, and analysis of the patient's laboratory and diagnostic testing data.

Data collected from a thorough history and physical examination contribute to both the medical and nursing decisions for therapeutic interventions and allow the CCN to anticipate and plan key nursing interventions for and with the patient. The CCN participates in the development of the plan-of-care by incorporating the elements of the physical examination, review of history, and data to identify the patient's problems. The CCN develops realistic goals and corresponding interventions, and evaluates successful completion of the goals; revising the plan-of-care as necessary.[7] The CCN physical assessment includes but is not limited to:

Neurological Assessment

Level of consciousness
Speech
Motor function
Pupillary function
Glascow Coma Scale
Respiratory patterns
Any changes in mental status
Maintenance of chemical paralysis

Cardiovascular Assessment

Pulses and capillary refill
Jugular venous distention
Pacemaker settings and function
Presence of edema
Heart rate and rhythm
Blood pressure
Heart sounds

Pulmonary Assessment

Respiratory pattern/effort
Breath sounds
Secretions
Ventilator/noninvasive ventilation
Chest tube data including air leaks/drainage
Airway including tracheostomies or endotracheal tubes

Gastrointestinal Assessment

Bowel sounds
GI tubes including location and drainage
Presence or absence of bleeding
Nutrition including weight, diet, signs of wasting

Renal Assessment

Edema
Weight
Intake and output
Dialysis access

Patient Safety

Risk for fall
Need for restraints

Skin Integrity Assessment

Presence of pressure wounds/staging
Need for specialty bed
Presence of abnormalities – rash, abrasions, other injuries

Pain Assessment (In Conscious and Unconscious Patients)

Source of pain
Intensity (using the 1–10 scale, greater than 4 requires intervention)
Indicators of pain – physiologic or behavioral
Effect of pain intervention

Psychosocial Assessment

Patient/family's response to stress
Social support

Patient's ability to get sleep
Confusion/agitation – need for sedation
Patient's environmental influences
Spiritual needs
Adjustment to illness
Adjustment to functional decline, self care deficits, and body image changes can delay or prevent a patient's return to a preillness state.

Nursing care plans and goals should intergrate the treatment plan and reflect the multidisciplinary approach to the patients management.

Documentation of the physical assessment, data derived from patient monitoring, patient and family education, and the plan-of-care, has traditionally been done using a critical flow sheet.

Critical care nursing documentation in a flow sheet format provides access to information in a standardized manner and allows for rapid communication among team members. Additionally, assessment parameters can be organized on the form to communicate standards-of-care, facilitate the nursing process, and save nursing time. The structure of a flow sheet format results in standardized documentation that simplifies quality assurance review and eliminates duplicate documentation. Nursing staff members comment on how easy charting is when the standards for documentation are clear and consistent.[8]

Increasingly, hospitals are moving to electronic medical records (EMR). Paper charts have multiple problems including illegible handwriting, inaccessibility, and misfiled or lost records. Some of the potential benefits to an EMR include improved information access, better ability to manage and store data, improved and legible documentation, reduction in medication errors, and support for clinical research. These improvements in information access will ultimately lead to improved patient care.

Prevention of Nosocomial Disorders in the ICU Patient

The literature has repeatedly documented that meticulous nursing care, in association with strict adherence to clinical practice guidelines, leads to improved patient outcomes.[9] All patients admitted to the ICU must have prophylactic strategies implemented, in accordance with current practice guidelines, to prevent or decrease the incidence of the following common complications:

Deep Vein Thrombosis (DVT)

Nurses must assess patients' mobility status and assess the risk of developing a DVT. Patients requiring admission to the ICU are at risk for developing DVT secondary to prolonged bed rest related to critical illnesses and the monitoring required to manage the patient's care, which also contributes to limited mobility. The decision to institute pharmacological or mechanical measures to prevent the development of a DVT should be initiated based on the patients' level of mobility and sensitization to pharmacological agents used for prophylaxis. Nurses should be aware that even low-dose heparin may cause platelet dysfunction in the sensitive patient. Contraindications to anticoagulant therapy include:

- Active bleeding
- Cerebral vascular hemorrhage
- Platelet dysfunction or bleeding disorder
- Allergy to heparin
- Patients who are at high risk for falls
- Noncompliance

Patients recovering from recent surgical procedures respond well to the application of inflatable compression devices; these should be implemented in the operating room, prior to surgery and continued into the postoperative period.

Skin Breakdown

Immobility, impaired nutritional intake, and exposure to moisture and medications contribute to skin breakdown in the critically ill patient. Nurses have an excellent opportunity to examine the patient's skin while delivering routine nursing care. Subtle changes that may progress to the development of skin breakdown can be noted by nurses and timely intervention may prevent decubitus ulcers from forming. The nurse must assess the patient's severity-of-illness and if a specialized bed is warranted. Specialty bed manufacturers offer numerous choices, for a variety of patient needs. Most specialty beds have low pressure air mattresses that evenly distribute, and therefore minimize, pressure to the dependent portions of the patient's body; air circulation promotes drying. These beds may have additional features such as rotation & percussion, chair positioning, and the ability to place the patient safely in a prone position. Low air loss, such as Clinitron therapy and water beds may be used with burn and skin-grafted patients. However, the time-tested approach of turning and repositioning the immobilized person every 2 hours, in conjunction with massaging pressure points to reestablish circulation, are still effective interventions to prevent skin breakdown. Consultation with specialized wound care nurses to ascertain which specialty bed is appropriate should occur as soon as the patient is determined to be at risk.

Infection Control

Development of nosocomial infections in the hospital has generated a great deal of concern from the healthcare industry, public health organizations, insurance companies, and patient rights organizations. The reasons for an increased incidence of nosocomial infections are varied but include:

- Rapidly growing population with increased crowding
- Impaired immunity secondary to advancing age
- Pathogen adaptation and drug resistance
- Over use of antibiotics
- Improper infection control and hand sanitation

Infections are more likely to be acquired in an ICU than on a general medical floor because of the increased use of invasive monitoring lines, indwelling catheters, and an impaired immune response secondary to critical illness. Common sites for nosocomial infections include surgical wounds, the urinary tract, and the lower respiratory tract. Despite the prevalence of invasive catheters and higher risk factors in the ICU, there are proactive steps that the multidisciplinary team can implement to decrease the likelihood of infection. Since nurses are a constant presence at the bedside, they should ensure that:

- All hospital personnel wash hands with an approved rinse-less foam or gel, or soap and water before and after patient contact.
- Healthcare providers, dietary and housekeeping staff consistently utilize protective equipment.
- Strict adherence to isolation protocols, ensuring signage is prominently displayed and isolation carts are stocked and accessible.
- Negative pressure ventilation is maintained when appropriate.
- Disposable, single patient use equipment is utilized
- Thorough cleaning of all nondisposable equipment with an antimicrobial solution is provided.
- Room cleanliness between patients including terminal cleaning in rooms that have housed patients with resistant organisms is assured.

An important part of nursing advocacy is to assure that the above is followed consistently by all members of the healthcare team. It is a daunting task to remind clinicians in authority to wash hands, wear protective clothing, or note that sterility has been broken during a procedure; however, as a patient advocate, the nurse should not ignore breeches in protocol.[10]

Moreover, nurses are responsible to assure that best care practices are consistently implemented. They will be held accountable for known lapses in protocol.

Patient Safety

The CCN plays an important role in assuring patient safety. A patient safety practice has been defined as "a type of process or structure whose application reduces the probability of adverse events resulting from exposure to the health care system across a range of diseases and procedures; in other words, practices that make health care safer."[11]

To improve care, the primacy of patient safety must be enhanced through training, an administration that supports a culture of safety, and by making clinical systems function efficiently while providing redundant safety measures. A culture of safety has been described as "how the organization behaves when no one is watching." Institutional systems' policies and procedures depend upon the actions of individuals and groups for their successful implementation. The successful and safe execution of a procedure requires the actions of properly trained individuals who understand the importance of the underlying intent, accept their responsibility for the task, and appreciate that taking a potentially unsafe shortcut would be wrong.

The values of the group help shape the beliefs and attitudes of the individual, which in turn, play a significant role in determining individual behaviors.[12]

Patient safety is every healthcare team member's business and priority. Knowing and understanding The Joint Commission's National Patient Safety Goals (NPSG) are just one step in achieving a culture of safety that makes healthcare safer for a patient. The 2009 NPSG as defined by the Joint Commission are:

- Improve the accuracy of patient identification.
- Improve the effectiveness of communication among caregivers.
- Improve the safety of using medications.
- Reduce the risk of healthcare-associated infections.
- Accurately and completely reconcile medications across the continuum.
- Reduce the risk of patient harm resulting from falls.
- Encourage patients' active involvement in their own care as a patient safety strategy.
- Identify safety risks inherent in the patient population.
- Improve recognition and response to changes in a patient's condition.
- The organization meets the expectations of the Universal Protocol.

Understanding the policy on patient-restraints, being trained to correctly insert a central line, practicing universal precautions correctly, performing a time-out prior to an invasive procedure, clear and concise communication, and checking that the correct medication with the correct dosage has been ordered are all examples of patient safety issues.

Another example of how the CCN advocates for patient safety is during transport (See Chapter 14 on Transport of the critically ill patient). Transportation of critically ill patients is always challenging and the nurse must relate to the ordering physicians the practicality of moving an unstable patient. Often the risk vs. benefit ratio does not favor transport. Too often, in the quest to determine the cause of the disease, unreasonable expectations are created. Certainly, diagnostic testing is necessary for making an appropriate diagnosis, but a nurse's responsibility is to assure that the patient does not assume unreasonable risk in the process. For example, the patient with severe ARDS will often desaturate during minimal exertion such as turning or suctioning; transporting such a patient safely may not be possible. CCNs are responsible for discussing their observations and concerns with the ordering physician. Often, there are alternative bedside options to the planned test or procedure, or transport may be delayed until later in the hospital course.

Inadequate pain management leads to increased morbidity and mortality as well as prolonged length of stay. Utilization of pain scales which consider objective and observational data as well as the patients perceived level of pain will guide appropriate pain relief measures.

Pain Management

Unrelieved pain in the ICU can significantly impact patient satisfaction, morbidity and mortality, and length of stay. Despite advances in assessment through Face, Legs, Activity, Cry, Consolability (FLACC) scales, pharmacologic advances, and overall education of healthcare

providers, patients continue to have avoidable pain in ICU settings.[13] The primary cause is that pain is a subjective and variable individualized response that can be difficult to assess in the nonverbal, critically ill patient. However, it is also true that clinicians have been inappropriately concerned with the potent, addictive nature of opioids and have undermedicated moderate-to-severe pain. The Joint Commission in Healthcare has established guidelines for pain management with the goal of eliminating all preventable pain. CCNs are required to assess for the presence of pain and evaluate treatment at frequent intervals. Nurses are skilled in the verbal and nonverbal signals of distress in patients that may be unable to articulate pain. Nurses utilize FLACC scales; assess increased guarding, heart and respiratory rates, diaphoresis, and facial grimacing in minimally responsive or intubated patients. Nurses also attempt to decrease pain using alternative pain relief measures such as body positioning, thermal pads, massage, and relaxation techniques. When appropriate, pain management physicians are consulted.

End of Life/Bereavement

Facing end-of-life decisions is daunting and can be overwhelming for the patient and family. The CCN is integral to this process. The CCN, as well as other healthcare providers "play a critical role in shaping the experience at the end-of-life."

"The results of this survey suggest that for patients and families, physical care is expectedly crucial, but is only one component of total care. Whereas physicians tend to focus on physical aspects, patients and families tend to view the end of life with broader psychosocial and spiritual meaning, shaped by a lifetime of experiences. While physicians' biomedical focus is a natural outgrowth of medical care that emphasizes the physical self, physicians should recognize patients' other needs and facilitate means for them to be addressed. Physicians should also recognize that there is no one definition of a good death. Quality care at the end of life is highly individualized and should be achieved through a process of shared decision-making and clear communication that acknowledges the values and preferences of patients and their families."[14]

The end-of-life process should always be centered on directives the patient has specified after adequate information has been given about the options for care. The goals of the process should strive for dignity, comfort, and respect for physical, psychological, and spiritual needs.

As the patient approaches end of life, the CCN assesses for the presence of an advance directive and/or DNR orders. The CCN will communicate regularly with the patient family to answer questions and facilitate communication with other members of the healthcare team. The goal is for the decision-making process to be focused on the patient and the patient's family. Throughout the end-of-life process, the CCN works to ensure that the patient and family's emotional, spiritual, and practical needs are acknowledged and, if possible, met. The CCN collaborates with the healthcare team to provide for symptom management and comfort care.

Ethics

The American Nurses Association provides the source of ethical guidance for the nursing profession. The 9 provisions are:

1. The nurse, in all professional relationships, practices with compassion and respect for the inherent dignity, worth, and uniqueness of every individual, unrestricted by considerations of social or economic status, personal attributes, or the nature of health problems.
2. The nurse's primary commitment is to the patient, whether an individual, family, group, or community.
3. The nurse promotes, advocates for, and strives to protect the health, safety, and rights of the patient.
4. The nurse is responsible and accountable for individual nursing practice and determines the appropriate delegation of tasks consistent with the nurse's obligation to provide optimum patient care.
5. The nurse owes the same duties to self as to others, including the responsibility to preserve integrity and safety, to maintain competence, and to continue personal and professional growth.
6. The nurse participates in establishing, maintaining, and improving healthcare environments and conditions of employment conducive to the provision of quality health care and consistent with the values of the profession through individual and collective effort.

7. The nurse participates in the advancement of the profession through contributions to practice, education, administration, and knowledge development.
8. The nurse collaborates with other health professionals and the public in promoting community, national, and international efforts to meet health needs.
9. The profession of nursing, as represented by associations and other members, is responsible for articulating nursing values, for maintaining the integrity of the profession and its practice, and for shaping social policy.

SUMMARY

The CCN is a highly visible and respected member of a multidisciplinary healthcare team. CCNs, utilizing a specialized body of knowledge and skills, seek to create an environment supportive of healing for patients and their families. These nursing professionals practice in settings where patients require complex, high-intensity therapies and interventions, and continuous (often invasive) monitoring.

In the complex world of modern healthcare, the CCN also often collaborates with hospital and health system administrators, to ensure that appropriate policies and procedures are in place and consistently followed by all members of the healthcare team.

In addition to the high-tech armamentarium of the modern ICU, and the crucial management and administrative roles that many CCNs assume, the CCN also provides comfort and succor directly to the patient; this has always been the providence of the nursing professional. They are the individuals, who because of their close and ongoing presence at the bedside often are the first to notice new problems, or a change in the patient's status.

The CCN ´s role in the ICU is to manage the complex, rapidly changing, highly technical care required by the critically ill patient while principally advocating and protecting the patients´ rights and directives.

Finally, although the CCN has many roles and responsibilities, they are the first and foremost patient advocate. They respect and support the basic values, rights, and beliefs of the critically ill patient; in this role they serve not only the patient, but also the patient's family.

REVIEW QUESTIONS

1. **The CCN functions as a patient advocate in which of the following ways?**
   - **A.** Uses a holistic approach to the critically ill patient's problems and concerns
   - **B.** Utilizes evidence-based knowledge and experience in reacting to patient responses
   - **C.** Facilitates the protection, promotion, and optimization of the critically ill patient's health and abilities
   - **D.** All of the above

2. **One of the nurse's functions as part of the critical care team is to:**
   - **A.** Evaluate and communicate the patient's response to therapies
   - **B.** Recite vital signs
   - **C.** Diagnose complex metabolic disorders
   - **D.** The nurse does not need to be included in patient rounds

3. **The CCNs contribution to developing the interdisciplinary plan-of-care for the patient is based on all of the following except:**
   - **A.** An understanding of the pathology of the disease processes affecting the patient
   - **B.** Repetition of a consultant's recommendation
   - **C.** Review of patient's history and analysis of the patient's laboratory and diagnostic testing data.
   - **D.** Systematic physical examination

4. **Which of the following are 2009 NPSG?**
   - **A.** Improve the accuracy of patient identification
   - **B.** Improve the safety of using medications
   - **C.** Reduce the risk of healthcare-associated infections
   - **D.** All of the above

5. **Which of the following is the "time-tested" nursing intervention to prevent skin breakdown in the immobilized patient:**
   - **A.** Low air loss mattress therapy
   - **B.** Rotating bed
   - **C.** Repositioning patient every 2 hours
   - **D.** Application of protective skin gels

ANSWERS

1. D. The AACN defines advocacy as respecting and supporting the basic values, rights, and beliefs of the critically ill patient. In order to advocate for the critically ill patient, the CCN must utilize a comprehensive approach to coordinate the care of the patient and family, relying on knowledge and experience.
2. A. As a member of the critical care team, and the caregiver who interacts with a patient throughout their stay, the CCN is a valuable source of information regarding the minute to minute status of the patient's condition, and response to therapy. Documentation of clinical data is but one part of the process, as the CCN assists in assessing the patient to further reach the goal of treatment.
3. B. The CCN caring for acutely and critically ill patients has a responsibility to assess and analyze the level of care needed by the patient. The process involves assessing the needs of the patient, making realistic goals to achieve them, planning the interventions, assessing the results, and revising the plan as necessary.
4. D. The Joint Commission's NPSG are just one step in achieving a culture of safety that makes healthcare safer for a patient. Each individual healthcare facility has to achieve a safe environment by assuring that each of these goals is met. Specific policies are devised to achieve this goal. The CCN is responsible for implementing safe practices in areas such as restraints, medication administration, infection control, and fall prevention.
5. C. While there are many ways to prevent and treat skin breakdown such as gels, and low air loss mattresses, the simple procedure of turning a patient from side to side every 2 hours is effective in preventing decubiti. The challenge in the critical care environment is the patient's hemodynamic status which must be assessed before turning a patient. Patients who are critically ill may not be candidates for every 2 hours turning and other methods must then be utilized to prevent patient breakdown.

CHAPTER 14

SCOTT A. SCHARTEL AND ERNEST L. YEH

Transport of Critically Ill Patients

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter you should be able to do the following:

Interhospital patient transport

- Reasons for interhospital transport
- Legal requirements governing interhospital transport
- Methods of interhospital transport
- Logistics of interhospital transport

Intrahospital patient transport

- Reasons for intrahospital transport
- Risks and complications during intrahospital transport
- Logistics of intrahospital transport
- Avoiding complications during intrahospital transport
- Equipment needs and guidelines for intrahospital transport
- Critical care during intrahospital transport

INTRODUCTION

Transport of critically ill patients from one location to another is a common occurrence in modern medical practice. This transport can be interhospital, moving patients between hospitals or from the community to a hospital; or intrahospital, moving patients from one location in a hospital to another location within the same hospital. Examples of interhospital transport include the transport of an injured patient from the scene of an accident to a hospital, and the transport of a critically ill patient from one hospital to another in order to receive specialized treatment. Examples of intrahospital transport include the transfer of a patient from a critical care unit to the radiology department, and the transfer of a patient in cardiogenic shock from the emergency department to the cardiac catheterization laboratory. Critically ill patients who require transport, both interhospital and intrahospital, present challenges related to the complexity of their medical management. Their need for advanced monitoring, vasoactive drug infusions, mechanical ventilation, mechanical circulatory support, and the possible need for active intervention and resuscitation complicate this process. This chapter will address issues that are critical to safe interhospital and intrahospital transport of patients.

CASE STUDY: PART 1

GW, a 55-year-old-male with severe COPD, was admitted to the intensive care unit of General Community Hospital because of respiratory failure. He has a history of multiple prior ICU admissions related to his chronic lung disease. During the current admission, he required tracheal intubation and mechanical ventilation. In the preceding 24 h, he has developed a ventilator-associated pneumonia and sepsis requiring infusion of dopamine and norepinephrine to maintain a mean arterial pressure of 60 mmHg. His primary physician contacts the director of critical care at Tertiary Care University Hospital to discuss transferring the patient to that hospital. In addition to an advanced respiratory intensive care unit, Tertiary Care Hospital has a chronic ventilator rehabilitation unit and a lung transplant program, resources not available at the community hospital.

INTERHOSPITAL TRANSPORT

Most interhospital transports involve ground transport teams, but long distance transport may involve rotor or fixed-wing aircraft.

Interfacility transport of patients may be necessary for a variety of reasons including patient preference, specialty center referral, and health system/managed care organization repatriation. The vast majority of transfers use ground transport teams. Long distance transfers may require air medical services including rotor wing and fixed-wing aircraft. Considerations for the mode of transport include logistics of distance and geography, medical crew configuration, and specialty equipment requirements.

State regulations define the scope of practice and establish licensing and certification levels for clinicians who provide medical care in the out-of-hospital environment.

Emergency medical service (EMS) systems are typically established to provide prehospital care to patients who require rapid assessment and treatment prior to arrival at a healthcare facility. EMS is generally accessed via a public safety answering point (PSAP) such as the 911 systems. Some 911 EMS systems participate in interfacility transports, whereas others cannot provide interfacility transport services because of local statutes. In these areas, interfacility transport is usually provided by private agencies. There are state regulations that define the scope of practice and establish the licensing and certification levels for clinicians who provide medical care in the out-of-hospital environment.[1] There are state and regional variations in these requirements.

BLS crews use an EMT and a driver. ALS crews have a paramedic and an EMT or driver. SCT crews usually include a paramedic and a registered nurse and may include other specialized personnel.

Crew configurations include basic life support (BLS), advanced life support (ALS), and specialty care transport (SCT), also called mobile intensive care units or critical care transport. BLS crews are typically comprised of an emergency medical technician (EMT) and a driver. Since EMTs are trained in basic first aid and CPR, these crews can provide basic care including vital sign monitoring, wound care, fracture immobilization, and administration of oxygen. BLS crews are used for stable patients who should not require any critical interventions en route. ALS crews are staffed with a paramedic and an EMT or driver. Paramedics are capable of providing more advanced care, including advanced airway management (e.g., tracheal intubation), intravenous medication and infusion administration, and cardiac monitoring. The medications and infusions paramedics may administer and the procedures they are permitted to perform vary between states. Not all states allow for medication-assisted intubation and rapid sequence intubation by paramedics. SCT crews usually include a paramedic and a registered nurse. These crews allow for a wider range of medication administration, treatment options, and monitoring capabilities. Again, there is state-to-state variation in the scope of practice for both paramedics and nurses. Additional personnel, such as respiratory therapists, cardiovascular perfusion technicians, and physicians, may be needed to augment the capabilities of the transport team.

Pediatric and neonatal transport teams are among the most common type of specialized transport teams.

Tertiary care hospitals frequently have specialized transport teams that provide advanced transport capabilities. One of the most common specialized teams is the pediatric transport team. These teams are a mix of paramedics, nurses, respiratory therapists, and physicians who provide significantly higher levels of care than the typical interfacility transport team.[2] Neonatal retrieval teams are another type of highly specialized transport team. These teams transport critically ill neonates who may require isolettes, specialized ventilators, and an accompanying neonatologist. The level of care required during a transport should dictate the modes of transport and medical crew configuration.[3] Figure 14-1 presents an algorithm for organizing interhospital transport developed by the American College of Critical Care Medicine (ACCCM).

Alliances between community hospitals and tertiary care centers allow the initial diagnosis and stabilization of critically ill patients in the community hospital setting. These patients are then transported to the affiliated tertiary care center for advanced diagnostic procedures and treatment. An example of this includes the patient with severe cardiac disease who undergoes

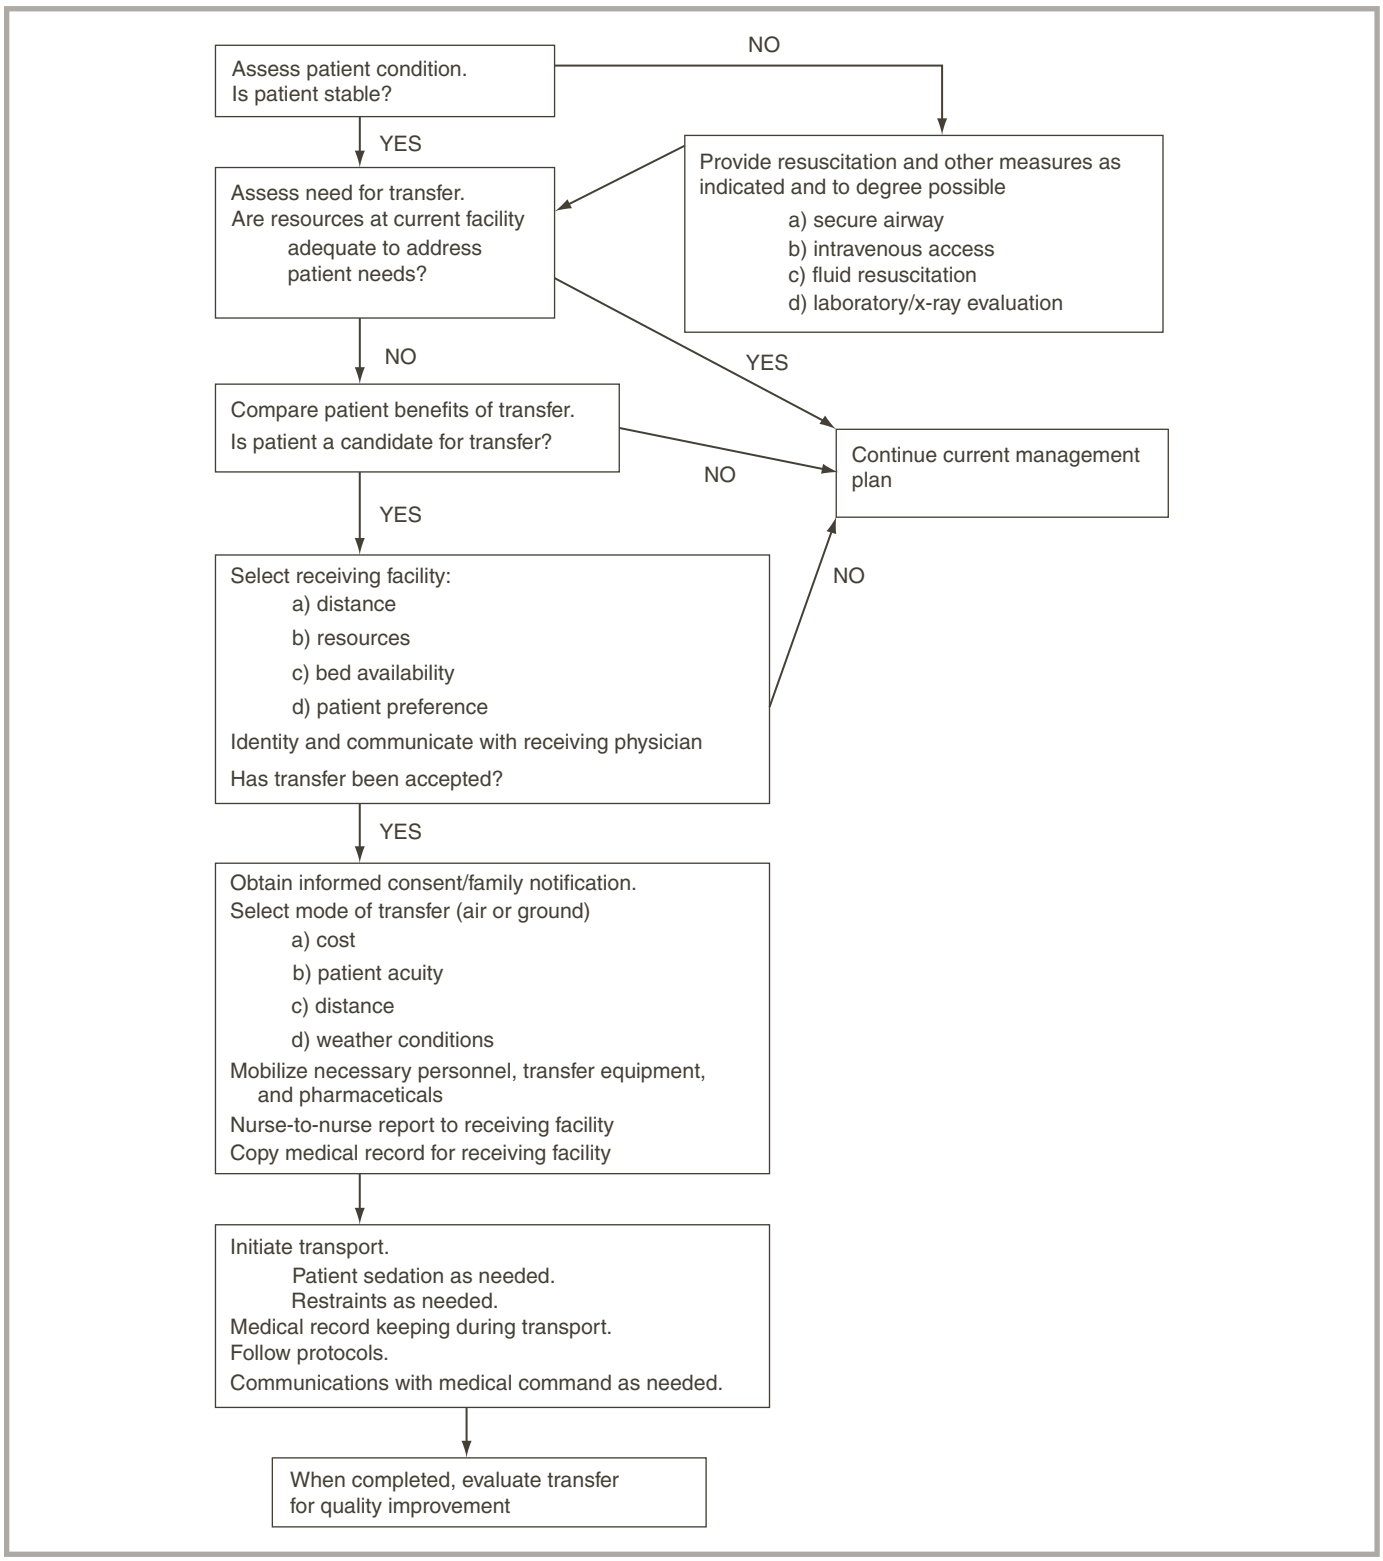

FIGURE 14-1

Interhospital transport algorithm (adapted from Warren et al,[21] with permission from Lippincott, Williams & Wilkins).

initial treatment and stabilization for acute myocardial infarction at a community hospital. If the patient develops severe decompensated heart failure and requires intra-aortic balloon counterpulsation or ventricular assist device therapy, a highly specialized transport team will be needed to transport the patient to the tertiary care center. The logistics of transfer include determining what equipment is needed for the transfer and the type and size of the vehicle needed. This determination must take into account the amount of space required for the equipment and the medical crew and electrical power required for the equipment. Ground transports are primarily used for short distances and for longer distances when air transport is unavailable due to weather restrictions or lack of appropriate landing zones. Air transports pose unique problems related to temperature and atmospheric pressure changes, which may affect patient physiology, as well as equipment performance. It is important to verify with the interfacility transport agency that the crew is capable of providing the level of care the patient requires en route.

Interfacility transfer of patients must meet the requirements of the EMTALA.

Interfacility transfer of patients must meet the requirements of the Emergency Medical Treatment and Active Labor Act (EMTALA).[4] Patients should be assessed, treated, and stabilized to the capabilities of the transferring facility. Unstable patients should be transferred to another facility only when the transferring facility is incapable of providing the necessary care and the receiving facility is capable of providing it. Appropriate referral and acceptance, with physician to physician (or designees) discussion prior to transfer, are also required. It is the sending physician's responsibility to ensure that the appropriate level of care and appropriate means of transportation are used for transfer.[5-7] A complete copy of the patient's record, including the results of laboratory tests, other diagnostic tests, and copies of diagnostic images, must accompany the patient during the transfer. Table 14-1 provides a checklist for organizing interhospital patient transport.

TABLE 14-1

CHECKLIST FOR INTERHOSPITAL TRANSPORT OF CRITICALLY ILL PATIENTS

CHECKLIST ITEM	EXAMPLES	NOTES
Reason for transfer	Patient request/preference	Continuity of care/primary physician
	Necessary medical services not available at current facility	Tertiary care center referrals (trauma center, obstetrics, critical care services)
Patient stability	If unstable, have Emergency Medical Treatment And Active Labor Act (EMTALA) requirements been met?	Treatments, even if not definitive, must be provided prior to transfer of an unstable patient
	Have all available stabilizing treatments/measures been taken?	
	If stable, no further EMTALA obligations	Definition of stability not clearly defined although includes that the treating physician must determine that no material deterioration is likely to occur during transfer and/or that the medical benefits of transfer outweigh the risks of transfer
Patient consent	Patient or appropriate designee	Benefits and risk of transport must be explained and proper consent obtained
Transfer	Appropriate transport method/level of care	Responsibility of the transferring physician to determine the most appropriate means of transport including personnel and transport equipment
		The transferring hospital must send copies of all medical records related to the emergency medical condition. If the physician on call refuses or fails to assist in the patient's care, the physician's name and address must be documented on the medical records provided to the receiving facility
Receiving hospital obligation	Ensure that space and resources being requested are available	Hospitals with specialized capabilities are obligated to accept transfers if they have the capabilities to treat them. Medical care cannot be delayed by questions about methods of payment or insurance coverage

SOURCE: Adapted from National Highway Traffic Safety Administration. Guidelines for interfacilty patient transfer[5]

CASE STUDY: PART 2

GW was transported to the respiratory intensive care unit at Tertiary Care Hospital. Now, on his third hospital day he has developed abdominal distention associated with diffuse tenderness and diminished bowel sounds. The critical care physician consults a surgeon who recommends that the patient have an abdominal CT scan. The patient is ventilator dependent, has a multilumen central venous catheter, an interarterial catheter, and is receiving infusions of dopamine, norepinephrine, vasopressin, and lorazepam. He has a chest tube in the left hemithorax that was placed because of a pneumothorax.

INTRAHOSPITAL TRANSPORT

Intrahospital transport of critically ill patients is a frequent event in modern critical care medicine. Because of the complexity of the patients' diseases and treatments, these transports can be a period of significant risk for the patients. During the transport, it is necessary to maintain the same level of care and monitoring that was in place while the patient was in a stationary location, while simultaneously moving the patient through the hospital, often over long distances and involving one or more elevator trips.

During the transport, it is necessary to maintain the same level of care and monitoring that was in place while the patient was in a stationary location, while simultaneously moving the patient through the hospital, often over long distances and involving one or more elevator trips.

In 1975, Waddel[8] reported on the movement of critically ill hospitalized patients. During a 5-month period, there were 86 patient transports in a total of 55 patients in an ICU that specialized in the treatment of shock and respiratory failure. Clinical observations were made during the transport in 33 moves involving 20 of the most ill patients. Significant changes attributable to the move were seen in seven patients who were stable prior to the move. During the study period, one patient per month suffered respiratory collapse or death as a direct result of the transport. In a second part of this report, 70 postsurgical patients, 60 with stable vital signs prior to transport, were observed during and after return to the ward. These patients showed stability during and after the transport with only five patients having limited changes in heart rate or blood pressure.

Insel et al[9] studied cardiovascular changes in 37 patients transported to an ICU following major general or vascular surgery, cardiac surgery, and carotid endarterectomy. They also studied 11 ICU patients who were transported from the ICU for diagnostic or therapeutic procedures. They found significant changes in the heart rate or blood pressure only in those patients who had undergone general or vascular surgery or carotid endarterectomy. This was attributed to the emergence from inhalational anesthesia during the period of transport. One cardiac surgery patient had an episode of ventricular fibrillation within 3 min of movement from the operating room table to the ICU bed. This was treated with electrical defibrillation and the patient remained stable thereafter. There were no complications or need for interventions in the ICU patients who were transported.

In an effort to evaluate the risk, cost, and benefit of transporting critically ill patients for diagnostic studies, Indeck et al[10] performed a prospective study of 103 consecutive transports in 56 patients. The average duration of the transport was 81 min and involved 3.3 people. Ninety-four patients were receiving mechanical ventilation, 26 had pulmonary artery catheters, and 26 had 3 or more infusion pumps. Sixty-eight percent of the patients experienced serious physiologic changes lasting 5 min or more. There were 113 serious changes that required an increase in support, with 31 patients having more than one serious change. Only 25 of the transports resulted in a change in management within 48 h of the move. Thus, there was a 76% chance that there would be no change in management as a result of the diagnostic study prompting the transport. The average cost of the transport was estimated to be $465.

Another group of investigators, Hurst et al,[11] also evaluated risks and costs during intrahospital transport of critically ill patients. This prospective study included 100 surgery/trauma patients and a matched-control group of patients in the same ICU. Physiologic changes of at least 5 min duration occurred in 66% of the transported patients and 60% of the control patients. During the transport period, arterial blood gases showed no differences in pH or $PaCO_2$, but an increase in PaO_2 was noted. The increase in oxygen level was

Physiologic changes occur frequently in critically ill patients during patient transport, but physiologic changes also occur with a similar frequency in control-matched patients who are stationary in an ICU.

attributed to the higher inspired oxygen concentration administered during the transport. The diagnostic studies for which the patients were transported resulted in changes in management in only 39% of the patients. Changes in management occurred most frequently as a result of transport for CT scan (51%) or angiography (57%). The estimated average cost to the hospital for the transport was $452. While transported patients had a large number of physiologic changes during the transport period, this did not significantly differ from the physiologic changes seen in matched-control patients who had not been transported during the same period.

The most common mishaps during transport are ECG lead disconnect, monitor power failure, a combination of the above, IV infiltration or disconnect, vasoactive drug disconnect, pulmonary artery catheter and central venous catheter mishaps, arterial catheter disconnect, and ventilator disconnect.

To characterize the frequency and type of mishaps during intrahospital transport of ICU patients, Smith et al[12] prospectively studied 125 transports. In this study, one-third of the patients had at least one mishap. Most of the affected patients had 1 mishap (23%), while a smaller number had 2 (9%) or 3 (2%) mishaps. Seventy-one percent of the mishaps occurred during trips for CT scans, which was the most common reason for patient transport (41% of total). In decreasing order of frequency the mishaps included the following: ECG lead disconnect, monitor power failure, a combination of the above, IV infiltration or disconnect, vasoactive drug disconnect, pulmonary artery catheter and central venous catheter mishaps, arterial catheter disconnect, and ventilator disconnect. Seventy-five percent of the mishaps occurred at the diagnostic testing site, with the majority occurring before or during the procedure. There was no correlation between mishaps and the number of invasive catheters, other types of physiologic support, or monitoring modalities. The patients' conditions on return to the ICU were unchanged in 76% and worse in 24% of patients.

A prospective cohort-matched study involving 175 patients transported from an ICU for diagnostic testing or operative intervention was conducted by Szem et al.[13] Patients in this study were divided into high-risk and low-risk groups. The mortality rate for all transported patients was higher than that for matched-control patients who were not transported. While this difference was statistically significant, the mortality rate for the low-risk patients was not significantly different from their matched controls. Additionally, while the mortality rate for high-risk patients was significantly higher than their matched controls, it was not statistically higher than their predicted mortality. No mortality was the direct result of the transport. The patients in the transport group had ICU stays that were 3 times longer than the control patients.

Hypotension, hypertension, tachycardia, and oxy-hemoglobin desaturation are among the most common patient-related events during transport.

In an audit of 97 intrahospital transports, Lovell et al[14] found that some difficulty or complication occurred during 62% of transports. Thirty-one percent were patient related, 45% were equipment or transport environment related, and 15% had problems in both areas. Among the most common patient-related events were hypotension, hypertension, tachycardia, and oxy-hemoglobin desaturation. The most common equipment-related problems included difficulty in pushing IV poles, difficulty in seeing monitors, ventilator disconnection, intravenous line disconnection, difficulty reaching intravenous lines, monitor battery failure, monitor interference or poor tracings, and infusion medications running-out without readily available replacements.

Physiologic derangements during transport of head-injured patients can result in secondary insults that worsen outcome.

It is recognized that patients with head injury who suffer secondary insults after the primary injury are at risk for poorer outcomes. To evaluate the risk for secondary insults during transport, Andrews et al[15] prospectively studied a group of head-injured patients. Physiologic data was collected from 4 h before until 4 h after patient transport. Hypertension, hypotension, increased intracranial pressure (ICP), decreased cerebral perfusion pressure, hypoxia, decreased jugular venous bulb saturation, increased temperature, bradycardia, and tachycardia were some of the conditions that required evaluation and treatment. Insults were characterized and graded by severity. The number of insults during transport correlated significantly with the number and duration of insults before and after the move. A correlation was seen between the injury severity score and posttransfer insults, with the highest injury severity scores being associated with the greatest increases in insult frequency. Insults occurred in a greater proportion of patients following transport from the emergency department than from the ICU. All patients who had an increase in ICP during transport had had an elevated ICP at least once before the transport. Treatment of ICP within 2 h prior to the transport decreased the occurrence of increased ICP during or after transport. The authors speculated that the instability seen following patient transport might be related to inadequate therapy during the period of the transport.

CASE STUDY: PART 3

During transport to the CT scanner GW becomes hypotensive. The nurse caring for him discovers that the norepinephrine infusion has become disconnected. While the nurse is reconnecting the infusion the patient's oxygen saturation decreases to 88% and he develops atrial fibrillation with a ventricular response of 142 beats/min.

In a small prospective study[16], an increased ICP was noted in neurosurgical intensive care unit patients during transport for CT scan. The highest ICP values occurred during the scan. The authors speculate that the supine position during the scan contributed to this change. All patients were mechanically ventilated and were receiving continuous infusions of propofol, fentanyl, and vecuronium during the study period.

An association between patient transport and an increase in VAP has been observed.

Patient transport from an intensive care unit has also been associated with an increased incidence of ventilator-associated pneumonia (VAP). Kollef et al[17] found that the risk of developing VAP was 24.2% in mechanically ventilated patients who had been transported from the ICU compared to a 4.4% risk in patients who had not been transported (relative risk 5.5, $p<0.001$). Multiple logistic regression analysis identified patient transport as an independent risk factor. The authors point out that the association between patient transport and an increase in VAP does not prove that the transport is the cause of the increase. Some other factor occurring during the transport may be the true cause (e.g., supine position, increased severity of illness in transported patients).

The above studies link intrahospital transport with potential risk(s) to patients, either by a worsening of the underlying disease process or because of mishaps that occur during transport. Physiologic changes may occur during the period of transport that are related to a patient's disease process rather than the transport itself. However, because of the additional complexity of moving a critically ill patient through the hospital, it is possible that less attention will be directed to the patient's management. And some treatments and interventions may need to be interrupted during the trip. As will be discussed later, planning, coordination, and adequate personnel are all important to ensure safe intrahospital patient transport.

AVOIDING COMPLICATIONS ASSOCIATED WITH THE TRANSPORT OF CRITICALLY ILL PATIENTS

Bedside CT scan and performance of some surgical procedures in the ICU can be alternatives to transport in selected patients.

Some authors have identified alternative patient care strategies that eliminate the need to transport patients from an ICU for diagnostic or therapeutic procedures. A portable CT scanner was found to be acceptable to physicians in an ICU, especially for patients with cardiovascular instability or those receiving extracorporeal support.[18] Other authors[19,20] have reported that performing surgical procedures in the ICU can be used as an alternative to moving critically ill patients to the operating room. The surgical procedures performed in the ICU included tracheostomy, percutaneous endoscopic gastrostomy, inferior vena cava filter placement, and laparotomies to remove or change packs, drain abscesses, and place jejunostomy tubes.

Before any patient transport, the physicians responsible for the patient's care must consider the risks, benefits, and alternatives to the transport.

Recognizing the risks that may be associated with the transport of critically ill patients within a hospital, it is essential for the physicians responsible for the patient's care to weigh the potential transport risks against the benefits likely to result from the transport. Alternative tests or procedures that can be performed at the bedside should be considered. This is especially important in patients requiring complex levels of ventilatory or hemodynamic support, mechanical circulatory support, renal replacement therapy, or who are unstable while stationary in the ICU. If it is concluded that bedside alternatives are not available, appropriate, or adequate for the patient, a careful plan is necessary to ensure a safe transport.

In 2004, the ACCCM and the Society of Critical Care Medicine (SCCM) developed guidelines for the transport of critically ill patients.[21] These guidelines were based on a

review of the available medical literature and expert opinion. The recommendations in the intrahospital section are largely based on nonrandomized investigations, review articles, editorials, case series, and expert opinion. Table 14-2 provides a summary of the guidelines. The Australasian College for Emergency Medicine, Australian and New Zealand College of Anaesthetists, and Joint Faculty of Intensive Care have also published minimum standards for intrahospital transport of critically ill patients;[22] these are summarized in Table 14-3.

Hospitals should have established protocols and guidelines governing the transport of critically ill patients. Everyone participating in patient transport must be adequately trained, not only in the bedside care of the patient, but also in the special requirements of the transport. As noted above, the transport must be justified. The physician responsible for the overall management of the patient must participate in making this judgment.

Coordination and planning are essential before any critically ill patient is transported.

Coordination and planning must occur to ensure that the personnel at the destination are immediately available to care for the patient upon arrival. The patient should not have to wait in a hallway or holding area prior to entering the testing or procedure room. Any equipment necessary to care for the patient at the destination (e.g., mechanical ventilator) should be immediately available. The ACCCM guidelines strongly recommend that a minimum of two health care providers accompany every critically ill patient. One of these providers will usually be a registered nurse; other providers can include respiratory therapists, critical care technicians, other registered nurses, and physicians. The guidelines also recommend that a physician with airway and ALS skills accompany unstable patients.

TABLE 14-2

SUMMARY OF ACCCM GUIDELINES FOR INTRAHOSPITAL TRANSPORT OF CRITICALLY ILL PATIENTS

Pretransport coordination and communication
If an alternative team will assume care for the patient at the destination, physician to physician and/or nurse to nurse hand-off communication occurs
Before transport the receiving location confirms immediate readiness for the patient
All personnel involved in transport are notified about the timing and equipment needed
Responsible physician is made aware
Documentation in medical record of the indication for transport and the patient status throughout the transport and time away from ICU
Accompanying personnel
A minimum of two people accompany a critically ill patient
One is usually a nurse, also respiratory therapist, second registered nurse, critical care technician
A physician with training in airway management and advanced cardiac life support and critical care training or equivalent, accompany unstable patients
Accompanying equipment
Blood pressure monitor (or standard blood pressure cuff), pulse oximeter, and a cardiac monitor/defibrillator accompany every patient without exception
Basic resuscitation drugs, including epinephrine and antiarrhythmic agents
More complete drugs should accompany or be available along the way and at the receiving location
Adequate supply of fluids and vasoactive or infusion medications regulated by battery operated pumps
All battery operated equipment is fully charged and capable of functioning for the duration of the transport
Bag-valve-ventilation usually used. Adequate supply of oxygen for the trip plus 30 min reserve supply
If a transport ventilator is used, it must have alarms to indicate disconnection and excessively high airway pressures and must have a backup battery power supply
Monitoring during transport
Critically ill patients receive the same level of basic physiologic monitoring during transport as they had in the intensive care unit
At a minimum, continuous electrocardiographic monitoring, continuous pulse oximetry, and periodic measurement of blood pressure, pulse rate, and respiratory rate

TABLE 14-3

AUSTRALASIAN GUIDELINES FOR INTRAHOSPITAL TRANSPORT OF CRITICALLY ILL PATIENTS

Protocol	A protocol for intrahospital transport of critically ill patients should be developed and disseminated. Transport must be justified weighing risks and benefits
Equipment	Equipment, must be able to pass through doorways and into elevators No equipment placed on patient ECG, heart rate, blood pressure, oxygen saturation for all patients Capnometer for all mechanically ventilated patients Infusion pumps Spare batteries Defibrillator and suction available Airway equipment, emergency drugs, sedatives, analgesics, muscle relaxants Procedure to ensure that all equipment are regularly checked
Staffing	Identify key personnel for each transport, at least an appropriately qualified nurse and physician and an orderly
Predeparture procedures	All equipment are available and checked, monitor alarms appropriately set, adequate drugs and fluids, spare batteries for all equipment, patient record, and necessary forms available
Patient status	Final check of patients and equipment. Anticipate the patient's clinical needs during transport, administer medications if necessary. Connected to all equipment, confirm appropriate function and alarm settings. Confirm that IVs and infusions are functioning properly
In-transit procedures	Plan best route. Secure or reserve elevators. Adequate communication must be available during transit and at destination. Patient checked periodically during transit
Arrival procedures	Check the equipment at destination if it will be used for the patient. Reassess the patient after connecting to the equipment at destination. Hand-over the report to the team at destination if they will assume care of the patient
Documentation	Clinical record should document the patient's status during transport
Quality assurance	Intrahospital transport of patients should be continually evaluated to identify system problems and suggest solutions

Australasian College for Emergency Medicine, Australian and New Zealand College of Anaesthetists and Joint Faculty of Intensive Care Medicine

SOURCE: Data from Emergency Medicine (Australasia).[22]

If the transporting personnel will continue to care for the patient at the destination, they must be familiar with the environment, the location of emergency equipment, resuscitation carts, phones, electrical, medical gas, and vacuum outlets. If personnel at the destination will assume care of the patient, a complete report should be given to those individuals, by the nurse or physician accompanying the patient. A standardized approach to patient hand-off, such as SBAR, should be used. Table 14-4 outlines the SBAR process. The receiving team should not accept the responsibility for care of the patient until they are satisfied that they fully understand the patient's conditions and needs.

Whenever there will be a transfer of patient care responsibility during the transport, there must be comprehensive hand-off communication between the providers relinquishing and those assuming the responsibility for the patient's care.

TABLE 14-4

SBAR HAND-OFF COMMUNICATION

Situation	Describe the reason why the patient is being transported
Background	Patient identity, medical history, allergies, pertinent physical findings and laboratory test results, medications and therapies, intravenous access and invasive monitoring, ventilator settings or oxygen therapy
Assessment	Summary of patients current clinical status (stable, unstable), readiness for transport, potential needs during transport and after arrival
Recommendations	What needs does the patient have during the trip or at the destination, what medications or treatments should the patient receive while in transit and at the destination, who should be contacted (and how) for problems during the transport period

CASE STUDY: PART 4

The results of the CT scan were inconclusive; however, over the subsequent 24 h, the patient's condition has continued to deteriorate and he has developed a metabolic acidosis and an elevated white blood cell count. He is receiving pressure-controlled ventilation with a drive pressure of 32 cm H_2O, PEEP 12.5 cm H_2O, respiratory rate 24, I:E ratio 1:1.5, and FiO_2 1.0. His oxygen saturation is 91%. The patient requires transport to the operating room for an exploratory laparotomy for suspected ischemic bowel.

EQUIPMENT REQUIRED FOR THE TRANSPORT OF CRITICALLY ILL PATIENTS

Electronic equipment used during patient transport should be small, light weight, and able to operate on battery power.

The next area to consider is equipment. Both the ACCCM and Australian guidelines delineate the equipment that is necessary for the transport of critically ill patients. The ACCCM guidelines recommend a blood pressure monitor (automated or standard cuff), pulse oximeter, and cardiac monitor/defibrillator. Basic resuscitation drugs (e.g., epinephrine and antiarrhythmics), adequate fluids, scheduled medications that will be due for administration during transport, and other medications dictated by the patient's condition must accompany the patient. There must be adequate amounts of continuous drug infusions for the duration of the trip. If the amount remaining in an infusion container is inadequate for the duration of the transport, it is prudent to replace the container with one that has an adequate amount. Alternatively, a replacement container can be taken along on the transport, but this will require changing the container during the transport, possibly at an inopportune time; this is a less desirable option. Allowances for delays during the transport should be factored into decisions regarding the amount of fluids, drugs, and infusions necessary for the trip. If emergency resuscitation supplies (code carts) are not located at the destination or along the way, those medications also need to accompany the patient. Patients with chest tubes and significant air leaks may require battery powered portable suction devices to maintain lung expansion.

All electronic equipment used during the transport (monitors, infusion pumps, transport ventilators) must be able to operate on battery power. If the equipment has batteries that can be exchanged, spare batteries are a reasonable safety precaution. Electronic equipment should be connected to electrical outlets at the destination to minimize the time the equipment is operating on battery power. This will also allow the devices to recharge prior to the return trip. Many hospital elevators have an electrical outlet that can be used in an emergency.

SMVDs are the most common method of maintaining mechanical ventilation during patient transport.

A full E cylinder of oxygen has a pressure of 1,900 psi and contains 660 L of oxygen. The amount of oxygen remaining in an oxygen cylinder is directly proportional to the pressure in the cylinder.

Patients receiving mechanical ventilation will usually be ventilated with a self-inflating manual ventilation device (SMVD). Some institutions may use a Jackson Rees or Mapleson-type manual ventilation device, especially in pediatric patients. A disadvantage of these devices is their inability to provide ventilation in the absence of an oxygen supply. A self-inflating device can administer room air if there is a failure of oxygen supply. For many critically ill patients, room air would provide an inadequate inspired oxygen concentration, but it still provides ventilation. An anesthesia or resuscitation mask must be available for use in the event of unintentional tracheal extubation. A manual ventilation device and mask are also necessary for patients whose tracheas are not intubated, in the event of apnea or cardiac arrest. The oxygen tank that accompanies the patient should have an adequate amount of oxygen for the predicted total duration of the transport and at least a 30-min additional supply, as a margin of safety. A full E cylinder of oxygen has a pressure of 1,900 psi and contains 660 L of oxygen. The amount of oxygen remaining in the cylinder is directly proportional to the pressure in the tank. At a flow rate of 10 L/min, a full E cylinder will provide oxygen for 66 min. If the pressure is 1,000 psi, then the amount of oxygen remaining is 1,000 psi/1,900 psi × 660 L, approximately 347 L. At a flow rate of 10 L/min, this would last for approximately 34 min. If the trip is long or the flow rates are high, it is prudent to take an extra cylinder of oxygen.

An alternative to manual ventilation is the use of a transport ventilator. A more detailed discussion of manual ventilation devices and mechanical transport ventilators can be found later in this chapter. If a transport ventilator is used, the ACCCM guidelines state that it must have alarms to indicate disconnection and high airway pressure and be able to operate on battery power.

The final section of the ACCCM guidelines discusses monitoring during transport. Patients should receive the same level of monitoring during the transport as they were receiving prior to the transport. This should include continuous electrocardiogram, continuous pulse oximetry, periodic or continuous arterial blood pressure, respiratory rate, and pulse rate. Pulmonary artery, central venous, and intracranial pressure monitoring should be continued if in use in the ICU. Portable monitors may impose limits on the number of parameters that can be monitored during transport. In this case, priority should be given to those parameters that are identified as most important based on the patient's condition. As technology advances, end-tidal carbon dioxide monitoring may become more available for use during transport. This may be beneficial in managing manual ventilation.

Monitoring during transport should include continuous electrocardiogram, continuous pulse oximetry, periodic or continuous arterial blood pressure, respiratory rate, and pulse rate.

In order to have a smooth and safe transport, it is essential to be well-organized. The authors believe that all equipment should be mounted on the ICU bed, if possible. IV poles attached at the head and foot of the bed allow infusion pumps and other equipment to be mounted on the bed. An effort should be made to eliminate the need to transport the patient with equipment mounted on rolling IV poles. Rolling IV poles increase the complexity of moving through the halls, around corners, into elevators, and through doorways. It may also increase the likelihood that an intravenous catheter will be pulled out or become disconnected due to an increased distance between the rolling IV pole and the bed; this can happen if the rolling pole encounters an obstruction while the bed continues to move. Controlling rolling IV poles may also distract care givers from watching the patient and monitors. When choosing infusion pumps small size and light weight are desirable features. This will make the pumps easier to transport and easier to attach to bed poles. Monitors may be attached to the side rails of the bed, bed poles, a shelf attached to the foot of the bed, or placed on the bed next to the patient. As with infusion pumps, portable monitors that have a small size and light weight are easier to use during transport.

Organization of monitors, infusion pumps, intravenous tubing, other tubes, lines, and drains contributes to smooth and safe transports.

Intravenous lines, drains, chest tubes, and monitoring lines should be organized before transport. While this is seen by some as merely an aesthetic suggestion, the ability to find various catheters, injection ports, and drains in a crisis situation is important for patient safety. Also, well-organized, clearly marked tubes, lines, and drains will decrease the likelihood of administration of a medication into an inappropriate line. In general, placing intravenous fluid containers on the same side of the bed as the catheter to which they are connected will decrease the amount of tangle in the lines. Electronic transducers must be located at an appropriate height to ensure that the pressures displayed are accurate. Specialized carriers for E cylinders are available that will mount into one of the bed's IV pole receptacles or hang on the foot board. Figure 14-2 shows a bed prepared for transport.

At the destination, if the patient needs to be moved from the ICU bed to a procedure table or gantry, it is essential that this be coordinated to ensure that the move will occur in a smooth and controlled manner. All intravenous tubing, other tubes, lines, and drains, must have an adequate length to prevent tension being placed on them during the patient-move.

Movement of the patient from a bed or stretcher to a procedure table requires coordination and care to ensure that tubes, lines, and drains are not unintentionally dislodged.

FIGURE 14-2

Photograph of an ICU bed ready for transport. Note that all equipment are attached to the bed.

One person, typically the person controlling the patient's head and airway, should coordinate the move. There needs to be a clear communication about when to move the patient and about each person's role during the move. Special transport sliding boards or rollers may make it easier to slide the patient from one location to another. When everyone is ready, a clear command from the person controlling the head and airway should initiate the move. For example, the leader may say, "on my count of three we move, one, two, three." After the patient has been moved, there should be confirmation that all tubes, lines, and drains remain intact and connected. For patients requiring mechanical ventilation, auscultation of the chest should be done to confirm correct endotracheal tube placement.

ESSENTIALS OF PROVIDING CARE TO THE CRITICALLY ILL PATIENTS DURING TRANSPORT

During the transport, while at the destination, and during the return trip to the ICU the patient's care must continue uninterrupted. Scheduled medications should be administered and treatment of physiologic changes should be instituted as appropriate. If a physician has not accompanied the patient, the nurse should have protocols for the treatment of problems that develop or have rapid phone access to the physician responsible for the patient's care. As noted in the studies cited at the beginning of this section, physiologic changes are common during transport. The process of moving an inadequately sedated patient may lead to hypertension and tachycardia. Inattention to volume administration may lead to hypotension. Careful preparation and planning make it possible to move very ill patients safely over long distances within the hospital.

Special Considerations for the Mechanically Ventilated Patients

For SMVDs, the delivered oxygen concentration may vary depending on the oxygen flow rate into the device, the respiratory rate, the size of the delivered tidal volume, and the presence and type of oxygen reservoir.

Oxygen reservoirs of the bag type tend to be more effective than corrugated tubing reservoirs.

Six of 16 SMVDs tested had a delivered oxygen concentration below 90% under at least one testing condition. Performance of devices should be considered when making purchasing decisions.

Use of a SMVD is the most common method of providing mechanical ventilation to patients during transport. These devices are usually disposable, can be connected to an oxygen source, and often have a built-in PEEP valve. A variety of investigations have demonstrated that the delivered oxygen concentration may vary depending on the oxygen flow rate into the device, the respiratory rate, the size of the delivered tidal volume, and the presence and type of oxygen reservoir. The delivered tidal volume is influenced by whether the device is compressed using one or two hands.

SMVDs are designed to reinflate automatically following compression. If they are connected to an oxygen source, the gas used for the reinflation will be a combination of oxygen and room air. The proportion of oxygen and room air will depend on the oxygen supply flow rate, the volume of gas needed for the reinflation, and the rate of reinflation. The addition of a reservoir that will accumulate oxygen between reinflations can decrease the amount of room air entrained during the reinflation. Two types of reservoirs are used: a reservoir bag or a length of corrugated tubing attached to the end of the SMVD.

Nam et al[23] conducted a laboratory study of the concentration of oxygen delivered by a SMVD at various oxygen flow rates, tidal volumes, and reservoir configurations. They demonstrated that the delivered oxygen concentration was lowest when the oxygen flow rate was low (5 L/min), tidal volume and respiratory rates were high, and there was no oxygen reservoir. The addition of a reservoir, either a bag or corrugated tubing, improved the delivered oxygen concentration. Without a reservoir, the delivered oxygen concentration was only 69% at an oxygen supply of 15 L/min and a tidal volume of 500 mL. A delivered oxygen concentration of at least 96% was achieved at an oxygen flow rate of 15 L/min with a 250-mL corrugated tubing reservoir, at 10 L/min with a 500-mL corrugated tubing reservoir, and at 7.5 L/min with a 1,600-mL reservoir bag. In general, reservoir bags are more effective than corrugated tubing reservoirs.

Mazzolini and Marshall[24] conducted a review of sixteen disposable SMVDs. They subjected the devices to a variety of bench tests, measuring the delivered oxygen concentration

and tidal volumes at two respiratory rates (12 and 20 breaths/min) and with one or two hand compression of the devices. Using one hand for compression, the tidal volumes ranged from 0.55 to 0.7 L, depending on the device. With two hands the tidal volumes ranged from 0.7 to 0.85 L. All devices tested passed a drop test for durability. PEEP valves were easily attached, without an adapter, in 14 devices. All except two of the tested devices were latex-free. Figure 14-3 shows the delivered oxygen concentration of the 16 devices under the four test conditions. Six of the devices had a delivered oxygen concentration below 90% under at least one of the test conditions. The ability of a SMVD to deliver an oxygen concentration close to 100% and to maintain PEEP is an important consideration when choosing devices.

The need for high inspired oxygen concentration, high levels of PEEP, large minute ventilation requirements, pressure control ventilation, inverse ratio ventilation and/or use of inhaled nitric oxide (INO) all add complexity to providing appropriate and safe ventilatory support during transport. For patients who have serious lung pathology, it is prudent to do a trial of the method of ventilatory support planned for the trip in the ICU. For example, if manual ventilation with a SMVD is planned, the patient should be connected to the device and manually ventilated for several minutes while observing the oxygen saturation. If the oxygen saturation decreases this method of transport ventilation will not be adequate. It may be possible to improve the delivered oxygen concentration for patients with a high oxygen requirement and a high minute ventilation by providing more than 15 L/min of oxygen supply to the SMVD. Most oxygen regulators for E cylinders will deliver a maximum of 15 L/min. However, by connecting the output of two cylinders to the SMVD up to 30 L/min oxygen flow can be provided. This can be done by using tubing and a Y-connector to link the flow from the two oxygen tanks. Figure 14-4 shows a picture of such a connection.

Gervais et al[25] measured arterial blood gases during the transport of a group of patients using three different modes of ventilation: SMVD, SMVD with measurement of the exhaled tidal volume, and a portable transport ventilator set with the same settings as the patients' ICU ventilators. They found that the patients who were managed with a standard SMVD or transport ventilator were hyperventilated. Those ventilated with a SMVD with monitoring of

Manual ventilation without monitoring the tidal volume tends to result in hyperventilation.

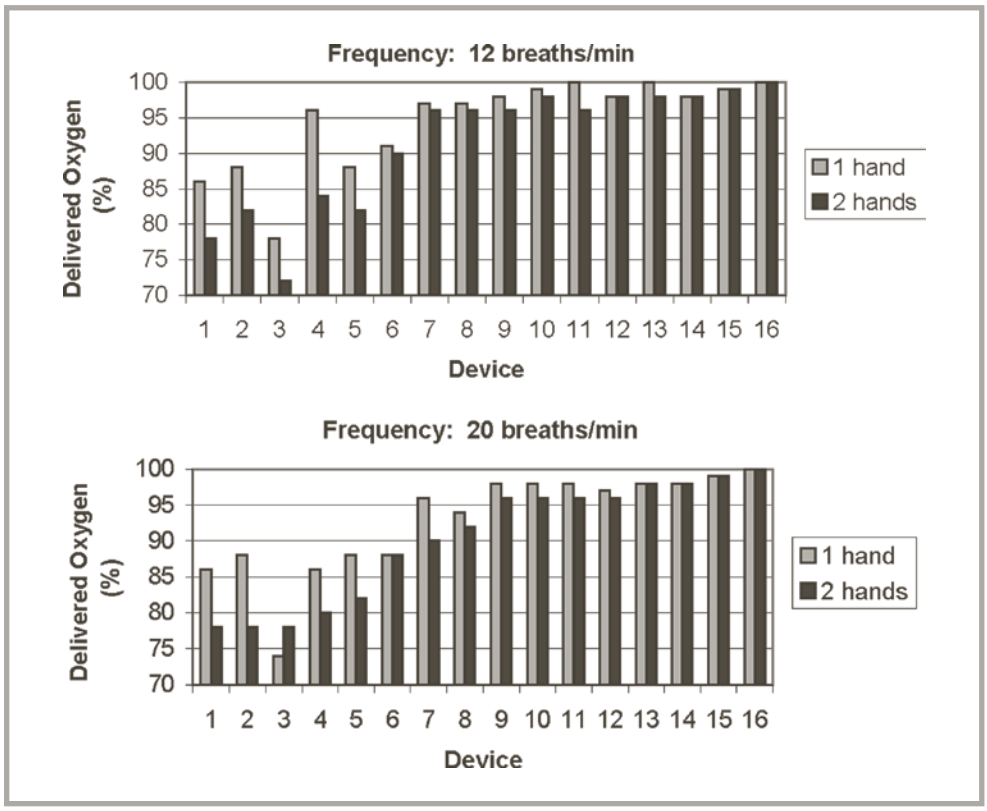

FIGURE 14-3

Comparison of oxygen delivery by self-inflating manual ventilation devices (SMVDs). Comparison of oxygen concentration delivered by 16 disposable manual resuscitation devices at respiratory frequencies of 12 or 20 breaths/min, using one or two hands to compress the device. Oxygen supply to each device was 15 L/min (data from Mazzolini et al[24]).

FIGURE 14-4

The oxygen flow from 2 E cylinders is combined using a Y-connector and tubing. This can provide flow rates up to 30 L/min.

the exhaled tidal volume had no significant change in arterial carbon dioxide. Weg and Haas[26] reported that there were no significant changes in pH or $PaCO_2$ between mechanical ventilation before and after transport and manual ventilation during transport in a group of twenty patients. They did note that some patients had small (not statistically significant) increases or decreases in $PaCO_2$ during the manual ventilation.

In 1995, Evans and Winslow[27] reported that 53% of critically ill, mechanically ventilated patients had clinically important changes in arterial oxygen saturation, heart rate, and/or systolic blood pressure during transport. SMVD ventilation was used during the transport. A decrease in SpO_2 of 5% or more occurred in 6 of 36 patients (17%). The maximum decrease in oxygen saturation was 16% (from 100 to 84%). They noted that five patients experienced a decrease in oxygen saturation at the test or procedure site.

Arterial blood gases were compared between ventilation with a SMVD or a transport ventilator by Hurst and associates.[28] In this study, patients were ventilated with one method on the outbound trip and the other method during the return trip. They found that arterial pH increased (7.39–7.51) and arterial $PaCO_2$ decreased (39–30 mmHg) with manual ventilation. There was no significant change with ventilation by the transport ventilator. Other investigators[29,30] have found fewer changes in pH or $PaCO_2$ with the use of transport ventilators compared to manual ventilation.

ECRI, an independent testing organization, has identified the following features as requirements for in-hospital transport ventilators: assist/control and SIMV volume breaths, CPAP and pressure support, PEEP, assist control and SIMV pressure breaths, adjustment of flow profile, volume monitoring, automatic breathing circuit compensation, and high-pressure oxygen supply inlet. In a recent publication,[31] ECRI reviewed currently available portable/transport ventilators. Of the nine devices reviewed, five were rated as "worth considering."

SUMMARY

Critically ill patients frequently require transport from one location to another. In preparing for interhospital transport, it is important to consider the distance to be traveled, the equipment required, and the personnel needed to care for the patient. State regulations govern the scope of practice of EMTs, paramedics, and nurses during interhospital transport. Interfacility

transfer of a patient is governed by the provisions of EMTALA, which require that patients be assessed, treated, and stabilized prior to transfer to another facility; the statute also requires that a hospital refrain from transferring unless the benefits of the transfer outweigh the risk to the patient. For specialized transport, a dedicated transport team may go to the transferring hospital and assume care for the patient during the transport.

Intrahospital transport of critically ill patients is a common occurrence, usually prompted by the need for diagnostic testing or interventional therapy that cannot be performed in the ICU. Numerous studies have documented the physiologic changes and problems that occur during transport in this patient population. Some of the physiologic changes that are seen may represent the underlying disease process and be unrelated to the transport itself. However, recognition and treatment of these changes is complicated by the transport environment. Intrahospital transport is a resource-intensive event, both in terms of equipment and personnel.

For both interhospital and intrahospital patient transport, it is essential to consider the risks, benefits, and alternatives to the transport. If this consideration supports the transport, careful planning and implementation of the plan by an experienced team will result in a safe trip for the patient.

REVIEW QUESTIONS

1. One of the most important considerations in interhospital transports is:
- **A.** Type of vehicle
- **B.** Insurance of patient
- **C.** Level of care required during transport
- **D.** Distance from referring to receiving hospital
- **E.** None of the above

2. Which of the following is correct?
- **A.** EMTs and paramedics have identical scope of practice
- **B.** All ambulances have nurses who can provide medical care en route
- **C.** There are national guidelines for scope of practice for EMTs and paramedics but each state has specific requirements and limitations that vary based on certification and licensure in each state
- **D.** ALS crews provide the highest level of care in an ambulance

3. Which of the following is correct?
- **A.** Unstable patients should never be transferred to another facility
- **B.** It is the sending physician's responsibility to ensure that appropriate level of care is provided during transport
- **C.** Only laboratory test results are required in the patient record
- **D.** EMTALA is the Emergency Medical Transfer and Licensure Authority
- **E.** Physician to physician communication can occur at any time after the patient has arrived at the receiving facility

4. Reasons for intrahospital transport of critically ill patients include:
- **A.** Need for CT scan
- **B.** Need for surgery
- **C.** Need for admission to critical care unit
- **D.** Need for arteriogram
- **E.** All of the above

5. The oxygen concentration delivered by a SMVD is influenced by:
- **A.** Oxygen flow rate
- **B.** Ventilation rate
- **C.** Type of reservoir
- **D.** Delivered tidal volume
- **E.** All of the above

6. The most frequent change in arterial blood gas parameters during patient transport with manual ventilation is:
- **A.** Decreased PaO_2
- **B.** Decreased pH
- **C.** Decreased $PaCO_2$
- **D.** Increased $PaCO_2$
- **E.** Decreased SaO_2

7. The first step in intrahospital patient transport is:
- **A.** Evaluating risks/benefits of transport
- **B.** Coordinating personnel
- **C.** Identifying availability of receiving location
- **D.** Obtaining informed consent for the procedure
- **E.** Connecting patient to portable monitoring equipment

8. An E cylinder of oxygen has a pressure of 800 psi. At a flow rate of 10 L/min approximately how long will the oxygen supply last:
- **A.** 15 min
- **B.** 25 min
- **C.** 35 min
- **D.** 45 min
- **E.** 65 min

ANSWERS

1. C. Level of care required during transport.
2. C. There are national guidelines for scope of practice for EMTs and paramedics but each state has specific requirements and limitations that vary based on certification and licensure in each state.
3. B. It is the sending physician's responsibility to ensure that appropriate level of care is provided during transport.
4. E. All of the above.
5. E. All of the above.
6. C. Decreased $PaCO_2$.
7. A. Evaluating risks/benefits of transport.
8. B. 25 min.

PART II

Pathophysiologic Disease States Encountered in the Critically Ill Patient

CHAPTER 15

GERARD J. CRINER

Respiratory Failure

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Define respiratory failure.
- Classify respiratory failure into hypoxemic or hypercapnic subtypes.
- Recognize the signs and symptoms of respiratory failure.
- Define the alveolar gas equation and apply it to evaluate respiratory failure.
- Recognize the changes in blood gases that accompany respiratory failure.
- Know the major treatment strategies for respiratory failure.

DEFINITION OF RESPIRATORY FAILURE

Respiratory failure affects all ages and varies markedly in presentation.

Despite the varied causes of respiratory failure, the pathophysiologic mechanisms and approach to the evaluation, diagnosis, and treatment are similar.

Respiratory failure is one of the most common and important entities treated by the critical care practitioner. Respiratory failure affects patients of all ages and can vary markedly in presentation. Episodes of respiratory failure may present as an acute crisis in a previously normal patient (e.g., the patient sustains a flail chest after a motor vehicle accident), or as an acute exacerbation of a chronic disorder (an exacerbation of chronic obstructive pulmonary disease [COPD]). Although the causes of respiratory failure are diverse, the pathophysiologic mechanisms and approaches used for the evaluation, diagnosis, and treatment of respiratory failure are very similar.[1]

CASE STUDY: PART 1

A 70-year-old-woman with a known history of mild COPD developed worsening shortness of breath during the past several days, following an upper respiratory tract infection. During the past 4 days, the patient complained of purulent nasal discharge, postnasal drip, cough, and fever. Recently, these symptoms had been complicated by the expectoration of thick, yellow mucus and increased shortness of breath. Her chronic airways obstruction had been well maintained by regular administration of inhaled long acting beta-agonists and anticholinergic bronchodilators, inhaled corticosteroids, use of supplemental oxygen at 1 L/min continuously, and intermittent courses of systemic steroids.

Today, the patient's breathlessness was worse upon awakening and she experienced shortness of breath that continued to worsen in severity throughout the day. She failed to respond to several bronchodilator treatments, and on examination was found to have a marked increase in the work of breathing, heralded by the use of accessory muscles of the neck and pectoral girdle, a respiratory rate of 38 breaths/min, and evidence of paradoxical inward motion of the upper abdomen during inspiration. She was transported from the outpatient pulmonary clinic to the emergency room for further evaluation and treatment.

- Respiration defines the processes by which gas exchange occurs between an organism and its surrounding environment.
- The function of the respiratory system is to supply the body's organ with adequate oxygen and to remove its metabolic waste product, carbon dioxide.
- Respiration is accomplished by three distinct processes: ventilation, diffusion, and circulation.
- The respiratory system functions both as a pump and as an area of gas exchange.

This chapter provides an organized overview of respiratory failure by (1) defining respiratory failure; (2) reviewing the pathophysiologic mechanisms responsible for its development, and (3) providing indications for the evaluation, diagnosis, and treatment of respiratory failure.

In general terms, respiration defines the process whereby gas exchange occurs between an organism and its surrounding environment. Specifically, the respiratory system supplies the body with adequate oxygen for aerobic metabolism while simultaneously removing its major metabolic waste product, carbon dioxide. Respiration is achieved through three distinct processes: (1) ventilation, the process by which ambient air is delivered to the alveoli where it is exposed to blood; (2) diffusion, the movement of oxygen and carbon dioxide in opposite directions across the alveolus and capillary walls; and (3) circulation, the process whereby oxygen is carried from the site of active gas exchange in the lung, via the blood to the body's organs where active cellular aerobic metabolism occurs.

To accomplish the task of respiration as defined above, the respiratory system must really provide two distinct physiological functions: (1) a pump function that provides effective ventilation and (2) a gas exchange function (Fig. 15-1).[2] Failure of the respiratory system to perform optimally, either in its pump or gas exchange functions may result either in an elevation of carbon dioxide (i.e., hypercapnia), or a reduction in blood oxygen content (i.e., hypoxemia). Both parameters, hypoxemia and hypercapnia, are considered as indices of respiratory

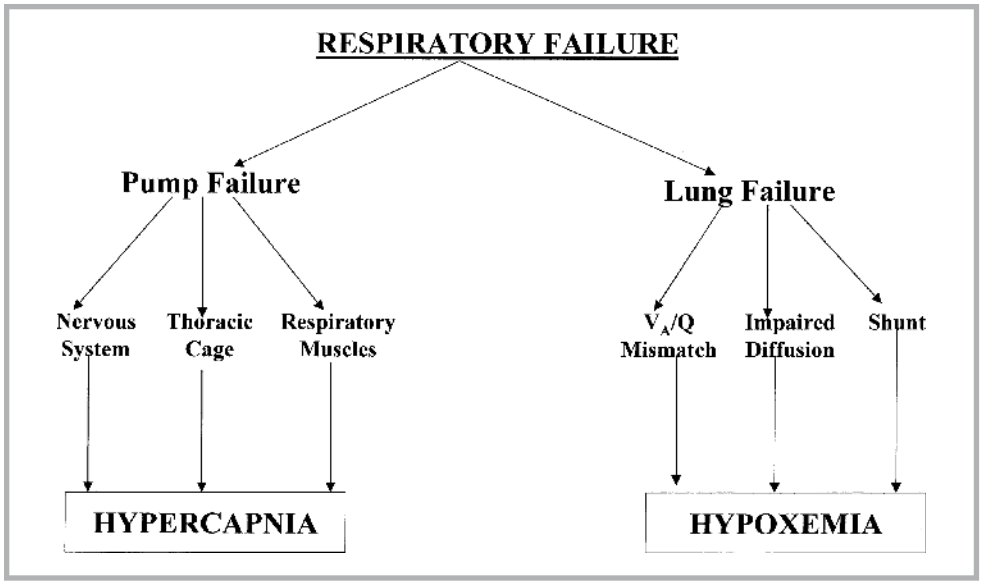

FIGURE 15-1

Characterization of respiratory failure as hypercapnic (i.e., pump failure) and hypoxemic (i.e., lung failure) subtypes. Pump failure results in hypercapnia; lung failure results in hypoxemia.

system failure. Therefore, respiratory failure is impaired gas exchange; that is, hypoxemia and/or hypercapnia.

Although it is helpful to characterize respiratory failure into the primary disorder that results in either pump or lung failure, it is important to recognize that patients who present with hypoxemic respiratory failure may also develop hypercapnia, or impaired pump function. However, characterization of the primary process causing respiratory failure into hypercapnic or hypoxemic subtypes remains useful as a tool to guide the clinician in determining the most important precipitating factor(s) and the most efficient and successful treatments.[2]

Pump failure indicates conditions that impair the bellows function of respiration. Even if a patient has normal lung function, a decrease in central respiratory drive, impaired peripheral nerve transmission to the respiratory muscles, or severe weakness of the respiratory muscles may result in an inability to exhale carbon dioxide and, if severe enough, may cause arterial hypoxemia.[3] Similarly, conditions that severely impair chest wall integrity, such as a flail chest or kyphoscoliosis, may impact the bellows function of respiration. On the other hand, lung failure occurs in conditions where the lung parenchyma is severely impaired and the neuromuscular and chest wall apparatus functions normally. In this scenario, abnormalities that affect the lung at the level of the alveolus, airway, lung interstitium, or pulmonary vasculature causes arterial hypoxemia severe enough to precipitate the development of respiratory failure.[4]

Although the function of the respiratory system can be easily subdivided into its pump and gas exchange components, the anatomic components that constitute the respiratory system are multiple and diverse in nature. Overall, the respiratory system is divided into seven distinct anatomic components: (1) the central nervous system; (2) the peripheral nervous system, including the spinal cord; (3) the neuromuscular system, including the myoneural junction and respiratory muscles; (4) the thorax and pleura; (5) the upper airways; (6) the cardiovascular system, including the red blood cells and hemoglobin, which carry oxygen and carbon dioxide; and (7) the lower airways, including the alveoli. Normal respiration is dependent on the optimum and integrated action of all these vital links, and malfunction of one or several of these components can lead to respiratory failure (Fig. 15-2). As one may expect, because of all the different components required for optimum respiration, the disease processes that can precipitate respiratory failure are also numerous and diverse in nature.

Separating the disorders that cause pump failure from those that precipitate lung failure is also a helpful method to characterize the many different disease processes that precipitate respiratory failure. Table 15-1 lists the pathophysiologic processes that cause primarily pump vs. lung failure.[4] In addition to classifying respiratory failure into its pump and lung failure subtypes, it is important to further subdivide respiratory failure into acute and chronic presentations (Table 15-2). In acute presentations of either hypoxemic or hypercapnic respiratory failure, the disease process occurs within minutes to hours, whereas in chronic conditions, respiratory failure ensues over several days or longer. Patients who present with acute episodes of respiratory failure, whether hypercapnic or hypoxemic in nature, usually present

Respiratory failure defines the inability to maintain normal gas exchange, that is, hypoxemia and/or hypercapnia.

Characterization of the process causing respiratory failure as hypercapnic or hypoxemic serves as a tool to determine the most appropriate treatment to correct the primary cause of respiratory failure.

Pump failure indicates impairment in the respiratory system acting as a bellows.

Severe arterial hypoxemia results from processes that affect the lung at the levels of the alveolus, airway, interstitium, or pulmonary vasculature.

Respiration is dependent on optimum and integrated function of multiple discrete anatomic units which includes the brain, peripheral nervous system, the chest wall and respiratory muscles, the pleura, upper airways, the heart, red blood cells, and lungs.

A useful way to characterize the many different diseases causing respiratory failure is to separate disorders that cause pump failure from those which cause lung failure.

Respiratory failure must be classified not only into hypercapnia and hypoxemic subtypes but also into acute and chronic presentations.

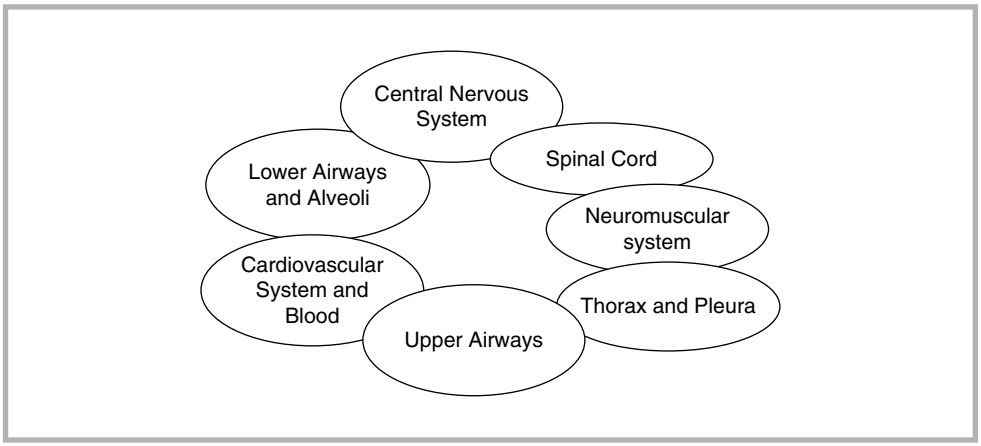

FIGURE 15-2

Anatomic components of the respiratory system. Optimum and integrated function are vital to maintaining normal respiration. Disruption in the function of any component can have serious implications for normal respiration and can precipitate the development of respiratory failure.

CASE STUDY: PART 2

The patient presents to the emergency room in severe respiratory distress. She appears lethargic and unable to speak in complete sentences, secondary to dyspnea. She is unable to follow simple commands. On examination, her respiratory rate is 40 breaths/min. She has obvious contractions of the sternocleidomastoid and scalenus muscles of the neck; paradoxical inward motion of the upper abdomen was pronounced, as was nasal flaring. The patient was promptly intubated and placed on mechanical ventilation. While inspiring 100% oxygen on ventilator settings at a respiratory rate of 10 breaths/min and tidal volume of 500 mL, an arterial blood gas showed a PaO_2 of 110, $PaCO_2$ of 38, and pH of 7.44. A chest X-ray showed diffuse alveolar infiltrates and slight hyperinflation.

After intubation, rectal temperature is recorded at 101°F, respiratory rate is 12 breaths/min, blood pressure is 128/72 mmHg, and heart rate is 114 beats/min. Chest examination shows diffuse end-expiratory wheezes with bilateral rhonchi and end-inspiratory crackles and bronchial breath sounds. The rest of the physical examination is within normal limits.

TABLE 15-1

CLASSIFICATION OF DISEASES THAT CAUSE RESPIRATORY FAILURE INTO PUMP (i.e., HYPERCAPNIC) OR LUNG FAILURE (i.e., HYPOXEMIC) SUBTYPES

PUMP FAILURE	LUNG FAILURE
Central nervous system	Asthma
Drug overdose	Chronic obstructive pulmonary disease (COPD)
Stroke	Bronchitis
Head trauma	Pneumonia
Spinal cord, neuromuscular disease	Pulmonary embolism
Myasthenia gravis	Acute respiratory distress syndrome
Guillain–Barré	Alveolar hemorrhage
Polio	Cardiac
Polymyositis	Pulmonary edema
Neuromuscular blocking agents	Valvular abnormalities
Critical illness polyneuromyopathy	
Chest wall	
Kyphoscoliosis	
Burn eschar	
Flail chest	
Upper airways	
Glottic stenosis	
Paradoxical vocal cord dysfunction	
Laryngospasm	

TABLE 15-2

CLASSIFICATION OF RESPIRATORY FAILURE INTO ACUTE AND CHRONIC PRESENTATIONS

PREDOMINANT TYPE	HYPERCAPNIC	HYPOXEMIC
Acute		
Time course	Minutes to hours	Minutes to hours
Compensatory changes	None	None
Chronic		
Time course	Days to minutes	Days to minutes
Compensatory changes	↑ HCO_3 ↑ pH	↑ Hemoglobin, hematocrit

In an acute episode of respiratory failure, compensatory mechanisms do not have time to develop; therefore, the symptoms and physical exam abnormalities of respiratory failure are more severe.

Secondary polycythemia and bicarbonate elevation are two examples of compensatory mechanisms that attenuate the presence of chronic hypoxemia and acidemia, respectively.

with severe symptoms and physical findings. During acute presentations of respiratory failure, there is insufficient time to develop compensatory mechanisms to attenuate the negative sequelae of hypercapnia or hypoxemia.

In cases of chronic hypoxemia, patients develop secondary polycythemia, and the severe manifestations of hypoxemia are somewhat attenuated by increased blood oxygen content. In cases of chronic hypercapnic respiratory failure, renal conservation of bicarbonate buffers chronic elevations in carbon dioxide levels, and the resultant pH is higher. In addition to clinical history taking, measurement of blood pH can aid in distinguishing acute from chronic presentations of hypercapnic respiratory failure (see Table 15-2).

THE PATHOPHYSIOLOGY OF RESPIRATORY FAILURE

Six different pathophysiologic processes can lead to severe derangements in gas exchange and respiratory failure. However, a reduction in the inspired partial pressure of oxygen and increased venous admixture are infrequent causes.

The mechanisms of normal gas exchange have been comprehensively examined in other textbooks and will not be reviewed here. This section will focus only on abnormalities that result in disturbed gas exchange and lead to hypoxemic and/or hypercapnic respiratory failure. Although there are six different pathophysiologic processes (diffusion abnormalities, ventilation–perfusion inequality, intrapulmonary shunt, hypoventilation, reductions in inspired partial pressure of oxygen, increased venous admixture) that can lead to severe derangements in gas exchange and episodes of respiratory failure, not all of them are commonly encountered in clinical settings. Reductions in the inspired partial pressure of oxygen and increased venous admixture are less common mechanisms for the development of respiratory failure.

Reductions in inspired oxygen concentration may be encountered in patient populations residing at high altitude or patients exposed to reductions in ambient oxygen in commercial aircraft, which are pressurized to simulate altitudes as high as 10,000 feet and provide ambient concentrations of oxygen as low as 100 mmHg. Increased venous admixtures leading to hypoxemic respiratory failure arise in conditions where cardiac output is significantly reduced or oxygen consumption is extremely high. Under these conditions, pulmonary venous oxygen is significantly reduced and, as a consequence, arterial oxygenation is severely impaired. In clinical scenarios where increased venous admixture leads to hypoxemia, patient management and prognosis center on cardiac dysfunction. This topic is extensively covered in Chaps. 18, 27, and 47.

When increased venous admixture leads to hypoxemia, patient management should focus on cardiac dysfunction.

The transfer of oxygen and carbon dioxide across the alveolar capillary membrane is accomplished by the process of diffusion, a process that depends on the physical characteristics of the membrane, including its thickness, area, diffusibility, and the solubility of the gases diffusing across it. However, from a clinical standpoint, impaired diffusion is a minor contributor to arterial hypoxemia and plays only a minor role in gas exchange imbalance in acute respiratory failure. Even in patients with severe lung disease with markedly reduced diffusion, ventilation–perfusion imbalance and intrapulmonary shunting appear to be far more important determinants of arterial oxygenation.

Diffusion abnormalities are rarely the sole cause of respiratory failure.

The three most important abnormalities resulting in disturbances in gas exchange that lead to respiratory failure are ventilation–perfusion inequality, intrapulmonary shunt, and hypoventilation.

Ventilation–perfusion mismatch is the most frequent contributor to clinically important oxygen desaturation.

The most important pathophysiologic mechanisms that impair gas exchange include intrapulmonary shunt, mismatched pulmonary blood flow and ventilation, and decreased alveolar ventilation (V_A).

Ventilation–Perfusion Inequality

Six different pathophysiologic processes (diffusion abnormalities, ventilation–perfusion inequality, intrapulmonary shunt, hypoventilation, reductions in inspired partial pressure of oxygen, increased venous admixture) can lead to severe derangements in gas exchange and episodes of respiratory failure.

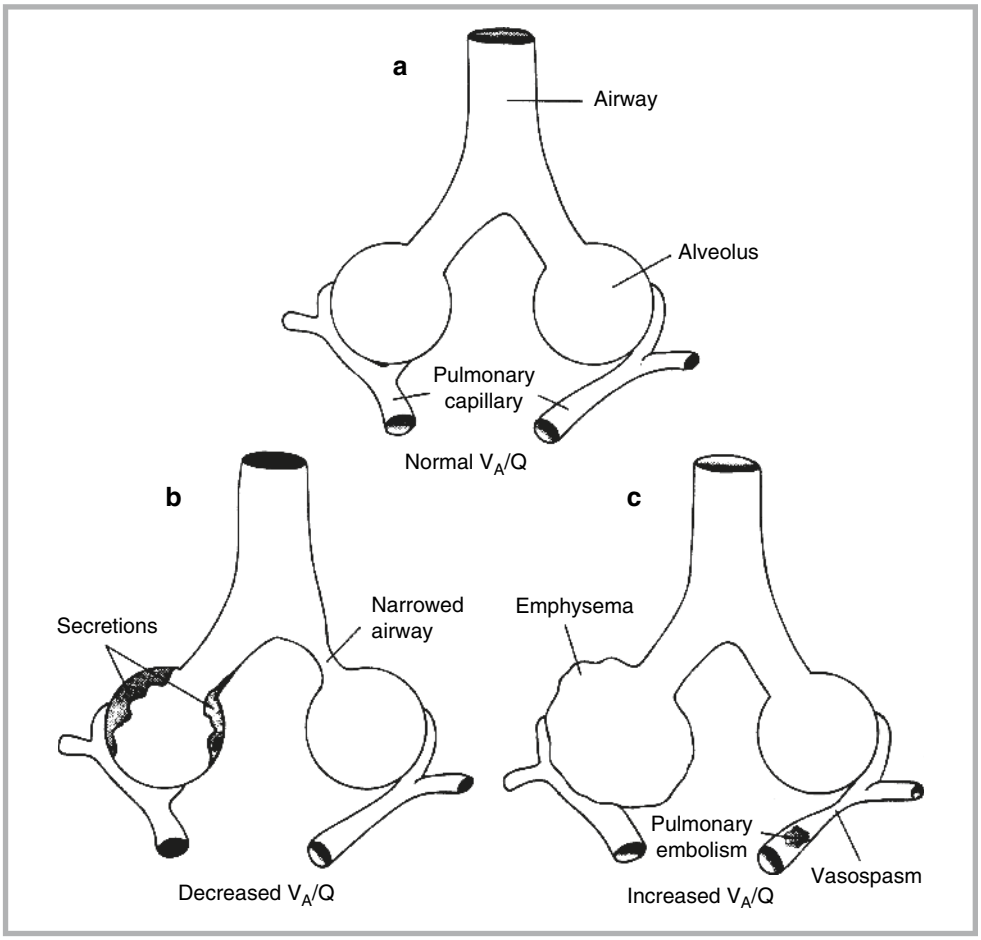
Ventilation–perfusion (V_A/Q) mismatch is the most frequent contributor to clinically important oxygen desaturation. Ideally, each alveolar capillary exchange unit would have perfect matching of ventilation and perfusion, such that optimum gas exchange occurs across each alveolar unit. Realistically, however, the lungs do not act as multiples of identical and ideal gas exchange units, but rather as millions of units that are perfused in parallel and ventilated both in parallel and in series, resulting in some degree of V_A/Q imbalance even in healthy individuals. In normal individuals, there is a spectrum of V_A/Q ratios that range from relatively underventilated units to those lung units which are ventilated but not perfused. In normal lungs, V_A/Q may range from 0.6 to 3.0, with the distribution of all units of the lung in aggregate usually averaging a V_A/Q of approximately one. The distribution of ventilation varies with common events, such as changes in body posture, lung volumes, and age. Increasing age produces a gradual increase in the degree of the V_A/Q inequality. However, despite this range of ventilation–perfusion imbalance in a normal lung, ventilation–perfusion balance on the whole remains a fairly tightly controlled process. In the setting of disease, however, the distribution of V_A/Q may become markedly abnormal, and lower and higher V_A/Q units predominate and may contribute to the development of respiratory failure.

Ventilation–perfusion imbalance exists even in the normal lung, depending on the region, but remains fairly tightly regulated when assessing normal lung aggregate function.

Figure 15-3 shows examples of ventilation–perfusion imbalances that occur in different disease states. In patients with obstructive or restrictive ventilatory diseases, decreased ventilation may result from structural or functional abnormalities of the airway and can lead to

FIGURE 15-3

Examples of ventilation–perfusion imbalance. (**a**) Normal idealized alveolar capillary unit. (**b**) Examples of decreased ventilation–perfusion units as a result of secretions in the airway or airway bronchoconstriction. (**c**) Examples of increased ventilation–perfusion units due to the development of emphysema or decreased pulmonary blood flow secondary to pulmonary embolism or pulmonary artery vasospasm.



HPV is a reflex mechanism that tends to minimize the effects of V_A/Q inequality to avoid the detrimental effects of impaired gas exchange.

decreased V_A/Q units (Fig. 15-3b). On the other hand, lung units with increased V_A/Q ratios can develop disorders that lead to overventilation of lung units, conditions such as emphysema, for example, in which patients have airspace enlargement as a result of the destruction of the alveolar sac distal to the terminal bronchiole. Moreover, the development of impaired perfusion through the pulmonary vasculature, as observed in cases of pulmonary embolism or pulmonary vasospasm, may cause high V_A/Q ratios (Fig. 15-3c). Reflex mechanisms are present in the lung to minimize the effect of V_A/Q inequality, thus avoiding or minimizing the detrimental effects of impaired gas exchange. One mechanism is hypoxic pulmonary vasoconstriction (HPV), whereby a fall in V_A/Q leads to the development of alveolar hypoxia, which in turn causes vasoconstriction of the perfusing arteriole. This effect is beneficial for pulmonary gas exchange because it decreases the denominator of the V_A/Q relationship, thereby partially correcting regional V_A/Q imbalance and improving arterial hypoxemia. HPV appears to operate over a range of alveolar PO_2 values between 30 and 150 mmHg. The mechanism by which alveolar hypoxia sends the message to trigger regional vasoconstriction is unclear, but may involve the release of humoral messengers.

HPV operates at alveolar PO_2 values that range from 30 to 150 mmHg.

Many factors, however, can significantly interfere with HPV, including certain drugs, such as calcium channel blockers, beta-agonists, and inhalational anesthetic agents. Lower respiratory tract infections or disease processes that cause elevations in left atrial pressure can also interfere with HPV. In addition, although HPV may be helpful in improving arterial hypoxemia, a progression in vasoconstrictor effect can lead to the development of secondary pulmonary hypertension and, eventually, right heart failure.

HPV, if unabated, can lead to the development of secondary pulmonary hypertension and right heart failure.

The development of V_A/Q abnormalities can have a dramatic effect on gas exchange and interfere with the transfer of both oxygen and carbon dioxide. The oxygen and carbon dioxide content of end-capillary gas for each of the two gases depends on the gas pressure in the alveolus and their respective hemoglobin dissociation curves. One may expect, therefore, that V_A/Q

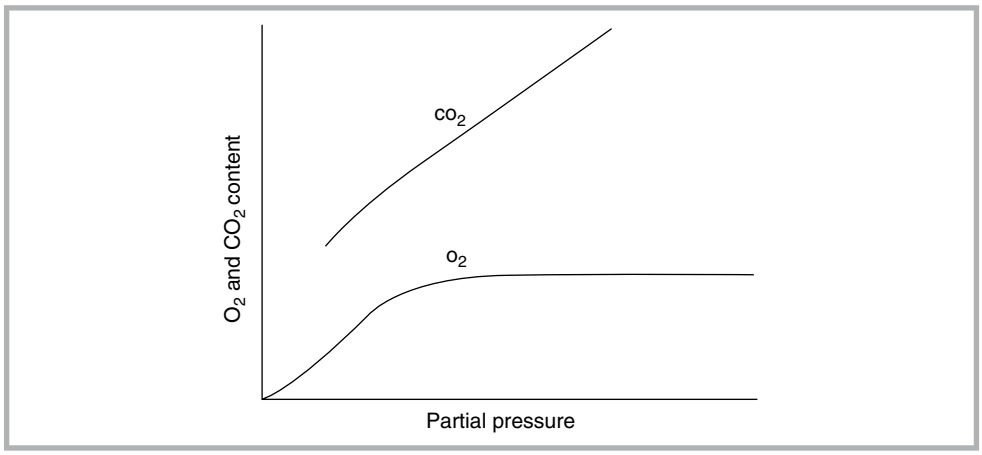


FIGURE 15-4

Carboxy hemoglobin and oxyhemoglobin dissociation curves. Oxygen and carbon dioxide contents vs. the partial pressures of carbon dioxide and oxygen. An increase in oxygen partial pressure above a certain level (60 mmHg) does not result in increased oxygen content of the blood. However, a linear relationship is seen between the partial pressure of carbon dioxide and carbon dioxide blood content (adapted from Dantsker and David.[27] Reprinted with permission from Elsevier).

inequality would result in both hypoxemia and hypercapnia; however, most of the clinical derangement observed following mild V_A/Q inequality is attributable to the development of profound hypoxemia rather than hypercapnia. In fact, most patients with mild V_A/Q inequality have normal $PaCO_2$ levels or are hypocapnic. Hypoxemia with normocapnia as a result of V_A/Q inequality appears to be best explained by the differences in the shapes of the oxyhemoglobin and carbon dioxide hemoglobin dissociation curves (Fig. 15-4). An increase in $PaCO_2$ is sensed by chemoreceptors and stimulates increased ventilation, predominantly to lung units already ventilated. However, because of the nonlinear portion of the oxyhemoglobin curve, increased PaO_2 does not result in an increase in blood oxygen content. In contrast, because of the linear relationship of carbon dioxide content with the partial pressure of carbon dioxide, increased minute ventilation results in a decrease in the partial pressure of carbon dioxide and consequently lower carbon dioxide content. In essence, in the presence of V_A/Q inequality, increased minute ventilation prevents CO_2 retention, but cannot influence the development of hypoxemia.

Hypercapnia is not seen in mild V_A/Q imbalance, secondary to the linear relationship of the partial pressure of CO_2 and carbon dioxide hemoglobin dissociation curves.

Hypoxemia as a result of V_A/Q imbalances responds in a variable way to increases in inspired oxygen concentration. This fact helps to distinguish V_A/Q imbalance from intrapulmonary shunt as the primary cause of hypoxemia. As shown in Fig. 15-5, disease processes associated with mild V_A/Q imbalance show an increase in arterial PaO_2 in response to increasing inspired oxygen concentrations that is relatively linear and may even approximate the normal condition. With moderate or more severe V_A/Q imbalances, however, higher concentrations of oxygen are required to demonstrate an increase in arterial PaO_2. It is important to note that even with severe V_A/Q imbalances, high concentrations of supplemental oxygen may result in substantial increases in arterial PaO_2.

V_A/Q inequality causing hypoxemia is relatively responsive to the inspiration of supplemental oxygen.

Intrapulmonary shunt represents lung units that are perfused but receive no ventilation. Although intrapulmonary shunt can be considered as an extreme case of V_A/Q inequality, intrapulmonary shunt results from a different category of clinical disorders that require different forms of therapy. Because of this, intrapulmonary shunt should be considered as an entity distinct from V_A/Q imbalance. Under normal conditions, 1–3% of mixed venous blood flows directly from the systemic circulation through the bronchial and thebesian blood vessels. Clinical disorders causing hypoxemic respiratory failure may be found in diseases associated with shunt physiology resulting from either cardiac or pulmonary diseases.

Intrapulmonary shunt indicates that lung units are being perfused but not ventilated.

Disorders causing hypoxemic respiratory failure, secondary to shunt physiology, occur in cardiac or pulmonary diseases.

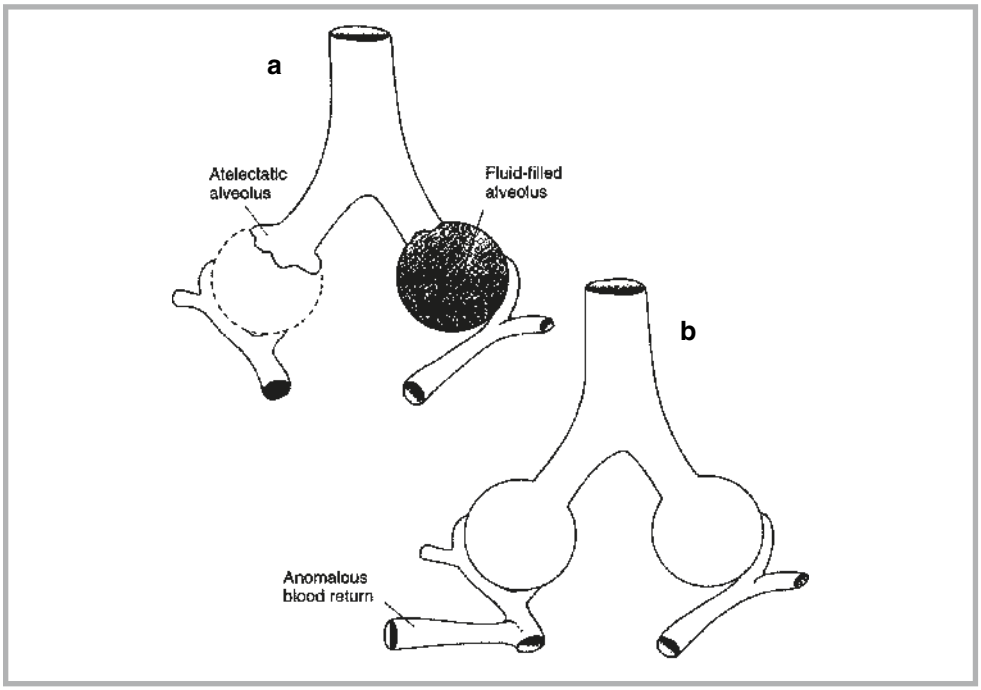
Examples of intracardiac shunts include atrial and ventricular septal defects, especially in conditions where pulmonary hypertension is present. When the pressure becomes high enough in the pulmonary vascular circuit, right-to-left intracardiac shunt occurs and

The intracardiac shunts include right-to-left intra-atrial or intra-ventricular blood transit.

Intrapulmonary shunts are caused by alveoli that are collapsed, filled with fluid or inflammatory debris, and not ventilated.

FIGURE 15-5

Examples of intrapulmonary shunt. **(a)** Collapsed and fluid-filled alveoli are examples of intrapulmonary shunt. **(b)** Anomalous blood return of mixed venous blood bypasses the alveolus and thereby contributes to the development of intrapulmonary shunt.



Intrapulmonary shunts of greater than 30% cause hypoxemia that is relatively refractory to the inspiration of supplemental oxygen.

When testing for intrapulmonary shunt, it is important to remember to administer 95–100% inspired oxygen.

The treatment of intrapulmonary shunt requires methods that increase lung volume with continuous positive airway pressure (CPAP), positive end-expiratory pressure (PEEP), or mechanical ventilation.

profound hypoxemia may develop. In cases of intrapulmonary shunt, mixed venous blood passes through the capillary walls of alveoli that are collapsed (i.e., atelectatic) or filled with fluid (i.e., congestive heart failure) or inflammatory debris (i.e., pneumonia) and are thus nonventilated (see Fig. 15-5a).

As shown in Fig. 15-6b, intrapulmonary shunts of 30% or greater are remarkably resistant to the inspiration of high inspired oxygen concentrations. Even breathing 100% oxygen has minimal impact on increasing arterial PaO_2 in patients with severe shunts. In fact, use of 100% oxygen can serve as a clinical tool to help distinguish intrapulmonary shunt from V_A/Q inequality as the underlying major pathophysiologic mechanism responsible for hypoxemia in patients with elevated alveolar–arterial (A-a) oxygen gradients. In contrast to patients with severe shunts, patients with elevated A-a gradients resulting from V_A/Q inequality exhibit substantial increases in PaO_2 when breathing high levels of inspired oxygen. When testing for the presence of intrapulmonary shunt, it is important to remember to administer 95–100% inspired oxygen because severe V_A/Q inequalities may result in levels of hypoxemia similar to shunt until 100% oxygen is administered (Fig. 15-6a).

To test for the percentage of intrapulmonary shunt present, the patient should be administered 100% supplemental oxygen for 15 min, until all the alveoli can be presumed to be filled with pure oxygen. The percentage of shunt can then be calculated with the following formula:

$$Q_S / Q_T = (CcO_2 - CaO_2) / (CcO_2 - C\bar{v}O_2) \times 100.$$

In this equation, C denotes content, and c, a, and v denote end-capillary, arterial, and mixed venous blood, respectively. When making these calculations, it is assumed that end-capillary and calculated alveolar oxygen tensions are equivalent.

Because of the refractoriness of moderate-to-severe shunts to respond with an increase in arterial oxygen to inspiring higher concentrations of supplemental oxygen, the application of positive pressure to the airway in the form of CPAP or PEEP is considered. A full discussion of the treatment of refractory oxygenation is given in Chaps. 2, 26, and 48.

Hypoventilation

To avoid the development of respiratory acidosis, the carbon dioxide produced each day as an end product of aerobic metabolism (approximately 17,000 mEq of acid) must be exhaled.

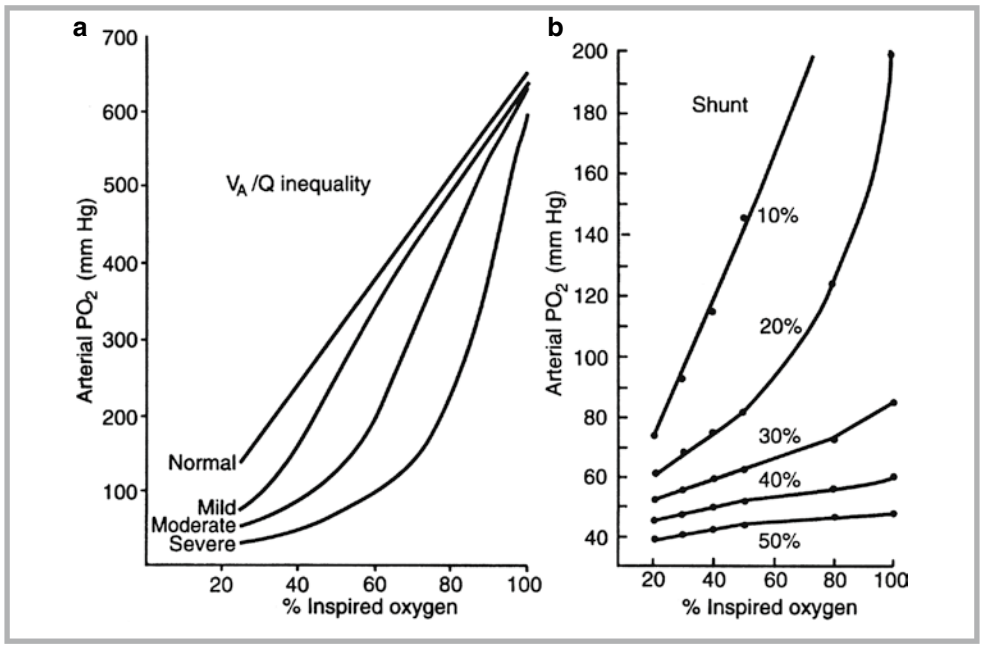


FIGURE 15-6

Differing responses of ventilation–perfusion inequality or intrapulmonary shunt to increases in inspired oxygen. (**a**) Ventilation–perfusion inequality under mild to severe circumstances. Even in the presence of severe ventilation–perfusion imbalance, high levels of supplemental oxygen have a profound effect on increasing arterial PaO_2. (**b**) In contrast, intrapulmonary shunts of 30% or greater are relatively refractory to supplemental oxygen increasing arterial PaO_2 (adapted from Dantzker and David.[27] Reprinted with permission from Elsevier).

To achieve balance between the production and elimination of carbon dioxide, the central nervous system and carotid body chemoreceptors must be able to adjust ventilation over a broad range of carbon dioxide production. Hypoventilation, therefore, can be defined as an inadequate delivery of fresh alveolar gas required to maintain a normal $PaCO_2$.

$PaCO_2$ is directly related to VCO_2 production and inversely directed to V_A.

The relationship between V_A, carbon dioxide production (VCO_2), and the partial pressure of carbon dioxide in the blood ($PaCO_2$) can be described using a modification of the Fick principle of mass balance that quantitates VCO_2 as the product of V_A and the fractional concentration of carbon dioxide in the alveolar gas. Under steady-state conditions, with the elimination of carbon dioxide from the body at a rate equal to the rate at which it is produced, the relationship between $PaCO_2$, VCO_2, and V_A is:

Carbon dioxide must be eliminated from the body at a rate equal to that at which it is produced.

$$PaCO_2 = \frac{VCO_2 K}{V_A}.$$

In this condition, K is a constant that equals 0.863. This constant is required because VCO_2 is expressed at standard temperature and pressures dry (STPD), whereas V_A is expressed at body temperature, ambient pressure, and saturation conditions (BTPS). Within the normal lung, V_A is a fixed proportion of overall expired minute ventilation (V_E). V_E is the total expired ventilation, usually measured over a 1-min collection period. V_E has two components, ventilation that contributes to the elimination of CO_2, termed V_A, and ventilation which does not contribute to the elimination of CO_2, termed V_D. V_D is the portion of minute ventilation that insufflates the conducting airways and does not participate directly in gas exchange. V_D therefore approximates the volume of the conducting airways. However, in disease states that result in conditions of higher physiologic dead space (e.g., exacerbation of COPD), if the patient does not mount a corresponding proportional increase in V_E, V_A will decrease.

V_E is the total expired ventilation measured during 1 min.

Dead space ventilation (V_D) is that portion of minute ventilation that insufflates the conducting airways and does not participate directly in gas exchange.

V_A can be expressed as the total expired minute ventilation minus V_D ($V_A = V_E - V_D$). If one rewrites the equation provided earlier and substitutes $V_E - V_D$ for V_A, the relationship between $PaCO_2$, VCO_2, and V_A becomes:

V_A is equal to the total expired minute ventilation minus V_D.

$$PaCO_2 = \frac{K(VCO_2)}{V_E - V_D}.$$

Therefore, states of alveolar hypoventilation are those in which minute ventilation (V_E) is reduced or V_D is high. Either or both of these mechanisms will result in decreased V_A. V_A that

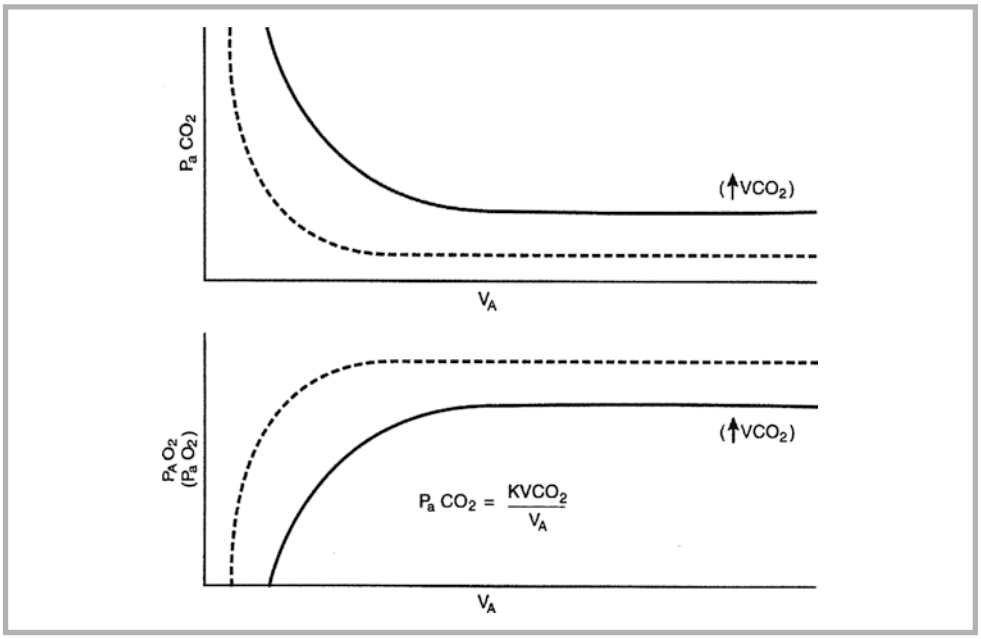

FIGURE 15-7

Relationships of $PaCO_2$, P_AO_2, and PaO_2 to alveolar ventilation (V_A). As V_A increases, $PaCO_2$ decreases. As CO_2 production (VCO_2) increases, the relationship shifts upward and to the *right*. In contrast, with an increase in V_A, alveolar oxygen (P_AO_2) and consequently arterial oxygen (PaO_2) increase (adapted from Dantzker and David.[27] Reprinted with permission from Elsevier).

is inadequate to compensate for the increased metabolic production of VCO_2 results in a rise in $PaCO_2$.

Hypoventilation may also indirectly reduce the partial pressure of oxygen in the blood (PaO_2) by reducing alveolar oxygen tension (PAO_2). As illustrated in Fig. 15-7, a fall in V_A or a rise in carbon dioxide production greater than the increase in V_A results in an increase in $PaCO_2$, a decrease in alveolar PO_2, and a consequent decrease in PaO_2. In this latter case, because all the parameters used in calculating the alveolar PO_2 change simultaneously, the alveolar–arterial (A-a) oxygen gradient remains normal.

V_A inadequate to compensate for increased metabolic production of VCO_2 results in a rising $PaCO_2$.

It is important to differentiate between hypoxemia caused by alveolar hypoventilation and hypoxemia caused by V_A/Q imbalance or intrapulmonary shunt because the disease processes and their treatments differ markedly. Determination of the alveolar gas equation, which is discussed later in this chapter (see arterial blood analysis), is extremely useful in determining whether hypoxemia is caused by hypoventilation, as opposed to hypoxemia caused by conditions attributable to V_A/Q inequality, or intrapulmonary shunt. Although hypoxemia regardless of pathophysiologic mechanism may be treated by the inspiration of enriched oxygen, in most cases, hypoventilation must be treated with an augmentation of ventilation to avoid progressive respiratory acidosis.

When alveolar hypoventilation occurs, the A-a gradient remains normal.

It is important to differentiate hypoxemia that results from alveolar hypoventilation from V_A/Q inequality or intrapulmonary shunt because the treatments are different.

Hypoventilation in most cases must be treated by augmentation of ventilation.

DIAGNOSIS OF RESPIRATORY FAILURE

History

The process of diagnosing respiratory failure and elucidating the precipitating factors begins with the history, the symptoms, and the clinical manifestations of severe gas exchange imbalance; the clinician must often bring to bear a high level of clinical insight.[2-6] Hypoxemia and hypercapnia are the major final precipitating disturbances found in patients presenting with respiratory failure (Table 15-3). However, the severity and acuity of the event leading to respiratory failure, and the patient's underlying condition(s), will influence the temporal progression of the patient's symptoms and the need for prompt evaluation and treatment. In patients who present with catastrophic disorders or have severe underlying diseases with already compromised respiratory reserve, respiratory failure may develop rapidly. Examples of these types of patients include those who suffer an intracranial hemorrhage, pneumothorax, or acute tracheobronchitis with underlying COPD. In circumstances where respiratory

Hypoxemia and hypercapnia precipitate disturbances that elicit abnormalities on history and physical exam in patients presenting with respiratory failure.

failure is chronic in nature, symptoms and clinical manifestations present insidiously over weeks to months after compensatory mechanisms fail to further attenuate the progression of hypoxemia and hypercapnia. Examples include chronic respiratory failure developing in patients with slowly progressive neurologic diseases, such as myotonic dystrophy or chronic spinal muscle atrophy.

Most patients who present with respiratory failure complain of dyspnea. Dyspnea appears first with exertion, and later, with progression of the disease, is present even at rest. Hoarseness, cough, sputum production, and chest pain are not symptoms of respiratory failure per se, but are clues that a primary pulmonary process may be the trigger for the development of respiratory failure. As the condition precipitating the respiratory failure progresses and severe gas exchange imbalances appear (i.e., hypoxemia with or without hypercapnia), neurologic manifestations predominate (headache, visual disturbances, confusion, memory loss, anxiety, seizures, or, in extreme cases, loss of consciousness).

Most patients who present with respiratory failure complain of dyspnea.

As gas exchange imbalances worsen, neurologic manifestations predominate.

Physical Examination

Physical examination of patients presenting with respiratory failure begins with a quick but thorough general assessment (Table 15-4).[7] The initial priority on the part of the clinician should be to characterize those patients who are presenting with severe manifestations of respiratory failure who may need prompt airway control, oxygenation, and ventilation. In patients who present with severe manifestations of respiratory failure, a decrease in mental alertness, more severe breathlessness, and evidence of an elevated respiratory workload are present.[8,9] Hypoxemia and hypercapnia both can contribute to neurologic manifestations and a decrease in cognitive function that ranges from anxiety to coma. Patients who have severe airways obstruction are unable to speak in complete sentences, signifying a FEV_1 of 1L or less. A respiratory rate greater than 35 breaths/min, heart rate 20–30 beats/min greater or lesser than the normal heart rate, and the presence of pulse paradoxus (e.g., a 15-–20-mmHg decrease in systolic pressure during inspiration) are all manifestations of an increased ventilatory workload.

Physical examination of patients with respiratory failure begins with a quick, but thorough, general assessment.

The initial priority is to triage patients who present with severe forms of respiratory failure from those with less severe forms.

TABLE 15-4

PHYSICAL EXAMINATION IN RESPIRATORY FAILURE

- General findings
  - Mental alertness
  - Ability to speak in complete sentences
  - Respiratory rate > 35 breaths/min
  - Heart rate > or < 20 beats from normal
  - Pulsus paradoxus present?
  - Elevated work of breathing?
    - Using accessory muscles
    - Rib cage or abdominal paradox
- Specific organ dysfunction
  - Pulmonary
    - Stridor
    - Wheezes
    - Rhonchi
  - Crackles
  - Cardiac
    - Tachycardia, bradycardia
    - Hypertension, hypotension
    - Crackles
    - New murmurs
  - Renal
    - Anuria
  - Gastrointestinal
    - Distended
    - Pain to palpation
  - Decreased bowel sounds

Parameters that show metabolic instability, or show severe respiratory distress, signify more severe episodes of respiratory failure.

A change in breathing pattern is helpful in indicating the severity of the episode of respiratory failure.

Extrapulmonary abnormalities on physical examination may identify the cause of respiratory failure.

Because physical and historical symptoms are nonspecific in diagnosing all aspects of respiratory failure, laboratory testing is necessary.

An elevated work of breathing may be diagnosed by the observation of the patients' pattern of breathing. The use of accessory muscles of the neck (palpable or visual contraction of the sternocleidomastoid muscles, flaring of the ala nasi), tensing of the abdominal muscles, or paradoxical movements of the rib cage and abdominal compartments are indications of respiratory distress.[10] Paradoxical rib cage or abdominal motions during inspiration (e.g., rib cage and abdominal compartments move in opposite directions, rather than similar outward movements) signify the development of a ventilatory workload that is higher than the ventilatory capacity or the development of an underlying respiratory muscle dysfunction such as respiratory muscle fatigue or respiratory muscle weakness.[3]

The presence of specific abnormalities on physical examination related to an isolated organ dysfunction may indicate the primary underlying process contributing to the development of respiratory failure (see Fig. 15-4). The presence of abnormal ausculatory sounds of the upper airway (stridor) or lower airways (wheezes, rhonchi, or rales) may indicate a primary underlying pulmonary process (i.e., exacerbation of airflow obstruction, pneumonia, or interstitial lung disease). Similarly, the presence of cardiac, renal, or gastrointestinal abnormalities on physical examination may indicate those organs as the source of the patient's severe illness. Although these findings may indicate the severity of, or in some cases provide clues to the etiology of respiratory failure, in most cases, the clinical history and physical examination of the patients who present with respiratory failure are fairly nonspecific, and identification of the cause of respiratory failure requires laboratory testing.

USE OF LABORATORY TESTS IN THE DIAGNOSIS

Laboratory testing for respiratory failure includes arterial blood gas analysis, measurement of respiratory mechanics, chest imaging, and general laboratory testing.

Laboratory testing for respiratory failure encompasses four major areas: (1) arterial blood gas analysis; (2) measurement of respiratory mechanics; (3) chest imaging; and (4) general laboratory testing (Table 15-5). A brief description of the most important features of each of these tests as they pertain to the management of respiratory failure follows.

TABLE 15-5

LABORATORY TESTING IN RESPIRATORY FAILURE

- Arterial blood gas
  - PaO_2
  - $PaCO_2$
  - pH
- Chest imaging
  - Chest X-ray
  - Computed tomography (CT) scan
  - Ultrasound
  - Ventilation–perfusion scan
- Respiratory mechanics
  - Spirometry (FVC, FEV_1, peak flow)
  - Respiratory muscle pressures
    - MIP (maximum inspiratory pressure)
    - MEP (maximum expiratory pressure)
    - MVV (maximum voluntary ventilation)
- Other tests
  - Hemoglobin, hematocrit
  - Electrolytes, blood urea nitrogen, creatinine
  - Creatinine phosphokinase, aldolase
  - EKG, echocardiogram
  - Swan–Ganz catheter
  - Electromyography (EMG)
  - Nerve conduction study

Arterial Blood Gas Analysis

An arterial blood gas provides an indication of the duration and severity of the episode of respiratory failure. It measures PaO_2, $PaCO_2$, and pH.

Analysis of arterial blood gas is the single most important laboratory test that can classify the subtype of respiratory failure. This test indicates the duration and severity of the episode of respiratory failure. Analysis of the arterial blood gas provides information on the presence and magnitude of three distinct abnormalities: hypoxemia (reduction of partial pressure of oxygen in the blood), hypercapnia ($PaCO_2 > 45$ mmHg), and arterial pH.

Hypoxemia

Oxygenation failure is defined as $PaO_2 < 60$ mmHg, while inspiring oxygen concentrations ≥40%.

Hypoxemia is a reduction in the partial pressure of oxygen in the blood. The normal resting PaO_2 ranges from 75 to 80 mmHg. A PaO_2 below 60 mmHg is considered the lower limit of safety, because lower values represent displacement onto the steep slope of the oxyhemoglobin dissociation curve. At PaO_2 values less than 60 mmHg, even small declines in the partial pressure of oxygen result in substantial decreases in arterial oxygen content (see Fig. 15-4). In cases of respiratory failure, oxygenation failure is usually defined as a PaO_2 less than 60 mmHg while inspiring oxygen concentrations of 40% or greater.

As previously discussed, the mechanisms by which clinically significant reductions in PaO_2 occur include right-to-left intracardiac shunts, intrapulmonary shunts, ventilation–perfusion imbalance, and alveolar hypoventilation. Hypoxemia caused by alveolar hypoventilation is characterized by a normal alveolar–arterial oxygen difference ($P_AO_2 - PaO_2$), a feature that distinguishes hypoxemia associated with hypoventilation from hypoxemia caused by shunt or ventilation–perfusion imbalance. The alveolar–arterial oxygen gradient can be calculated by using the alveolar gas equation to estimate alveolar oxygen (P_AO_2) and measuring the arterial oxygen blood tension during arterial blood gas analysis (PaO_2).

Water vapor pressure observed at 100% saturation is 47 mmHg.

As fresh gas is inspired at atmospheric pressure, the gas is warmed and humidified. The concentration of the inspired oxygen (P_IO_2) depends on the barometric pressure (P_B). At sea level, P_B is 760 mmHg, or 1 atm. $P_IO_2 = F_IO_2$ (P_B – water vapor pressure), where P_IO_2 is the partial pressure of oxygen in the central airways, F_IO_2 is the concentration of inspired oxygen, and P_B represents P_B at sea level (760 mmHg). Water vapor pressure exerted at 100% saturation is 47 mmHg, the condition that exists in the lower airways at one atmosphere (1 atm).

The A-a gradient serves as an index of the efficiency of gas exchange by the lung.

Measurement of alveolar gas exchange is important because the gradient between P_AO_2 and measured PaO_2 serves as an index of the efficiency of gas exchange by the lung. The amount of oxygen at the alveolar level (P_AO_2) can be calculated by the simplified alveolar gas equation:

$$P_AO_2 = \frac{P_IO_2 - PaCO_2}{R}.$$

The alveolar–arterial oxygen gradient is normally 10–20 mmHg in the normal patient, but increases with age and the percent of inspired oxygen and is also affected by body posture.

An example calculation of the alveolar–arterial oxygen gradient is provided for a representative patient:

$$\text{Alveolar - arterial (A - a) oxygen gradient} = \frac{P_IO_2 - PaCO_2}{R} - PaO_2.$$

R equals the respiratory exchange ratio ($R = 0.8$), which is determined by metabolic events ($R = VCO_2/\dot{V}O_2$). $P_IO_2 = F_IO_2$ (P_B – 47 mmHg), and PaO_2 and $PaCO_2$ are measured by the arterial blood gas.

If the patient breathes room air oxygen ($F_IO_2 = 0.21$) at sea level ($P_B = 1$ atm = 760 mmHg), water vapor pressure is 47 mmHg and P_IO_2 becomes 150.

$$\begin{aligned} P_IO_2 &= F_IO_2\,(760 - \text{water vapor}) \\ &= 0.21\,(760 - 47) \\ &= 150. \end{aligned}$$

If arterial blood gas measures $PaCO_2$ of 56 mmHg and PaO_2 of 70 mmHg, the alveolar–arterial oxygen gradient becomes 10. Mild hypoxemia in this case is a result of hypoventilation, not intrapulmonary or cardiac shunting or ventilation–perfusion imbalance.

$$\begin{aligned} \text{Alveolar-arterial (A - a) oxygen gradient} &= P_IO_2 - \frac{PaCO_2}{R} - PaO_2 \\ &= 150 - \frac{80}{0.8} - 40 \\ &= 10. \end{aligned}$$

Hypercapnia

Hypercapnia is an elevation in arterial carbon dioxide tension ($PaCO_2$) greater than the upper limit of 45 mmHg. Hypercapnia is commonly present in chronic cases of respiratory failure resulting from neuromuscular disease, thoracic cage abnormalities, or COPD. Hypercapnia that presents in acute situations (i.e., status asthmaticus or sepsis) usually represents acute respiratory failure and has more ominous implications. In most cases, hypercapnia results from the presence of hypoventilation, and is not caused by V_A/Q imbalance, because of the linear relationship of the partial pressure of carbon dioxide with CO_2 content (see Fig. 15-4). However, in extreme cases of ventilation–perfusion imbalance, hypercapnia may develop.

Arterial pH

The relationship described by the Henderson–Hasselbach equation between $PaCO_2$ and plasma bicarbonate dictates the arterial pH.

$$\text{Henderson - Hasselbach Equation : } pH = 6.1 + \log \frac{[HCO_3]}{PaCO_2 \times 0.0301}.$$

R is determined by metabolic events: $VCO_2/\dot{V}O_2$.

Hypercapnia is $PaCO_2 \geq 45$ mmHg.

By using the arterial blood gas to measure arterial pH and $PaCO_2$, the Henderson–Hasselbach equation can be used to calculate the bicarbonate level. Only small to negligible increases in plasma bicarbonate accompany acute increases in $PaCO_2$ that occur over hours. Over a period

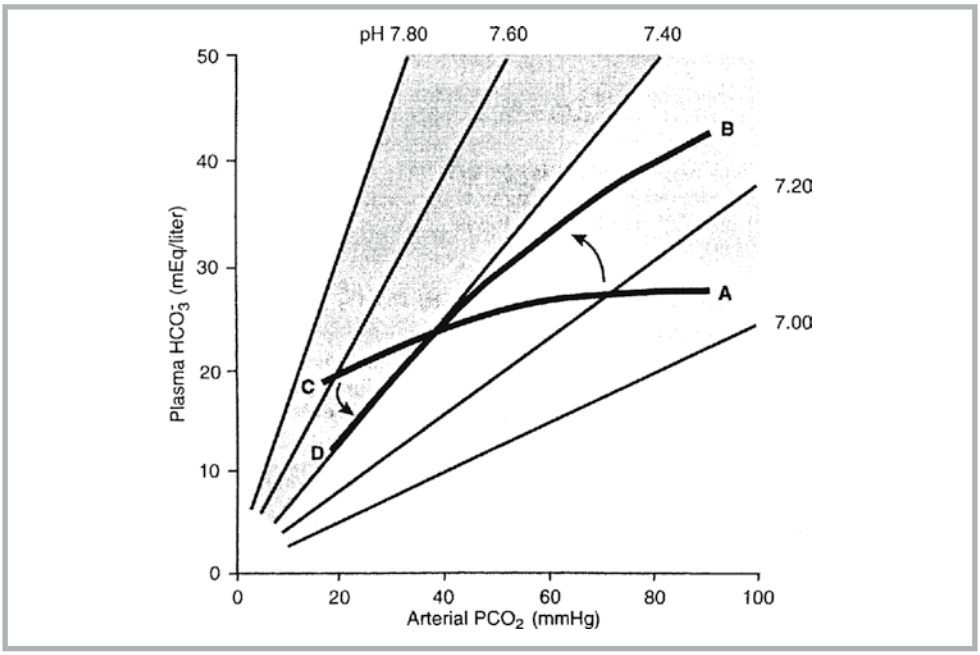

FIGURE 15-8

Effects of acute and chronic variation in $PaCO_2$ on plasma bicarbonate and pH. The line connecting points *C* and *A* represents the effect of an acute change in $PaCO_2$ to a value above or below 40 mmHg. A more chronic rise in $PaCO_2$ that allows renal compensation to occur shows a shift in this relationship to the line connecting points *D* and *B*. During the chronic rise in $PaCO_2$, identified by the line connecting points *D* and *B*, renal conservation of bicarbonate attenuates the decline in pH induced by a rise in arterial carbon dioxide (reproduced with permission from Murray.[28] Reprinted with permission from Elsevier).

of several days to weeks, however, the renal conservation of bicarbonate results in increased bicarbonate levels. Higher serum bicarbonate attenuates the decline in pH that would otherwise occur because of an increased partial pressure of carbon dioxide. As a result, reductions in pH are less severe in situations in which carbon dioxide is chronic, in contrast to conditions associated with acute elevations in CO_2. Examples of acute and chronic $PaCO_2$ elevation with regard to the impact of plasma bicarbonate and pH levels are shown in Fig. 15-8.

Hypercapnia usually results from hypoventilation, not V_A/Q imbalance.

The Henderson–Hasselbach equation defines the relationship between $PaCO_2$, pH, and plasma bicarbonate.

Measurement of Respiratory Mechanics

Measurement of respiratory mechanics might not only help to grade the severity of the abnormality provoking respiratory failure but also can provide causative insight.

Respiratory mechanics measured at the bedside in patients with respiratory failure include spirometry and measurement of respiratory muscle pressures.

A vital capacity (VC) <10 mL/kg of body weight indicates significant dysfunction of the respiratory system.

Although the measurement of respiratory mechanics is limited in critically ill patients, in certain circumstances measurement of respiratory mechanics might help not only to grade the severity of the abnormality causing respiratory failure but also to provide some insight into the mechanism. In most cases, measurement of bedside spirometry or respiratory muscle pressures is the only respiratory mechanics test applicable for evaluating patients presenting with respiratory failure.

Measurements of VC, forced expiratory volume in 1 s (FEV_1), and peak expiratory flow rate (PEFR) are the most common lung function tests used in the ICU to assess for the presence of airflow obstruction or respiratory muscle weakness as causes of respiratory failure. VC is the maximum volume of air exhaled after a maximal inspiration; it provides an indication of the patient's maximum ventilatory capacity. VC is influenced by optimum functioning of the central and peripheral nervous systems, the elastic properties of the lung and the chest wall, and airway caliber. It cannot be used to assess specific abnormalities of the individual components of the respiratory system but helps to provide a simple global estimate of respiratory system function. In most patients, the minimal acceptable VC before respiratory failure develops is approximately 10–15 mL/kg of body weight. Lower values usually signal significant respiratory muscle pump dysfunction and predict imminent need for ventilatory assistance. However, as with any other laboratory assessment, the results of this test must be viewed in the context of an individual patient's clinical scenario.

Forced expiratory volume in 1 s is that portion of the forced VC measured during the first 1 s of expiration and is another method to measure the severity of airflow obstruction. An FEV_1 value less than 25% of predicted is usually associated with an increased $PaCO_2$. Measurement of the PEFR is the maximum point on the forced expiratory limb of the flow volume curve and provides information similar to the FEV_1. Both FEV_1 and PEFR can be used to serially assess the patient's response to bronchodilator therapy.

Measurements of respiratory muscle pressures may be helpful in identifying the cause and also the severity of muscle weakness contributing to respiratory failure. Maximum inspiratory and expiratory mouth pressures are global assessments of inspiratory and expiratory muscle strength, respectively. Measurement of respiratory muscle pressures must be performed under conditions of maximum effort at a known lung volume. Because lung volume affects the precontraction length of the respiratory muscles, maximum inspiratory pressure (MIP) must be recorded at or near residual volume and maximum expiratory muscle pressure (MEP) must be recorded at or near total lung capacity. When measured under the conditions addressed here, the precontraction length of the inspiratory and expiratory muscles is optimized, and maximum muscle contraction results in a more accurate measurement of muscle strength. However, controlling for lung volume and ensuring maximum patient effort is problematic when measurements are conducted at the bedside in critically ill patients. To obtain meaningful results of respiratory muscle testing, methods must be used that optimize patient and operator performance and simultaneously minimize the impact of lung volume on measured values.[5] Other measures of respiratory muscle strength that are more sensitive and specific to detect respiratory muscle weakness, diaphragm paralysis, or even respiratory muscle fatigue have been done in selected patients for research purposes.[10-16] None of these tests are routinely used in the clinical assessment of patients. However, Cohen et al. have shown that the development of paradoxical inward movements of the upper abdomen, associated with an increased respiratory rate, correlate with electromyography (EMG) evidence of diaphragm fatigue and occur prior to the development of hypercapnia.[17] Figure 15-9 illustrates this point in patients who develop respiratory failure due to diaphragm fatigue while weaning from mechanical ventilation.

Both FEV_1 and PEFR are used to diagnose airflow obstruction and assess the response to treatment.

Respiratory muscle pressures may help to identify the cause of respiratory failure by examining the degree of respiratory muscle strength.

Measurement of respiratory muscle pressures depends on patient effort, operator technique, and the lung volumes at which the pressures are measured.

CHEST IMAGING

Common chest imaging in the evaluation of respiratory failure includes the portable chest X-ray, and occasionally, chest CT and ventilation–perfusion lung scanning.

Ventilation–perfusion lung scanning may be important in the diagnosis of pulmonary embolism as the cause of respiratory failure.

Chapter 11 reviews radiologic imaging in the critically ill patient in detail. This section only discusses chest imaging as it relates to the evaluation of respiratory failure. In selected patients, chest imaging can provide important information as to the cause of respiratory failure. The imaging test most commonly used for evaluating respiratory failure is the chest X-ray; however, in some circumstances, chest computed tomography (CT) and ventilation–perfusion lung scanning may also be valuable.

The chest X-ray may be important in demonstrating the severity of the chest wall abnormality that contributes to the development of respiratory failure. The chest X-ray can identify patients who present with respiratory failure due to severe kyphoscoliosis or flail chest. In patients with severe kyphoscoliosis, the degree of thoracic spine deviation seen on chest X-ray can be quantitated and used to predict the onset of hypercapnic respiratory failure. Chest X-ray findings may suggest the cause and magnitude of the primary pulmonary process that is contributing to the respiratory failure; including the presence and extent of severe COPD, pneumonia, diffuse infiltrates, or pulmonary edema. A chest X-ray may also be helpful in assessing patients' response to therapy.

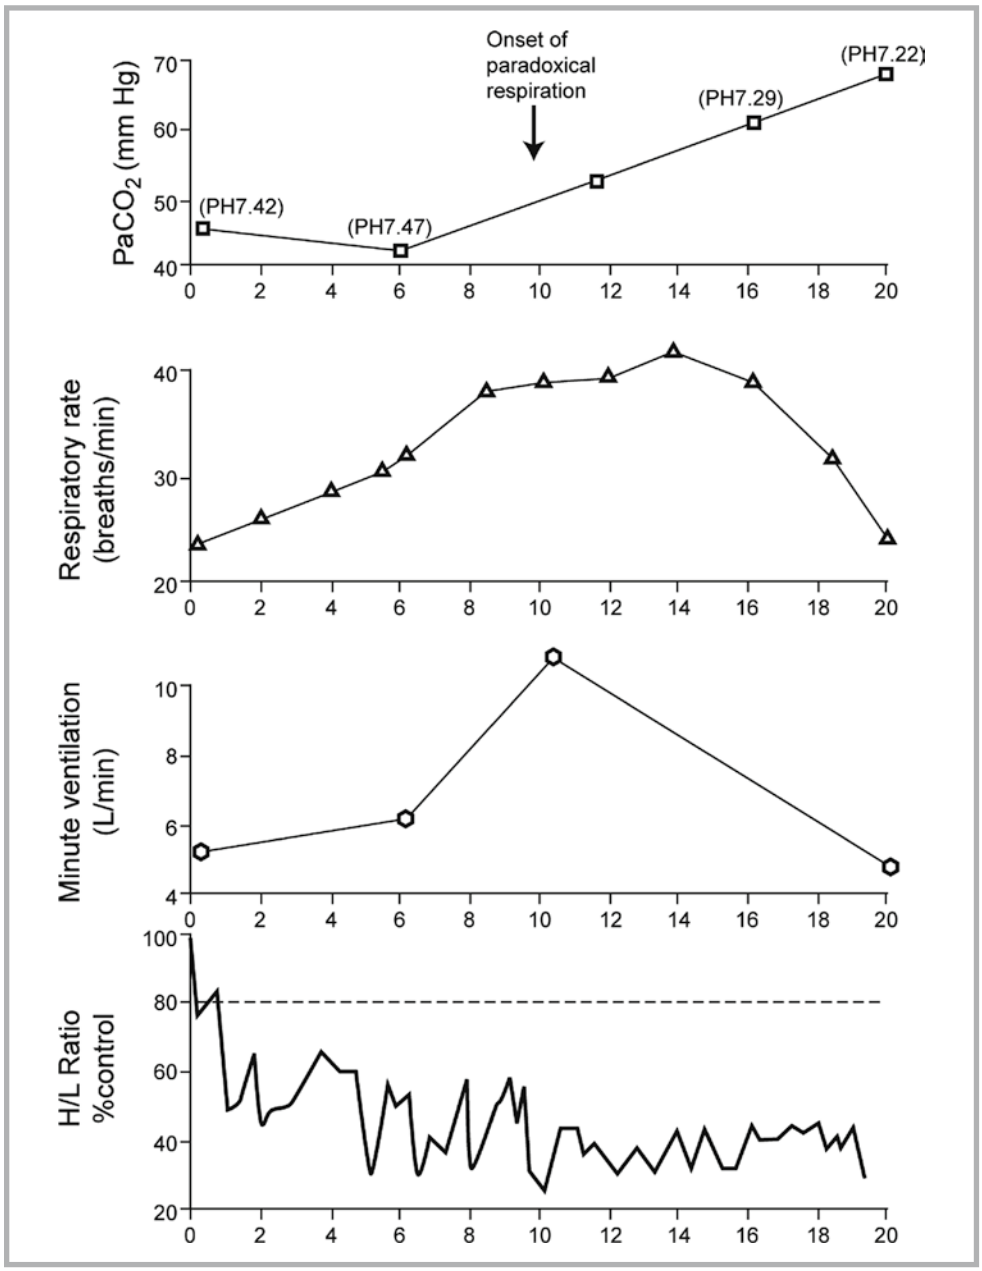
In comparison to the chest X-ray, the chest CT is a more sensitive and specific imaging tool in differentiating pleural from parenchymal abnormalities. The chest CT may also be more specific in characterizing the pattern of lung involvement by the underlying disease process. The use of intravenous contrast during chest CT imaging may also help to identify pulmonary vascular abnormalities (e.g., pulmonary embolism, arteriovenous malformation) and their potential role in the pathogenesis of respiratory failure.

In patients who suffer predominantly from unexplained hypoxemic respiratory failure, lung ventilation–perfusion scanning may be helpful in assessing individual lung region participation in ventilation and perfusion. Specific patterns of ventilation–perfusion abnormalities can be considered diagnostic of pulmonary thromboembolism and aid in the diagnosis of pulmonary embolism as a cause for respiratory failure. If lung ventilation–perfusion scanning is nondiagnostic, pulmonary angiography or spiral CT with contrast may help rule-in or rule-out pulmonary embolism.

CASE STUDY: PART 3

The patient was admitted to the intensive care unit and maintained on mechanical ventilation in the assist control mode. She remained on 100% oxygen with increasing levels of PEEP to decrease intrapulmonary shunt and to improve oxygenation by increasing end-expiratory lung volume. After 12 cm H_2O PEEP was applied with an F_IO_2 of 100%, her PaO_2 increased to 220 mmHg. F_IO_2 was decreased to 60% to maintain SaO_2 at 94%. The patient continued to receive aggressive bronchodilator therapy to alleviate bronchospasm and was also administered sedative/hypnotics and intermittent neuromuscular blocking agents to facilitate patient–ventilator synchrony and to decrease patient effort.

A sputum Gram stain showed a marked increase in the number of white blood cells and gram-negative cocci. The patient was administered cefepime 1 g twice daily and placed on prophylactic therapy for gastritis and deep venous thrombosis. She was started on enteral feeding via a nasogastric feeding tube.



Laboratory tests helpful in diagnosing problems contributing to respiratory failure include hemoglobin, hematocrit, electrolytes, bicarbonate level, anion gap, and concentration of electrolytes, including calcium, magnesium, potassium, and phosphate.

In selected patients, assessment of neuromuscular and cardiovascular status is important.

FIGURE 15-9

The sequence of changes that occur in respiratory rate, pattern of breathing, minute ventilation, electromyographic activity of the diaphragm and $PaCO_2$ in a patient weaning from mechanical ventilation who develops diaphragm fatigue. Paradoxical movement of the upper abdomen and an increase in respiratory rate (*arrow*) coincide with a reduction in the diaphragm EMG H/L ratio indicating the development of diaphragm fatigue contributing to the development of respiratory failure (Illustration by Alice Chen, modified from reference 17).

Other Laboratory Tests

In some patients, nonpulmonary tests may help provide clues to the cause or the temporal nature of the disorder precipitating respiratory failure. The presence of secondary polycythemia indicates the presence of chronic hypoxemia. Metabolic testing can show electrolyte abnormalities that may explain respiratory pump dysfunction (e.g., hypocalcemia, hypokalemia, hypomagnesemia, and hypophosphotemia; all impair skeletal muscle contractility) and also related metabolic abnormalities, such as metabolic acidosis or alkalosis, which have major implications for respiratory workload, cardiopulmonary function, and the oxyhemoglobin dissociation curve.[18] In some patients, cardiac ischemia and cardiac dysfunction may contribute to respiratory failure, and assessment with electrocardiography, echocardiogram, or right heart catheterization (e.g., Swan–Ganz catheter) may be indicated.[19,20] Finally, measurements of creatine phosphokinase, aldolase, or EMG, or tests for nerve conduction may be important to determine whether systemic neurologic diseases are causing respiratory pump failure.

TREATMENT OF RESPIRATORY FAILURE

As with identifying the cause of respiratory failure, treatment of respiratory failure is based on characterizing the underlying process with regard to whether it impairs pump capacity (i.e., hypercapnia) or gas exchange (i.e., hypoxemia). Therefore, organizing diagnostic testing and treatment for respiratory failure is best done after it has been characterized as hypoxemic, hypercapnic respiratory failure, or as hypoxemic, nonhypercapnic respiratory failure. Figure 15-10 outlines the approach to treatment of respiratory failure based on whether pump failure or lung failure is the predominant cause. More specific guidelines for oxygenating the patient (Chap. 2), the use of mechanical ventilation (Chaps. 44, 45, and 46), and providing hemodynamic support (Chaps. 48 and 49) are provided in specific chapters. This section briefly outlines the treatment for the patient who presents with respiratory failure.

Oxygenation

Oxygen should always be used as the initial treatment for hypoxemic respiratory failure.

Many devices may be able to provide supplemental oxygen to patients in respiratory failure; nasal prongs are comfortable, but inefficient.

Masks are cumbersome but more efficient in increasing supplemental oxygen concentration.

A venturi delivery device allows more precise delivery of supplemental inspired oxygen.

Regardless of etiology, the initial approach to the treatment of patients with respiratory failure is to identify those who need supplemental oxygen. Oxygen is frequently necessary for patients who present with hypoxemia or with conditions known to predispose to hypoxemia. Most of the initial morbidity and mortality that occurs in patients who present with respiratory failure results from the consequences of untreated hypoxemia.

Various types of external oxygen delivery devices are now available to provide variable concentrations of inspired oxygen. The choice of a particular device depends on (1) the magnitude of supplemental oxygen required by the patient to achieve effective oxygenation; (2) the need for precise control of supplemental oxygen to avoid excessive oxygenation and the development of hypercapnia; (3) whether airway control is needed to suction the patient for excessive secretions; and (4) whether other techniques are needed to increase oxygen by increasing lung volume (externally applying positive pressure to the airway by CPAP or PEEP.

Delivering supplemental oxygen using nasal prongs is the simplest and most comfortable method. However, despite its comfort, this apparatus cannot be used to provide high levels of oxygen. Moreover, it does not provide enriched oxygen in an extremely precise manner, because room air is entrained when patients mouth-breathe or during high levels of spontaneous ventilation. Face mask devices (outlined in Chap. 2) fit more tightly and may have nonrebreathing valves that, coupled with an inspiratory reservoir of oxygen, provide higher and more precise concentrations of supplemental oxygen. Using these types of face masks may allow the inspired oxygen concentration to reach 80–95%. In addition, these devices can accommodate the use of valves, which allow application of external levels of PEEP, and simultaneously increase lung volume, decrease intrapulmonary shunt, and improve oxygenation. Moreover, delivery of oxygen by means of a face mask with a Venturi device (a calibrated

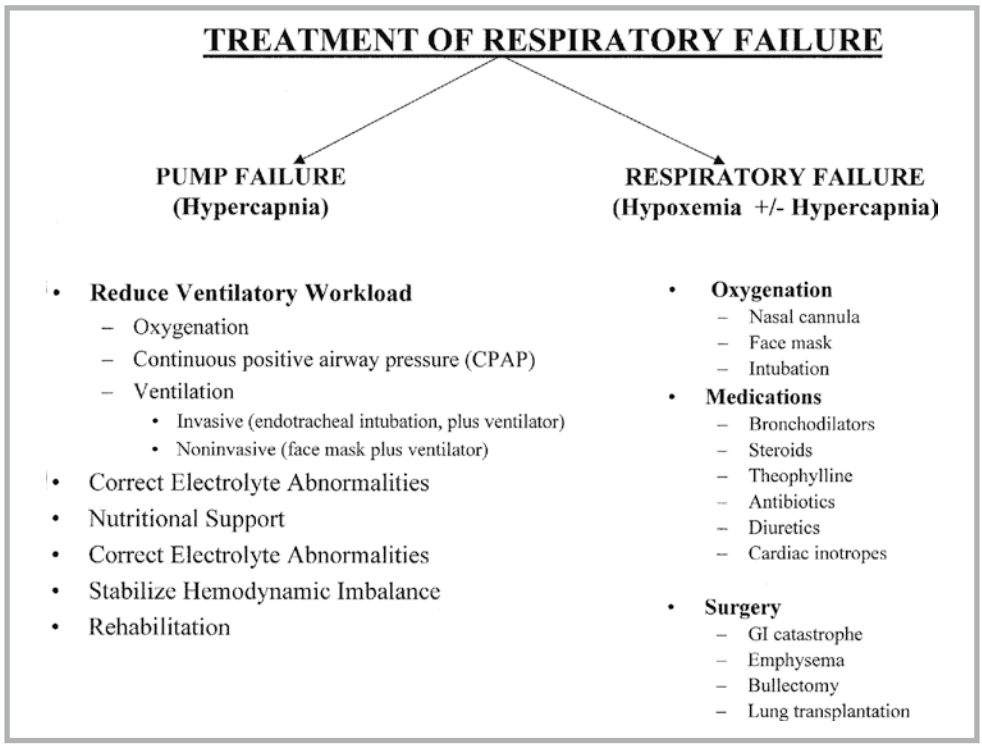


FIGURE 15-10

Treatment of respiratory failure organized into pump (hypercapnic) and lung (hypoxemia with, or without, hypercapnic) respiratory failure.

inline device) can provide high flows of oxygen in a more precise manner and minimize the effect of room air entrainment.

Medications

The use of medications in the treatment of respiratory failure depends on the underlying disorder. In patients who present with an exacerbation of airway obstruction, bronchodilators, corticosteroids, theophylline preparations, and possibly antibiotics, are required. In patients who present with pulmonary edema due to volume overload, or with cardiac dysfunction, diuretics are in order. In patients who have more pronounced cardiac dysfunction, the selected use of cardiac inotropes may be required. Other medications may be useful to improve the pump performance of the diaphragm and other respiratory muscles by increasing either diaphragm blood flow or diaphragm contractility.[21-25]

Invasive or noninvasive mechanical ventilation is used to augment spontaneous ventilation.

Supportive Therapy

Acid–base or electrolyte disturbances may compromise respiratory pump function and contribute to an elevated ventilatory workload. Hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphotemia all have been identified as conditions that lead to skeletal muscle weakness and, specifically, respiratory skeletal muscle weakness.[18,26] Correction of these abnormalities can markedly improve ventilatory muscle strength and increase respiratory reserve. Additionally, regardless of etiology, metabolic acidosis increases ventilatory workload and its presence should be identified and appropriately treated. For example, diabetic ketoacidosis responds to infusion of fluids, electrolyte management, and administration of insulin. In other cases, severe metabolic acidosis that causes respiratory compromise and leads to respiratory failure may be best treated by hemodialysis. The use of ancillary testing and physical examination must appropriately diagnose the cause of metabolic acidosis because effective therapy of this disorder is a crucial part of the overall treatment plan for respiratory failure.

Nutritional support and, in some cases, reconditioning are also important in restoring respiratory pump function and reversing the presence of respiratory failure.[1] Undernutrition,

found in at least 40% of hospitalized COPD patients, has major implications on respiratory muscle mass and affects the composition of respiratory muscle fiber type. Renutrition increases respiratory muscle mass and restores ventilatory muscle endurance, an important beneficial physiologic effect that results in an improvement in respiratory pump function. Moreover, rehabilitation of patients who present in a deconditioned state, or with disuse atrophy after a critical illness, is similarly important in restoring respiratory pump function.

Reducing Ventilatory Workload

In some patients, the methods described here are inadequate for reducing ventilatory workload so as to permit spontaneous ventilation. In these cases, ventilatory workload far exceeds capacity, and the patient's spontaneous effort must be augmented with mechanical ventilation until the condition causing the higher workload resolves or the patient's ventilatory capacity increases.

Augmentation of the patient's spontaneous breathing effort can be achieved by either invasive or noninvasive forms of mechanical ventilation. In noninvasive mechanical ventilation, a nasal or nasal oral face mask is used to augment the patient's spontaneous efforts without the use of an artificial airway. In the case of invasive ventilation, an artificial conduit is inserted in the patient's airway, either an endotracheal tube or a subglottically placed tracheotomy tube. In both cases, the ventilator can be manipulated to adjust the amount of applied ventilation, the pattern of breathing, the inspiratory flow rate, and the concentration of inspired oxygenation. Details on the specific use of noninvasive mechanical ventilation are provided in Chap. 46 and the use of invasive mechanical ventilation is discussed in Chaps. 44 and 45.

Invasive ventilation is the method most frequently used to augment a patient's spontaneous respiratory effort. When using invasive ventilation, endotracheal intubation is considered mandatory for the patient's therapy so as to (1) provide airway protection; (2) serve as a conduit for suctioning patients with excessive mouth or lower respiratory tract secretions; (3) achieve higher inspired oxygen concentrations than are possible with a face mask; and (4) apply positive pressure via the ventilator to increase lung volume to treat refractory hypoxemia.

As outlined in Chap. 1, endotracheal intubation may be accomplished by either nasal or oral translaryngeal intubation. Oral intubation uses a larger endotracheal tube and is easier to perform under emergent conditions because the vocal cords are visualized directly with a laryngoscope or via a fiberoptic endoscope. In addition, nosocomial sinusitis is less likely to develop in patients who have oral intubations. However, in the long term, the oral intubation route is uncomfortable for patients, securing of the endotracheal tube is less stable, and providing optimal oral hygiene is difficult. Nasal intubation is easier to perform in the spontaneously breathing patient, is anchored to the patient's face less obtrusively, and therefore facilitates patient comfort. However, nasal intubation is not without its own set of complications. Nasal intubation for longer than 5–7 days is associated with a higher incidence of nosocomial sinusitis and nosocomial pneumonia; also, because of its smaller size, the nasal tube has a higher resistance to gas flow than larger, orally placed tubes. These latter factors may be important in patients who require intubation for the treatment of respiratory failure for more than several days, or have a primary increase in airways resistance due to asthma or COPD as a cause of respiratory failure. In both these examples, nasal intubation may hinder the weaning process and lead to more complications. Although no general guidelines can be given for all patients, patients who require a longer intubation for respiratory failure, on balance, probably benefit more from oral vs. nasal intubation. If a prolonged weaning process is anticipated a tracheotomy should be considered.

Mechanical ventilators are intended to stabilize gas exchange imbalances until the primary process resolves, not necessarily to achieve normal gas exchange parameters of pH, PaO_2, or $PaCO_2$. In some patients, normal values of gas exchange cannot be easily obtained without significant complications arising because of mechanical ventilation. For example, if maintaining a normal $PaCO_2$ or pH predisposes the patient to unacceptably high airway pressure or lung volumes, and results in hypotension or ventilator-induced lung injury, the benefit

CASE STUDY: PART 4

The patient continued to improve with the use of bronchodilators, antibiotics, and supportive care measures. Subsequent chest X-rays showed significant clearing of pulmonary infiltrates. The patient's inspired oxygen concentration was decreased to 40%, and PEEP was discontinued. While performing a spontaneous breathing trial via a 40% T-piece setup, the patient demonstrated satisfactory hemodynamic parameters, and respiratory variables, and was extubated. Following extubation, the patient continued to exhibit severe weakness of the lower extremities, secondary to the prior use of high-dose steroids and intermittent administration of neuromuscular blocking agents. The patient was transferred to an intermediate care unit where she received whole-body rehabilitation, respiratory toilet, continuation of bronchodilator therapy, and completion of an antibiotic course. As the patient improved, swallowing function was evaluated, and the patient was restored to normal eating. The tracheotomy tube was downsized and eventually the patient was decannulated. The patient was discharged and successfully transitioned from the hospital to home. The final diagnosis for this patient was mild chronic obstructive lung disease with the development of multilobar Pseudomonas pneumonia and respiratory failure.

from achieving normal gas exchange is lost. The goal of ventilation must be readjusted to one that stabilizes the patient's gas exchange imbalance without further subjecting the patients to undue complications from the mechanical ventilation process itself. More details on choosing the appropriate form of ventilation and ventilator settings and identifying the complications of mechanical ventilation are provided in Chaps. 44–46.

The goal of mechanical ventilation is to stabilize gas exchange disturbance. Obtaining normal values for $PaCO_2$ and PaO_2 is not the primary objective.

Other Therapy

In some patients, surgery may have a limited but occasionally important role in the treatment of respiratory failure. Patients who present with an intraabdominal catastrophe from a ruptured viscus, vascular accident, or severe gastrointestinal bleeding may be required to undergo surgery to treat the underlying problem contributing to respiratory failure. These cases are mainly patients who present with acute manifestations of respiratory failure and usually require surgical intervention during the initial phases of their treatment for respiratory failure.

Surgery has a limited, but occasionally important role in the treatment of respiratory failure.

On the other hand, selected patients with severe, advanced lung disease with chronic forms of respiratory failure may be candidates for surgical treatment of respiratory failure per se. In these cases, stabilization of the chest wall in patients who suffer from flail chest, decortication of fibrotic pleura trapping the lung after a preceding pleural space inflammatory process, and resection of large bulla that compromise otherwise viable lung tissue in patients with advanced COPD, are indications for surgery as a primary treatment for chronic respiratory failure. In the last 10 years, single-lung, double-lung, and heart–lung transplantations have also been used to treat some patients with advanced lung diseases causing respiratory failure. In these cases, respiratory failure can be the result of end-stage COPD, interstitial lung disease, cystic fibrosis, or pulmonary hypertension. However, to optimize survival, this therapy is relegated to patients who present with chronic forms of respiratory failure that do not require ICU care or the use of invasive ventilation.

SUMMARY

The approach to the patient who presents with respiratory failure includes a systematic effort to identify the cause of respiratory failure and categorize it as a pump or lung failure subtype, using clinical history, physical examination, and selected laboratory tests. Treatment options are also organized on the basis of whether pump or lung failure is the predominant cause of respiratory failure, and treatment is implemented in a logical fashion to treat the underlying disorder, correct derangements in gas exchange, and reduce ventilatory workload.

REVIEW QUESTIONS

1. **An example of a disorder that primarily causes respiratory system pump failure is multilobar pneumonia. This statement is:**
   A. True
   B. False

2. **A 30-year-old woman presents to the emergency room 1 h after injecting heroin and is found to have an oxygen saturation of 82% by pulse oximetry. An arterial blood gas taken while the patient breathes room air oxygen shows that PaO_2 is 55 mmHg, $PaCO_2$ is 48 mmHg, and pH is 7.32. The patient is placed on a 100% face mask; 1 h later, oxygen saturation by pulse oximetry is 88–90%. The most likely cause of hypoxemia in this patient is:**
   A. Ventilation–perfusion mismatch
   B. Intracardiac shunting
   C. Intrapulmonary shunting
   D. Alveolar hypoventilation

3. **The most important and initial laboratory test to perform in the assessment of respiratory failure is:**
   A. Chest X-ray
   B. Serum magnesium
   C. Ventilation–perfusion lung scan
   D. Hemoglobin level
   E. Arterial blood gas

4. **One of the first therapies to consider in a patient presenting with respiratory failure is:**
   A. Mechanical ventilation
   B. Surgical intervention
   C. Antibiotics
   D. Bronchodilators
   E. Supplemental oxygen

5. **A 28-year-old man presents with a change in mental status over the past 4 days. He has a known diagnosis of chronic spinal muscle atrophy and is followed in neurology clinic. Over the last several days to weeks, the patient's family has noted an increase in morning headaches, the development of hypersomnolence, and increased forgetfulness. An arterial blood gas while the patient is breathing room air oxygen shows that PaO_2 is 40 mmHg, $PaCO_2$ is 80 mmHg, and pH is 7.29. The most likely cause of hypoxemia in this patient is:**
   A. Ventilation–perfusion imbalance
   B. Intracardiac shunting
   C. Intrapulmonary shunting
   D. Alveolar hypoventilation

ANSWERS

1. The answer is B. False. Multilobar pneumonia is an example of lung failure wherein hypoxemia results when the alveolus becomes filled with inflammatory debris and fluid; this results in hypoxemic respiratory failure as a result of intrapulmonary shunting and ventilation–perfusion imbalance. Diseases in which respiratory failure is caused by pump failure include disorders that affect the cerebral and peripheral nervous system, chest wall, upper airways, and respiratory muscles.
2. The answer is C. Intrapulmonary shunting. Although this patient presented with a disorder that could lead to alveolar hypoventilation, namely heroin overdose, the patient's blood gas does not show profound hypoventilation. By using the alveolar gas equation, the patient's A-a gradient was found to be 35. The patient demonstrated refractoriness to improving her oxygenation by the use of a high concentration of inspired oxygen. Hypoxemia in this patient's cause is associated with an elevated A-a gradient, which is refractory to a high concentration of inspired oxygen; this would most likely be a result of intrapulmonary or intracardiac shunting. In this case, without prior cardiac history, and in light of a known condition that can lead to pulmonary aspiration of gastric contents or heroin-induced cardiogenic edema, a pulmonary disease such as multilobar pneumonia, aspiration pneumonia, or acute respiratory distress syndrome, leading to intrapulmonary shunting, is the most likely diagnosis.
3. The answer is E. The arterial blood gas. The arterial blood gas analysis allows one to measure three important components in determining the cause, the severity, and finally the chronicity of the disturbance causing respiratory failure. With a blood gas, one measures PaO_2, $PaCO_2$, and pH. One can also calculate the alveolar–arterial oxygen gradient to determine whether a reduction in PaO_2 is secondary to hypoventilation vs. intrapulmonary, intracardiac shunt, or ventilation–perfusion imbalance.
4. The answer is E. Supplemental oxygen. In most patients who present with respiratory failure, hypoxemia is present. In fact, in almost all cases of respiratory failure, hypoxemia is the most important derangement in gas exchange. If untreated, hypoxemia can contribute to the development of stroke, myocardial dysfunction, or some other manifestation of severe organ dysfunction. Therefore, oxygen is the first therapy to contemplate in the patient who presents with respiratory failure. In patients who present with pump dysfunction, the use of devices to augment spontaneous ventilation are required, that is, mechanical ventilation in the form of noninvasive or invasive modalities. Similarly, bronchodilators and antibiotics have a role as adjunctive therapy when patients present with bronchospasm or infection. However, oxygen is the first therapy to consider because hypoxemia is the major disturbance in patients who present with respiratory failure, which has substantial morbidity and mortality.
5. The answer is D. Alveolar hypoventilation. In the patient breathing room air at sea level, the P_IO_2 is 150. Subtracting from this value, the $PaCO_2$/R (assuming $R=0.8$) and then subtracting PaO_2 of 40 mmHg measured from an arterial blood gas, the alveolar–arterial oxygen gradient is 10. An A-a gradient of 10 suggests that the lung is normal and the patient's hypoxemia is a result of respiratory pump failure, or hypoventilation. The pH is greater than expected

if this was due to an acute condition causing respiratory failure, suggesting that this is an acute-on-chronic presentation of respiratory failure, or a compensated chronic respiratory acidosis. Features from the patient's history documenting a decline in mental function over several days to a week, the development of hypersomnolence, and an early morning headache all suggest an insidious onset of progressive hypercapnia.

Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Define acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).
- Recognize the signs and symptoms of ALI/ARDS.
- Recognize the inflammatory mechanisms involved in ALI/ARDS.
- Recognize the changes in respiratory mechanics that accompany ALI/ARDS.
- Know the major treatment strategies for ALI/ARDS.

HISTORY AND DEFINITION

Pulmonary edema in the absence of heart failure was first noted by Laennec in *A Treatise on Diseases of the Chest*[1] when he described "idiopathic anasarca" of the lungs. As medical technology progressed, pulmonary edema became a well-recognized medical condition; however, in the absence of mechanical ventilation and modern ICU care, most patients did not survive long enough for the distinction between cardiogenic and noncardiogenic pulmonary edema to be recognized.

With the advent of temporary military hospitals, located close to the battlefield and equipped with X-ray equipment, physicians first recognized in the 1950–1960s that wounded soldiers would sometimes present with a chest X-ray appearance of "wet lungs," "shock lungs," or "white lungs." It was coined "Da Nang lung" during the Vietnam War because so many cases were treated at a medical facility in that Vietnamese city. As military doctors returned home and entered private practice, they encountered a similar lung condition among patients of all ages and many became suspicious that it was similar to Da Nang lung.

In 1967, Ashbaugh, Bigelow, Petty, and Levine[2] described an acute respiratory distress syndrome (ARDS) with the clinical features of dyspnea, tachypnea, refractory cyanosis, decreased pulmonary compliance, diffuse alveolar infiltrates, vascular congestion, atelectasis, hemorrhage, pulmonary edema, and hyaline membrane formation at autopsy that was caused by a wide range of systemic insults including aspiration, trauma, sepsis, and drowning. The A in ARDS was changed from acute to adult after a 1971 paper[3] used this nomenclature to distinguish it from infant respiratory distress syndrome. In 1988, Murray et al.[4] attempted to define ARDS with a four-point scoring system that was based on oxygenation, PEEP, respiratory compliance, and CXR findings.

Due to confusion regarding the definition and nomenclature surrounding ARDS, the American–European consensus conference on ARDS (AECC) was conferred in 1992, with the intention of bringing "clarity and uniformity to the definition of ALI and ARDS." ARDS was defined as "a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiologic, and physiologic abnormalities that cannot be explained by, but may coexist with left atrial or pulmonary capillary hypertension, and is associated most often with sepsis syndrome, aspiration, primary pneumonia, and multiple trauma and less commonly with cardiopulmonary bypass, multiple transfusions, fat embolism, pancreatitis, and others."[5] Formal criteria for diagnosis of ALI and ARDS were agreed upon; ALI was defined as (1) diffuse bilateral infiltrates of acute onset, (2) pulmonary capillary wedge pressure (PCWP) <18 cm H_2O, (3) hypoxemia with a PaO_2/FiO_2 ratio of <300; ARDS is present when the PaO_2/FiO_2 ratio is <200.

Definition of ALI
1. Acute onset
2. Diffuse bilateral infiltrates
3. PCWP <18 cm H_2O
4. Hypoxemia with PaO_2/FiO_2 <300

Definition of ARDS
1. Acute onset
2. Diffuse bilateral infiltrates
3. PCWP <18 cm H_2O
4. Hypoxemia with PaO_2/FiO_2 <200

Other recommendations were to redefine again the A in ARDS as *acute* instead of *adult*; reinforcing the notion that ARDS is not limited to adults. The committee also established the concept of acute lung injury (ALI) as a separate entity that may be contiguous with ARDS; i.e., all patients with ARDS have ALI but not all patients with ALI develop ARDS.

There are numerous difficulties in using the more recent formal definition of ARDS in clinical practice. Specifically, the PaO_2/FiO_2 does not account for the level of PEEP or the intensity of mechanical ventilation. PEEP was not included in the definition because many patients have an inconsistent response to PEEP and the length of time a patient is on a given level of PEEP can influence its efficacy. Additionally, the PaO_2/FiO_2 cut off of <200 was determined arbitrarily. Cut offs of <150 and <250 were discussed, with most authorities agreeing that the former would be more specific and the latter more sensitive. A PCWP of <18 cm H_2O was chosen to differentiate ARDS from cardiogenic pulmonary edema, but with the dwindling use of pulmonary artery catheters (PACs), the clinical absence of a diagnosis of cardiogenic pulmonary edema will eventually replace the PCWP criterion.

Pathologic confirmation with lung biopsy is not required with the newer definition of ARDS/ALI and does not categorize patients according to direct or indirect lung injury, or the presence or absence of nonpulmonary organ dysfunction. Thus, in a recent series of autopsy patients, the current clinical criteria had only a moderate sensitivity of 75% when compared with a tissue diagnosis of diffuse alveolar damage, but were more accurate for patients with indirect lung injury than those with direct lung injury. Furthermore, there

The lack of specificity in diagnostic criteria may account, in part, for the variability in incidence and outcomes found in various epidemiological studies of ARDS/ALI.

CASE STUDY: PART 1

A 55-year-old man presents to the emergency room with a chief complaint of abdominal pain, nausea, and vomiting. The patient reports mild abdominal pain that started approximately 2 days ago. This morning he developed worsening pain and vomiting. Currently, he cannot tolerate solids or liquids. His past medical history is significant for hypertension and hepatitis C. He smokes approximately one pack of cigarettes per day and drinks 4–5 six-packs a week.

On physical exam:

- BP 110/60, HR 109, Temp 100.2, RR 18, O_2 sat 96% on 2 L nasal cannula
- General: well developed, in moderate distress
- HEENT: PERRL, anicteric, dry mucus membranes, no JVD
- Heart: tachycardia, regular rate, no mummers or gallops
- Lung: clear to auscultation bilaterally
- Abdomen: marked tenderness midline, bowel sounds quiet, voluntary guarding, no masses or hepatomegaly
- Extremities: cool dry, no clubbing, cyanosis, or edema
- Initial laboratory values: Hemoglobin 15.5 g/dL, Hematocrit 45%, White blood cell count 10.8 K/mL, Platelets 452 K/UL, Chemistry, Sodium 145 Mmol/L, Potassium 4.2 Mmol/L, Chloride 110 Mmol/L, Bicarbonate 23 Mmol/L, Creatinine 1.2 mg/dL, Bun 22 mg/dL, Amylase 350 U/L, Lipase 400 U/L, Liver function tests, ALT 35 U/L, AST 36 U/L, Alk Phos 73 U/L, Direct bilirubin 0.4 mg/dL, Total bilirubin 1.1 mg/dL, Total protein 6.4 g/dL, Albumin 4.1 g/dL

CXR shows increased interstitial opacity more prominent on the right consistent with infectious process vs. CHF The patient is admitted with a diagnosis of acute pancreatitis.

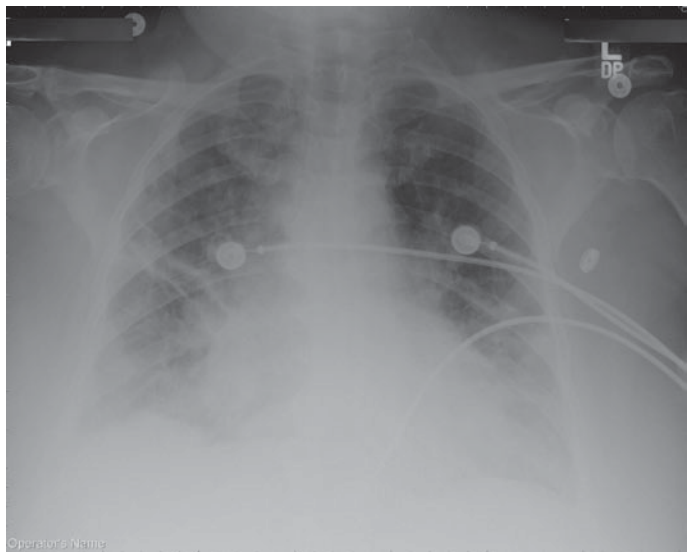

TABLE 16-1

HISTORY OF ARDS

1821	Described by Laennec[1] as "idiopathic anasarca of the lung"
1950–1960s	Noncardiogenic pulmonary edema recognized. Referred to as "shock lung," "wet lung," and, during the Vietnam War, "Da Nang Lung"
1967	Ashbaugh et al.[2] publish modern description of ARDS
1988	Murray et al.[4] describe lung injury score to better characterize ARDS
1992	Bernard et al.[5] American–European Consensus Conference on ARDS (AECC) generates formal criteria for diagnosis
1994	NHLBI, NIH establish ARDSnet. www.ardsnet.org

is high interobserver variability amongst experienced clinicians applying the definition's radiographic criterion. The calculation of the PaO_2/FiO_2 is less reliable when applied to an FiO_2 less than 0.5 and a PaO_2 greater than 100 mmHg, and the level of PEEP is not considered. The lack of specificity in the diagnostic criteria may in part account for the variability in incidence and outcomes found in various epidemiologic studies.

ARDSnet is a clinical research network aiming to identify new agents for treatment, develop protocols, facilitate conduct and monitoring of trials, and report study results.

In 1994, the National Heart, Lung, and Blood Institute, National Institutes of Health, initiated a clinical network to carry out multicenter clinical trials of ARDS treatment (ARDSnet). ARDSnet consists of a clinical research network of approximately 42 hospitals, organized into 12 clinical sites, and a coordinating center. The ARDSnet goal is to identify promising new agents for the treatment of ARDS, develop protocols, facilitate the conduct and monitoring of the trials, and report study results (Table 16-1).

EPIDEMIOLOGY

Incidence

ALI/ARDS is a prevalent and costly condition with an estimated 190,600 cases occurring annually; patients with these diagnoses consume 3.6 million hospital days each year. The overall incidence of ALI/ARDS is 78.9/100,000 (ALI) and 58.7/100,000 (ARDS) with both conditions more common in older age groups; 16/100,000 in 15–19-year-olds and 306/100,000 in 75–84-year-olds.[6,7]

ALI/ARDS can be caused by either direct or indirect injury to the lung.

Causes

ALI/ARDS can be caused by either direct or indirect injury to the lung. Conditions that can directly injure the lungs include pneumonia, inhalation injury, aspiration of gastric contents, and near-drowning. Conditions that indirectly injure the lungs include sepsis, massive blood transfusion, severe trauma and burns, pancreatitis, fat embolism, postobstruction of the upper airway, lung and bone marrow transplantation, and drug overdose. Other factors that contribute to the risk of developing ARDS include alcoholism, tobacco abuse, absence of diabetes, and greater severity of illness[8] (Table 16-2).

Conditions that can directly injure the lungs include pneumonia, inhalation injury, aspiration of gastric contents, and near-drowning.

Conditions that indirectly injure the lungs include sepsis, massive blood transfusion, severe trauma and burns, pancreatitis, fat embolism, postobstruction of the upper airway, lung and bone marrow transplantation, and drug overdose.

Genetic Factors

Interestingly, only some of the patients with these relatively common conditions go on to develop full blown ARDS; this suggests the involvement of genetic factors in ARDS development. Surfactant protein-B (SP-B) is one of the hydrophobic proteins crucial to the surface-lowering properties of surfactant. A polymorphism containing a variable number of tandem repeats of the SP-B gene was found in infants with respiratory distress syndrome. This variant SP-B gene was found to be associated with the development of ARDS in women with direct lung injury but not in men.[9] The renin-angiotensin system may also be influential in the development of ARDS by increasing vascular permeability, vascular tone, and fibroblast activity, and by reducing alveolar epithelial cell survival. Almost half of the variability in plasma ACE activity is accounted for by an ACE insertion/deletion (I/D) polymorphism. The D allele is associated with higher activity. Patients with ARDS were found to have an increased frequency of the DD phenotype compared to other intubated critically ill patients.[10] The relevance of the DD phenotype is not apparent. How the polymorphism relates to the propensity for ARDS development requires elucidation.

Some of the patients with only relatively common conditions go on to develop full blown ARDS, suggesting the involvement of genetic factors in ARDS development.

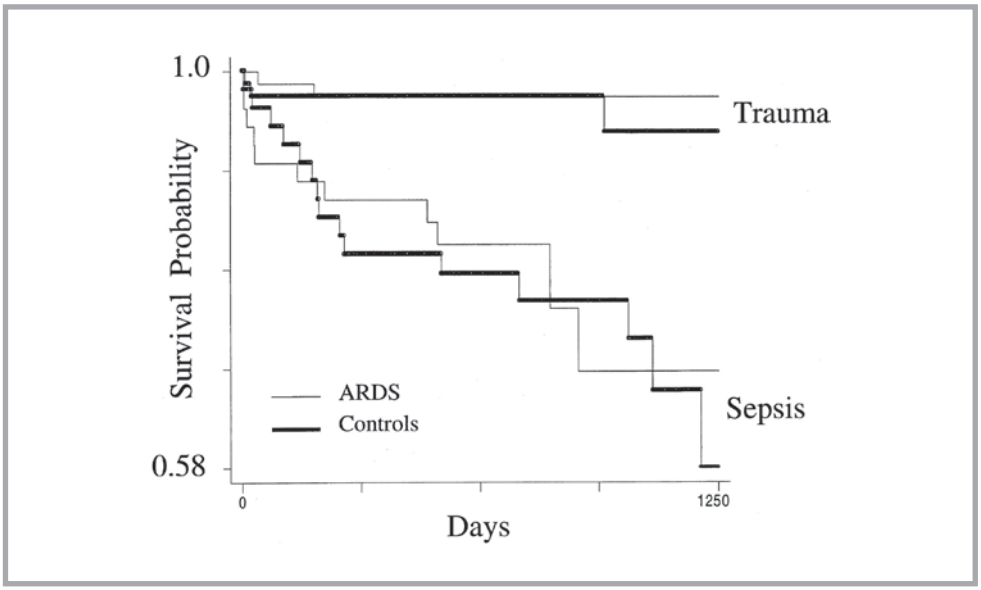
TABLE 16-2

INDIRECT AND DIRECT LUNG INJURIES THAT CAUSE ALI/ARDS

INDIRECT LUNG INJURY	DIRECT LUNG INJURY
Sepsis	Aspiration of gastric contents
Trauma	Pneumonia
Acute pancreatitis	Fat embolism
Shock	Amniotic fluid emboli
Multiple transfusions	Air embolism
Bone marrow transplantation	Upper airway obstruction
Disseminated intravascular coagulation	Cocaine
Burns	Near drowning
Drug overdose	Toxic gas inhalation
Thrombotic thrombocytopenic purpura	Lung contusion
Cardiovascular bypass	Radiation exposure
Head injury	High altitude exposure

FIGURE 16-1

Survival of hospitalized patients after discharge. There was no difference in survival between sepsis patients with and without ARDS and trauma patients with and without ARDS (reprinted with permission from Davidson et al.[12] the Official Journal of the American Thoracic Society. ©American Thoracic Society).



Mortality

Both ALI and ARDS carry significant mortality, 38.5% in ALI vs. 41.1% in ARDS.

Difference in mortality among age groups may be due to differences in the underlying cause of ARDS.

Overall, survival in ARDS has improved; however, it is important to recognize that mortality depends upon the underlying illness.

Both ALI and ARDS carry significant mortality, 38.5% in ALI vs. 41.1% in ARDS. Mortality increases in older age groups to 24% in 15–24-year-olds vs. 60% in those greater than 85 years of age. The difference in mortality among age groups may be due to differences in the underlying cause of ARDS. The elderly are more likely to develop ARDS due to sepsis while trauma is the most frequent inciting event in the young. Interestingly, the cause of death in ARDS is usually due to sepsis with multiorgan failure (30–50%); respiratory failure is relatively uncommon (13–19%).[11] The best prognosis for survival in ARDS is found in young trauma patients. When ARDS patients were followed long-term (average 753 days), the mortality for patients with sepsis-induced ARDS was no different than the mortality for patients with sepsis who did not develop ARDS; the same held true for trauma patients.[12] This reinforces the concept that the outcome from ARDS is dependent on the underlying cause (Fig. 16-1).

Multiple studies have assessed predictors of mortality in ARDS: increased fraction of dead space ventilation, persistent hypoxemia, the severity of respiratory illness as assessed by the oxygenation index, cirrhosis, right ventricle dysfunction, the inciting event (sepsis or indirect lung injury vs. trauma or direct lung injury), blood transfusion, pH < 7.22 during the first 24 h, impaired alveolar fluid clearance, and advanced age all correlate with increased mortality. Interestingly, the severity of gas exchange initially present does not correlate with mortality (unless very severe with PaO_2/FiO_2 ratio < 50), nor does the level of PEEP required, the lung compliance, or the degree of radiographic abnormality[13-17] (Table 16-3). Overall, survival in ARDS has improved; however, it is important to recognize that mortality depends upon the underlying illness.

PATHOPHYSIOLOGY OF ALI/ARDS

Overview of Pathogenesis of ALI/ARDS

The NHLBI ALI/ARDS working group consensus is that ARDS is a systemic syndrome. Systemic responses to stress involve neural, endocrine, pro-, and antiinflammatory mechanisms that are adaptive or pathologic.

ARDS is a syndrome of lung injury defined by physiologic and radiologic criteria in which diffuse damage to cells and the alveolar capillary membrane occurs within hours to days of a predisposing insult. The National Heart, Lung, and Blood Institute (NHLBI) ALI/ARDS working group consensus is that ARDS is a systemic syndrome. Systemic responses to stress involve neural, endocrine, pro-, and antiinflammatory mechanisms that are adaptive or pathologic.

CASE STUDY: PART 2

The patient is admitted to a general medical floor. The admit orders include normal saline at 150-cc/h, NPO, metoclopramide as needed for nausea, dilaudid as needed for pain, and a nasogastric tube is placed. Overnight, the patient has increasing shortness of breath and oxygen requirements. By the morning, he requires 100% oxygen by nonrebreather face mask and his O_2 saturation by pulse oximetry is 96%. A CXR is obtained showing bilateral diffuse alveolar infiltrates consistent with pulmonary edema. Shortly after the X-ray, the patient develops worsening shortness of breath and his arterial oxygen decreases to 86%. The patient is intubated and transferred to the intensive care unit. He is placed on the assist control mode of mechanical ventilation with a respiratory rate of 14 breaths/min, tidal volume of 650 mL, 100% FiO_2, and PEEP of 5 cm H_2O. The peak inspiratory pressure is 46 cm H_2O; and the plateau pressure is 42 cm H_2O.

On physical examination:

- BP 104/60, HR 122 bpm, Temp 100.6°F, RR 18 bpm, O_2 sat 96% on 100% FiO_2
- Weight 90 kg, height 74 in.
- General: sedated on the ventilator
- HEENT: PERRL, anicteric, dry mucus membranes, no JVD
- Heart: tachycardia, regular rate, no mummers or gallops
- Lung: scattered crackles bilaterally, bronchial breath sounds on right
- Abdomen: marked tenderness midline, bowel sounds quiet, voluntary guarding, no masses or hepatomegaly
- Extremities: cool dry, no clubbing, cyanosis, or edema

Laboratory values:
An arterial blood gas shows a pH of 7.45, $PaCO_2$ of 32 mmHg, PaO_2 of 88 mmHg, and an oxygen saturation of 95%.

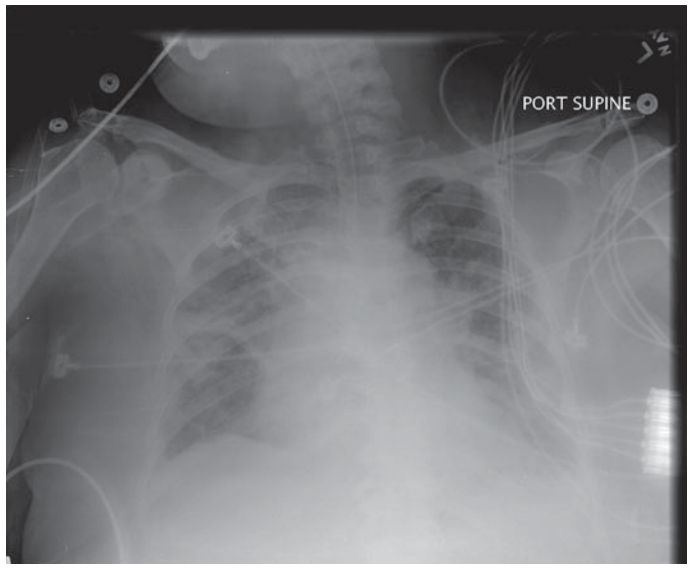


TABLE 16-3

PREDICTORS OF MORTALITY IN ARDS

Increased dead space fraction $(PaCO_2 - PeCO_2)/PaCO_2$
Oxygenation index Mean airway pressure × FiO_2 × 100/PaO_2
Right ventricular dysfunction
Mechanism of lung injury (direct vs. indirect)
Severity of underlying medical condition
Multiple blood transfusions
pH < 7.22 during first 24 h
Persistent hypoxemia
Advanced age
Cirrhosis
$PaO_2/FiO_2 < 50$

The inciting factor for lung injury may be a direct insult to the lungs, such as pneumonia or aspiration, or an indirect cause, such as the systemic inflammation associated with sepsis or severe trauma. Regardless of how it is initiated, this injury incites a pulmonary inflammatory response, which, when coupled with repeated injury to the lung from inappropriate mechanical ventilation or secondary injuries, may lead to worsening of the pathological manifestations of ARDS. The multi-hit model provides a conceptual framework within which the pathogenetic roles of inflammation, surfactant regulation, and mechanical ventilation may be studied.

The multihit model provides a conceptual framework within which the pathogenetic roles of inflammation, surfactant regulation, and mechanical ventilation may be studied.

Specifically, cells of the alveolar capillary membrane as well as those of the immune and hemostatic systems are targets of damage and may magnify the injury in ARDS. The alveolar capillary barrier comprises the microvascular endothelium and the alveolar endothelium.

As endothelial permeability increases, protein-rich edema fills the air spaces. Resultant damage to alveolar epithelial type II cells causes surfactant production to decrease. Further disruption of alveolar/epithelial integrity leads to increased permeability and alveolar flooding of edema. In addition, neutrophils adhere to the damaged capillary membrane and transfer into alveolar air spaces.

The degree of alveolar epithelial injury is an important predictor of outcomes.

Alveolar macrophages secrete cytokines; interleukins (IL-1, IL-6, IL-8, IL-10) and tumor necrosis factor alpha (TNF-α). These act locally to advance chemotaxis and activate neutrophils, further compromising oxygenation and decreasing contractility. Alveolar epithelial cells produce cytokines in response to stimuli such as lung stretch, which is exacerbated by mechanical ventilation forces. The degree of alveolar epithelial injury is an important predictor of outcomes. Lung stretch induces local and systemic cytokine release. These mechanical ventilation based mediators, endotoxins, and bacteria may also translocate into systemic circulation. Genetic factors may be responsible for its onset, as significantly smaller subsets of patients in any ARDS trigger group go on to develop this severe inflammatory process.

The first phase is the acute or exudative phase, with rapid onset of respiratory failure, bilateral infiltrates, and refractory hypoxemia. Diffuse alveolar damage occurs and progresses rapidly. This occurs in context of capillary injury and disruption of the alveolar capillary membrane. Other complications include mechanical ventilation-induced barotrauma and thrombotic considerations.

Later phase changes include a subgroup of patients who progress to fibrosing alveolitis complicated by alveolar tissue necrosis; pulmonary hypertension may be severe. However, in many patients radiographic and pulmonary function tests return to normal. The following sections discuss the individual cellular, molecular and pathological responses of the lung to injury, and repair that occurs during ALI and ARDS.

Pathology of ALI/ARDS

The three temporal histopathological stages of ARDS are the exudative, proliferative, and fibrotic stages.

Throughout all three phases, there is vascular involvement characterized by thrombus formation and obliteration of vasculature.

There are three temporal histopathological stages of ARDS: the exudative, proliferative, and fibrotic stages. The exudative phase (day 0–5) is characterized by edema formation and destruction of type I pneumocytes. Diffuse alveolar damage is present on pathology consisting of hyaline membrane formation, edema fluid in alveolar spaces, epithelial disruption and infiltration of the interstitium, and air spaces with neutrophils. During the proliferative phase (day 5–7), there is organization of the intraluminal exudates, proliferation of type II cells, epithelial cell regeneration, and fibroblastic proliferation. The fibrotic phase (>day 7) consists of cellular proliferation, deposition of collagen and proteoglycans, extensive fibroblastic proliferation, and incorporation of the hyaline membranes. Throughout all three phases, there is vascular involvement characterized by thrombus formation and obliteration of vasculature.

Physiology of ALI/ARDS

Pulmonary edema formation is driven by injury to the alveolar capillary membrane. The alveolar capillary membrane is composed of two subunits: the capillary endothelium and the alveolar epithelium. Damage to both parts is found in ALI/ARDS.

The primary physiologic abnormality in ALI/ARDS is the accumulation of proteinaceous fluid, flooding first the lung interstitium and ultimately the alveolar space that worsens gas exchange, and contributor to a loss of lung compliance. Pulmonary edema formation is driven by injury to the alveolar capillary membrane. The alveolar capillary membrane is composed of two subunits: the capillary endothelium and the alveolar epithelium. Damage to both parts is found in ALI/ARDS.

Alveolar Capillary Membrane Changes during ALI/ARDS

During the early phases of ARDS, there is profound damage to both type I and II epithelial cells, resulting in an increase in permeability combined with a decrease in fluid reabsorption.

Alveolar Epithelium

The alveolar epithelial membrane is composed of type I and type II alveolar epithelial cells, also known as type I and type II pneumocytes. Type I alveolar epithelial cells form the blood-air barrier in the alveolus and prevent fluid from extravasating into the alveolar space.

Type II alveolar epithelial cells are responsible for the synthesis and secretion of surfactant, serve as progenitors for type I cells, and provide protection against edema formation by reabsorbing alveolar fluid. During the early phases of ARDS, there is profound damage to both type I and II epithelial cells, resulting in an increase in permeability combined with a decrease in fluid reabsorption.

Capillary Endothelium

The capillary endothelium is dysregulated in ARDS. Endothelial activation is part of the response to local injury or inflammation and is defined as a change in phenotype or function of the endothelial cell in response to stimuli from the environment. Endothelial activation due to cytokines, thrombin, lipopolysaccharide (LPS), and hemodynamic instability results in a change in the expression of adhesion and signaling molecules and the accumulation of neutrophils. The functional changes that occur due to endothelial activation in localized infection are usually reversible and limited. Dysregulated or unregulated endothelial activation is thought to occur in ARDS and contributes to neutrophilic accumulation and worsening cell injury. This, along with structural changes, including endothelial cell contraction and widening of intercellular junctions, all worsen the profound capillary leak characteristic of ARDS. Thus, the normal function of the capillary endothelium is impaired in ARDS in response to injury and inflammation, which leads to the accumulation of extravascular, proteinaceous lung water.

Endothelial activation in ARDS results in a change in the expression of adhesion and signaling molecules and neutrophil accumulation.

Normal function of the capillary endothelium is impaired in ARDS, which leads to the accumulation of extravascular, proteinaceous lung water.

Role of the Neutrophil

The neutrophil is the predominant cell type found in broncho-alveolar lavage fluid or lung biopsies in humans or animal models of ARDS. Due to the narrow diameter of pulmonary capillaries relative to the neutrophil, they are normally found in higher numbers in the pulmonary capillaries compared to the blood.

Neutrophil recruitment starts with activation of monocytes and macrophages in the lung and peripheral blood. These cells release IL-1 and IL-1β or tumor necrosis factor (TNF), which leads to the appearance of adhesion molecules on endothelial or epithelial cells and the release of chemokines and growth factors. Accumulation of and retention of neutrophils in the alveolar space results from two mechanisms: adhesion to endothelial cells, which prolongs neutrophil retention, and neutrophil stiffening, which traps neutrophils within the pulmonary capillaries. Neutrophil stiffening is accentuated in immature band forms and may explain the worsening of ARDS seen after recovery from neutropenia. Once neutrophils are activated, they enhance the inflammatory response through the secretion of inflammatory mediators. This, along with the generation of reactive oxygen species and proteolytic enzymes, serves to worsen the damage to the alveolar capillary membrane and promote alveolar flooding.

Accumulation and retention of neutrophils in the alveolar space results from two mechanisms: adhesion to endothelial cells and neutrophil stiffening.

Activated neutrophils enhance the inflammatory response through the secretion of inflammatory mediators.

Release of inflammatory mediators by neutrophils and generation of reactive oxygen species and proteolytic enzymes damages the alveolar capillary membrane and promotes alveolar flooding.

Role of Platelets

The normal healthy lung remains in a fibrinolytic state. In ARDS, leakage of coagulation factors, expression of procoagulant molecules, and an increase in inhibitors of fibrinolysis lead to unopposed procoagulant activity. There is formation of fibrin/platelet microthrombi in capillaries, and fibrin-rich proteinaceous casts appear in airspaces, leading to an increase in V/Q mismatch. Fibrin and thrombin also seem to activate neutrophils and the vascular endothelium directly, leading to an increase in vascular permeability and increased release of TNF-α, and IL-1β (beta) or IL-8.

In ARDS, leakage of coagulation factors, expression of procoagulant molecules and an increase in inhibitors of fibrinolysis leads to unopposed procoagulant activity.

Surfactant

Surfactant is secreted by type II alveolar epithelial cells; it acts to decrease surface tension, has antimicrobial properties and participates in host defense. In ARDS, changes occur in the composition and structure of surfactant. Impairment in the function of surfactant leads to abnormal surface tension properties, which predisposes alveoli to collapse. Areas of

microatelectasis increase *V*/*Q* mismatch, worsen arterial hypoxemia, and lead to decreased lung compliance or the development of "stiff lungs."

Ventilator-Induced Lung Injury

Advances in mechanical ventilation were crucial to the management of ARDS. Paradoxically, this lifesaving therapy may cause or worsen ALI/ARDS.

Advances in mechanical ventilation were crucial to the recognition and management of ARDS. Without mechanical ventilation, most patients with ARDS would not have lived long enough for the clinical syndrome to fully mature and be recognized. Paradoxically, this lifesaving therapy may cause or worsen ALI/ARDS. The lung during ARDS can be divided into three parts: fluid-filled airways, patent airways, and atelectatic areas. The atelectatic areas, due to repeated opening and closing with positive pressure ventilation, are subject to ventilator injury. The patent airways can become damaged due to over-distention. Over-distention causes lung injury in multiple ways: direct disruption of the alveolar capillary membrane, impairment of alveolar clearance, and by contributing to local and systemic inflammation. The fluid-filled areas have extreme *V*/*Q* mismatch and participate minimally in gas exchange.

Resolution of ARDS

ARDS rapidly resolves in some patients, these patients quickly wean from mechanical ventilation and show dramatic improvement in oxygenation. Other patients have a more prolonged course due to the development and progression of fibrosing alveolitis. Resolution of ARDS is dependent upon termination of the inflammatory response, clearance of fluid and debris from the alveoli, and repair of the alveolar capillary membrane. Fluid reabsorption occurs by active transport of sodium by type II epithelial cells. Maximal fluid clearance is associated with lower mortality and shorter duration of mechanical ventilation.[15] Type II epithelial cells differentiate into type I cells and cover the denuded epithelium. Apoptosis of neutrophils in the alveolar space occurs and is the main mechanism for cellular clearance. The alveolar microcirculation is recanalized and damaged endothelium is replaced. The alveolar interstitium is restored by expansion of fibroblasts and deposition of extracellular matrix proteins.

Fibrosing alveolitis, due to exuberant fibrotic response and maladaptive repair processes, may develop approximately 5–7 days after the inciting event in ARDS. Elevated levels of procollagen III, a marker of collagen synthesis, has been found early in the development of ARDS and correlates with increased mortality.[18]

HISTORY AND PHYSICAL EXAM

Physical Examination

Physical examination of ALI/ARDS shows signs and symptoms of acute respiratory failure, but also shows features consistent with the underlying condition.

The clinical course of ARDS is variable and depends on the primary insult and on the numbers and types of other organ dysfunction.

The physical examination shows signs and symptoms of acute respiratory failure. The patient is usually in distress, with tachypnea, tachycardia, and hypoxemia that is refractory to treatment with supplemental oxygen (Table 16-4). The physical examination will also show features consistent with the underlying condition. In the vast majority of cases, hypoxemia worsens and mechanical ventilation is required. The clinical course of ARDS is variable and depends on the primary insult and on the number and type of other organ dysfunctions. Some patients have a fulminant course and die within a few days, some recover rapidly, and others may require prolonged mechanical ventilation and either die or have a favorable outcome with no sequelae.

Laboratory Data

There are no specific laboratory manifestations for the diagnosis of ALI/ARDS; the findings usually relate to the underlying process. Leukocytosis and anemia can be present. Renal and

CASE STUDY: PART 3

The initial ICU ABG and CXR before and 4 h after intubation are reviewed. ABG pH 7.45, $PaCO_2$ 32 mmHg, PaO_2 88 mmHg, oxygen saturation 95%. CXR 4 h after intubation shows endotracheal tube in good position with worsening pulmonary edema. The PaO_2/FiO_2 of 88 in the absence of signs or symptoms of CHF is consistent with ARDS complicating acute pancreatitis. The ventilator settings are changed to low tidal volume ventilation. Ideal body weight is calculated to be 77.6 kg (51.65 + (1.85 × (74 in.-60)). PEEP is increased to 12.5 cm H_2O. Over the next 4 h, the FiO_2 is titrated down to 70%. New ventilator settings: Assist control, respiratory rate 14 breaths/min, tidal volume 460 cc, 70% fraction of inspired oxygen, positive end-expiratory pressure 12.5 cm H_2O. On these settings, the peak inspiratory pressure was measured at 33 cm H_2O and plateau measured at 30 cm H_2O. An ABG is obtained on these settings 30 min later pH 7.30, $PaCO_2$ 48 mmHg, PaO_2 110 mmHg, oxygen saturation 100%.

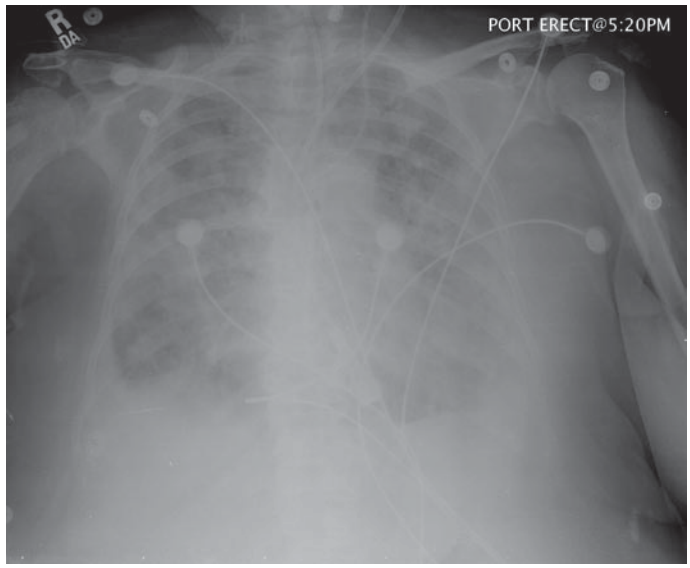

TABLE 16-4

PHYSICAL EXAM FINDINGS CONSISTENT WITH ALI/ARDS

Vital signs: HR>100 beats/min, RR>20 breaths/min hypotension or hypertension, O_2 saturation <90% while inspiring room air, may be febrile
General: disoriented, anxious
Skin: peripheral or central cyanosis
HEENT: absence of jugular venous distention
Heart: tachycardia, no S3 or S4 gallop
Lungs: tachypnea, crackles bilaterally, may have scattered wheeze or rhonchi
Abdomen: paradoxical respirations, absence of hepato-jugular reflex
Extremities: cyanosis, cool/clammy

TABLE 16-5

LABORATORY TESTS TO OBTAIN

Arterial blood gas	pH, PaO_2, O_2 saturation, carboxyhemoglobin, methemoglobin, $PaCO_2$
Complete blood count	White blood cell count, hemoglobin/hematocrit
Chemistry panel	Electrolytes, renal function
Liver function panel	Albumin, evaluate for hepatic injury
Brain natriuretic peptide	May help rule out cardiogenic pulmonary edema
Lipase/amylase	May rule out pancreatitis as a cause
Blood culture, sputum culture, and urine culture	May rule out sepsis as a cause

hepatic function can be impaired, reflecting injury by the same inflammatory mechanisms mentioned above (Table 16-5).

Differential Diagnosis

The differential diagnosis of ALI/ARDS includes any entity in which the patient presents with acute onset of respiratory failure and infiltrates on chest X-ray. Distinguishing ARDS from acute pulmonary edema due to heart failure can be challenging. Patients with heart failure are more likely to have cardiomegaly, a decreased ejection fraction, as documented on echocardiography, and an elevated brain natriuretic peptide (BNP).[19] However, these findings do not exclude ARDS. It is estimated that approximately 20% of patients with ARDS have concomitant left ventricular dysfunction and patients with sepsis also can have depressed cardiac

The differential diagnosis of ALI/ARDS includes any entity in which the patient presents with the acute onset of respiratory failure and infiltrates on chest X-ray.

TABLE 16-6

DIFFERENTIAL DIAGNOSIS OF ALI/ARDS

function. When in doubt, pulmonary artery catheterization can be used. A PCWP <18 cm H_2O rules out cardiogenic edema, but it is important to remember the presence of cardiogenic edema does not exclude a diagnosis of ARDS. The two conditions can exist simultaneously.

Other conditions can resemble ARDS such as diffuse pulmonary infections (bacterial, viral, or fungal), alveolar hemorrhage, acute interstitial pneumonia, idiopathic acute eosinophilic pneumonia, hypersensitivity pneumonitis, bronchiolitis obliterans organizing pneumonia (BOOP), neurogenic pulmonary edema, and cancer (lymphoma, acute leukemia) (Table 16-6).

Hypoxemia and Dead Space Ventilation

Fluid-filled and collapsed alveoli create severe *V*/*Q* mismatch leading to intrapulmonary shunt. Intrapulmonary shunt represents an extreme of *V*/*Q* mismatch; some lung units receive no ventilation (low *V*) but are perfused (high *Q*). The lung in ARDS is heterogeneous with respect to ventilation and perfusion, in that some segments of the lung receive almost no ventilation due to extensive areas of pulmonary edema and some units are relatively normally ventilated. Alveolar perfusion is also disrupted by the presence of arterial thrombi that worsens *V*/*Q* mismatch.

A representative arterial blood gas obtained in a patient with ALI/ARDS will show hypoxemia with a low PaO_2 despite breathing high concentrations of oxygen, an elevated alveolar-arterial (A-a) gradient, and respiratory alkalosis with a low CO_2 due to alveolar hyperventilation. The findings on subsequent arterial blood gases reflect continued hypoxemia and an increase in CO_2. Respiratory acidosis may occur due to elevated dead space ventilation in severe ARDS, which portends a poor prognosis for survival. This may become the main acid–base disorder later in the course of the disease despite a markedly elevated minute ventilation.

Radiology

Radiographic findings are not specific in ARDS and therefore not reliable; they vary depending on when the CXR is taken relative to the temporal course of the patient's disease.

Radiographic findings are not specific in ARDS and therefore not reliable; they also vary depending on when the chest radiograph is taken relative to the temporal course of the patient's disease. Within the first 12 h of the initial insult that precipitates ALI/ARDS, the chest X-ray may be normal despite the clinical signs and symptoms of respiratory failure. Within the next 24 h, diffuse alveolar infiltrates are usually present bilaterally, but unilateral cases have also been reported. The pulmonary edema pattern observed on chest X-ray in ARDS predominantly shows a peripheral distribution with a lack of increased central vascular distention. However, this pattern is not unique enough to distinguish it conclusively from cardiogenic pulmonary edema. Computed tomography done within the first 48 h of onset shows areas of dense consolidation bilaterally in the dependent portions of the lower lobes, interspersed with areas of normal lung.

On days 3–7 after injury, radiographic consolidations in ARDS become less confluent and an interstitial or ground glass pattern is observed. The radiographic expression of

positive pressure ventilation is seen as an increase in lung volumes and a decrease in the degree of opacification; this can give a false impression of improvement. Patients at this point are at risk for the development of barotrauma due to the effects of positive pressure ventilation. The first sign of barotrauma is the development of pulmonary interstitial emphysema. Radiographically pulmonary interstitial emphysema presents as vesicular cystic changes, lucent lines streaking toward the hilum, radiolucent halos around vessels or bronchi, pneumatocele formation, and subpleural emphysema.

Radiographic findings on days 7–10 and onward in ARDS are related to the complications of mechanical ventilation such as pulmonary infections (pneumonia, abscess, and cavitations), alveolar rupture, pneumomediastinum, soft tissue emphysema, pneumothorax, and pneumoperitoneum. Patients who develop pulmonary fibrosis from ARDS will show a reticular pattern or honeycombing that is commonly seen in an anterior distribution on high resolution computed tomography.

Radiographic findings on days 7–10 and onward in ARDS are related to the complications of mechanical ventilation.

TREATMENT OF ALI/ARDS

Overview of Treatment Options

There is no effective therapy available to treat the underlying pathophysiology of ARDS; thus, initial therapy is focused on maintaining adequate oxygenation and tissue perfusion through mechanical ventilation and fluid management. Other goals include identifying and appropriately managing the initial injury or disease process, minimizing nosocomial complications of infection and immobility, preventing multiorgan dysfunction (MODS), and attenuating the inflammatory response.

The following section explores each of the most important therapeutic approaches to the ALI/ARDs patient in detail.

There is no effective therapy available to treat the underlying pathophysiology of ARDS.

Initial therapy in ARDS is focused on maintaining adequate oxygenation and tissue perfusion using mechanical ventilation and fluid management.

Mechanical Ventilation

The main initial treatment modality for ARDS is the appropriate use of mechanical ventilation. Significant attention has been devoted to protective strategies of mechanical ventilation in patients with ARDS. Pathologically, ARDS demonstrates heterogeneous atelectasis and pulmonary edema, leading to reduced lung compliance and reduced lung capacity. The main goal of mechanical ventilation in ARDS is to support the patient while preventing ventilator-induced lung injury. Animal and clinical studies suggest that mechanical stretch and alveolar over-distention may be responsible for alterations in alveolar-capillary permeability and edema.

The main goal of mechanical ventilation in ARDS is to adequately oxygenate and ventilate the patient while simultaneously preventing ventilator-induced lung injury.

Low Tidal Volume Ventilation

Amato et al. was one of the first to compare conventional mechanical ventilation vs. lung protective ventilation strategies.[20] This study randomized fifty-two patients to two separate ventilation groups. Conventional ventilation used a tidal volume of 12 mL/kg of ideal body weight and low PEEP. The protective lung ventilation strategy used a tidal volume of 6 mL/kg of ideal body weight, high PEEP, and permissive hypercapnia (Fig. 16-2). The protective ventilation group had a lower 28-day mortality rate and less incidence of barotrauma compared to the conventional ventilation group.

The National Heart Lung blood Institutes ARDS clinical research network (ARDSnet) subsequently conducted a larger randomized, prospective and controlled trial in ARDS to examine the effect of low vs. high tidal volume ventilation. Patients ($n=861$) received mechanical ventilation with either 12 or 6 mL/kg of ideal body weight.[21] The tidal volume was adjusted to keep the plateau pressure <35 cm H_2O. The lower tidal volume ventilation group had a significantly lower mortality rate (31 vs. 39.8%) at 28 days. There were also more ventilator-free days and organ failure-free days in the lower tidal volume group (Fig. 16-3).

Due to an evident reduction in mortality in the low tidal volume group, the trial was stopped early. Based on the findings in this study, the standard of ventilator care in ARDS is

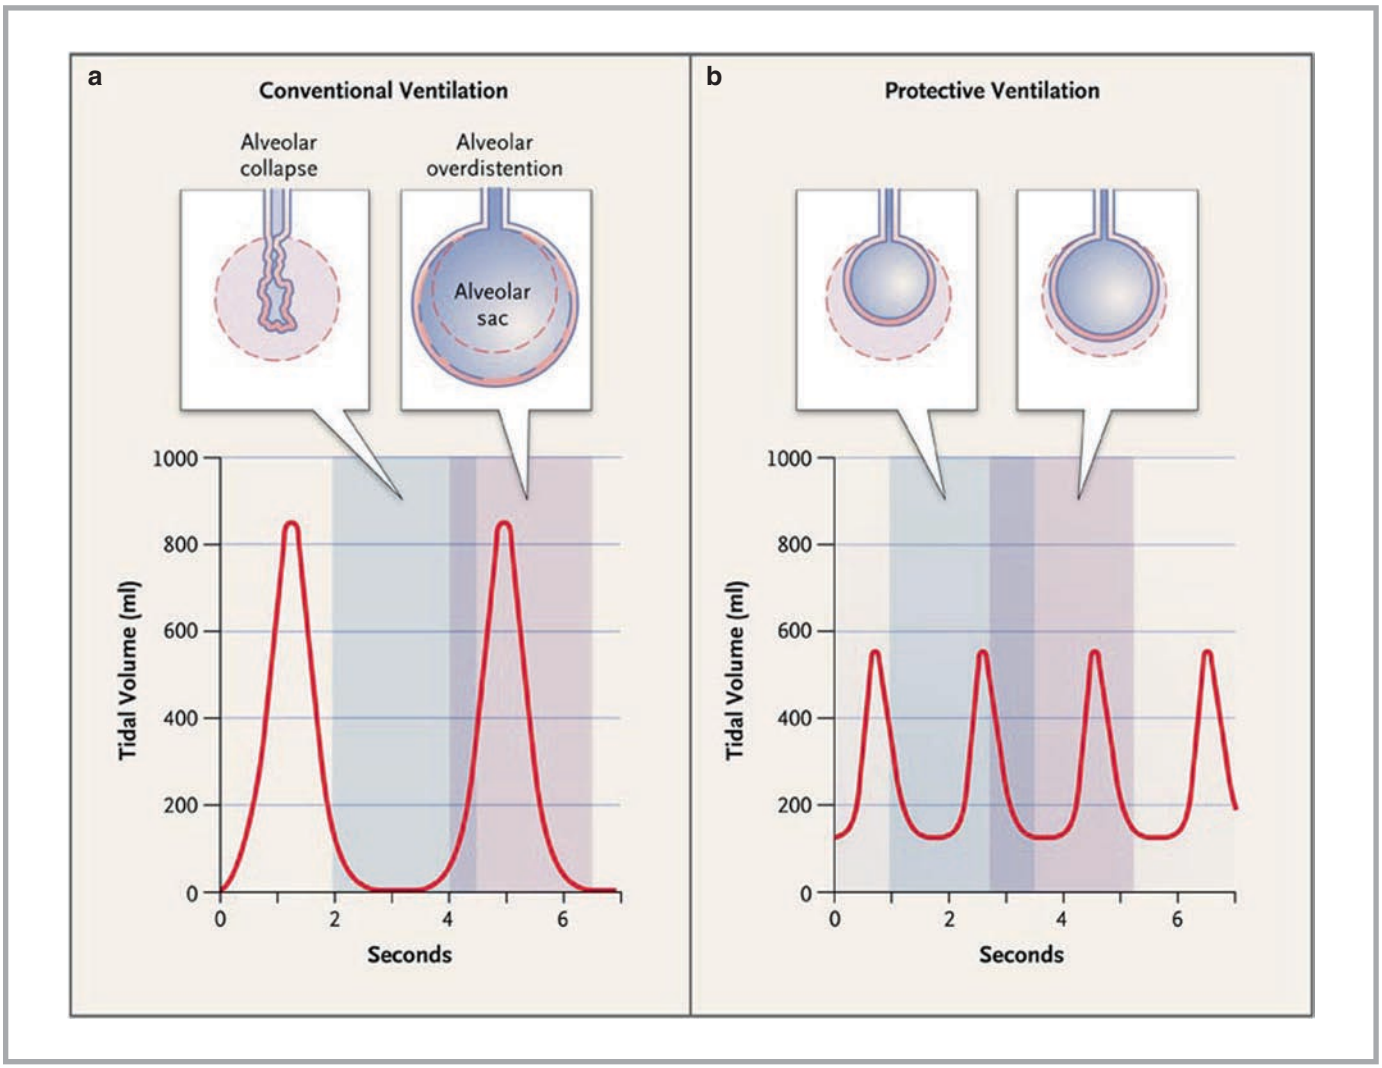

FIGURE 16-2

This example of ventilation of a patient with ARDS shows that ventilation at a tidal volume of 12 mL/kg keight and an end-expiratory pressure of 0 cm of water (*Panel **a***) can lead to alveolar over-distention and collapse. Protective ventilation at a tidal volume of 6 mL/kg (*Panel **b***) limits over-inflation and end-expiratory collapse by utilizing a low tidal volume and an adequate positive end-expiratory pressure (reprinted with permission from Malhotra.[37] ©Massachusetts Medical Society. All rights reserved).

to use tidal volumes of 6 mL/kg of ideal body weight, maintain a plateau pressure <35 cm H_2O, increase PEEP as hemodynamically tolerated to improve oxygenation, and allow permissive hypercapnia in order to achieve the above ventilatory targets.

Positive End-Expiratory Pressure

Positive end-expiratory pressure is used to improve oxygenation by increasing functional residual capacity.

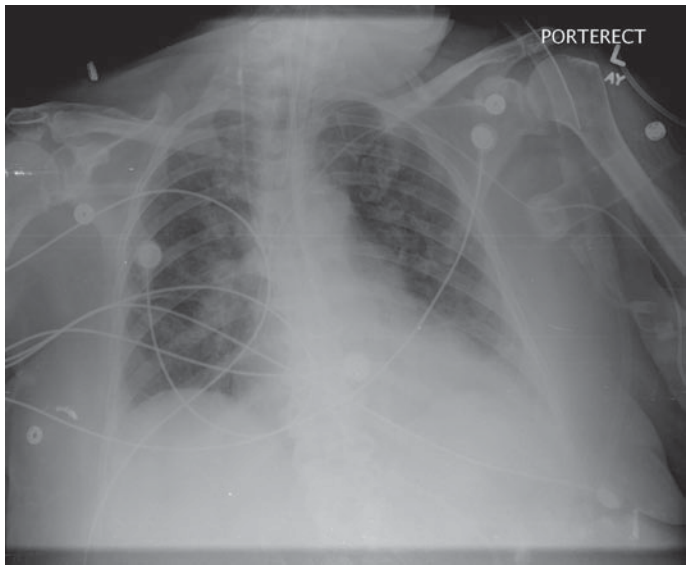
Positive end-expiratory pressure is used to improve oxygenation by improving functional residual capacity. The disadvantages of PEEP are impaired cardiac output, increased right ventricular afterload, and increased lung volumes and airway pressures that may lead to ventilator-induced lung injury. PEEP may help prevent lung injury by stopping the repeated opening and closing of atelectatic lung units during positive pressure ventilation.

ARDSnet recently conducted a trial comparing the effects of high and low PEEP in ARDS patients.[22] This trial failed to show any survival advantage in the high PEEP group (Fig. 16-4).

A substudy also evaluated the benefit of recruitment maneuvers consisting of sustained

CASE STUDY: PART 4

The patient is supported on mechanical ventilation for the next 7 days. Over this time, his acute pancreatitis resolves and he is able to tolerate tube feeds. His ventilator settings currently are AC 14/450/50% PEEP 5 cm H_2O, peak pressure 32 cm H_2O; plateau pressure 29 cm H_2O. ABG preformed at this time pH 7.38, $PaCO_2$ 50 mmHg, PaO_2 88 mmHg oxygen saturation 98%. Due to hypotension, his net fluid balance is positive 18 L. Diuresis is begun; the patient's fluid balance is kept 1–2 L negative daily over the next 6 days. On day 14, the patient fails a trial of spontaneous breathing. On day 16, a tracheostomy is preformed.



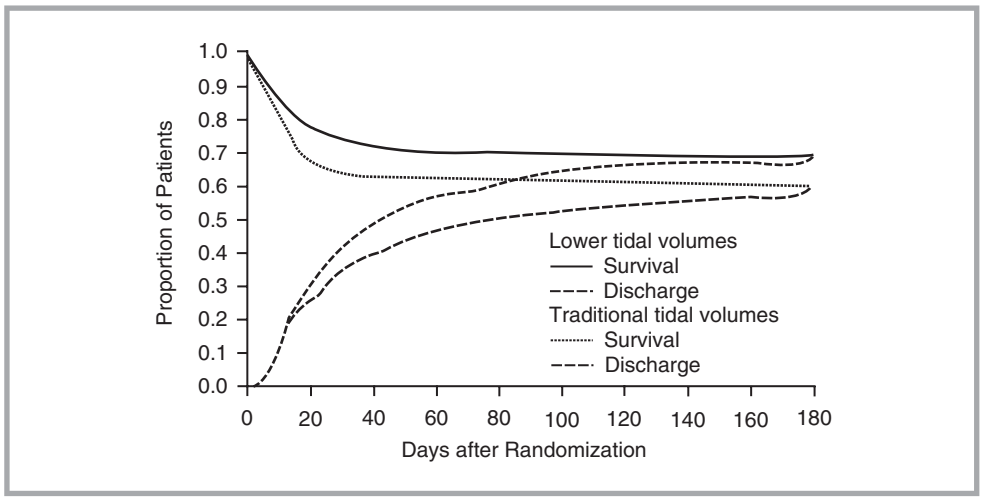


FIGURE 16-3

Patients ventilated with lower tidal volumes had a higher rate of survival and were more likely to be discharged from the hospital (reprinted with permission from The Acute Respiratory Distress Syndrome Network.[21] ©Massachusetts Medical Society. All rights reserved).

inflation of the lungs to higher pressures and volumes than tidal ventilation.[23] Only the high PEEP group underwent recruitment maneuvers, but this also failed to show a significant benefit. Extrinsic PEEP can be applied in order to decrease the FiO_2, maintain adequate oxygenation and prevent oxygen toxicity but provides no proven mortality benefit in ARDS. Other alternative modes of ventilation such as high frequency ventilation, proportional assist ventilation, and inverse-ratio ventilation remain unproven.

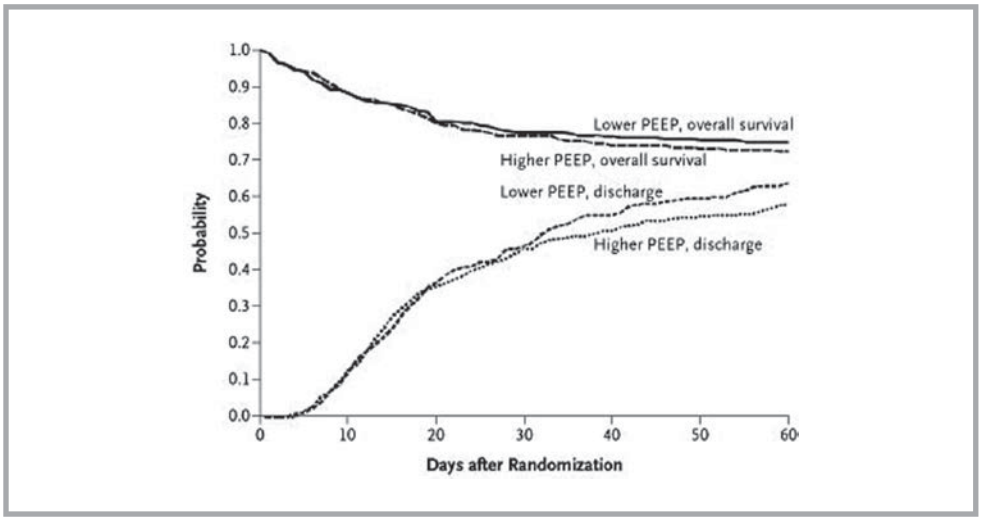
Prone Positioning

Prone positioning has been a focus of investigation since a 1976 report showed that placing a patient in the prone position may lead to a substantial improvement in arterial oxygenation. The proposed mechanisms responsible for improved oxygenation in ARDS patients in the

Mechanisms responsible for improved oxygenation with the prone position are increased end-expiratory lung volume, improved ventilation perfusion matching, and better coupling of chest wall mechanics with regional lung ventilation.

FIGURE 16-4

There was no survival advantage shown with higher levels of PEEP as compared to lower levels of PEEP (reprinted with permission from Brower et al.[22] ©Massachusetts Medical Society. All rights reserved).



prone position are an increased end-expiratory lung volume, improved ventilation perfusion matching, and better coupling of chest wall mechanics with regional lung ventilation.

Lamm et al. demonstrated improved ventilation to dorsal regions of the lung while in the prone position in an animal model.[24] Albert and Hubmayer determined the volume of lung parenchyma that was subjected to the weight of the heart using high resolution CT scans in the prone and supine position.[25] This study showed almost no lung compressed by the heart or mediastinum when patients were in the prone position. The effect of prone positioning on ARDS survival was assessed in a multicenter randomized trial by Gattinoni et al. Patients ($n = 304$) were enrolled from 30 ICUs in Italy and Switzerland, half of the patients received conventional treatment for ARDS and half received prone positioning for six or more hours per day for 10 days.[26] The primary outcome was mortality at 28 days; secondary outcomes were improvement in respiratory failure and organ failure at 10 days. An improvement was seen in arterial oxygenation in the prone groups, but there was no difference in the mortality rate between the prone and supine groups at 10 days (21 vs. 25%) or at 6 months (62.5 vs. 58.6%) (Fig. 16-5).

ARDS is initiated by excessive inflammation, so corticosteroids are used to inhibit production of inflammatory cytokines.

Corticosteroids may also have a role in decreasing collagen deposition by accelerating fibroblast procollagen messenger RNA degradation.

Corticosteroids have been tested for efficacy in ARDS at both of its clinical phases: to reduce inflammation in the acute, exudative phase and to reverse fibrosing alveolitis in the subacute phase.

Whether corticosteroids are effective in reversing fibrosing alveolitis in the subacute phase of ARDS remains a subject of debate.

Corticosteroids

Because ARDS is initiated by excessive inflammation, corticosteroids were the earliest treatment evaluated. Corticosteroids inhibit production of inflammatory cytokines, such as TNF-α, IL-1, IL-6, and IL-8. In addition, corticosteroids may have a role in decreasing collagen deposition by accelerating fibroblast procollagen messenger RNA degradation.

Corticosteroids have been tested for efficacy in ARDS at both of its clinical phases: to reduce inflammation in the acute, exudative phase and to reverse fibrosing alveolitis in the subacute phase. Two studies published in the 1980s showed that brief courses of high-dose, intravenous corticosteroids were ineffective in reducing mortality or reversing lung injury in the acute phase of ALI/ARDS; both studies compared a 48-h course of intravenous methylprednisolone, 30 mg/kg every 6 h, with placebo, one in 81 patients with ALI and the other in 99 patients with early ARDS. A recent metaanalysis pooled the 180 patients in these two studies, and confirmed no survival benefit with early corticosteroids. Whether corticosteroids are effective in reversing fibrosing alveolitis in the subacute phase of ARDS remains a subject of debate. Four small case series, one case report, and a randomized controlled trial (RCT) have suggested benefit. In 1998, Meduri and coworkers demonstrated that in 24 patients with unresolving ARDS, randomized on day 7 of mechanical ventilation, treatment with a lower dose of methylprednisolone for a longer treatment course (0.5 mg/kg every 6 h for 14 days, then tapering doses to day 32) reduced hospital mortality from 62% in the placebo group to 12% in the steroid group.[27] However, the major criticism of this study was its

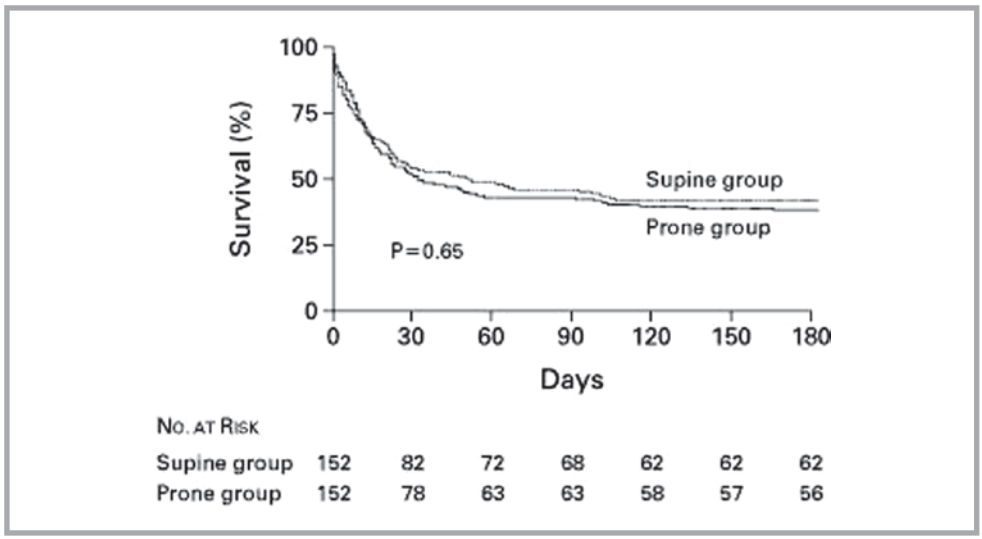


FIGURE 16-5

Improvement was seen in arterial oxygenation in the prone groups, but there was no difference in the mortality rate between the prone and supine groups at 10 days (21 vs. 25%) or at 6 months (62.5 vs. 58.6%) (reprinted with permission from Gattinoni et al.[26] ©Massachusetts Medical Society. All rights reserved).

early termination; it was originally calculated to need 99 patients to show an absolute survival benefit of 30% with a power of 0.95, but was stopped early with just 24 patients enrolled. Early termination of a study with a small sample size increases the risk of an imbalance in baseline prognosis, which may inflate the apparent treatment effect. Meduri et al. have recently published work providing evidence for the biological plausibility of a response to prolonged steroid administration in unresolving ARDS, describing in detail potential mechanisms of systemic inflammation-associated glucocorticoid resistance and the cellular response to exogenous steroids in patients with ARDS.

To definitively answer this question, the ARDS network designed the late steroid rescue study (LaSRS), a multicenter RCT comparing steroid with placebo in late phase (>7 days) ARDS.[28] Methylprednisolone was initially dosed at 2 mg/kg/day for 14 days and then tapered up to day 25. Outcomes were 60-day mortality, ventilator-free days, organ failure-free days, and a subgroup analysis compared steroid responsiveness in patients with high initial serum and BAL markers of inflammation and fibroproliferation to those with low initial levels. There was no difference found in mortality rates between the groups receiving corticosteroids or placebo at 60 and 180 days. In contrast, the corticosteroid group had a higher mortality rate at 60 and 180 days when receiving corticosteroids 14 days after the onset of ARDS. However, analysis of secondary endpoints (duration of mechanical ventilation, days free from MODS, ICU survival, and hospital survival) revealed improvement with the use of corticosteroids.

Inhaled Nitric Oxide

Pulmonary arterial hypertension is commonly found in association with ARDS. Using vasodilators to lower pulmonary artery pressure has been evaluated to improve ARDS management. Nitric oxide is a powerful vasodilator that, when inhaled, diverts pulmonary blood flow from poorly ventilated regions to better ventilated regions, thus improving ventilation perfusion matching and gas exchange. Rossaint et al. showed that nine out of ten ARDS patients who received 18 ppm of inhaled nitric oxide (iNO) had reduced pulmonary artery pressures (37–30 mmHg), decreased intrapulmonary shunting (35–31%), and an increased PaO_2 to FiO_2 ratio with iNO administration.[29] However, another study showed that improvements in oxygenation with iNO were not sustained after the first 24 h.[30] A randomized French study of 208 patients failed to show any effect of iNO on mortality or duration of mechanical ventilation.[31] At this time, iNO is not recommended for routine treatment but may be useful in a select group of patients with severe refractory hypoxemia and pulmonary hypertension.

Pulmonary arterial hypertension is commonly found in association with ARDS.

At present, iNO is not recommended for routine treatment but may be useful in a select group of patients with severe refractory hypoxemia and pulmonary hypertension.

Fluid Management

Fluid management in ARDS has been a long debated issue. ARDS is primarily due to non-cardiogenic pulmonary edema; therefore, some practitioners advocate aggressive diuresis with the attendant risk of hypotension and renal failure. Other practitioners advocate a more liberal volume strategy in the hopes of avoiding further organ damage. ARDSnet al.so recently conducted a prospective, randomized clinical trial assessing liberal (wet) vs. conservative (dry) fluid management strategies (the FACTT trial).[32] The conservative fluid strategy had a lower mean cumulative fluid balance than seen in the liberal group. There was no significant difference in 60-day mortality between the two groups, but the conservative (dry) fluid management group had a shortened duration of mechanical ventilation and improved lung function (Fig. 16-6).

A pulmonary artery catheter (PAC) is often used to assess volume status and intravascular pressure. Another arm of the conservative vs. liberal fluid management trial compared the benefit of PAC measurements to central venous catheter measurements in assessing and guiding fluid management strategies in ARDS patients.[33] This study found that the use of PAC's did not improve outcome and was associated with an increased rate of complications (Fig. 16-7).

ECMO has not been shown in past studies to improve survival. However, techniques and results have improved in recent years leading to a decrease in complications, and it may be appropriate to consider new studies utilizing ECMO.

Currently, ARDS study protocols are being suggested using combined treatment modalities. Well-designed, prospective, controlled trials are needed to assess the utility of combination therapy protocols in ARDS.

Extracorporeal Membrane Oxygenation (ECMO)

ECMO has not been shown in past studies to improve survival. However, techniques and results have improved in recent years, leading to a decrease in complications, and it may be appropriate to consider new studies utilizing ECMO. In addition, ARDS study protocols are being suggested in which treatment modalities are combined. A recent study used a combined treatment protocol of airway pressure control, iNO administration, prone position, and early triage of nonresponders to ECMO, and achieved an 80% overall survival rate. Well-designed, prospective, controlled trials are needed to assess the utility of combination therapy in ARDS patients.

Exogenous Surfactant Therapy

Given its proven efficacy in preventing and treating neonatal respiratory distress syndrome, exogenous surfactant has held promise for the treatment of ARDS. Since 1987, there have been several case reports, and phase 1 and 2 trials of various surfactant preparations, which

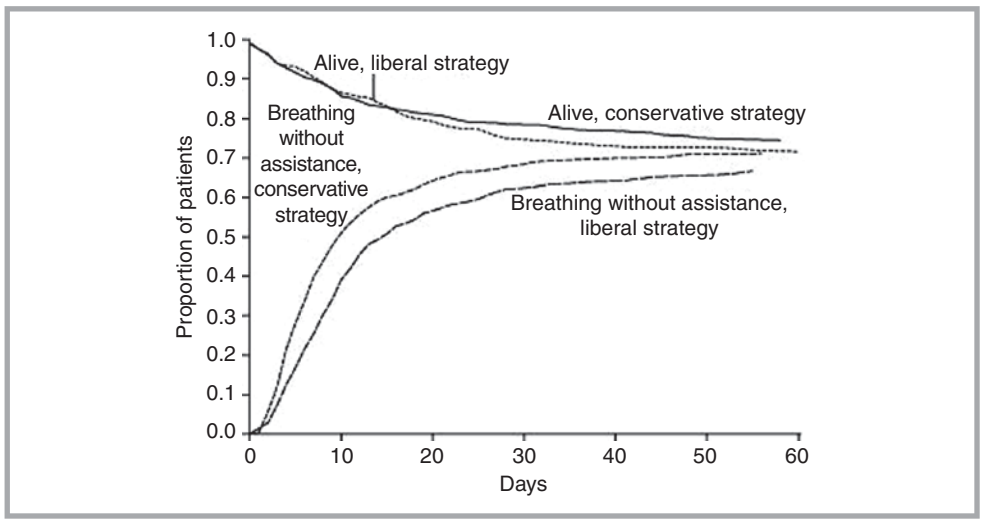

FIGURE 16-6

FACTT trial showed the conservative fluid strategy had a lower mean cumulative fluid balance than seen in the liberal group. There was no significant difference in 60-day mortality between the two groups, but the conservative (dry) fluid management group had a shortened duration of mechanical ventilation and improved lung function (reprinted with permission from The National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome Network (ARDS net).[32] ©Massachusetts Medical Society. FIGURE 16-7

Another arm of the FACTT trial compared the benefit of PAC measurements to central venous catheter measurements in assessing and guiding fluid management strategies in ARDS patients. This study found that the use of PACs did not improve outcome and was associated with an increased rate of complications (reprinted with permission from The National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome Network (ARDS net).[33] ©Massachusetts Medical Society. All rights reserved).

suggested a possible benefit. However, no RCT has shown a proven benefit in regard to patient outcome. In 1996, the first large, double-blind RCT tested an aerosolized, synthetic surfactant called Exosurf in 725 patients with sepsis-induced ARDS. This study showed no difference in survival, duration of mechanical ventilation, or oxygenation, perhaps owing to a low level of alveolar deposition by the aerosolized preparation, or to the absence of surfactant proteins.

The second and latest international double-blind clinical trial examined the effectiveness of Venticute, a recombinant surfactant protein C-based surfactant instilled up to 4 times intratracheally over a 24-h period. The study enrolled a total of 448 patients at 54 centers in North America and 55 centers in Europe and South Africa and was powered to show a difference in ventilator-free days. The results were published in August 2004: no significant difference was found between the treatment and control groups in ventilator-free days (median 0 days) or 28-day survival (mean 66%). However, oxygenation was significantly better during the 24-h treatment period with surfactant, suggesting a possible benefit for a longer treatment course. A second large clinical trial is now under way, examining the effectiveness of a longer treatment course of Venticute (up to 5 days) in patients with direct lung injury from aspiration or pneumonia. The results of that trial are eagerly awaited as there is currently no evidence to support the routine use of exogenous surfactant in all ARDS patients.

There is currently no evidence to support the routine use of exogenous surfactant in ARDS.

Prostaglandin Administration

The interest in prostaglandin E_1 (PGE_1) as a treatment option for ARDS is based on its function as an antiinflammatory mediator and vasodilator. In an early, single-center RCT performed with trauma patients, nebulized PGE_1 showed improved survival of 71% at 30 days vs. 35% survival in the placebo group. However, in a subsequent randomized multicenter study of patients with ARDS from trauma or sepsis, a survival benefit could not be shown, and PGE_1 administration was complicated by systemic hypotension. The systemic effects of PGE_1 can be partly overcome by using liposomes to deliver the drug in a lung-targeted manner, but even with this advancement, there has been no demonstrated survival benefit or reduction in ventilation time in ARDS patients.

There has been no demonstrated survival benefit or reduction in ventilation time in ARDS with the use of PGE_1.

Antioxidants

Reactive oxygen species, such as superoxide anion, hydroxyl radical, hydrogen peroxide, and hydrochlorous acid, are produced by neutrophils, alveolar macrophages, and pulmonary

Currently there is no clear evidence that *N*-acetylcysteine or procysteine improves mortality in ARDS.

endothelial cells during ARDS. Indices of oxidative damage, including lipid peroxidation, protein degradation, and further neutrophil recruitment, are higher in patients who die of ARDS. Healthy lungs contain antioxidants, such as glutathione, superoxide dismutase, and catalase, which provide defense against these radical oxygen species and their harmful effects; glutathione has been shown to be depleted in the lungs of ARDs patients. Thus, agents such as *N*-acetylcysteine and procysteine, which increase glutathione levels in the lungs, have been used to treat ARDS. The results of animal studies of *N*-acetylcysteine were favorable, but human trials were not definitively positive. One randomized, double-blind, placebo-controlled trial of 66 patients with ARDS compared *N*-acetylcysteine treatment at 150 mg/kg hourly for 6 days vs. placebo. No improvement occurred in oxygenation or survival in the *N*-acetylcysteine-treated group. Another study administered *N*-acetylcysteine, procysteine, and placebo to three groups in a randomized, double-blind, placebo-controlled trial of 46 ARDS patients. The two treatment groups had increased glutathione stores and improved lung function, with the largest benefit being seen in the procysteine-treated group, but there was no significant difference in survival. Another study of 61 patients with ALI randomized treatment with *N*-acetylcysteine, 40 mg/kg daily intravenously, vs. placebo for 3 days. The *N*-acetylcysteine-treated group had better oxygenation and less ventilatory support but did not have reduced mortality. Currently, no clear evidence exists that *N*-acetylcysteine or procysteine improves ARDS mortality.

Other Antiinflammatory Therapies

Some studies show that the levels of inflammatory cytokines in BAL fluid may predict outcome in ARDS. This suggests a causal relationship among inflammatory cytokines, lung inflammation, and progression of fibroproliferation.

Studies have shown that BAL fluid levels of inflammatory cytokines, such as TNF-α, IL-1, IL-2, IL-4, IL-6, and IL-8, may predict outcome in patients with ARDS. This finding suggests a causal relationship among inflammatory cytokines, lung inflammation, and progression of fibroproliferation. Interleukin IL-8 is produced by alveolar macrophages, type 2 pneumocytes, and pulmonary fibroblasts and is a major chemotactic factor for neutrophil recruitment. IL-8 also mediates neutrophil migration across vascular endothelium. In a study of acid-induced lung injury in rabbits, treatment with an anti-IL-8 monoclonal antibody was given 5 min before and 1 h after acid instillation, and neutralization of IL-8 was confirmed in the lung. At 24-h follow-up, anti-IL-8 given 1 h after acid instillation led to a more than 50% decrease in neutrophil influx and to a decrease in severity of ALI as measured by lung edema, alveolar-arterial gradient, arterial carbon dioxide, and peak airway pressures. These experimental results imply that anti-IL-8 antibodies may have a role in preventing ARDS from gastric aspiration in particular. However, there are concerns that anti-IL-8 treatment might increase the risk of infection and blunt protective aspects of the host inflammatory response. Evaluation of other anticytokine antibodies as treatment, including anti-TNF-α, anti-IL-1, and anti-IL-10 antibodies, are currently in progress.

Several nonsteroidal, antiinflammatory therapies have been evaluated for the treatment of ALI/ARDS, but none have demonstrated efficacy in reducing mortality or morbidity.

Several nonsteroidal, antiinflammatory therapies have been evaluated for treatment of ALI/ARDS, but none have demonstrated efficacy in reducing mortality or morbidity. The most recent large RCT of a novel, antiinflammatory therapy was the STRIVE study (Sivelestat Trial in ALI Patients Requiring Mechanical Ventilation), published in 2004. Sivelestat is a competitive inhibitor of neutrophil elastase, a key factor in endothelial injury and increased vascular permeability in ALI. It is already market approved and available in Japan for the treatment of ALI associated with systemic inflammatory response syndrome, based on a phase 3 study in Japan showing reduced ICU stay and improved pulmonary function. However, the STRIVE study was terminated early (with 492 enrolled patients from 105 sites in six countries) after the data and safety monitoring board found an increased mortality at 180 days. There was no difference in 28-day all-cause mortality (26% in both groups), or number of ventilator-free days.

Other therapies with antiinflammatory properties previously studied in ARDS that have not shown survival benefit include ibuprofen, ketoconazole, and lisofylline.

CASE STUDY: PART 5

The patient is transferred to a step down unit for weaning from mechanical ventilation. His course is complicated by one episode of ventilator-associated pneumonia caused by multidrug resistant Pseudomonas aeruginosa.

Over the next 2 weeks, the patient underwent intensive physical therapy and continued to wean from mechanical ventilation. On day 32 of his hospital stay, he was liberated from mechanical ventilation. The tracheostomy tube was downsized, and on day 38, the patient was decannulated. He was discharged to home on hospital day 41.

TABLE 16-7

SUMMARY OF ALI/ARDS MANAGEMENT

1. Use an initial low tidal volume ventilation strategy (6 mL/kg of predicted body weight) as in the ARDSnet trial.
2. Allow for some degree of permissive hypercapnia.
3. Maintain a plateau pressure <35 cm H_2O.
4. Use extrinsic PEEP to maintain adequate oxygenation and minimize FiO_2 to decrease the risk of oxygen toxicity.
5. Use prone positioning and iNO in selective cases of refractory hypoxemia in order to improve oxygenation.
6. Keep the lungs "dry" in patients in the exudative phase of ARDS by using a conservative fluid management strategy.

Long-Term Functional and Physiological Outcomes Following ARDS

Patients who survive the acute phase of ARDS are faced with long-term pulmonary and neurological sequelae.

Patients with severe ARDS have significantly lower pulmonary function tests than patients with less severe ARDS.

Patients who survive the acute phase of ARDS are faced with long-term pulmonary and neurological sequelae. Respiratory status as assessed by pulmonary function improves during the first 3 months postextubation; however, there is minimal additional improvement seen at 6 months and no further improvement at 1 year. A 2-year follow-up study showed persistent abnormalities in pulmonary function tests. Residual obstructive and restrictive defects and impaired gas exchange are common after severe ARDS. In one study, 25% of patients had an obstructive defect, 6% had a combined obstructive-restrictive pattern, and DLCO was decreased in 12%.[34] In addition, patients with severe ARDS have significantly lower pulmonary function tests than patients with less severe ARDS.

A study that assessed cognitive and psychological outcomes at hospital discharge and 1 year later found that all survivors had cognitive impairments, affective impairments, and problems with health status that affected quality of life. One year later, 30% of patients had significant cognitive decline and 78% of patients had impaired memory, attention, and decreased mental processing speed. Survivors also have an increased incidence of moderate-to-severe depression and anxiety up to 2 years after discharge.[35,36]

SUMMARY

ALI and ARDS are common, serious conditions that affect a heterogeneous population of critically ill patients. Other than low tidal volume ventilation, no specific intervention or therapy has improved survival. Table 16-7 provides a summary of current recommended management in ALI/ARDS. Understanding the epidemiology and pathogenesis of ARDS, and the rationale for previous clinical trials, is necessary for the development of new therapies and the comprehensive design of studies assessing their efficacy.

REVIEW QUESTIONS

1. **A 30-year-old woman is admitted with pneumonia; she rapidly develops increasing oxygen requirements and is placed on 100% oxygen with a nonrebreather face mask. There are no signs of volume overload or heart failure. Twelve hours later she is intubated due to increased work of breathing. Her ventilator settings are assist control with a rate of 14 breaths/min, tidal volume of 550 mL, 5 cm H_2O PEEP and 100%, FiO_2 an ABG shows a pH of 7.45, $PaCO_2$ of 36 mmHg and a PaO_2 of 288 mmHg. Vital signs showed a temperature of 103.2°F, blood pressure of 110/60, respiratory rate of 14, oxygen saturation of 100%. A chest X-ray shows right lower lobe pneumonia and bilateral alveolar infiltrates, which have developed in the past 24 h. The correct diagnosis is**
   - **A.** Community-acquired pneumonia
   - **B.** Community-acquired pneumonia with ARDS
   - **C.** Community-acquired pneumonia with ALI

2. **A 75-year-old man is admitted with ARDS due to gram-negative sepsis from a urinary tract infection. His past medical history is significant for diabetes mellitus, hypertension, hepatitis C with cirrhosis. He develops an upper GI bleed requiring transfusion of 4 U of packed red blood cells. All of the following are associated with increased mortality from ARDS except**
   - **A.** Sepsis as underlying cause
   - **B.** Multiple blood transfusions
   - **C.** Cirrhosis
   - **D.** Diabetes mellitus

3. **A 100 kg, 165 cm tall woman with ARDS is intubated. The correct ventilator settings are**
   - **A.** 100 mL
   - **B.** 600 mL
   - **C.** 340 mL
   - **D.** 540 mL

4. **All of the following improve oxygenation in ARDS except**
   - **A.** Steroids
   - **B.** Prone positioning
   - **C.** Extrinsic PEEP
   - **D.** iNO

5. **A patient with ARDS has the following hemodynamic variables: CVP 14, MAP 62, urinary output <0.5 mL/kg/h, cold mottled extremities with capillary refill time of >2 s. The most correct plan of action according to the FACTT trial is**
   - **A.** Furosemide
   - **B.** Dobutamine
   - **C.** Normal saline at 125-cc/h
   - **D.** Furosemide and Dobutamine

ANSWERS

1. C. Community-acquired pneumonia complicated by ALI. The patient has bilateral alveolar infiltrates that developed rapidly over 24 h, no signs of heart failure on exam, and a PaO_2/FiO_2 ratio that is less than 300 but greater than 200; all consistent with ALI.
2. D. Diabetes mellitus. The major cell type found in alveolar spaces in ARDS is the neutrophil. The reactive oxygen species, proteolytic enzymes, and inflammatory mediators released by activated neutrophils all serve to worsen the damage to the alveolar capillary membrane, leading to increased alveolar edema and worsening hypoxemia. Diabetes, with poorly controlled blood sugar, causes neutrophil dysfunction and is not associated with increased mortality in ARDS.
3. C. 340 mL Tidal volume should be set at 6 mL/kg of ideal body weight. Ideal body weight is calculated using the patient's gender and height.
   Formula:

   $$\text{Men: } 51.65 + (1.85 \times (\text{height in inches} - 60))$$

   $$\text{Women: } 48.67 + (1.65 \times (\text{height in inches} - 60)) > 57 \text{ kg}$$

4. A. Steroids. Steroids are the only intervention listed that have not been shown to improve survival.
5. D. Furosemide and dobutamine. The FACTT trial attempted to optimize fluid management in ARDS. Patients were divided into conservative vs. liberal fluid management groups. An algorithm was used to optimize use of pressors, IVF, and diuretics. Patients were assessed for the presence or absence of shock, the presence or absence of oliguria, and the presence or absence of ineffective circulation. The patient described has an elevated CVP, normal blood pressure, decreased urinary output and evidence of shock by clinical exam. The liberal fluid strategy recommended the use of IVF; the conservative strategy recommended the use of furosemide and dobutamine. The conservative fluid strategy was associated with improved lung function and shortened duration of mechanical ventilation and intensive care.

CHAPTER 17

NELSON B. FERRER AND GILBERT E. D'ALONZO

Management of Massive Pulmonary Embolism

CHAPTER OUTLINE

LEARNING OBJECTIVES

After completing this chapter, the reader should be able to:

- Define massive pulmonary embolism (MPE).
- Understand the hemodynamic and pulmonary gas exchange abnormalities associated with MPE.
- Recognize the different treatment options available for patients with MPE.

DEFINITION

Massive pulmonary embolism (MPE) is a life-threatening venous thromboembolic condition, which can be associated with both hypotension and cardiogenic shock. Certain articles in the literature identify hypotension as a systolic blood pressure of less than 100 mmHg but this definition shows a higher sensitivity but lower specificity for the diagnosis of MPE. In the International Cooperative Pulmonary Embolism Registry (ICOPER),[1] a large multinational study that prospectively analyzed a cohort of patients with pulmonary embolism, hypotension was defined as a systolic blood pressure of less than 90 mmHg. Since that trial was completed, systolic blood pressure of less than 90 mmHg has been validated as having a high specificity for identifying patients with MPE.[2] Another useful definition for hypotension is a drop of systolic blood pressure of more than 40 mmHg for greater than 15 min.[3]

Systolic blood pressure <90 mmHg has high specificity for identification of patients with MPE.

Hypotension occurs when systolic blood pressure drops more than 40 mmHg for over 15 min.

CASE STUDY: PART 1

A 65-year-old man with a past medical history of colon cancer who is actively receiving chemotherapy is brought to the emergency department by fire rescue following an episode of syncope. The patient was getting out of bed to go to the bathroom when he lost consciousness transiently. When he regained consciousness, he experienced severe shortness of breath and lightheadedness. Upon arrival to the emergency department, he was afebrile, with a systemic arterial blood pressure of 86/50 mmHg, a heart rate of 126 beats/min, and a respiratory rate of 32 breaths/min. His oxygen saturation by pulse oximetry was 87% on a 100% nonrebreather facemask. His physical examination revealed neck vein distention, tachycardia with an S3 gallop, and a diastolic murmur along the right sternal border. He appeared to have an increased work of breathing and all lung fields were clear to auscultation. Abdominal examination revealed mild right upper quadrant tenderness. The remainder of his physical examination was normal. While in the emergency department, he became somnolent and required intubation to protect his airway and to improve oxygenation, and he was eventually transferred to the medical intensive care unit.

Cardiogenic shock is usually diagnosed when cardiac index < 21/min/m² and pulmonary artery occlusion pressure >18 mmHg.

Cardiogenic shock is defined as an inappropriately low cardiac output despite normal or high right atrial pressures. It is usually diagnosed when the cardiac index is less than 2 L/min/m^2 and the pulmonary artery occlusion pressure is more than 18 mmHg. In the context of acute cor pulmonale, as a result of an MPE, the diagnosis is made on clinical grounds, when there are signs of tissue hypoxia such as hypoxemia, diminished mental status, oliguria, tachycardia, and tachypnea.

EPIDEMIOLOGY

Increased mortality is associated with cancer, congestive heart failure, COPD, hypotension, right ventricular hypokenesis, and age >70 years.

MPE has a high mortality rate and a significant incidence of complications. Two large registries of consecutive patients with pulmonary embolism, ICOPER[1] and MAPPET (management strategies and determinants of outcome in acute major pulmonary embolism)[3] demonstrate an incidence of MPE that varies from 4.2 to 31.6%, respectively. Mortality is proportional to the level of hemodynamic compromise. In the MAPPET study, patients with a systolic blood pressure of <90 mmHg had a mortality of 15%, and if cardiogenic shock was present, mortality increased to 25%. In the ICOPER registry, 58% of patients that presented with hemodynamic instability died. Several factors have been associated with this increased mortality. An age greater than 70 years, cancer, congestive heart failure, chronic obstructive pulmonary disease, hypotension, and right ventricular hypokinesis[1] have all been shown to enhance MPE mortality risk.

Bleeding is a major complication for MPE patients treated with thrombolytic therapy.

Bleeding is a major complication for patients with MPE that are treated with thrombolytic therapy. In the ICOPER registry, the incidence of major bleeding after thrombolysis was 21.7%, with intracranial hemorrhage occurring in 3% of the patients. Pooled data from several key studies that included patients with MPE and compared patients who received either thrombolytics followed by heparin or heparin alone demonstrated a combined end-point of death and recurrent PE of 9 vs.19%, respectively.[4]

PATHOPHYSIOLOGY

Life-threatening MPE is often associated with < 50% anatomical obstruction of the pulmonary vasculature or occlusion of at least two pulmonary arteries in patients without prior cardiopulmonary disease.

Massive, life-threatening pulmonary embolism is often associated with greater than 50% anatomical obstruction of the pulmonary vasculature or the occlusion of at least two lobar pulmonary arteries in a patient without prior cardiopulmonary disease. In contrast, in a patient with known preexisting cardiopulmonary compromise, the clot burden necessary to produce hemodynamic instability is most likely less. The clinical picture would be similar in both groups of patients, as they generally present with hypotension, near-syncope/syncope, or even cardiac arrest. A basic understanding of the pathophysiologic mechanisms involved in

life-threatening pulmonary embolism should help the clinician decide on the most appropriate therapeutic intervention(s).

MPE produces profound alterations in pulmonary function that can be simplified into two categories: hemodynamic alterations that result in right heart dysfunction or in extreme cases, overt heart failure and gas exchange abnormalities that result in respiratory failure.

Categories of alterations in pulmonary function caused by MPE include (1) hemodynamic alterations resulting from right heart dysfunction or (2) overt heart failure and gas exchange abnormalities resulting in respiratory failure.

Hemodynamic Alterations

An acute obstruction of blood flow through the pulmonary vascular bed will increase pulmonary vascular resistance proportionally to the amount of vascular obstruction in patients without previous cardiopulmonary disease. A 25–30% vascular bed obstruction, determined angiographically, produces an abnormal increase in pulmonary artery pressure. A mean pulmonary artery pressure >40 mmHg represents severe pulmonary hypertension for a previously healthy patient, as this is the maximal pressure that a normal right ventricle can tolerate.[5] Pulmonary hypertension in a patient with preexisting cardiopulmonary disease can be even more pronounced secondary to adaptive right ventricular hypertrophy, which can generate higher pressures. Therefore, the degree of vascular obstruction does not correlate with pulmonary artery pressures in this subset of patients.

Acute blood flow obstruction in the pulmonary vascular bed increases pulmonary vascular resistance proportionally to the amount of vascular obstruction in patients without prior CPD.

Other factors can also contribute to an increase in pulmonary vascular resistance. Occlusive thrombi are coated with activated platelets, which release serotonin and thromboxane A2, two potent vasoconstrictors. Pulmonary arteries have baroreceptors in their arterial walls that respond to increases in pressure by reflex vasoconstriction, although its role as a mechanism of increased vascular resistance in MPE is unknown. Hypoxemia is another factor that can worsen vasoconstriction. Vasodilators have not been shown to alter pulmonary artery pressures significantly, thus reinforcing the concept that obstructive thrombi are the most important cause of increased pulmonary vascular resistance in acute pulmonary embolism.[6]

Obstructive thrombi are the most important cause of increased pulmonary vascular resistance in acute pulmonary embolism.

An increase in pulmonary vascular resistance directly translates to increased right ventricular afterload, which in turn stretches the right ventricular myofibers and causes RV dilatation. Initially, there is an increase in stroke volume along with catecholamine-induced tachycardia; blood pressure is maintained early on despite the presence of occlusive thrombi. Given the reciprocal relationship between RV stroke volume and vascular afterload, stroke volume decreases with an increasing embolic burden. Increased RV wall tension increases O_2 demand while simultaneously decreasing subendocardial perfusion. These changes result in myocardial ischemia and RV decompensation.[7]

RV decompensation is manifested primarily by an increase in RV volume, which causes septal shift to the left ventricle and pericardial restriction. Left ventricle diastolic filling decreases because of this intraventricular septal shift and restricted distensibility of the left ventricle. These changes cause a decrease in cardiac output and coronary perfusion, worsening RV perfusion and resulting in systemic arterial hypotension. This perpetuates a vicious life-threatening cycle of hemodynamic collapse and shock (Fig. 17-1).

Gas Exchange Abnormalities

Pulmonary gas exchange abnormalities are invariably encountered in patients with MPE. These abnormalities result from the interaction of different factors: size of the embolic vessel, character of the embolized material, the completeness of the pulmonary arterial occlusion, the presence or absence of underlying cardiopulmonary disease, and the time that has elapsed since the embolic event occurred. The two most common abnormalities are arterial hypoxemia with an increase in alveolar-arterial oxygen gradient, and hypocapnia. The mechanisms responsible for these abnormalities are increased dead space ventilation, V/Q mismatching, intrapulmonary or extrapulmonary shunting, and low mixed-venous O_2 saturation.[8]

Pulmonary gas exchange abnormalities result from interaction of various factors, including size of embolized vessel, character of embolized material, completeness of the pulmonary arterial occlusion, presence of cardiopulmonary disease, and time elapsed since the embolic event.

The most common gas exchange abnormalities are arterial hypoxemia with an increase in alveolar-arterial oxygen gradient, and hypocapnia.

Increased dead space ventilation is the result of continuous ventilation of lung units that are not being adequately perfused. Complete obstruction of a pulmonary artery may cause a substantial increase in physiologic dead space, which could impair carbon dioxide

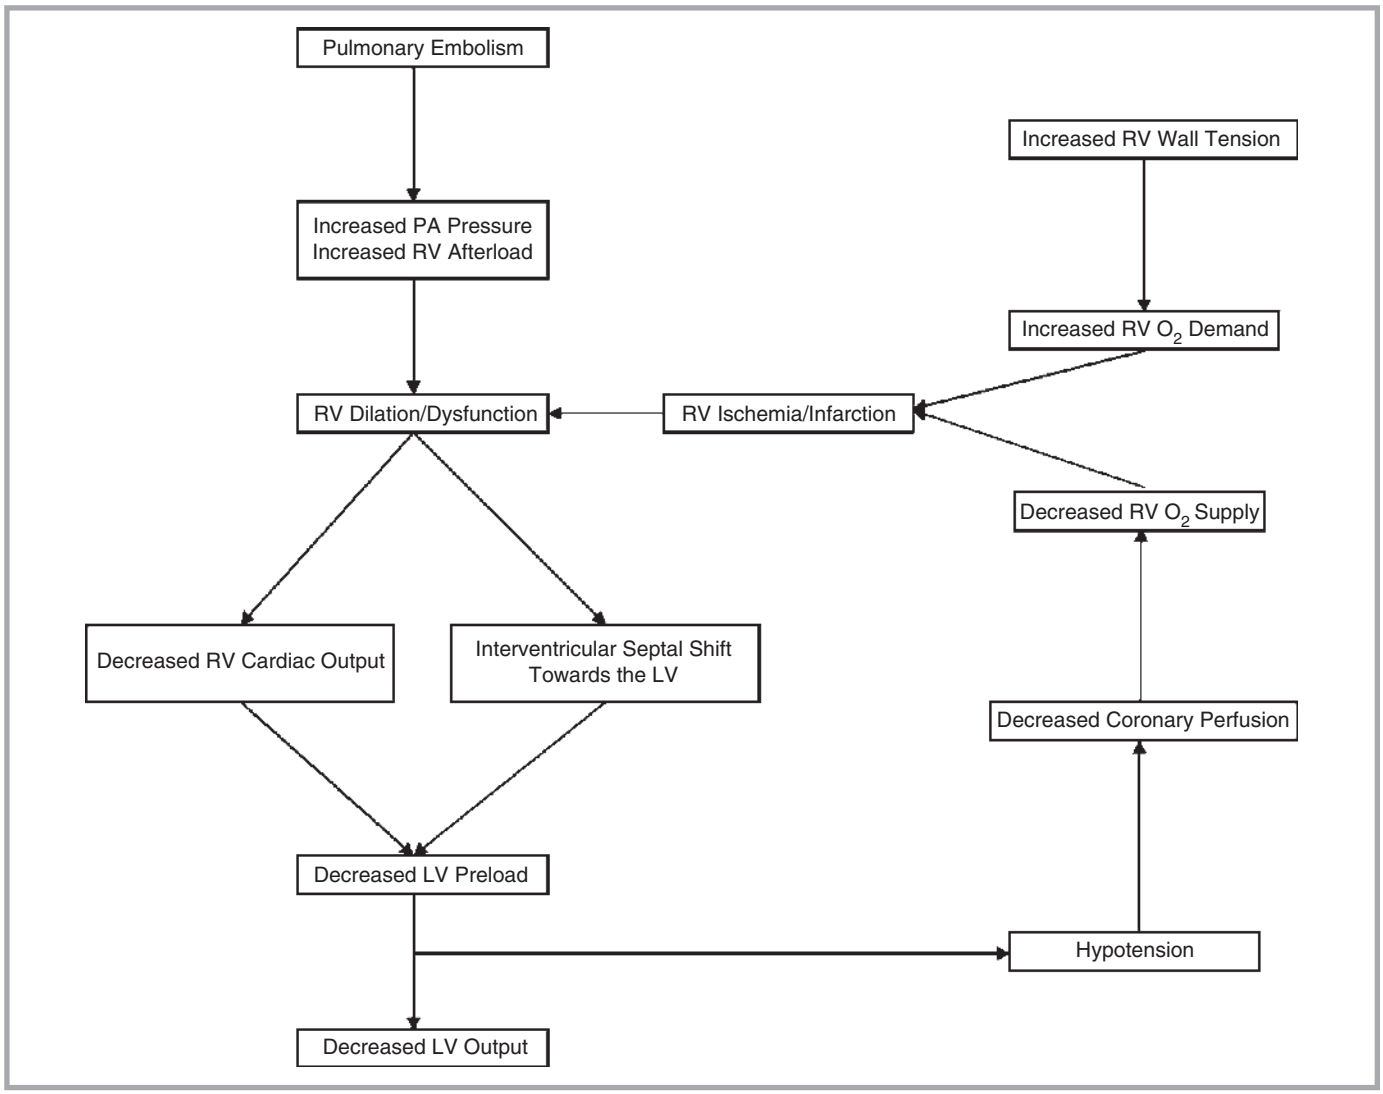

FIGURE 17-1

Pathophysiology of RV dysfunction, ischemia, and infarction after an acute pulmonary embolism (printed with permission from Goldhaber[1]).

Increased dead space ventilation is the result of continuous ventilation of lung units that are not being adequately perfused.

The degree of pulmonary vascular obstruction necessary to produce hypercapnia will likely lead to rapid right ventricular failure and death.

elimination. In the acute setting of pulmonary embolism, there is likely a transient increase in $PaCO_2$ that activates medullary chemoreceptors. This activation increases respiratory rate, then minute ventilation, and $PaCO_2$ rapidly decreases. It is this mechanism that explains the common finding of respiratory alkalosis in the setting of an acute thromboembolic event. It is thought that the degree of pulmonary vascular obstruction necessary to produce hypercapnia will likely lead to rapid right ventricular failure and death. However, patients who have severe underlying lung disease, such as chronic obstructive lung disease, may have preembolic hypercapnia and never show absolute hypocapnia but only a slight reduction from their baseline (relative hypocapnia).

Pulmonary embolism causes a redistribution of pulmonary blood flow, which results in some ventilated areas being under-perfused, while others areas are being over-perfused. Also, atelectasis may develop in lung regions beyond the area of vascular obstruction secondary to a loss of surfactant and/or alveolar hemorrhage, which may persist even after reperfusion occurs. Arterial hypoxemia caused by this V/Q inequality responds to an increase in inspired oxygen concentration (FiO_2). If the degree of pulmonary vascular obstruction is

large, as expected during a massive PE, there may be a degree of right-to-left intrapulmonary vascular shunting that will not correct with increases in FiO_2. Furthermore, approximately 15% of the normal population has the potential for the development of a patent foramen ovale and given the overall increase in pulmonary vascular resistance seen in MPE, there is a possibility for the opening of a right-to-left intracardiac shunt.

Low mixed-venous O_2 saturation secondary to reduced cardiac function can contribute to the hypoxemia seen following an MPE, especially in patients with preexisting cardiac conditions or severe right ventricular failure. This low mixed-venous O_2 saturation results from a decrease in cardiac output, which accelerates peripheral tissue oxygen extraction and results in a low end-capillary PO_2 that drives mixed-venous O_2 saturation downward. This increase in metabolic demand can overwhelm an already compromised cardiovascular system, thereby worsening hypoxemia.

Low mixed-venous O_2 saturation secondary to reduced cardiac function can contribute to hypoxemia following an MPE.

Changes in the degree of arterial hypoxemia after resolution of MPE are expected, but the degree of change is unpredictable given the interplay of these multiple potential etiologic factors.

DIAGNOSIS

History and Physical

Dyspnea and chest pain are the two most common symptoms associated with pulmonary embolism. Other symptoms include apprehension, cough, hemoptysis, and lightheadedness/syncope (Table 17-1). Pleuritic chest pain is most commonly associated with sub-MPE and smaller events that occlude peripheral arteries resulting in pulmonary hemorrhage and infarction with pleural irritation. Lightheadedness, near-syncope, and syncope are associated with a massive embolic event, since these signs indicate that acute pulmonary hypertension, right heart failure, and systemic hypotension are evolving. Past medical history may include one or several of the known risk factors for the formation of deep venous thrombosis, such as obesity, cancer, recent surgery, congestive heart failure, previous thromboembolic disease, and immobility (Table 17-2).

Tachycardia and tachypnea are found in more than 90% of patients with acute pulmonary embolism, and the degree of severity of these two signs often correlate with the severity of the pulmonary embolic event. An important group of physical findings present in MPE and

Dyspnea and chest pain are the most common symptoms associated with PE.

Other symptoms associated with PE include apprehension, cough, hemoptysis, and lightheadedness/syncope.

Lightheadedness, near-syncope, and syncope are also associated with MPE.

Severity of tachycardia and tachypnea often correlates with severity of a pulmonary embolic event.

Important physical findings present in MPE and acute cor pulmonale include systemic arterial hypotension, parasternal lift, elevation of jugular venous pressure, tricuspid regurgitation, and right ventricular S3 gallop.

acute cor pulmonale include systemic arterial hypotension, parasternal lift, elevation of jugular venous pressure, tricuspid regurgitation, and right ventricular S3 gallop. Other physical findings associated with pulmonary embolism are fever, inspiratory crackles and lower extremity phlebitic pain, edema, and erythema (Table 17-3).

Laboratory Abnormalities

Arterial blood gas values are almost universally altered in patients with MPE. Hypoxemia is the result of a marked abnormality in pulmonary gas exchange, and hypocapnia is the result of reactive hyperventilation. Acute respiratory alkalosis is the most common acid–base disorder encountered, but in patients with hypotension due to massive clot burden, hypercapnia may be present. The alveolar-arterial O_2 gradient is increased in patients with MPE, and the finding of a normal alveolar-arterial O_2 gradient would make the diagnosis of MPE, and for that matter pulmonary embolism in general, highly unlikely.

Two important laboratory tests identified in patients with MPE are the cardiac biomarkers troponin and B-type natriuretic peptide. Both cardiac troponin T and I are specific to cardiac muscle and are good markers for myocardial injury. In this setting, decreased myocardial perfusion leads to cardiac tissue ischemia and subsequent elevation in troponin levels. While the cutoff point in values is the same as the ones used in myocardial infarction, the peak levels are much lower, given the overall smaller mass of the right ventricle. Elevated troponin levels are also associated with a higher risk of short-term death and other adverse outcomes, such as shock, endotracheal intubation, vasopressor support, cardiopulmonary resuscitation, and recurrent pulmonary embolism.[9]

Cardiac biomarkers troponin and B-type natriuretic peptide are two important laboratory tests identified in MPE patients.

B-type natriuretic peptide is released from ventricular cells as a result of the increase in ventricular volume secondary to the vascular obstructive defect, with a subsequent increase in shear wall stress. The elevation of B-type natriuretic peptide takes hours, since this peptide is not stored in cells but is synthesized after the myocardial cell has been stimulated. The cutoff value for pulmonary embolism is lower than the one used for congestive heart failure; a value of <50 pg/mL is used to exclude MPE, while a value <90 pg/mL excludes heart failure.[10] Low cardiac troponin and B-type natriuretic peptide values have a high negative predictive value for excluding MPE.

D-dimer has only limited utility in assessment of unstable MPE patients due to a variety of conditions that can elevate it.

D-dimer is expected to be elevated in MPE, given the presence of a significant clot burden. The wide array of conditions that can elevate D-dimer (postoperative states, sepsis, cardiogenic shock) limits its utility in the assessment of these unstable patients who have MPE.

Ancillary Testing

Like the physical examination, the EKG often shows nonspecific alterations. Most patients with pulmonary embolism will present with sinus tachycardia and MPE is often associated with EKG changes that suggest RV strain, such as right axis deviation, $S_1Q_3T_3$ pattern, or an incomplete or complete right bundle branch block (Table 17-4).

CASE STUDY: PART 2

Upon arrival to the ICU, preliminary laboratory studies became available. His complete blood count revealed a hemoglobin concentration of 11 g/dL with a normal platelet count. The complete metabolic profile showed normal electrolytes, liver function profile, and renal function. An arterial blood gas test drawn on 100% nonrebreather mask revealed: pH 7.50, PaO_2 49 mmHg, and $PaCO_2$ 30 mmHg. Troponin I was 0.2 ng/mL (0.0–0.4 ng/mL) and B-natriuretic peptide was 76 pg/mL. A portable chest X-ray did not show an infiltrate, pleural effusion, or pneumothorax. Electrocardiogram (EKG) revealed sinus tachycardia with an incomplete right bundle branch block.

Intravenous heparin was started using a continuous drip after a bolus dose was administered. The patient continued to be hypotensive even after a rapid infusion of 500 mL of normal saline. A norepinephrine drip was started, with subsequent improvement of his mean arterial pressure. The patient was sent for a stat chest CT angiogram, which showed a large saddle pulmonary embolism. The heparin infusion was stopped and tissue plasminogen activator (t-PA), at a dose of 100 mg intravenously over 2 h, was administered.

Chest X-ray is useful for ruling out other disorders that can masquerade clinically as pulmonary embolism, such as pneumonia, congestive heart failure, and pneumothorax. Some radiographic findings associated with RV failure may also be present, including enlarged proximal pulmonary arteries, opacification of the retrosternal air space secondary to RV enlargement, and pleural or pericardial effusions. Computed tomography of the chest with contrast, using an angiographic pulmonary embolism protocol, will identify large intraluminal filling defects in the major pulmonary arteries and in their lobar branches, making the diagnosis easily evident. Four-chamber CT reconstructed views of the heart, with a ratio of RV diameter to LV diameter greater than 0.9 has been shown to predict an increased 30-day mortality.[11]

Most MPE patients present with sinus tachycardia, and MPE is often associated with EKG changes that suggest RV strain.

Chest X-ray may rule out disorders masquerading clinically as PE, such as pneumonia, congestive heart failure, and pneumothorax.

Chest CT with contrast using angiographic PE protocol makes diagnosis easily evident.

Echocardiography can be an effective test for diagnosing right ventricular failure. When proper views are achieved, echocardiography detects pulmonary hypertension, RV hypokinesis, and other associated conditions that have important therapeutic implications in the management of MPE (Table 17-5). The ICOPER registry identified right ventricular hypokinesis in patients with sub-MPE as having an increased risk of 30-day mortality.[1]

Echocardiography can detect pulmonary hypertension, RV hypokinesis, and other conditions associated with MPE.

Two common echocardiographic signs of MPE are RV dilation and hypokinesis. A distinctive pattern of regional wall hypokinesis sparing the apex, known as McConnell's sign, has a sensitivity of 77% and a specificity of 94% for distinguishing between RV dysfunction

TABLE 17-5

Two common echocardiographic signs of MPE are RV dilation and hypokinesis.

related to pulmonary embolism and dysfunction related to other conditions.[12] Other important findings that suggest cor pulmonale include paradoxical septal motion, lack of inferior vena cava collapse during inspiration, and tricuspid regurgitation. Two echocardiographic findings that have major therapeutic implications are patent foramen ovale and right heart thrombus formation. Both of these conditions are associated with a very high mortality and their presence implies potential surgical management.

Paradoxical septal motion, lack of inferior vena cava collapse during inspiration, and tricuspid regurgitation are important findings that suggest cor pulmonale.

Echo findings of patent foramen ovale and right heart thrombus formation have major therapeutic implications. Presence of both conditions implies potential surgical management.

MANAGEMENT

The ultimate management goal of MPE is rapid resolution of the acute obstructive defect, with hemodynamic and gas exchange improvements. Right ventricular failure with low cardiac output can prove to be rapidly fatal if not treated urgently and effectively. Stabilizing the patient by managing the hemodynamic derangement caused by RV failure will provide valuable time to complete the testing necessary to stratify the patient to the most effective and appropriate strategy.

Rapid resolution of the acute obstructive defect, with hemodynamic and gas exchange improvements is the ultimate goal of MPE management.

Stabilization of the patient by managing hemodynamic derangements will allow time to complete necessary testing to identify the most effective strategy.

Hemodynamic Management

Early during the course of an MPE, there is a catecholamine surge, which helps maintain a degree of hemodynamic sustainability; however, this effect is often short-lived, resulting in life-threatening hypotension. Volume resuscitation is the first step in the management of patients with impending or early shock, but MPE presents a challenge when it comes to fluid management because of the vascular obstructive nature of the disease. It has been demonstrated that patients with MPE and decreased cardiac output who were normotensive and without vasopressors increased their cardiac output with a 500-mL intravenous bolus of normal saline or dextran. The increase in cardiac output can be proportional to the right ventricular end-diastolic volume.[13]

A catecholamine surge occurring early during the course of MPE helps maintain a degree of hemodynamic sustainability. The effect, however, is often short-lived and results in life-threatening hypotension.

When patients have severe RV dysfunction with high RV end-diastolic volumes, further volume administration can worsen RV function and promote RV ischemia by over-distending the RV myocardium. The over-distended RV decreases sub-endocardial coronary flow and decreases coronary perfusion because of the concomitant decrease in left ventricular cardiac output. Therefore, volume expansion should be limited to 500 mL to 1 L of isotonic fluids, especially if there are signs of volume overload. Central venous pressure (CVP) measurement may be helpful in deciding the amount of fluid to be given; with a CVP > 12 cm H_2O favoring a fluid restrictive approach.

Volume expansion should be limited to 500 mL to 1 L of isotonic fluids in patients with severe RV dysfunction. CVP is a useful cue for fluid levels administered, with a CVP > 12 cm H_2O favoring a fluid restrictive approach.

Vasopressor use should be instituted early in the management of shock but there are no human studies comparing different vasopressors for the management of MPE. Therefore, therapeutic choices have to be made based upon the pharmacologic profiles of the drugs considered for therapy. An inotropic agent like dobutamine can improve cardiac output via β_1 (beta) receptor stimulation and enhanced biventricular function. Its main drawback is its potential to worsen hypotension, mediated by stimulating vasodilatory β_2 (beta) receptors. Therefore, it should be used in moderate cases of shock or in conjunction with an α (alpha) agonist such as phenylephrine. Animal studies support the use of norepinephrine, since it has both α_1 (alpha) vasoconstrictive and β_1 (beta) inotropic effects.[14]

Therapeutic choices of vasopressors must be based on pharmacologic drug profiles.

In the event that cardiac output remains low despite adequate doses of vasopressors and inotropes, a decrease in ventricular afterload should be considered. The conventional vasodilating agents like nitroglycerin, hydralazine, and nitroprusside have no role in this setting because of their systemic vasodilatory properties and resulting hypotension. More selective pulmonary artery vasodilators can have a role in reducing the RV afterload while definitive treatment is instituted. Inhaled nitric oxide and sildenafil are two pulmonary vasodilators that provide some physiologic rationale for their use in MPE, but the clinical evidence supporting the use of these therapies is sparse.

In the event that cardiac output remains low despite adequate doses of vasopressors and inotropes, a decrease in ventricular afterload should be considered.

Inhaled nitric oxide and sildenafil provide some physiologic rationale for use in MPE, but clinical evidence supporting the use of these therapies is sparse.

Case reports using inhaled nitric oxide have shown decreased pulmonary artery pressure with improved hemodynamics, along with improvements in pulmonary gas exchange.[15]

More studies are needed to determine the exact role of these agents in the management of MPE.

Further research is needed to determine the role of inhaled nitric oxide in management of MPE.

Ventilatory Support

Patients with MPE have varying degrees of arterial hypoxemia, depending on the interplay of the various pathophysiological mechanisms involved. Hypoxemia should be corrected with supplemental O_2 using an oxygen delivery device that can provide enough oxygen to keep the arterial O_2 saturation more than 90%. The decision to use mechanical ventilation depends not only on the degree of hypoxemia but also on the work of breathing exhibited by the patient. Increased work of breathing is associated with an increase in metabolic demand derived from accessory muscle use, increasing oxygen tissue demand and worsening hypoxemia. Neuromuscular blocking agents, while the patient is mechanically ventilated, will decrease the tissue oxygen requirement and improve arterial oxygenation when necessary.

The decision to use mechanical ventilation depends not only on the degree of hypoxemia but also on the work of breathing exhibited by the patient. Increased work of breathing is associated with an increase in metabolic demand, increasing oxygen tissue demand and worsening hypoxemia.

NMBAs decrease the tissue oxygen requirement and improve oxygenation in mechanically ventilated patients.

Once the decision has been made to mechanically ventilate a patient, certain considerations have to be made concerning the use of sedatives. Most sedatives will blunt the catecholamine surge associated with MPE with a potential of enhancing hypotension; therefore, inotropic agents should be readily available. Etomidate is a reasonable alternative, since it has a short half-life of 3–5 min and does not cause cardiovascular depression and histamine release during administration.

Careful consideration of sedative use is essential for mechanically ventilated patients, and inotropic agents should be readily available.

Mechanical ventilation can worsen RV function through a variety of mechanisms. Increased airway pressures, which induce higher transpulmonary pressures, increase RV afterload. Increases in airway pressures also can increase intrathoracic pressure, decreasing RV venous return and cardiac output. Finally, mechanical ventilation also increases transpleural pressure, which is transmitted to the pericardial surface. Increased pericardial pressure can decrease LV diastolic filling, which is already impaired by intraventricular septal displacement.

Mechanical ventilation can worsen RV function through a variety of mechanisms, including increased airway pressures and increased transpleural pressure.

Ventilatory strategies should aim to oxygenate while minimizing the potential of RV failure. Respiratory rate and inspiratory flow rate should be adjusted to limit alveolar gas trapping. Lower tidal volumes should be favored, which will decrease alveolar over-distention and resultant higher transpulmonary pressure. Finally, positive end-expiratory pressure (PEEP) should be used judiciously to limit its effect on pulmonary vascular resistance.

Ventilatory strategies should aim to oxygenate while minimizing the potential of RV failure.

Anticoagulation and Thrombolysis

Heparin

One of the first therapeutic measures to be instituted as soon as the diagnosis of MPE is seriously considered is the administration of high dose unfractionated heparin as long as an absolute contraindication is not present (Table 17-6). Studies have shown that heparin is more rapidly cleared from plasma in pulmonary embolism than in deep venous thrombosis.[16] The importance of an adequate dose of unfractionated heparin cannot be understated, the implication being that subtherapeutic heparin levels can contribute to fatality. It is preferable to administer a higher dose of heparin and reduce the dose rather than expose the patient to the risk of recurrent embolization with subtherapeutic anticoagulation.[17] Using a weight-based regimen of 80 U/kg of heparin as a bolus followed immediately by a continuous heparin infusion at 18-U/kg/h to achieve a target PTT of at least 80 s. It is important to use actual body weight when calculating heparin doses, as opposed to ideal body weight.

Administration of unfractionated heparin should be among the first therapeutic measures instituted following MPE diagnosis when absolute contraindications are not present.

Heparinoids

There are other drugs that provide effective anticoagulation in thromboembolic disease, but their effectiveness and safety in patients that are critically ill with MPE remain questionable and controversial. Low-molecular weight heparins and fondaparinux are viable alternatives in the treatment of uncomplicated DVT and nonMPE, but the same characteristics that make them attractive in these settings (once or twice daily administration and no need for

Heparinoids may provide effective anticoagulation in thromboembolic disease, but their effectiveness and safety in critically ill MPE patients remain controversial.

TABLE 17-6

CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY IN MPE[30]

Absolute contraindication	Active internal bleeding
	Recent spontaneous intracranial bleeding
Relative contraindication	Major surgery, delivery, organ biopsy, or puncture of noncompressible vessel within 10 days
	Ischemic stroke within 2 months
	GI bleeding within 10 days
	Serious trauma within 15 days
	Neurosurgery or ophthalmologic surgery within 1 month
	Uncontrolled severe hypertension (SBP>180 mmHg, DBP>110 mmHg)
	Recent cardiorespiratory resuscitation
	Platelet count <100,000
	Pregnancy
	Bacterial endocarditis
	Diabetic hemorrhagic retinopathy

SOURCE: adapted from Torbicki et al.[30] with permission from Oxford University Press

therapeutic laboratory monitoring) make them unpredictable in the context of the critically ill patient with MPE. A study done in surgical ICU patients with or without shock demonstrated that factor Xa activity was lower in patients that were using vasopressors, rendering therapy with low-molecular weight heparin less effective.[18] Another important drawback is their limitation in patients with renal insufficiency, since there is insufficient evidence for their use in that particular setting. In certain cases of MPE, appropriate treatment may involve invasive procedures that would be complicated by a long acting and difficult to reverse anticoagulant.

Thrombolytics

The role of thrombolytic therapy in the treatment of unselected patients with pulmonary embolism is controversial. The physiological rationale for using thrombolytics in patients with MPE comes from the fact that this treatment represents a medical embolectomy in an unstable patient. There are well-documented improvements in hemodynamic, scintigraphic, echocardiographic and angiographic measures following thrombolysis. By lysing the obstructive thrombus, RV dysfunction, a pathophysiological consequence of MPE that is associated with high mortality, can potentially reverse. However, meta-analyzes that pooled data from several studies that compared heparin alone to a thrombolytic therapy in the treatment of unspecified pulmonary embolism, have not found that the hemodynamic improvements that follow thrombolytic therapy translate into a decrease in mortality compared to the use of heparin alone. In contrast, subgroup analysis has indicated that patients with MPE demonstrate a statistical significant difference in treatment favoring the use of thrombolytic therapy.[19] One small trial, involving eight patients, compared patients with MPE who received heparin alone versus thrombolytic therapy. All four patients in the heparin arm of the trial died while the four patients in the thrombolytic arm survived.[20] Current guidelines issued by the American College of Chest Physicians,[21] the British Thoracic Society,[22] and the European Society of Cardiology[23] all support the use of thrombolytic therapy (with difference in the strength of the recommendation) in patients with MPE.

The role of thrombolytic therapy in the treatment of unselected patients with pulmonary embolism is controversial.

Current guidelines issued by the ACCP, BTS, and ESC support the use of thrombolytic therapy (with difference in the strength of the recommendation) in patients with MPE.

Internal bleeding and recent intracranial or ocular surgery are absolute contraindications for thrombolytic therapy.

Informed consent should be obtained if possible and invasive procedures should be avoided or minimized prior to the use of thrombolytic therapy.

Once the diagnosis of MPE is confirmed, several steps should be taken prior to deciding the method for clot lysis. Most of the contraindications for thrombolytic therapy are relative, with the exception of active internal bleeding and recent intracranial or ocular surgery (Table 17-6). In many settings, the only available treatment will be thrombolytic therapy, since invasive mechanical and surgical options are only available in centers with a particular interest in offering these nonpharmacologic treatment modalities. Informed consent should be obtained if possible and invasive procedures should be avoided or minimized prior to the use of thrombolytic therapy, especially arterial puncture and central venous line insertion, since these are the sites most likely to bleed after thrombolysis. Type and cross matching of blood products should be done in anticipation of possible hemorrhagic complications.

CASE STUDY: PART 3

After t-PA infusion was completed, a control partial thromboplastin time (PTT) was 110 s; 4 h later a control PTT was 54 s and heparin was restarted without a bolus. Six hours after completion of the t-PA infusion, the patient's blood pressure started to improve and the norepinephrine infusion was weaned off promptly. His supplemental oxygen requirements decreased, and 24 h after admission to the hospital, the patient was extubated successfully. On hospital day number 10, the patient was discharged home on oral warfarin after 5 days of therapeutic levels and concomitant heparin.

TABLE 17-7

APPROVED THROMBOLYTIC DRUGS FOR MPE

DRUGS	DOSING
Streptokinase	250,000 U over 30 min; then, 100,000 U/h for 24 h
Urokinase	4,400 U/kg over 10 min; then, 4,400 U/kg for 12 h
Tissue plasminogen activator (t-PA)	10 mg bolus; then 90 mg over 2 h

SOURCE: adapted from Carlbom DJ, Davidson BL. Pulmonary Embolism in the Critically Ill. *Chest*. 2007; 132:313-324. Reprinted with permission from the American College of Chest Physicians

Currently, there are three available thrombolytic agents that are approved by the Federal Drug administration (FDA) for the treatment of MPE (Table 17-7). t-PA is more fibrin specific than streptokinase or urokinase, but no single agent has been shown to be superior to any other. Peripheral intravenous catheters can be used to administer all three regimens and central catheter administration has not been proven to be superior and it increases the probability of bleeding at the insertion site. Heparin infusion must be stopped completely before thrombolytic therapy is started. Once the thrombolytic infusion is completed, a PTT should be obtained. Heparin should be restarted without a bolus-loading dose once the PTT is less than twice its upper limit of normal. If the PTT is higher than this number, it should be repeated every 4 h until this target is reached before starting the heparin infusion.

Currently, t-PA is the preferred agent for thrombolysis because complete administration is achieved in 2 h, as opposed to 12 h for urokinase and 24 h for streptokinase. Streptokinase has the added drawbacks of possible allergic reaction, hypotension, and the limitation that it can be given just once. Currently, tenecteplase is being studied for use in pulmonary embolism and if it is proven effective and safe, it can provide the added advantage of a 5 second onset for it full thrombolytic effect.

Major bleeding is the most common adverse effect of thrombolytic therapy, with an overall incidence of 21%, and it appears to be similar among different agents. Intracranial hemorrhage has an incidence of 3%, being fatal in 50% of the cases.[1] If intracranial hemorrhage is suspected, the thrombolytic agent should be stopped immediately, a CT scan of the brain without contrast should be obtained, and a neurosurgeon should be consulted. In case there is major bleeding, cryoprecipitate and fresh frozen plasma can be administered, while measuring hematocrit and repleting blood losses with packed red blood cells as needed. Protamine sulfate can be added to the treatment regimen to antagonize the action of any residual heparin in the system.

Lack of response to thrombolytic therapy is defined as persistent clinical instability and residual echocardiographic evidence of RV failure.

It is important to note that the rate of failure for thrombolytic therapy after adequate dosing is 8% according to recently published data.[23] Lack of response to thrombolytic therapy is defined as persistent clinical instability and residual echocardiographic evidence of RV failure.

Catheter-Based Mechanical Therapy

Catheter-based mechanical therapy represents an appealing option for patients presenting with MPE who have large, central thromboemboli in the main pulmonary artery or in the

right or left pulmonary arteries who are unable to receive thrombolytic therapy (Table 17-6). The American College of Chest Physicians Evidence Based Practice Guidelines currently recommends this approach (albeit weakly) if the above conditions are met and there are experts in the field available.[21]

None of the available mechanical thrombectomy devices have regulatory agency approval.

Currently, there are several devices available for mechanical thrombectomy; none of them having regulatory agency approval. Evidence concerning the treatment value of catheter intervention is sparse, and pooled data from studies involving different devices in >300 patients treated reveals a >80% success rate. Mortality has been reported to range from 0 to 25%.[24] The available catheters use different techniques for clot fragmentation. Earliest approaches involved simple aspiration of the thrombus and balloon angioplasty with fragmentation and dispersion of the clot. Newer models employ jet fragmentation with dispersion or aspiration of the clots.

Complications with the use of mechanical thrombectomy devices include pericardial tamponade, pulmonary hemorrhage, and pulmonary artery rupture.

Complications with the use of these devices include pericardial tamponade, pulmonary hemorrhage, and pulmonary artery rupture.[24] Cardiac arrhythmias can also occur as a result of catheter passage through the right heart. Mechanical hemolysis and a case of paradoxical worsening of hypotension after successful catheter-based thrombectomy have been reported. The explanation for this event is that free hemoglobin binds nitric oxide, which in turn worsens pulmonary vasoconstriction and accelerates cor pulmonale. If recognized, inhaled nitric oxide can be used.[25]

Overall, experience with catheter-based embolectomy is very limited.

Overall, experience with catheter-based embolectomy is very limited. An online worldwide registry is currently being established by the North American Thrombosis Forum to help standardize percutaneous mechanical thrombectomy in MPE.

Inferior Vena Cava Filters

Since the 1998 trial, IVC filter use has been recommended in three specific clinical scenarios: contraindications to anticoagulation, bleeding with anticoagulation and failure of anticoagulation.

Vena cava interruption using filters has been considered a reasonable alternative for patients with venous thromboembolic disease with contraindications for anticoagulation since 1973. Evidence for their effectiveness had been limited to multiple case series scattered in the literature until a well-designed, randomized controlled trial was published in 1998. This trial demonstrated that IVC filters, along with full anticoagulation, prevent early embolization but are associated with more long-term deep vein thrombosis and have no effect on mortality, when compared to full anticoagulation alone.[26] Since then, IVC filter use has been recommended in three specific clinical scenarios: contraindications to anticoagulation, bleeding with anticoagulation, and failure of anticoagulation.

When it comes to MPE, there is currently no evidence for IVC filter use, but two important points can be made that may help the clinicians with their decision process. First, in a follow-up analysis of the ICOPER study, it was found that patients with an MPE that had an IVC filter placed appeared to have less recurrent PE and a lower 90-day mortality.[27] These results have to be interpreted with caution, especially since the total number of patients that had an IVC filter was small. The second point refers to the use of IVC filters in the preoperative period of patients who have had a surgical thrombectomy, to prevent further embolization. This approach has been used successfully in a single center performing surgical pulmonary embolectomy.[28]

Surgical Embolectomy

This approach has been traditionally reserved for patients with MPE who have a significant contraindication for thrombolysis. Historical mortality figures have been in excess of 30%, but this number has shown improvement in recent trials. Some of the lessons learned and employed in more recent trials involve the routine placement of an inferior vena cava filter intraoperatively, avoidance of aortic cross clamping, and not generally operating on octogenarians and patients with an out-of-the-hospital cardiac arrest that have not restored spontaneous circulation.[28]

Surgical embolectomy is also recommended for patients with a patent foramen ovale or a right heart thrombus identified; since these two conditions carry a higher mortality. Another indication for surgical embolectomy is failed thrombolysis, which occurs in about 8% of

MPE cases. As reported recently, surgery has been performed safely following 72 h of thrombolytic therapy without fatal bleeding.[28]

Overall, thrombolytic therapy is the treatment of choice for a patient with MPE who does not have a contraindication for this therapy. Hospitals should determine in advance what the various management options are for thrombolysis failure, either by implementing a plan for invasive treatment within the hospital or for rapid referral to a specialized center.

Overall, thrombolytic therapy is the treatment of choice for a patient with MPE who does not have a contraindication for this therapy.

SUMMARY

MPE is a life-threatening event that carries a very high mortality. Once recognized by the clinician, effective treatment with thrombolytic therapy can be instituted with a reasonable margin of safety in more than 2/3 of cases. For the remainder of patients that are not eligible for thrombolytic treatment, transfer to a center that can provide catheter-based therapy and/or surgical embolectomy should be pursued.

REVIEW QUESTIONS

1. **Which of the following pathophysiological mechanisms of hypoxemia is not associated with MPE?**
   - **A.** *V*/*Q* inequality
   - **B.** Intracardiac Shunt
   - **C.** Hypoventilation
   - **D.** Low mixed-venous O_2

2. **Which of the following is the most common EKG finding in MPE?**
   - **A.** $S_IQ_{III}T_{III}$
   - **B.** Right bundle branch block
   - **C.** Right axis deviation
   - **D.** Sinus tachycardia

3. **Which of the following statements regarding cardiac biomarkers in MPE is false?**
   - **A.** Cutoff levels for troponins are the same as in myocardial infarction
   - **B.** Normal BNP levels are not associated with MPE
   - **C.** An increase in troponins correlates with an increase in mortality
   - **D.** The main stimulus for BNP synthesis is myocardial stretch

4. **A 34-year-old obese woman presents to the emergency department with acute onset of shortness of breath, apprehension, and some chest pressure. She is status post C-section 14 days ago and denies any lightheadedness, syncope, or chest pain. On physical examination, she is in moderate respiratory distress, afebrile, with a heart rate of 117 beats/min, a respiratory rate of 24 breaths/min and a blood pressure of 106/64 mmHg. She has neck vein distention, her lungs are normal to auscultation and her cardiac examination reveals a regular rate tachycardic rhythm, without a murmur or gallop. Which one of the following is the best management plan?**
   - **A.** Complete blood count, basic metabolic panel, coagulation profile, EKG, BNP, IV heparin, and CT of the thorax with IV contrast
   - **B.** Complete blood count, basic metabolic panel, coagulation profile, troponins, therapeutic low-molecular weight heparin, and CT of the thorax with IV contrast
   - **C.** Complete blood count, basic metabolic panel, coagulation profile, troponins, BNP, IV heparin, CT of the thorax with IV contrast, and transthoracic echocardiogram
   - **D.** Complete blood count, basic metabolic panel, coagulation profile, troponins, BNP, IV heparin, CT of the thorax with IV contrast

5. **Regarding the above-mentioned patient, her complete blood count, basic metabolic and coagulation profiles, and BNP were within normal limits and her troponin I was 0.3 ng/dL (normal <0.2 ng/dL). Two hours after admission her CT scan revealed a saddle embolus in the main pulmonary artery. While the echocardiogram was being performed, she complained of lightheadedness, her blood pressure was 88/50. The echocardiogram revealed a dilated, hypokinetic right ventricle with a patent foramen ovale. Which of the following is the best management strategy for this patient?**
   - **A.** IV fluid resuscitation with normal saline and thrombolytic therapy with t-PA
   - **B.** IV fluid resuscitation with normal saline, transfer to the ICU for hemodynamic monitoring, and immediate consultation with a cardiothoracic surgeon for urgent pulmonary artery embolectomy
   - **C.** IV fluid resuscitation with normal saline, transfer to the ICU for hemodynamic monitoring, and IV t-PA
   - **D.** IV fluid resuscitation with normal saline, transfer to the ICU for hemodynamic monitoring, and placement of a pulmonary catheter for intrapulmonary administration of t-PA.

ANSWERS

1. C. Normal lungs match ventilation and perfusion; an obstructive embolus in the pulmonary vascular bed redistributes pulmonary blood flow creating a *V*/*Q* inequality. In MPE, with more than 50% of the pulmonary arterial vascular bed obstructed by thromboemboli, there is intrapulmonary shunting of blood by virtue of perfused unventilated units due to hypocapnia-induced bronchoconstriction and atelectasis. Intracardiac shunting also occurs when volume overload increases the pressure in the right ventricle, which can potentially open a foramen ovale in 15% of the population. The obstructive pulmonary vascular defect decreases left ventricular end-diastolic volume, which in turn decreases cardiac output, with an increase of oxygen extraction at the peripheral tissue level and low mixed-venous oxygen at the pulmonary artery level. Alveolar hypoventilation would likely have no to at most a very minimal contribution to hypoxemia in MPE.
2. D. Right axis deviation, $S_IQ_{III}T_{III}$ pattern and right bundle branch block are EKG findings seen with RV strain, as is the case with MPE, but they are insensitive. Sinus tachycardia is by far more common, especially in the setting of hypotension.
3. B. Elevation of troponins is mild and short-lived when compared to myocardial infarction, since the amount of muscle mass in the RV is smaller than the LV, but the laboratory cutoff values are the same. A high troponin level in MPE indicates significant muscle tissue damage and myofibril degradation that releases troponins, which correlates with an increase in mortality. BNP is not stored in cells; an increase in shear wall stress stimulates its production. This process might take several hours; therefore, it is possible to see a normal level in the early phases of MPE.
4. C. This patient with two readily identifiable risk factors for PE presents to the emergency department with no signs of hemodynamic instability. Given the high pretest probability of pulmonary embolism, she should be started on unfractioned intravenous heparin empirically before any diagnostic testing is performed. Low-molecular weight heparin, at therapeutic doses, can make the management of bleeding complications more difficult if a decision to use thrombolytic therapy is considered later. Her initial laboratory testing should include cardiac biomarkers to differentiate between low-risk and intermediate-risk PE. At the same time, she should undergo a transthoracic echocardiogram to evaluate RV function for the possible need for thrombolytic therapy if she becomes hemodynamically compromised in the future.
5. B. During the course of hospital stay, the patient became hemodynamically unstable and there were evidence of an MPE with an intracardiac shunt. The fact that she had a recent C-section 2 weeks before admission represents a relative contraindication to thrombolytic therapy, but the presence of a patent foramen ovale indicates a high risk of mortality in this patient, approaching 50%. Surgical embolectomy, if an experienced cardiothoracic surgeon is available, represents the best option for this patient.

CHAPTER 18

PAUL J. MATHER AND GILBERT E. D'ALONZO

Heart Failure

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Define congestive heart failure (CHF).
- Classify the epidemiology of CHF.
- Understand the morbidity and mortality statistics of CHF.
- Recognize the signs and symptoms of CHF.
- Know the major treatment algorithms of CHF.
- Understand the pharmacology and pathophysiology behind the treatment regimens.
- Understand the limitations of the treatment regimens.

CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is a major health problem in the United States with a prevalence that has been increasing and a mortality rate that remains high, even as adverse outcomes from other forms of cardiovascular disease have declined. In a critically ill patient, cardiac failure is an ominous sign that requires prompt recognition and aggressive management.[1] Cardiac failure can be acute or more subtle in character, even as a chronic disease process. Heart failure can involve the right heart or left heart, or it can be biventricular in character, and it can occur during diastole or systole. Diastolic left ventricular (LV) failure can be very difficult to recognize and diagnose. The degree of valvular dysfunction associated with cardiac failure can vary even in an individual patient, depending on the status of ventricular function and the intravascular volume of the patient.[2]

CASE STUDY: PART 1

The patient was a 52-year-old man who was admitted to the coronary care unit after presenting in the emergency room with crushing substernal chest pain accompanied by pulmonary edema. This 52-year-old African-American man had a history of hypertension and coronary artery disease (CAD) and had several acute myocardial infarctions in the preceding decade. He also had a history of tobacco abuse and hypercholesterolemia. During the past 2 years, he had three admissions to the hospital for acute pulmonary edema and angina. He presented to the emergency room with crushing substernal chest pain accompanied by pulmonary edema, and he required intubation and mechanical ventilatory support with intra-aortic balloon counterpulsation. His wife stated that he awoke at 2:00 AM. that morning with complaints of chest pain and severe shortness of breath.

His family history was significant for CAD: myocardial infarction in his father at age 55 and in two brothers in their sixth decade. His current medications included a beta-blocker for hypertension and an HMG-CoA reductase inhibitor for cholesterol control. He was intermittently compliant with both medications.

His physical findings were as follows:

- Age: 52 years
- Sex: male
- Race: African-American
- Height: 5 ft, 10 in.
- Weight: 225 lb
- BP: 100/70 mmHg
- Pulse: 120 bpm
- Funduscopy: diffuse arteriolar narrowing
- Lungs: clear to auscultation and percussion
- Cardiac exam: tachycardia with an S4 and the sounds of an intra-aortic balloon counterpulsation; jugular venous distension (JVD) to 12 cm; diminished pulses in the lower extremities
- Edema: Trace pitting edema

More than four million people in the United States have CHF, and about 400,000 new cases are diagnosed each year. Heart failure is responsible for nearly one million hospitalizations annually. For each decade after the age of 45, the incidence of heart failure more than doubles. The prevalence of heart failure is similar for males and females. Males before the age of 64 years have the highest prevalence, but after 65 years of age the difference between males and females is insignificant.

Patients with hypertension and a prior history of myocardial infarction have the highest incidence of CHF. It has been postulated that the steady increase in the number of patients with heart failure is directly linked to the decreasing mortality rates of CAD, myocardial infarction, and stroke. With improved management of these underlying problems, patients are surviving long enough to develop CHF.

The number of deaths from CHF has increased fourfold over the past 20 years.[2] As for most diseases, the mortality rate increases with age and is higher in men than in women. Racially, it is higher at all ages in African-Americans than Caucasians. Hispanics and Asians appear to have a lower incidence of heart failure. Sudden death occurs in nearly 40% of patients with chronic heart failure.

Prognostically, patients with CHF are in a difficult situation. Half will die within 5 years of diagnosis, and for patients with advanced heart failure, the 1-year survival is approximately 30%.[1] On the brighter side, there has been an improvement in death rates during the first year after diagnosis, with a decrease from approximately 50–10% for some categories. Mortality quickly increases when the LV ejection fraction (EF) declines below 20%; this is usually found in patients who have poor functional performance. A functional class assessment by the New York Heart Association (NYHA) criteria of class IV is known to have a mortality of 50% at 1 year. A simple and prognostically relevant exercise test, the 6-min walk test, has been used to predict poor survival. Patients with heart failure who are allowed to walk at a self-pace for 6 min and who cannot travel more than 300 m have been shown to have a poor prognosis. Finally, certain hemodynamic abnormalities have been associated with a poor prognosis in patients with heart failure. A cardiac index of less than 2.25 L/min/m^2, a pulmonary arterial occlusion pressure of greater than 25 mmHg, and a right atrial (RA) pressure greater than 10 mmHg are all indicators of poor survival.

Definitions

Heart failure can be acute or chronic in character. In fact, acute heart failure can occur in individuals with chronic heart failure. The heart failure could be biventricular in nature or

CHF rates are increasing as the US population ages.

- Sudden death occurs in ~40% of chronic CHF patients.
- NYHA function class IV has a 1-year mortality ≥50%.
- CHF is mainly systolic in nature but can be a manifestation of diastolic disease.
- Most patients with CHF in the United States are elderly with ischemic disease.
- Determining the cause of CHF is crucial to identifying potentially reversible causes.
- Metabolic and endocrinologic abnormalities must be excluded for a diagnosis of idiopathic CM.

could involve mainly the left or right heart. Generally, cardiac failure is systolic in character, but in certain individuals, diastolic heart failure is the predominant feature.

In approximately 40% of patients with newly diagnosed heart failure, systolic function is normal.[3] The problem in these patients is a decrease in LV distensibility, a condition referred to as diastolic dysfunction (DD) or heart failure. DD refers to the inability of the left ventricle to accept blood at a low ventricular pressure, with an associated delay in chamber filling. In a compensatory fashion, left atrial pressure increases, and this condition can lead to pulmonary congestion and, with more progressive disease, even systemic congestion. Systemic congestion can actually occur in the absence of an abnormality in systolic function of the left ventricle. There are numerous etiologies responsible for DD (Table 18-1) but the common causes include ventricular hypertrophy, myocardial ischemia, pericardial disease, and positive-pressure mechanical ventilation. Most patients are elderly with ischemic heart disease and recurrent pulmonary edema despite normal LV systolic function. These patients generally have a long-standing history of systemic hypertension. Finally, patients with renal insufficiency and mitral regurgitation are even more likely to develop pulmonary edema when they have DD.

Etiologies

At present, the major causes of heart failure in the United States include ischemic heart disease, idiopathic or viral cardiomyopathy, and hypertensive heart disease. Many other disease processes can have an impact on the heart and cause cardiomyopathy. Regardless of the cause, the three major mechanisms for systolic dysfunction are loss of viable ventricular muscle, a primary abnormality of cardiac muscle, or a serious mechanical abnormality of the muscle, valves, or path of blood flow through the heart (Table 18-2). Determining the cause of heart failure in each patient is crucial to identifying potentially reversible causes, such as

TABLE 18-1

ETIOLOGIES OF DIASTOLIC DYSFUNCTION (DD)

Abnormal relaxation
Ischemia
Ventricular hypertrophy from hypertension
Increased stiffness
Infiltrative disorders such as amyloidosis
Extrinsic compression

Acquired cardiomyopathies (i.e., postpartum, obesity)
Primary abnormality of cardiac muscle
Infiltrative disorders
Glycogen storage disorders
Muscular dystrophies
Metabolic damage
Neoplastic disorders
Fibroelastic disorders
Genetic disorders (i.e., hypertrophic cardiomyopathies, hereditary dilated)
Mechanical abnormalities
Valvular
Congenital malformations

CASE STUDY: PART 2

The laboratory results were as follows.

- Chest X-ray: intra-aortic balloon pump (IABP) in the appropriate position.
- Mild cephalization and an enlarged cardiac silhouette with a large left pleural effusion. The left atrium (directly under the bifurcation of the carina) was enlarged, as was the right ventricle.
- Echocardiogram: severe LV dysfunction with an EF of 10–15%; anterior, apical, and septal dyskinesia with an aneurysm. Normal right ventricular (RV) function with mild mitral regurgitation, no aortic regurgitation, and an enlarged LV diastolic dimension. No pericardial effusion.
- Electrocardiogram: sinus tachycardia with a complete left bundle branch block and left axis deviation.
- Cardiac catheterization: normal main left coronary artery; 100% proximal occlusion of the left anterior descending coronary artery with right to left collaterals. Significant occlusions of the right and left circumflex coronary arteries, and extremely poor distal targets, which were considered to be unsuitable for surgical or noninterventional treatment. Right heart hemodynamics were as follows: RA pressure, 14 mmHg; pulmonary artery (PA) pressure, 52/29 mmHg (mean, 37 mmHg); pulmonary capillary wedge pressure (PCWP), 28 mmHg; cardiac index, 1.90 L/min/m^2; and systemic vascular resistance (SVR), 1,550 dynes/s/cm^5.

The impression is that of a 52-year-old man with multiple coronary risk factors and a prior history of myocardial infarctions. The patient presented with acute angina and pulmonary edema. He has developed a severe dilated cardiomyopathy from an ischemic origin. He continues to have myocardial infarctions as a result of poor coronary artery perfusion. He has nonrevascularized lesions and is in acute cardiogenic shock. His renal insufficiency is most likely caused by long-standing hypertension and a low cardiac index, which has led to diminution of the glomerular filtration rate. He may also have renal arteriopathy because of multiple areas of vascular disease, as noted in the decrease of his peripheral pulses when the intra-aortic balloon pump (IABP) was placed. The signs and symptoms of CHF in this patient indicate that acute ischemia has exacerbated an underlying ischemic cardiomyopathy.

correcting a valvular abnormality surgically or aggressively treating systemic hypertension. Although some patients may have relentless disease progression with no precipitating cause, many others have a definite triggering event. Before patients can be labeled as having idiopathic cardiomyopathy or nonischemic cardiomyopathy, they must be evaluated for subtle endocrine abnormalities, a variety of metabolic diseases, and certain connective tissue disorders.

Potentially reversible causes of cardiomyopathy include alcohol-induced disease, viral infection, noninfectious myocarditis, nutritional deficiencies such as thiamine deficiency or beriberi, and ischemic heart disease.

Chronic heart failure can take an acute course due to a variety of influences. Dietary indiscretion, especially sodium and alcohol intake, and inappropriate changes in medical therapy are the most common reasons for stable patients to decompensate suddenly. Other precipitating causes include new arrhythmias, specifically atrial fibrillation, metabolic abnormalities such as ketoacidosis, electrolyte imbalance, uremia, and pulmonary embolism.

Only an occasional patient has lung crackles.

Cheyne–Stokes respiration has been associated with a low cardiac output states.

The earliest sign of ventricular dysfunction is dyspnea on exertion.

With decompensated CHF, peripheral vasoconstriction occurs.

Cardiac filling pressures do not distinguish systolic vs. diastolic pressure.

DIAGNOSIS

Patients with systolic heart failure show persistence of various signs and symptoms. When these signs and symptoms occur despite maximum medical therapy, we call this form of heart failure refractory. Dyspnea that occurs during or following moderate exertion results from the development of anaerobic metabolism and its consequent metabolic factors such as lactic acidosis, which activates respiratory drive to eliminate carbon dioxide as a buffering effect. In contrast, the dyspnea that occurs at rest in patients with refractory heart failure results from elevated atrial and intrapulmonary vascular pressure.

Orthopnea, often accompanied by anorexia and gastrointestinal distress, is related to systemic venous congestion. Systemic venous congestion can be suspected if JVD is noted. Peripheral edema is present in only a minority of patients with heart failure. Only an occasional patient has lung crackles on physical examination of the chest. Patients with anorexia and early satiety often have abdominal discomfort and evidence of liver engorgement on

Lactic acidosis can activate the respiratory drive.

Dyspnea at rest is caused by elevations in atrial and intrapulmonary vascular pressure.

palpation. Tenderness on palpation of the right upper quadrant of the abdomen, but not hepatomegaly, is often found on examination.

In the presence of a sinus heart rhythm, the proportional blood pressure measurement is an important physical finding in patients with advanced heart failure. An arterial pulse pressure of less than 25% of the systolic pressure has been shown to be an indicator of a severely reduced cardiac index, generally less than 2 L/min/m^2. Finally, patients with severe LV dysfunction can experience disrupted sleep because of either sleep apnea or periodic breathing. Periodic breathing during sleep, or Cheyne–Stokes respiration, has been associated with a low cardiac output state.

The earliest sign of ventricular dysfunction is dyspnea at rest and during exertion. As already mentioned, an elevated jugular venous pressure and hepatojugular reflux or a positive abdominojugular test is associated with an increase in PCWP. At this stage, the stroke volume (SV) of the heart is maintained because the left ventricle is still preload responsive. The next stage is a substantial decrease in left ventricular stroke volume with an increase in heart rate. Tachycardia helps compensate for the reduction in SV, so that the cardiac output remains unchanged. At this stage, the dyspnea, especially during exertion, worsens, but there is still no evidence of peripheral edema. The final stage of heart failure is characterized by a decrease in cardiac output, marking the transition from compensated to decompensated heart failure. With decompensation, peripheral vasoconstriction occurs, which eventually causes further reduction in cardiac output and peripheral blood flow (Fig. 18-1).

Routine hemodynamic measurements cannot distinguish diastolic from systolic heart failure. The decrease in SV occurs in both systolic and diastolic failure. In systolic failure, the end-diastolic LV volume is elevated at a high diastolic pressure whereas in diastolic failure, the end-diastolic volume (EDV) at a comparable end-diastolic pressure is much lower. Therefore, monitoring cardiac filling pressures as an index of ventricular preload does not allow a distinction between systolic and diastolic heart failure.

The EDV is the best measure for identifying systolic and diastolic heart failure. EDV can be derived by the relationship between SV and the EF: EDV = SV/EF. The EF of the left ventricle can be measured noninvasively by radionuclide or echocardiographic techniques. The SV can be determined by right heart catheterization.

Right heart failure is prevalent in the intensive care unit, especially in patients who are ventilator dependent. The relationship between central venous pressure (CVP) and PCWP can be useful in identifying patients with right heart failure. In patients with a CVP that is greater than 15 mmHg and a CVP that equals PCWP or a CVP greater than PCWP, right heart failure should be considered. However, about one-third of patients with acute right heart failure do not satisfy these criteria because of the insensitivity of CVP. An increase in CVP is seen only in the later stages of right heart failure.

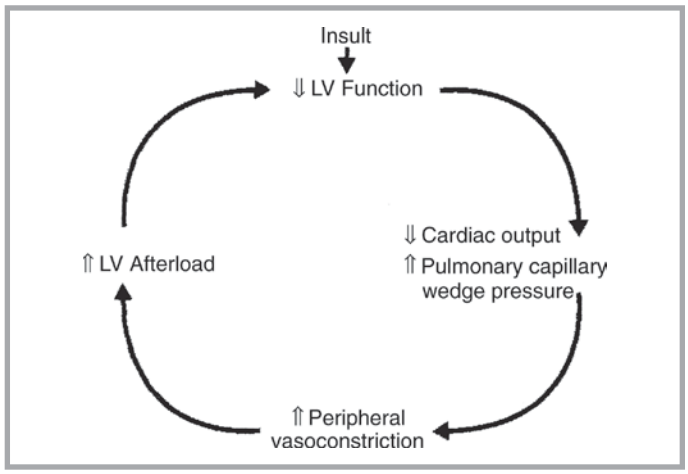

FIGURE 18-1

Pathophysiology of congestive heart failure (CHF). *LV* left ventricular.

TABLE 18-3

NEW YORK HEART ASSOCIATION (NYHA) FUNCTIONAL CLASSIFICATION OF HEART FAILURE

Class I	No limitations. Activities of daily living do not cause undue fatigue, malaise, dyspnea, or symptomatic palpitations
Class II	Mild limitations. Ordinary physical activity causes profound fatigue, dyspnea, and/or anginal symptoms. The patient is generally asymptomatic at rest
Class III	Severe limitations. Minimal activity causes significant symptoms; however, at rest, the patient is usually relatively asymptomatic
Class IV	Any physical activity will cause severe symptoms and discomfort. Symptoms of CHF are present even at rest

SOURCE: data from the Criteria Committee, New York Heart Association, Inc.[24]

Another problem with measuring cardiac filling pressures to identify right heart failure is the interaction between the right and left sides of the heart, so-called ventricular interdependence. Because the ventricles share the same septum, an enlargement of the right ventricle pushes the septum toward the left side, compromising LV chamber size and influencing pressure and function. This relationship can confuse the interpretation of ventricular filling pressures to the point that hemodynamic changes in right heart failure appear as pericardial tamponade. Finally, echocardiography can be useful at the bedside for determining right from left heart failure. Typically, right heart failure is associated with an increase in RV chamber size and paradoxical motion of the interventricular septum. These findings must be interpreted according to the clinical situation.

If the CVP≥PCWP, then right heart failure should be considered.

Heart failure can take months to years to develop. Patients commonly present with symptoms of exercise intolerance and dyspnea. Heart failure can also occur in asymptomatic patients with LV dysfunction. Identification of these patients with no or minimal symptoms, with the aim of preventing the development of overt heart failure, is an important diagnostic and therapeutic challenge. Currently, functional classification of heart failure is based on the NYHA classification system (Table 18-3). NYHA I patients have no symptoms, but their physiology is consistent with LV or RV dysfunction, whereas NYHA IV patients have serious symptoms at rest.

Echocardiography at the bedside can be useful to assess RV and LV function.

Identification of asymptomatic LV dysfunction is a diagnostic and therapeutic challenge.

PATHOPHYSIOLOGY

CHF is characterized as systolic, diastolic, or biventricular.

Heart failure is a clinical syndrome that results from the complex interaction between an initial myocardial insult and reactive, compensatory processes. During the natural course of heart failure development, patients progress from a clinically silent state in which the heart muscle undergoes changes in cellular function to preserve cardiac output and to normalize ventricular wall stress (e.g., by hypertrophy) to overt symptoms resulting from ventricular decompensation. Clinically, heart failure is classified as systolic or diastolic or both and can occur in the left or right ventricle or be biventricular. This definition can be extended to include chronic or acute decompensation. Understanding the pathophysiology of heart failure is vital to the management of this disease. Ventricular hypertrophy and remodeling occur in response to pressure-overloaded conditions, volume-overloaded conditions, or tissue injury and infarction. The role of the hypertrophic process is to preserve SV and cardiac output. Pressure-overloaded conditions stimulate cardiac hypertrophy. In this type, there is lateral expansion of the myocytes through addition of myofibril units in parallel. In contrast, volume-overloaded conditions stimulate ventricular cavity enlargement without a change in wall thickness. This enlargement occurs through replication of sarcomeres in series. Myocardial infarction leads to ventricular dilation because the infarcted segment expands or stretches. The dilation involves loss of myocytes and disruption of the normal architecture of the ventricular wall. Within the surviving myocytes, abnormal stretching increases tension in each cell and promotes hypertrophy. The dilation of the infarcted segment increases pressure on the noninfarcted myocardium and stimulates hypertrophy.

Hypertrophy and remodeling are ventricular responses to pressure overload conditions.

Volume overload stimulates LV cavity dilatation.

Chronic systolic dysfunction is the most common type of CHF.

Wall geometry and cavity size change as the ventricle decompensates.

Loss of ventricular compliance impairs relaxation.

A characteristic hemodynamic disturbance in DD is higher ventricular filling pressures at the same volume.

Pressure overload causes LV hypertrophy.

Fibrous tissue impairs myocyte contraction.

Loss of contractility occurs as a result of an insult in diastolic CHF.

CAD is the most common cause of systolic CHF.

Chronic systolic or low-output heart failure is the most common type of heart failure. Systolic failure is the condition that results when the weakened, dilated heart is unable to eject an adequate SV. The syndrome of systolic heart failure begins with a period of adaptive cardiac myocyte remodeling that involves changes in both wall geometry and cavity size. Left untreated, the systolic dysfunction will continue until compensatory mechanisms can no longer sustain circulatory function. The volume-overloaded ventricle will eventually decompensate. Contractility continues to decline, and ventricular filling pressure rises. The resulting greater oxygen demand on surviving cells promotes further cell loss. This continuous loss of cells disrupts the normal architecture of the ventricular wall, and the shape of the ventricle changes from elliptic to globular; hence, cardiomegaly develops, which is characteristic of end-stage CHF.

Diastolic heart failure results when the heart cannot fill effectively during diastole. It is most common when there is a loss of ventricular compliance that impairs relaxation, as can occur with LV hypertrophy, CAD, and normal aging. The characteristic hemodynamic disturbance in DD is higher ventricular filling pressures at the same volume. With this pathology, symptoms of pulmonary venous congestion develop in the absence of systolic dysfunction. If a hemodynamic evaluation, perhaps by echocardiography, shows that systolic function of the left ventricle is preserved and there is a reduced degree of diastolic filling, then therapy should be directed at improving diastolic ventricular function.

Three mechanisms are involved in the pathophysiology of diastolic heart failure (Table 18-4). These mechanisms often operate concomitantly, and all of them elevate the pressure–volume relationship of ventricular filling, in other words, decrease ventricular compliance. The first mechanism is impaired, slowed, or incomplete ventricular wall relaxation. During early diastolic filling, left atrial pressure can exceed LV pressure and pulmonary congestion symptoms can develop. Another mechanism increases the stiffness of the ventricle during both early and late diastole as a result of increased LV thickness and decreased internal chamber dimensions; it can be caused by an infiltrative disease process such as amyloidosis or by wall hypertrophy, which is seen in chronic, poorly controlled systemic hypertension. The final mechanism, high concentrations of ventricular wall collagen, generally occurs in conjunction with myocardial infarction where excess collagen is deposited in the injured segment; this change can affect each myocardial unit, causing increased stiffness, and can affect diastolic pressure as a whole. The LV hypertrophy associated with diastolic failure results from pressure overload, which stimulates concentric hypertrophy. As myocytes expand through addition of myofibril units in parallel, fibrous tissue is laid down to maintain structural integrity. In most cases, myocytes in a concentrically hypertrophied human heart contract normally, whereas the laying down of fibrous tissue impairs contractile efficacy. Active fibrosis isolates the individual muscle cells, destroying the ventricular structure and leading to diastolic stiffness. Hence, the loss of contractility that is considered the hallmark of heart failure is not the instigating mechanism in diastolic failure but rather the consequence of the initial insult.

CAD is the most common cause of systolic heart failure, but it is frequently associated with DD as well. Diastolic function deteriorates with normal aging. Both loss of myocytes and increased fibrosis have been described. Apoptosis or programmed cell death may be one factor contributing to the loss of myocytes, or hypertrophy itself may accelerate the cellular death process. Aging is also associated with collagen remodeling following myocyte necrosis. Some of this remodeling consists of fibrosis that replaces lost myocardium, but the predominant change occurs in the interstitium, where deposition of collagen occurs around myocytes, isolating individual muscle cells.

TABLE 18-4

PATHOPHYSIOLOGY OF DD

Impaired ventricular wall relaxation
Increased ventricular stiffness
Increased collagen deposition in the ventricular walls

The depression of contractile function that occurs in heart failure and is associated with myocardial remodeling is the result of certain changes in biochemical and molecular function and gene expression. Myocardial remodeling includes both structural and functional reorganization of cardiac cells. Various mechanisms appear to be involved in the development of hampered contractility, including alterations in the excitation–contraction coupling process, neurohumoral changes, and various actions of certain growth factors. Disruption in the mechanisms for handling calcium ion distribution within cardiac cells has been found in patients with heart failure.

Myocardial remodeling includes both structural and functional reorganization of cardiac cells.

A number of neurohumoral alterations are present in heart failure. Even before patients become symptomatic, there is a reflex increase in neurohumoral activity in response to the decreased cardiac output. Initially, activation of the sympathetic nervous system results in an increase in heart rate and myocardial contractility, which leads to enhanced cardiac output. Also, there is an increase in sympathetic vascular tone that maintains peripheral vascular resistance and perfusion pressure gradients to systemic organ beds. However, this intensified cardiac functioning places an increased demand for myocardial oxygen on the already weakened myocardial cells.

In heart failure, there is an increase in sympathetic vascular tone that maintains peripheral vascular resistance and perfusion pressure gradients to systemic organ beds.

As heart failure progresses, the heart is exposed to increasing levels of catecholamines that are toxic to the failing organ. Catecholamines have been shown to stimulate protein synthesis and enhance collagen deposition and myocardial fibrosis, leading to ventricular hypertrophy and remodeling. High doses of norepinephrine also can cause myocarditis, myocardial necrosis, and cardiomyopathy, and selective downward regulation of beta-1 receptor density occurs in response to this high adrenergic drive. The decrease of beta-1 receptors appears to be proportionate to the amount of ventricular dysfunction. Plasma levels of norepinephrine have prognostic importance. Elevated plasma norepinephrine is an important predictor of mortality in heart failure patients. Catecholamines, especially in the presence of myocardial ischemia, cause serious arrhythmias, a frequent mode of sudden death in heart failure patients. Also, norepinephrine increases arterial vasoconstriction, thus enhancing afterload on the failing left ventricle.

As heart failure progresses, the heart is exposed to increasing catecholamines that are toxic to the failing organ.

Plasma levels of norepinephrine have prognostic importance.

The renin-angiotensin-aldosterone system is activated in heart failure. The immediate response to a decrease in heart function and a reduction in blood pressure is a decrease in stretch stimulation of baroreceptors in the carotid and aortic sinuses. This change reduces the number of nerve impulses sent to regulatory centers in the CNS, resulting in a reflex increase in sympathetic outflow and a decrease in vagal stimulation to the heart and vasculature. The cumulative effect is to return blood pressure toward its previous level through increased heart rate and contractility and vasoconstriction of arterials. Underlying these rapid events is a slowly developing series of neurohumoral alterations that are also promoted by the decrease in cardiac output and blood pressure. These alterations include increases in plasma renin activity, promoting sodium and water retention, and increases in arginine, vasopressin, aldosterone, and endothelin, which induce vasoconstriction. Because the responsiveness to atrial natruretic peptide is blunted, peripheral dilation, diuresis, and natruresis are attenuated, and a vasoconstrictive and volume-overloaded environment ensures.

The renin-angiotensin-aldosterone system is activated in heart failure.

The abnormal neurohumoral cascade includes increases in plasma renin activity, promoting sodium and water retention and increases in arginine vasopressin, aldosterone, and endothelin, which induce vasoconstriction.

The systemic reflexes of vasoconstriction, fluid retention, and increase in heart rate generally maintain blood pressure at the expense of cardiac output. Accordingly, most patients with chronic heart failure are not hypotensive. However, the impaired heart must continue to work under excessive loading conditions. Continuous ejection of blood into this vasoconstricted vascular system, coupled with compensatory excess fluid volume in the circulatory system, increases myocardial oxygen consumption, contributes to myocardial ischemia, and produces an unstable cardiac cellular environment that increases the likelihood of lethal arrhythmias. All these factors act together to accelerate the deterioration of overloaded myocardial cells.

Systemic reflexes generally maintain blood pressure at the expense of cardiac output.

Increased myocardial oxygen consumption is ongoing in heart failure.

The decrease in contractility characteristic of heart failure can be viewed as a series of adaptive and maladaptive processes in response to an initiating pathologic event. After an initial insult from any number of causes, the heart adapts to various metabolic and structural changes. These changes, which result from a series of biochemical, biophysical, and molecular events that are set into motion by myocardial injury, can continue for months to years and keep the patient nearly symptom free.

The decrease in contractility characteristic of heart failure can be viewed as a series of adaptive and maladaptive processes in response to an initiating pathologic event.

CASE STUDY: PART 3

Treatment and follow-up. The patient was continued on his intra-aortic balloon counterpulsation and was started on intravenous nitroglycerin. He was also given an intravenous pressor (dobutamine) to increase his cardiac output. Intravenous dobutamine and intravenous nitroglycerin allowed weaning the patient from his intra-aortic balloon counterpulsation. He was given oral angiotensin-converting enzyme (ACE) inhibitors, digoxin, and diuretics, which were used to wean him from his intravenous pressor support. His right heart hemodynamics improved significantly with this medical regimen.

The rationale for the choice for intravenous dobutamine was to improve the patient's hemodynamics by increasing his cardiac index with a positive inotropic agent. The oral ACE inhibitors, digoxin, and diuretics were used to decrease his peripheral resistance and also increase his cardiac index. Once the burden of the acute ischemic event was overcome, the patient's CHF symptoms were stabilized with oral medication.

The patient was successfully weaned from the intravenous dobutamine and stabilized on his oral regimen. Because his CAD was considered to be inoperable, he was placed on a rigorous outpatient heart failure therapy program with close monitoring. He and his family had received intensive education regarding the signs, symptoms, and treatment of CHF while he was in the hospital. He was also strongly urged to cease alcohol and tobacco abuse and was given a plan for doing so. This patient would be considered for possible intervention with an orthotopic heart transplant in the future if necessary.

PHARMACOLOGIC MANAGEMENT STRATEGIES

Systolic Left Ventricular Failure

Managing heart failure should involve the maintenance of cardiac output with a secondary goal of decreasing venous capillary pressure and edema formation.

The optimal PCWP is the pressure that augments cardiac output without inducing clinically relevant pulmonary edema.

Managing heart failure should involve the maintenance of cardiac output with a secondary goal of decreasing venous capillary pressure and edema formation. Left heart failure can be either systolic or diastolic in nature. The approach to LV systolic failure generally focuses on optimizing PCWP and then on systemic arterial pressure. The correction of an inadequate filling pressure is imperative in the management of systolic LV heart failure. The optimal PCWP is the pressure that augments cardiac output without inducing clinically relevant pulmonary edema. This pressure can be best demonstrated by reviewing ventricular function curves for the normal and failing left ventricle. As PCWP increases, cardiac index increases, but there is a balance between intravascular volume or LV filling pressure and the formation of lung edema. The optimal PCWP or ventricular filling pressure must be determined on an individual basis. When the colloid osmotic pressure (COP) of the blood is normal (20–25 mmHg), the optimal PCWP ranges between 18 and 20 mmHg. If the COP is lower, then the optimal PCWP is lower. Higher pressures, in a low COP state, will induce pulmonary edema.

Once the optimal PCWP is determined, attention must be directed to optimizing systemic arterial blood pressure. Vasoconstrictor medications may be needed to optimize arterial blood pressure. Certain medications, such as dopamine, may be necessary to improve a low systemic arterial blood pressure; other medications, such as nitroprusside or nitroglycerin, may be necessary to reduce a high systemic arterial pressure. Medication such as dobutamine is used to enhance inotropic function of the myocardium and to increase cardiac output without significantly altering systemic arterial vascular resistance.[4] Medication such as milrinone is used to increase cardiac output and lower afterload.[5] All these medications are used to optimize cardiac index.

If a high LV filling pressure or PCWP cannot be safely reduced with diuretic therapy, therapies such as dobutamine and milrinone can be used if the cardiac output is low. Nitroglycerin or nitroprusside can be used if the cardiac output is normal. The use of a diuretic alone, such as furosemide, often causes a decrease in cardiac output in patients who have high LV filling pressures or PCWP with a normal cardiac output, which again emphasizes the importance of intravascular volume as a partial determinant of cardiac output.

The optimal treatment for diastolic heart failure remains unknown. In diastolic heart failure, the systolic function of the left heart is normal and is unresponsive to changes in afterload. Therefore, diuretic therapy should be avoided. Medications that relax myocardial tissue are likely to be most helpful; these are called lusitropic agents. Medications such as calcium channel blockers and ACE inhibitors and receptor blockers may have lusitropic actions.

DD can be related to abnormalities of ventricular muscle relaxation or abnormalities of a relaxed ventricle. Hypertrophic states caused by aortic stenosis, systemic hypertension, and hypertrophic cardiomyopathy; ischemic states caused by unstable angina and myocardial infarction; and cardiomyopathic states caused by diabetes mellitus are all associated with abnormalities of dynamic relaxation. Abnormalities of a relaxed ventricle include atrial fibrillation with a decreased ventricular filling time, mitral stenosis with a reduced ventricular filling capacity, and increased myocardial stiffness caused by infiltrative diseases such as amyloidosis or endomyocardial fibrosis. Also, one must consider in the differential diagnosis a variety of extrinsic abnormalities relating to pericardial constriction and tamponade and the interventricular interaction of an overloaded right ventricle or RV infarction. Compared to systolic heart failure, diastolic heart failure appears to be less morbid.

The optimal treatment for DD is unknown.

There are no large clinical trials to help us understand how to treat DD. Lowering the systemic arterial blood pressure by treating essential hypertension, including systolic hypertension, lowers LV filling pressures and helps reduce dyspnea. Maintaining a sinus heart rhythm at a low rate is important. When patients with DD develop rapid atrial fibrillation, especially in the presence of mitral regurgitation, they experience a major increase of symptoms and sometimes cardiovascular collapse and pulmonary edema. Diuretic therapy is often required. Finally, ACE inhibitors, angiotensin I receptor blockers, beta-blockers, nitrates, and calcium channel blockers have all been used with some success.

Lusitropic agents are most likely to be useful in DD.

TREATMENT OF SYSTOLIC HEART FAILURE

Preload and Afterload Reduction

Patients with chronic heart failure often achieve their best cardiac output when their LV filling pressures are close to normal. Lower filling pressures are likely to improve subendocardial perfusion and reduce ventricular wall stress. Actually, lower LV filling pressures may occur without a significant change in LV volume, suggesting that there was a beneficial influence on RV distension and RA distension and a consequent decrease in coronary sinus pressures, resulting in improved myocardial venous drainage and LV compliance. Even more so, a higher SV from the left ventricle might occur because of a forward redistribution of regurgitant flow. The redistribution of regurgitant flow occurs in the right and left ventricle by reducing mitral and tricuspid regurgitant SVs. Pulmonary arterial wedge pressures less than 16 mmHg have been associated with a significantly lower 1-year mortality in patients with advanced systolic heart failure.

Pulmonary arterial wedge pressures less than 16 mmHg have been associated with a significantly lower 1-year mortality in patients with advanced systolic heart failure.

Preload reduction is likely indicated in patients with dilated cardiomyopathy, provided they have reasonable renal function. Diuretics are commonly used to reduce preload. Diuretics reduce circulatory volume, thereby decreasing EDV and myocardial oxygen consumption, which reduces ventricular wall tension.

Afterload reduction is indicated for nearly every patient with heart failure. Angiotensin-converting enzyme inhibitors (ACE inhibitors) are the primary class of medications prescribed to reduce afterload.[6] ACE inhibitors vasodilate and reduce circulatory fluid volume.[7] The resulting decrease in SVR allows better ventricular emptying, which, along with the decrease in circulatory fluid volume, shifts the pressure–volume curve to the left (Fig. 18-2). Other medications can reduce SVR and thereby decrease LV afterload.

ACE inhibitors are the drugs of choice in CHF.

ACE inhibitors vasodilate and reduce circulatory fluid volume.

The improvement in cardiac performance produced by inotropic therapy allows end-systolic pressure and volume to decrease.

Inotropic Therapy

Inotropic therapy can benefit patients with heart failure. Digoxin, a historically important medication, increases myocardial contractility without significantly increasing myocardial oxygen consumption.[8] The resulting augmentation of SV stimulates the arterial baroreceptors, which, in turn, decreases sympathetic outflow to the peripheral vasculature. The improvement in cardiac performance produced by inotropic therapy allows end-systolic pressure and volume to decrease, thus shifting the pressure–volume curve to the left. End-stage heart

End-stage heart failure often requires the use of more potent inotropic agents to support the failing heart.

Interrupt the conditions that contribute to myocardial deterioration when treating heart failure.

Combination therapy increases the EF, reduces LV end-diastolic diameter, and contributes to an improved cardiac performance.

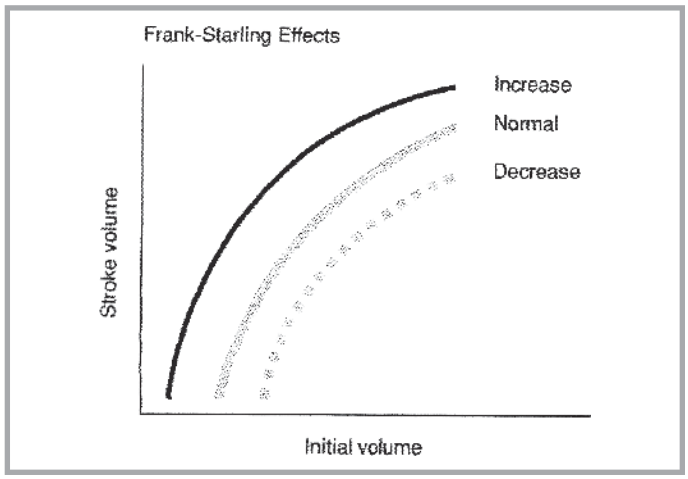

FIGURE 18-2

Starling curves show ventricular end-diastolic volume (EDV) plotted on the *x*-axis and stroke volume (SV) (ventricular performance) plotted on the *y*-axis. *Increase* means an increased contractile state; *decrease* means a decreased contractile state. The *normal curve* is shown for comparison.

failure often requires the use of more potent inotropic agents to support the failing heart. Beta-adrenergic agonists such as dobutamine and phosphodiesterase inhibitors such as milrinone should be considered.

Combination Therapy

The cocktail of therapies is often led by the ACE inhibitors in combination with digoxin and a diuretic.

All therapies would fail if they were not supported by important dietary restrictions and exercise regimens.

The ideal management strategy for patients with heart failure, particularly when it has progressed beyond the compensatory stage, is to interrupt the conditions that contribute to myocardial deterioration. An elevated preload, an elevated afterload, and a reduced contractility must all be addressed. Diuretics, ACE inhibitors, and digoxin are often used in combination to gain a synergistic benefit of the combined individual actions, namely, volume reduction, decreased peripheral resistance, and increased myocardial contractility. The pressure–volume curve often shifts substantially to the left. Combination therapy increases the EF, reduces LV end-diastolic diameter, and contributes to a substantially improved cardiac performance and reduced myocardial oxygen consumption.

PHARMACOLOGY OF HEART FAILURE

The pharmacology of heart failure consists of a myriad of treatments, often administered concurrently. The cocktail of therapies is often led by the ACE inhibitors in combination with digoxin and a diuretic. More recently, beta-blockers have been added to this therapy. When treating heart failure, multiple issues must be addressed to maintain patient stability. All these therapies would fail if they were not supported by important dietary restrictions and exercise regimens. The multidisciplinary approach coupled with close follow-up care is essential to assuring a reasonable quality of life for the patient with heart failure.

Diuretics

Diuretics, considered a mainstay of therapy for heart failure, are used to decrease hypervolemia, which helps reduce body edema, including pulmonary congestion.[9] Many diuretics could be considered, and they vary according to their site of pharmacologic activity, effects on fluid and electrolyte balance, and adverse reactions. The choice of the appropriate diuretic and its dosage requires careful consideration of individual patient factors. Loop diuretics decrease sodium reabsorption by interfering with the sodium chloride/potassium chloride cotransport system located on the apical membrane of the ascending limb (thick segment) of Henle's loop. Thiazides decrease sodium reabsorption by inhibiting the same

cotransport system located on the apical membrane of the early portion of the distal convolution. Potassium-sparing diuretics decrease sodium reabsorption in the late portion of the distal convolution and in the collecting tubule. Diuresis with diuretic therapy can cause renin release. Increased renin blood level stimulates the release of aldosterone, which in turn enhances sodium reabsorption. Therefore, diuretics when used in large doses may paradoxically contribute to the reaccumulation of fluid and actually exacerbate heart failure.

Common adverse effects from diuretics include hypotension, weakness, sexual dysfunction, and a variety of metabolic and electrolyte changes such as hypokalemia, hypomagnesemia, hypercalcemia, hyperglycemia, hypercholesterolemia, hypertriglyceridemia, and hyperuricemia. Tolerance can develop with the consistent use of certain diuretics. Tolerance to loop diuretics may be managed by more frequent dosing, continuous intravenous dosing, or coadministration of a thiazide diuretic coupled with more stringent dietary sodium restriction. Diuretic resistance arising from a decline in cardiac function should be managed by optimizing vasodilator therapy and ensuring patient compliance with the prescribed medical regimen.

Loop diuretics decrease sodium reabsorption by interfering with the sodium chloride/potassium chloride cotransport system located on the apical membrane of the ascending limb (thick segment) of Henle's loop.

Diuresis with diuretic therapy can cause renin release.

Tolerance can develop with the consistent use of certain diuretics.

Glycosides

The role of digoxin and other cardiac glycosides in heart failure remains a subject of ongoing debate and controversy.[10] Proponents believe that the use of digoxin and its mild positive inotropic effects help prevent worsening of CHF and improve the symptoms of this low cardiac index state. However, opponents maintain that exposure to the continuous positive inotropism of digoxin may actually hasten myocardial cell demise.

Digoxin is generally recommended for patients with more severe forms of heart failure who have a dilated left ventricle and a moderate to severely diminished EF. Studies have demonstrated that digoxin substantially reduces the risk of CHF exacerbation, but it does not improve exercise tolerance. The effect of digoxin on survival remains unclear.

The principal mechanisms of action of digoxin and other cardiac glycosides are not completely understood and are probably very complex. Involvement of cardiac muscle directly and of the cardiac autonomic nervous system indirectly results in a positive inotropic action, specifically an increase in the force in velocity of myocardial systolic contraction and a decrease in conduction velocity through the atrioventricular node. In the failing heart, digoxin increases cardiac output and decreases end-diastolic pressure. The magnitude of the positive inotropic effect depends on contraction frequency; the rate of onset is dependent on serum concentration of ions, particularly potassium, sodium, and magnesium.

The factors affecting digitalis pharmacokinetics include serum electrolyte abnormalities, drug interactions affecting gastrointestinal absorption, drug interactions with other cardiovascular agents, and thyroid disease, renal dysfunction, autonomic nervous system tone, and respiratory disease. Hypokalemia, hypomagnesemia, and hypercalcemia potentiate the effects of digoxin, thus producing digitalis toxicity.

Exposure to the continuous positive inotropism of digoxin may actually hasten myocardial cell demise.

The effect of digoxin on survival remains unclear.

Many factors affect digitalis pharmokinetics.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors have emerged as important agents in the treatment of heart failure.[6,7] Despite growing evidence from a variety of important clinical trials that they improve symptoms, increase exercise capacity, and improve survival, ACE inhibitors are underused in treating CHF. Furthermore, when ACE inhibitors are used, the dosages are often inadequate.

ACE inhibitors, when used in patients with CHF, increase cardiac index and SV and decrease systemic and pulmonary vascular resistance. Tachyphylaxis does not occur. Improved myocardial compliance with diminished or reversed LV hypertrophy and, most importantly, improved survival have been reported with the regular use of ACE inhibitor therapy. ACE inhibitors may slow the progression of disease, delaying the onset of overt heart failure in patients with asymptomatic LV dysfunction.

Pharmacodynamically, ACE inhibitors decrease the formation of angiotensin II with a resultant decrease in vasoconstriction and decrease in aldosterone secretion, leading to decreased sodium and water reabsorption, attenuation of sympathetic activity, and increased bradykinin levels. ACE inhibitors reduce arteriolar constriction, thus decreasing total

ACE inhibitors may slow the progression of heart failure.

ACE inhibitors decrease the formation of angiotensin II.

Bradykinin appears to participate in the beneficial effects of these ACE inhibitors by stimulating the production of cyclic guanosine monophosphate (cGMP), nitric oxide, and prostaglandins.

ACE inhibition reduces presynaptic release of norepinephrine.

Adverse effects associated with ACE inhibitors include hypotension, renal dysfunction, hyperkalemia, cough, and angioedema.

A persistent, dry cough occurs in as many as 20% of patients treated with ACE inhibitors.

Angiotensin II type 1 (ATI) receptor blockers can be used as substitutes or concomitantly with ACE I inhibitors.

peripheral resistance. Cardiac output and SV improve in patients with heart failure and PCWP, and left atrial and ventricular filling volumes both decrease. ACE inhibitors block the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor that also fosters the secretion of aldosterone from the adrenal cortex. Reduction in plasma levels of angiotensin II decreases blood pressure, reduces salt and water reabsorption in renal tubules, and increases plasma renin activity via a negative feedback.

ACE inhibitors reduce the local accumulation of bradykinin. Bradykinin appears to participate in some of the beneficial effects of these drugs by stimulating the production of cGMP, nitric oxide, and prostaglandins. ACE inhibitors attenuate the abnormally high levels of sympathetic nervous system activity found in CHF. This attenuation may result from improved hemodynamics as well as direct inhibition of angiotensin II-mediated control of peripheral nervous system activity. Angiotensin II can stimulate sympathetic activity. ACE inhibition reduces presynaptic release of norepinephrine. ACE inhibitors decrease the amount of circulating angiotensin II, which results in less angiotensin I receptor activation on vascular and smooth muscle membranes as well as sympathetic postganglionic terminals, which attenuates sympathetic activity.

ACE inhibitors increase circulating levels of bradykinin because kinase, which degrades bradykinin, is identical to the ACE. Bradykinin is a potent vasodilator, but the importance of bradykinin-related effects to the hemodynamics of ACE inhibitors remains unknown. However, bradykinin has been implicated in the genesis of cough and angioedema associated with the entire class of ACE inhibitors. Other significant adverse effects associated with ACE inhibitors include hypotension, renal dysfunction, and hyperkalemia. Patients at the greatest risk for renal dysfunction are those who are volume depleted or salt depleted, or both, from aggressive diuretic therapy and individuals with bilateral renal artery stenosis. Increases in serum potassium may occur from decreased aldosterone levels induced by ACE inhibitors. Finally, a persistent, dry cough occurs in as many as 20% of patients treated with ACE inhibitors. This cough can substantially affect quality of life. The cough does not respond to conventional antitussive preparations or antiasthmatic preparations, and the ACE inhibitor must be discontinued to eliminate the coughing.

There are now AT1 receptor antagonists.[11] The AT1 receptor blockade provides an alternative for heart failure patients who are intolerant of ACE inhibitors because of the adverse effects of angioedema or cough. Clinical trials assessing the efficacy and safety of these receptor antagonists in heart failure have shown improvement in symptoms and exercise capacity similar to that seen with ACE inhibitors.

Direct Vasodilators

Other direct vasodilators are an effective alternative therapy for patients who have heart failure and cannot tolerate ACE inhibitors. Hydralazine and isosorbide dinitrate, in combination, can be considered a definitive alternative therapeutic approach.[12] This combination therapy improves symptoms and the prognosis of chronic heart failure. Direct vasodilators can also be used as second-line therapy in combination with ACE inhibitors.

The rationale for the use of vasodilators in the therapy of heart failure is based on the concept that, in the context of a high-afterload state coupled with a high-preload state, peripheral arterial vasodilation improves cardiac output. As already mentioned, in some patients a decrease in preload volume may also improve cardiac output, depending on the position of the patient on the Frank–Starling curve of ventricular function. Direct vasodilators relax vascular smooth muscle and induce vasodilatation. Vasodilators may have a predominant effect on the arterial or venous circulation. An arterial vasodilator such as hydralazine can improve cardiac output with little change in end-diastolic LV pressure. Nitrates, used primarily as venous dilating agents, decrease preload with little change in systemic arterial resistance. Balance vasodilation, with equal action on vascular capacitance and resistance, can be a desirable effect in heart failure treatment. Often, the combination of a predominantly arterial vasodilator and a strong venodilating agent improves forward flow while decreasing filling pressure and improving congestive symptoms.

Problems with vasodilators, in general, derive from the induction of symptomatic arterial hypotension, especially in the setting of intravascular volume depletion. Patients who use

chronic vasodilator therapy should be assessed frequently and carefully for orthostatic changes in pulse and blood pressure as well as a deterioration in renal function.

Inotropic Support

A decrease in preload volume may also improve cardiac output.

Hydralazine can improve cardiac output with little change in end-diastolic LV pressure.

Nitrates decrease preload with little change in systemic arterial resistance.

Intravenous inotropic support can often temporarily improve ventricular performance and achieve clinical stabilization.

The two most commonly used parenteral inotropic agents are the sympathomimetic amine dobutamine and the phosphodiesterase inhibitor milrinone.

A major limitation in the use of dobutamine is a progressive loss of beta-1 receptor responsiveness.

Dobutamine has chronotropic effects that can induce arrhythmias.

Milrinone is more likely than dobutamine to cause hypotension.

Degradation of cAMP increases intracellular calcium concentrations and myocardial contractility.

Milrinone is a selective inhibitor of phosphodiesterase isoenzyme in the myocardium and vascular smooth muscle.

The principal use of intravenous inotropic support is for the patient with advanced heart failure, generally decompensated, with evidence of a reduction in systemic blood pressure and cardiac output that threatens vital end-organ perfusion.[4,5] These patients are generally either end-stage CHF patients or individuals with severe CHF that has been unresponsive to conventional therapy. Intravenous inotropic support can often temporarily improve ventricular performance and achieve clinical stabilization. The choice of a particular parenteral inotropic agent for an individual patient generally depends on the experience of the clinician and the target actions of the drug that has been selected.

The two most commonly used parenteral inotropic agents are the sympathomimetic amine dobuttamine and the phosphodiesterase inhibitor milrinone. Both beta-adrenergic stimulation and phosphodiesterase inhibition share a final common pathway in leading to an increase in intracellular cyclic AMP. Cyclic AMP increases the intracellular concentration of calcium via subsequent phosphorylation of several proteins. These actions enhance myocardial contractility and improve diastolic relaxation.

Treatment with intravenous inotropic agents is usually done in the hospital setting, either in the intensive care unit or a special cardiac unit where intravenous therapy can be used. The patients are carefully monitored and the medication is titrated, generally with a right heart catheter in place and a continuous electrocardiogram. Blood pressure monitoring is done on a frequent basis. Daily monitoring of urine output, serum electrolytes, and renal function is advisable.

Dobutamine is a synthetic catecholamine. It has a predominant beta-1 agonist effect and produces increased cardiac contractility and reduced aortic impedance, thereby augmenting SV and cardiac output while decreasing LV filling pressure. The reason why dobutamine enhances clinical improvement, including a reduction in symptoms and an increase in exercise performance, remains an enigma. An improvement in myocardial energetics may occur with a course of dobutamine therapy. A major limitation in the use of dobutamine is the potential for a progressive loss of beta-1 receptor responsiveness to this agonist, or so-called desensitization, necessitating the use of this drug in an intermittent infusion fashion. As with any parenterally administered medication, dobutamine may cause problems at the injection site, particularly if infiltration occurs. Often, this medication is given via a central line catheter. Other problems with dobutamine use reflect its positive inotropic and chronotropic effects, that is, an increased heart rate, blood pressure, and ventricular ectopy, all of which are dose related. Hypotension may also occur suddenly with the use of this medication, and thus continuous electrocardiogram and blood pressure monitoring are advisable.

Milrinone is a selective inhibitor of phosphodiesterase isoenzyme in the myocardium and vascular smooth muscle. The inhibition of phosphodiesterase reduces the degradation of cyclic AMP, which is associated with an increase in intracellular calcium, which in turn increases myocardial contraction force. Also, the decrease in cyclic AMP breakdown results in increased phosphorylation of contractile proteins and relaxation and vascular smooth muscle. Thus, milrinone, similar to dobutamine, exerts positive inotropic as well as vasodilatory effects. The vasodilatory properties of milrinone are more likely than dobutamine to cause hypotension, particularly in patients with underlying renal insufficiency. The hypotension induced by milrinone can be dangerous because the average elimination half-life of milrinone is nearly 2 h in patients with substantial heart failure. Finally, milrinone has shown an ability to reduce pulmonary hypertension because of its potent vasodilatory action.

Calcium Channel Blockers

Calcium channel blocker therapy has historically been avoided in CHF because of negative inotropic effects. However, newer therapies are reported to have less pronounced cardiodepressant

Calcium channel blocker therapy is avoided in CHF because of negative inotropic effects.

Calcium channel blockers inhibit the transmembrane influx of calcium into vascular smooth muscle and cardiac muscle.

New-generation dihydropyridine drugs, such as amlodipine, do have a role in the treatment of CHF.

Sympathetic neurotransmitters can cause heart cell death and impair cardiac cell function.

effects than the earlier generation drugs. Calcium channel blockers may prove useful in some patients with heart failure because they are effective vasodilators, thereby reducing SVR. They also decrease myocardial oxygen demand in the ischemic heart. However, calcium channel blockers as a class tend to worsen symptoms, and may even increase mortality in CHF patients with systolic ventricular dysfunction, including patients with CHF caused by ischemic disease. Calcium channel blockers may have value in treating heart failure caused by diastolic LV dysfunction, such as heart failure resulting from hypertensive or idiopathic hypertrophic cardiomyopathies.

Calcium channel blockers inhibit the transmembrane influx of calcium into vascular smooth muscle and cardiac muscle. The contractile mechanism of cardiac muscle relies on the movement of extracellular calcium ions in the cardiac muscle cells through specific ion channels.

The most significant adverse effects related to calcium channel blocker therapy is hypotension, lightheadedness, bradycardia, palpitations, and peripheral edema. The only class of calcium channel blockers used in the treatment of heart failure are the dihydropyridine drugs such as amlodipine, because other classes of calcium channel blockers induce a negative inotropic effect.

Beta-Blocker Therapy

Beta-adrenergic blocking agents have had an erratic history in the treatment of heart failure. Early studies demonstrated a trend toward prolongation of survival in dilated cardiomyopathy with the use of a beta-blocker. There is likely a subset of patients, those with dilated cardiomyopathy and impaired systolic function, who benefit from the use of a beta-blocker therapy, such as metoprolol. Later, it was found that beta-blocker therapy could be cautiously used in some patients with CHF caused by ischemic cardiomyopathy.[13] Beta-blocker therapy was used at low doses with very slow and gradual upward titration. Metoprolol improves myocardial performance and energetics in patients with dilated cardiomyopathy.[14]

At present, several beta-blockers, including carvedilol and metoprolol, have shown survival benefit, reduced progression of heart failure, and improvement in functional performance. Beta-blockers have been shown to be particularly helpful in patients who are already taking digoxin, a diuretic, and an ACE inhibitor. The ultimate mechanisms of beta-blocker effects in CHF are unknown but probably lead beyond the beta receptor and into the ensuing cascade of effects down to the cellular membrane milieu.

Downregulation of beta receptors further impairs cardiac cell function and decreases myocardial contractility.

The physiologic rationale for beta-blocker therapy in the treatment of chronic heart failure involves several mechanisms related to the adverse effects of chronic sympathetic stimulation of the heart. Sympathetic neurotransmitters can cause heart cell death and impair cardiac cell function, thereby reducing contractility. Increased activity of the sympathetic nervous system can lead to downregulation of beta-1 receptors on the myocardial cell surface. Antagonism of the sympathetic nervous system with beta-blocker therapy can improve the metabolic and hemodynamic status of the failing heart. In heart failure, the compensatory increase in sympathetic nerve activity compromises cardiac function. The resulting chronic elevation of norepinephrine produces a change in intracellular activity that "down-regulates" beta-1 receptors so that there are fewer receptors available for activation. This downregulation of beta receptors further impairs cardiac cell function and decreases myocardial contractility. When a beta receptor antagonist is used, many of these effects are blocked, resulting in an increase in beta receptor function and upregulation of beta-1 receptors. Beta blockage combined with the upregulation of beta-1 receptors may improve overall cardiac function in the presence of compensatory sympathetic stimulation, as occurs in heart failure.

In the elderly, a beta-blocker may increase fatigue and reduce mental acuity.

Beta-blocker therapy, as a class, can be associated with numerous adverse effects. CHF symptoms may initially be exacerbated by the negative inotropic effect of the beta-blocker therapy, but over time a crucial benefit may actually occur. The use of beta-blocker therapy is typically limited to patients with less severe heart failure, although new studies may shed further light on patients with class IV NYHA CHF. Beta-blocker therapy is avoided in patients with potential for bronchospasm, including patients with asthma and other chronic obstructive pulmonary diseases. In the elderly, a beta-blocker may increase fatigue and reduce mental acuity. Obviously, beta-blocker therapy can precipitate chronic CHF and induce serious hypotension. Various types of cardiac arrhythmias can develop while patients

are on beta-blocker therapy, including AV nodal conduction problems and even more serious heart block. In the diabetic, blunting of the epinephrine effect may impair the ability of the patient to perceive the onset of a hypoglycemic attack.

EMERGING THERAPIES

Statins

Statins work by inhibiting HMG-CoA (3-hydroxy-3-methylglutaryl-CoA) reductase, and are well-established therapies in the prevention and treatment of atherosclerotic cardiovascular disease. In recent years, the "pleotropic" effects of statins have gained increasing attention; recent studies have shown effects on endothelial function, inflammation, neovascularization, and immunomodulatory activities.[15] The use of statins in the course of chronic heart failure, beyond secondary prevention of underlying coronary disease, is an area of active research.

Calcium Channel Sensitizers

Commonly used inotropes for decreased cardiac contractility work through the *B*-receptor-cAMP-protein kinase A pathway. An effect of this therapy is the potential increase in intracellular calcium possibly resulting in an increased incidence of fatal arrhythmias. An alternative mechanism of great interest are agents that act on the cardiac myofilament responsiveness to calcium, without increasing intracellular calcium concentration. This class of medications have been termed "calcium channel sensitizers."

An early drug of this class, which has long been approved for use in Japan, is pimobendan. Pimobendan is a positive inotrope through its calcium-sensitizing effects and inhibition of phosphodiesterase III.[16] The most widely studied medication of this class is levosimendan. Levosimendan acts to enhance cardiac myofilament responsiveness to calcium by binding to cardiac troponin C, and by opening ATP-dependant potassium channels in myocytes and smooth muscle cells.[17] Levosimendan does not increase myocardial oxygen consumption. Although beneficial hemodynamic effects were seen in this trial, further trials with prolonged therapy and follow-up may reveal mortality reduction as is suggested in the early literature regarding levosimendan.

Vasopressin Antagonists

Vasopressin (antidiuretic hormone) is released from the posterior pituitary in response to increased plasma osmolality, severe hypovolemia, hypotension, and angiotensin II. Vasopressin acts predominantly via three receptor subtypes: V1a (vascular), V1b (pituitary), and V2 (renal). It is thought that actions on V1a receptors mediate vasoconstriction while actions on V2 receptors mediate intravascular volume by renal tubular cells. Vasopressin levels are noted to increase in patients with HF, and thus contribute to resultant increased volume and sodium imbalance in these patients. The resultant hyponatremia caused by this imbalance has been shown to be a predictor of poor outcomes in HF. Of this class of medications, the two agents that have been most investigated are conivaptan and tolvapatan.

Conivaptan is a nonselective V1a/V2 receptor antagonist.[18] Compared to placebo, these doses reduced PCWP and RA pressure within 3–6 h following administration. Conivaptan was found to reduce PCWP and RA pressure within 3–6 h following administration, and increase urine output in a dose-dependent fashion, without resultant difference in blood pressure or heart rate from placebo.

1. Tolvapatan is an oral V2 selective receptor antagonist. The largest trial to date, the 2007 EVEREST study, reported outcomes from 4,133 patients with NYHA class III/IV symptoms randomized to oral tolvaptan or placebo, initiated 48 h within admission for HF exacerbation.[19] At a mean follow-up of nearly 10 months, researchers found no statistically significant effect on mortality or heart failure-related morbidity over placebo.

Currently, no ACC/AHA guidelines exist in regards to this class of medications. Although short-term outcomes in acute congestion remain promising, long-term mortality benefits remain to be described in the literature.

MECHANICAL SUPPORT

Devices as "Add-On" Therapy

Patients with advanced heart failure, particularly those presenting with acute decompensated heart failure, often manifest diuretic resistance. Furthermore, concern has been raised regarding the potential adverse impact of high-dose diuretic treatment, including renal impairment and neurohormonal activation. For these reasons, mechanical solutions – specifically ultrafiltration or aquapheresis – have increasingly been considered as an alternative or add-on form of treatment. A newer system (Aquadex 100, CHF Solutions®, Brooklyn Park, MN) has recently been the subject of a number of clinical investigations. This system requires a low volume of extracorporeal blood and employs either central and/or peripheral venous cannulation. Up to 500 mL/h of isotonic fluid can be removed with rates regulated to minimize the incidence of hypotension and renal impairment. The UNLOAD Trial randomized 200 patients hospitalized with worsening heart failure to receive either conventional treatment with diuretics or early, short-term treatment with ultrafiltration.[20] Ultrafiltration appears to represent a useful modality to facilitate correction of fluid overload, present in the vast majority of patients hospitalized with worsening heart failure. However, the optimal approach to utilizing ultrafiltration – whether early during the admission or only after failure of standard therapy – remains to be defined. More careful and rigorous approaches to measuring intravascular volume and the rate of plasma refill during aquapheresis may augment the clinical effectiveness of ultrafiltration and serve to further improve clinical outcomes achieved.

Continuous aortic flow augmentation (CAFA), such as Cancion® (Orqis® Medical, Lake Forest, CA), represents a promising investigational approach to managing patients with decompensated heart failure who are not responding optimally to conventional medical therapy. Clinically, CAFA is achieved using an extracorporeal, magnetically driven centrifugal flow pump, with 12-French inflow and outflow catheters, positioned percutaneous via the left and right femoral arteries, respectively. Initial, recently published clinical feasibility results from patients with acute decompensated heart failure demonstrated that CAFA treatment was associated with progressive reduction in PCWP and SVR with a gradual, progressive increase in cardiac output and a trend toward improved renal function.[21] The combined changes in LV filling pressure and in forward output represented an upward shift in the LV Starling curve, consistent with an improvement in cardiac performance. The notion of CAFA as "add-on" therapy stems, in part, from the presumption that this mode of treatment, imparted for several days, will break a vicious cycle of worsening heart failure by correcting abnormalities in aortic flow, inducing a withdrawal of reflex vasoconstriction, improving renal performance, unloading the heart, and augmenting cardiac output, thereby yielding a longer-term improvement in the patient's hemodynamic and clinical condition. A longer-term implantable device for delivery of CAFA treatment is presently in preclinical investigation.

Intra-aortic Balloon Pump

The IABP induces diastolic augmentation of blood pressure with systolic afterload reduction.

IABP is contraindicated in patients with substantial aortic regurgitation or aortic dissection.

Intra-aortic balloon counterpulsation can provide mechanic circulatory support in patients with severe LV dysfunction. The IABP induces diastolic augmentation of blood pressure with systolic afterload reduction, and it is the most common assist device used today. A balloon tip catheter is inserted through the femoral artery, up the aorta, and positioned just beyond the origin of the left subclavian artery. The balloon can be inflated during diastole, accelerating blood to the periphery of the body, and it deflates during systole, reducing end-diastolic pressure, thereby reducing LV afterload and promoting SV. During diastole, when the balloon is inflated, coronary perfusion also increases.

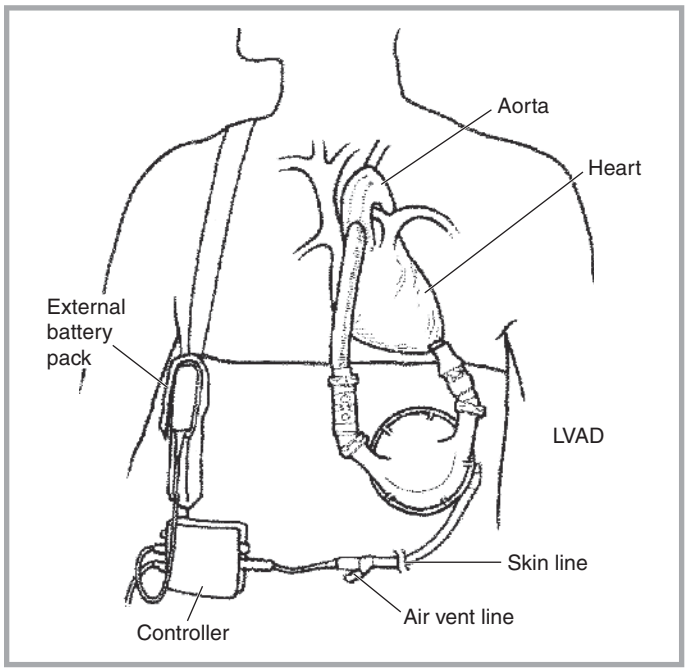

FIGURE 18-3

A left ventricular assist device (VAD). The outflow cannula is in the LV apex and the return (inflow) cannula is in the proximal ascending aorta.

IABP is generally used before and after coronary artery bypass surgery and cardiac transplantation, during acute myocardial infarction with cardiogenic shock, and during acute mitral insufficiency. Most frequently, it is used immediately postoperatively following cardiopulmonary bypass surgery. IABP is contraindicated in patients with substantial aortic regurgitation or aortic dissection. The procedure is complicated by leg ischemia and infection. Finally, weaning from intra-aortic counterpulsation can be difficult, but in most patients it occurs within a 24-h period.

Ventricular Assist Devices

A ventricular assist device (VAD) (Fig. 18-3) is a pump that is implanted into the body and can either support the right ventricle (RVAD), the left ventricle (LVAD), or both ventricles (BiVAD).[22] The pump enhances total systemic arterial blood flow and is generally used in patients with severe or end-stage cardiac disease with a life expectancy of less than 1 year; it is often used as a bridge to heart transplantation. LVAD is generally employed in patients who are dependent on vasopressor therapy, with hemodynamics that are poorly supported with such pressors: these hemodynamics include high PCWP, low mean systemic arterial pressure, and low cardiac index, generally less than 2 L/min/m^2.[23]

Bleeding, systemic embolization, and infection are the most frequent complications of ventricular assist devices (VADs).

VADs are not used in patients who have noncorrectable bleeding disorders, bone marrow suppression, or severe immune suppression. Bleeding, systemic embolization, and infection are the most frequent complications. However, thromboembolic complications have been kept to a minimum because the device often undergoes vascular surface changes, namely endothelialization of the pumping chamber.

HEART TRANSPLANTATION

Despite aggressive medical management, many patients with end-stage heart failure may require heart transplantation. The mortality rate for NYHA classification IV heart failure remains 30–40% per year. For patients whose disease progresses rapidly despite optimal treatment or whose 1-year life expectancy is far less than the survival probability for transplant patients, cardiac transplantation may be a viable option. However, donor availability remains the rate-limiting step for heart transplantation for patients with advanced heart failure.

Donor availability remains the rate-limiting step for heart transplantation.

CASE STUDY: PART 4

This patient had several systemic complications of his acute coronary event. He had pulmonary edema requiring mechanical ventilatory support, and he required intra-aortic counterpulsation to increase coronary artery perfusion and to provide afterload reduction. His physical examination findings were consistent with long-standing hypertension and vascular disease, including diffuse arteriolar narrowing and poor peripheral pulses. His habitus was that of an obese patient having multiple coronary risk factors, including tobacco and alcohol use.

The patient had signs and symptoms of CHF that were acute in presentation but probably chronic in origin from an underlying ischemic cardiomyopathy due to his multiple infarctions. His echocardiogram showed an aneurysmal LV apex, which suggested a previous old myocardial infarction, and his new event showed a minimal spillage of creatinine, phosphokinase, and isoenzymes, suggestive of a small area of ischemia.

However, in the context of severely decompensated and diminished ventricular performance and function, as in this patient, these small ischemic events can precipitate acute pulmonary edema and cardiogenic shock. This patient required intravenous inotropic support and mechanical ventilation with mechanical counterpulsation to try to augment his cardiac performance. With the use of oral ACE inhibitors and medical management, he could be weaned from his mechanical support.

The patient's clinical evidence suggests that his renal insufficiency is probably multifactorial, deriving from a vascular etiology, a hypertensive etiology, and a low cardiac output state.

SUMMARY

Our increased understanding of the pathophysiology of heart failure has led to better treatment strategies and prolonged survival. However, more effective and earlier recognition of disease is still needed, and the challenge for the futures rests in preventing the disease from occurring or progressing to its morbid state. For now, proper therapy includes not only the correct combination of medications but also proper diet, fluid intake, and exercise, which can often prevent repeated hospitalizations for heart failure patients.

REVIEW QUESTIONS

1. Which of the following cardiovascular disease entities has increased in prevalence over the last decade?
- **A.** CAD
- **B.** Hypertension
- **C.** Valvular heart disease (including mitral valve prolapse)
- **D.** CHF

2. NYHA class III–IV patients have a 1-year survival rate of
- **A.** 10–20%
- **B.** 80–90%
- **C.** 30–50%
- **D.** 60–70%

3. Which of the following factors are important in the regulation of the SV?
- **A.** Venous return
- **B.** SVR
- **C.** Concentration of extracellular calcium
- **D.** All of these
- **E.** A and C only

4. The cardiac remodeling that occurs during chronic failure is part of the compensatory response to preserve cardiac output and to normalize ventricular wall stress.
- **A.** True
- **B.** False

5. "Higher ventricular filling pressures at the same volume" best describes the hemodynamic disturbance found during
- **A.** CHF
- **B.** RV failure
- **C.** Systolic heart failure
- **D.** Diastolic heart failure
- **E.** Biventricular failure

ANSWERS

1. The answer is D. Heart failure is the only major cardiovascular condition in the United States for which the incidence and prevalence have steadily increased. Approximately 4.8 million Americans suffer from heart failure, and about 400,000 new cases are discovered each year. This steady increase in the number of patients with heart failure is directly linked to the decreasing mortality rates of coronary heart disease, myocardial infarction, and stroke. The improved management of these underlying problems has resulted in patients surviving long enough to develop a weakened heart and subsequent heart failure.
2. The answer is C. The outlook for patients with CHF remains poor. Half will die within 5 years of diagnosis, and for patients with severe heart failure, 1-year survival is only 30–50%.
3. The answer is D. Stroke and volume is the amount of blood ejected with each heart beat. All the factors listed are important in regulating SV. SV depends on (1) the EDV, which is dependent on venous return; (2) the load against which the heart must contract, which is dependent on the SVR; and (3) the level of cardiac contractility, which is determined by the concentration of intracellular calcium that attaches to troponin C. In cardiac muscle, the amount of calcium released from internal stores to attach to troponin C is related to calcium entry from outside the cell, which is related in part to the extracellular concentration.
4. The answer is A. Cardiac remodeling is an extremely important part of the initial response to myocardial injury. Remodeling is associated with several changes in cardiac geometry, including ventricular hypertrophy. Compensatory ventricular hypertrophy results in an increase in the number of myofilaments (which helps to maintain SV and thus cardiac output) and an increase in myocardial wall thickness (which decreases ventricular wall stress, thereby reducing myocardial oxygen consumption).
5. The answer is D. Diastolic heart failure is associated with inability of the ventricle to fill adequately during diastole. In diastolic heart failure, filling pressure becomes disproportionately elevated in relation to small changes in diastolic volume. This situation occurs with loss of ventricular compliance. Diastolic heart failure can lead to CHF, with the development of pulmonary or systemic edema (or both). RV failure can result from diastolic failure, but it can also occur because of systolic failure, in which the characteristic ventricular dysfunction is inadequate emptying during systole rather than improper filling during diastole. Diastolic as well as systolic failure can occur in both ventricles (i.e., be biventricular).

Cardiac Arrhythmias

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the fundamental properties of excitability and refractoriness.
- Know basic conduction system anatomy.
- Develop a basic understanding of arrhythmia mechanisms, with particular attention to reentry, which is responsible for most clinically relevant arrhythmias.
- Develop a systematic approach to the diagnosis and treatment of common bradycardic and tachycardic rhythms.
- Understand the impact, evaluation, and treatment options of arrhythmias occurring during several common clinical syndromes (long QT syndrome and acute myocardial infarction).

INTRODUCTION

This chapter provides an overview of basic cellular electrophysiology, conduction system anatomy, and mechanisms of common cardiac arrhythmias. A discussion follows on the clinical recognition of common arrhythmias, based primarily on ECG characteristics and arrhythmia response to noninvasive maneuvers. The clinical characteristics, diagnostic features, and treatment options of specific arrhythmias are discussed. The last section provides an overview of specific arrhythmia syndromes.

CELLULAR ELECTROPHYSIOLOGY

Cardiac electrical activities are determined by the cellular transmembrane potential, the voltage difference between the intracellular and extracellular environments. The action potential (AP) is expressed as the voltage change over time during depolarization and repolarization of the cardiac cell; it consists of five phases.

Understanding the basic mechanism of arrhythmia initiation, maintenance, and termination requires knowledge of electrical properties of the cardiac cells. The major ion carriers (Na^+, K^+, Ca^{++}, and Cl^-) and their movement across the cell membrane create the flow of currents needed to generate excitation and signals. These ionic flows are governed by specialized channels and pumps, often, voltage-sensitive. It is the difference between the intracellular and the extracellular concentrations of these ions that sets up the transmembrane potential and electrochemical gradient.

The AP is expressed as the change in cellular membrane voltage over time during depolarization and repolarization of the cardiac cells. AP consists of five phases (Fig. 19-1). Phase 0 is the rapid upstroke or cellular membrane depolarization phase, caused by fast sodium (Na^+) ion influx. The slope of phase 0 determines the maximum rate of depolarization of the cell and impulse propagation. Phase 1 represents early, transient repolarization (early notch), caused by the rapid inactivation of sodium channels and activation of outward potassium channels. Phase 2 represents the early plateau, during which a slow inward L-type calcium channel and outward movement of potassium through slow delayed rectifier potassium channels are activated. The membrane conductance to all ions remains low and cells are unresponsive to stimuli regardless of strength. The cell is said to be in its absolute refractory period.

Cardiac cell AP: during phases 0, 1, and 2 the cells are inexcitable. During phase 3, cells gradually recover excitability; during phase 4, the cell is fully excitable.

Phase 3 represents the rapid repolarization of the cell, caused by inactivation of the slow inward calcium current while the delayed rectifier potassium channels remain open. A net outward current results during Phase 3, causing the cells to repolarize. During phase 3, cells gradually recover their ability to respond to stimuli; that is, they recover "excitability." A sufficiently strong stimulus applied near the end of phase 3 may encounter enough recovered sodium channels to allow depolarization to threshold and generate a new AP; this is known as the relative refractory period. Still later in phase 3, essentially all sodium channels are readily available. The cell is once again fully excitable, and stimuli will generate a normal AP.

Phase 4 is defined by the resting membrane potential and represents the period from the end of repolarization until the next depolarization (AP). Although most cardiac cells require a stimulus of sufficient strength to excite the resting membrane potential to threshold in order to generate an AP, some specialized cells display spontaneous phase 4 depolarizations (Fig. 19-2). This is the result of reduced membrane permeability to outward potassium flow coupled with a passive inflow of sodium ions. The net positive charges cause a gradual Phase 4 depolarization that eventually reaches threshold and induces a spontaneous cardiac AP. These specialized cells

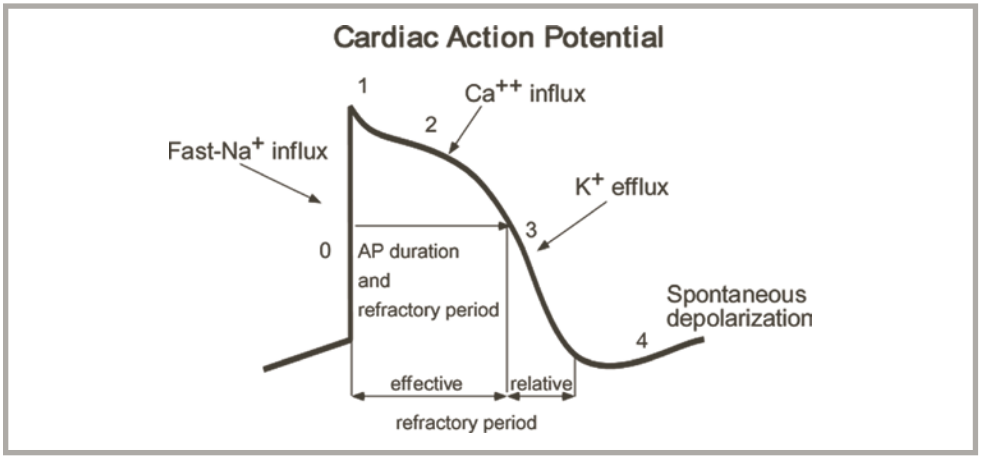

FIGURE 19-1

Cardiac action potential (AP). The rapid upstroke represents cellular depolarization referred to as phase 0, mostly due to rapid sodium influx. Repolarization is divided into three phases. Phase 1 represents early and rapid repolarization. Phase 2 is known as the plateau phase, and phase 3 represents the final rapid repolarization of the cell. Calcium influx is essential in maintaining the plateau membrane potential and potassium efflux is responsible for cellular repolarization. Phase 4 is the period from the end of repolarization until another AP is generated. Also depicted are the effective (absolute) and relative refractory periods.

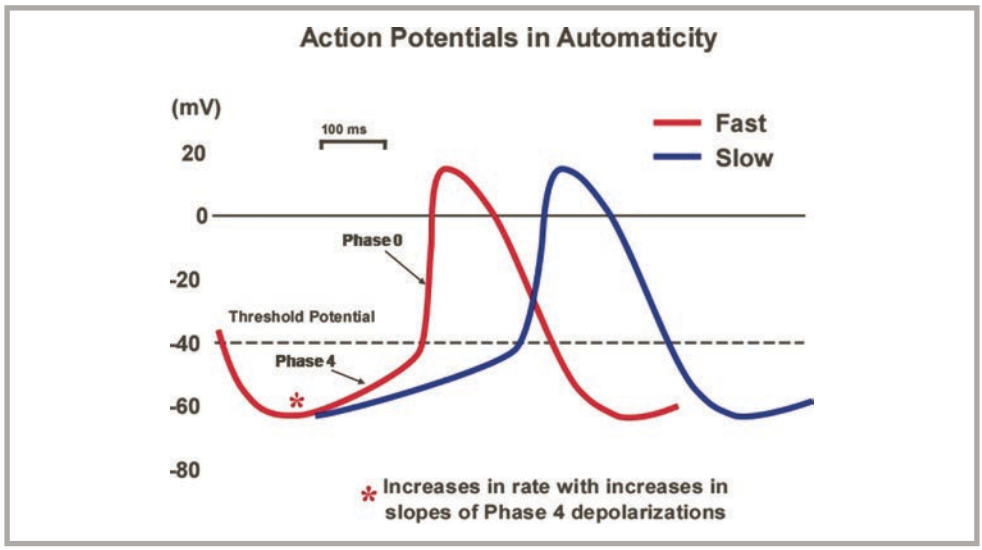

FIGURE 19-2

Cardiac automaticity arises from spontaneous phase 4 depolarization due to a net positive ionic influx. The cellular membrane potential reaches the threshold potential and induces spontaneous cardiac APs. Automaticity is commonly found in cells at the sinoatrial (SA) node and atrioventricular node (AVN), as well as in the junctional region. The spontaneous discharge rate (automaticity) is dependent on the slope of the phase 4 depolarization. A higher slope is associated with a faster rate.

that possess the property of automaticity are commonly located at the sinoatrial (SA) node, parts of the atria, the atrioventricular (AV) junctional region, and the His-Purkinje system (HPS).

CARDIAC CONDUCTION SYSTEM

Under normal conditions, the pacemaker function of the heart originates from the SA node. The SA node is located epicardially in the high lateral right atrium near the entrance of the superior vena cava. The blood supply for the SA node is from the right coronary artery (RCA) in 60% of cases and from the left circumflex artery (LCx) in 40% of cases (Fig. 19-3). Once an impulse exits the SA node, it traverses the atrium until it reaches the AV node that lies at the base of the right interatrial septum. The electrophysiologic properties of the AV node provide

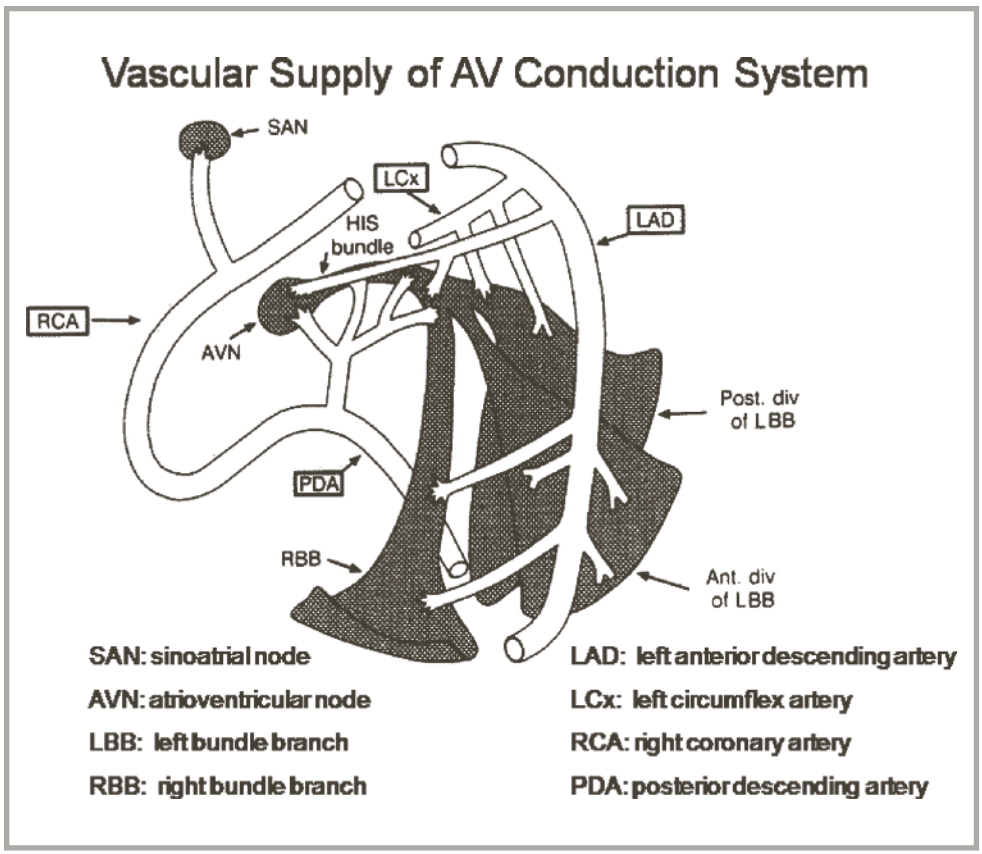

FIGURE 19-3

Vascular supply of AV conduction system. The blood supply to the SA node is 60% from the right coronary artery (RCA) and 40% from the left circumflex artery (LCx). The AV node also has a dual blood supply from PDA/RCA and the septal branches of left anterior descending (LAD). The bundle of His and the right bundle branch (RBB) predominately receive blood from the LAD circulation. The blood supply to the anterior fascicle is from the LAD, and the posterior fascicle has dual blood supply from the LAD and the LCx (modified from DeGuzman[37]).

variable delay in AV conduction under normal circumstances. The AV node often receives dual blood supply from the RCA (90%) and the left anterior descending coronary artery (LAD).[1] This may explain the frequent occurrence of reversible AV nodal conduction disturbances during inferior myocardial infarctions. The Bundle of His penetrates the central fibrous body and then branches into left and right bundle branches (RBBs) that course over the left and right sides of the interventricular septum. Conduction is especially rapid through the HPS. The left bundle branch divides into two fascicles. The blood supply to the anterior fascicle is from the LAD, and the posterior fascicle has dual blood supply from the LAD and the LCx. Consequently, the development of left posterior hemi-block after a myocardial infarction is a poor prognostic sign, indicating compromise of two major cardiac circulations.

The SA and AV nodes are significantly influenced by autonomic tone. The electrophysiologic property of the AV node determines AV conduction. HPS has little autonomic innervations.

The SA and AV nodes are significantly influenced by autonomic tone, whereas the HPS has little autonomic innervation. Vagal tonic effect dominates during normal conditions and is the major determinant of resting heart rates. Vagal influence depresses automaticity of the sinus node and prolongs AV nodal conduction and refractoriness, and is responsible for the rapid modulation of heart rate and AV conduction. Sympathetic influence increases sinus node automaticity, accelerates AV nodal conduction, and shortens AV nodal refractoriness. It is responsible for sustained acceleration of pacemaker activity (chronotropic) and enhanced conduction (dromotropic) responses during exercise or stress.

MECHANISMS OF ARRHYTHMIAS

Disorders of Impulse Formation

The mechanisms responsible for cardiac arrhythmias are typically divided into abnormalities of impulse formation and abnormalities of impulse conduction. Disorders of impulse formation can be further divided into abnormal automaticity or triggered activity. Abnormal automaticity occurs when cardiac cells undergo spontaneous diastolic (Phase 4) depolarizations, resulting in ectopic APs at an abnormally fast rate. Clinical arrhythmias believed to be caused by abnormal automaticity include paroxysmal sinus tachycardia (ST), focal atrial tachycardias (AT), accelerated junctional tachycardias, and some forms of ventricular tachycardia.

Arrhythmias caused by triggered activity are initiated by "afterdepolarizations," which are abnormal oscillations in cell membrane voltage triggered by one or more preceding APs, often associated with prolonged repolarizations. These triggered depolarizations may occur before the cell membrane has completely repolarized, called early afterdepolarizations (EADs), or after full recovery of the cellular membrane potential, called delayed afterdepolarizations (DADs) (Fig. 19-4). EADs usually occur in late phase 2 or phase 3 of the AP, especially when the heart rate is markedly slowed. EADs may be responsible for reperfusion arrhythmias and polymorphic ventricular tachycardia of *torsades de pointes* associated with the long QT syndrome. DADs occur in late phase 3 or early phase 4 when the AP is almost fully repolarized. The development of DAD is related to conditions that increase intracellular calcium concentrations and can be induced by digitalis excess and exposure to catecholamine. DADs are thought to be responsible for certain digitalis toxic arrhythmias as well as catecholamine-dependent atrial and ventricular tachycardias.

Disorders of Impulse Conduction

Reentry is responsible for most clinical tachycardias. Basic requirement for reentry are (1) multiple limbs in a circuit, (2) unidirectional conduction block in one limb, and (3) slow conduction via an alternative pathway.

Disorders of impulse conduction can result in either bradycardia or tachycardia. Bradyarrhythmias occur when impulse propagation is delayed or blocked. Clinical examples include sinus node dysfunction (SND), various degrees of AV block (AVB), and bundle branch block (BBB). Most of the clinical tachyarrhythmias are based on reentry mechanisms. Basic to all forms of reentry are (1) multiple anatomic or functional pathways, (2) unidirectional conduction block in one limb of the circuit, and (3) slow conduction down the alternative pathway.

The impulse propagation down the alternative limb must be sufficiently slow that the tissue proximal to the area of the unidirectional block recovers excitability and allows the impulse to reenter the circuit (Fig. 19-5). Reentry may exist in (1) a microreentrant circuit, as found in ischemic ventricular tachycardia, (2) a macroreentrant circuit that encompasses larger areas of the

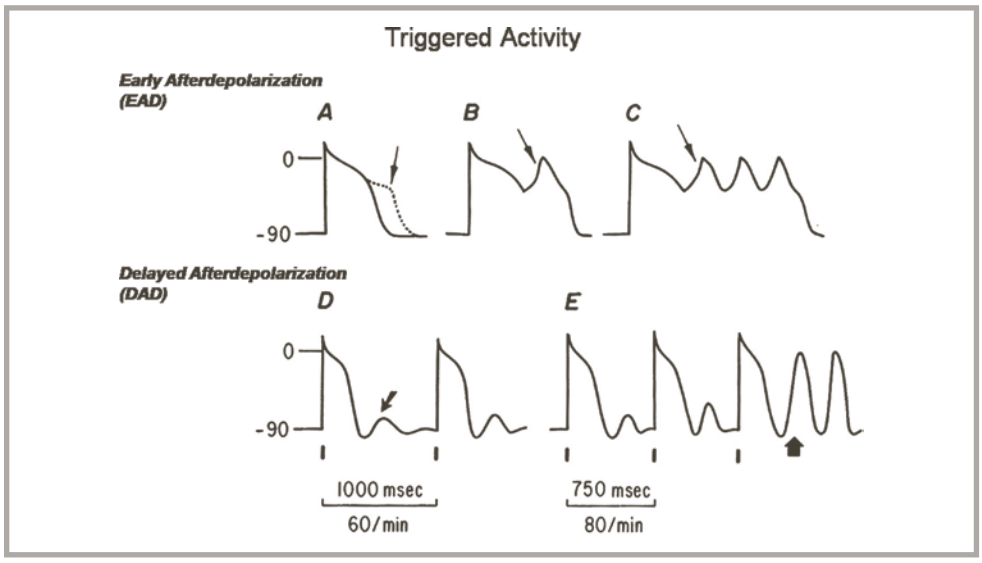

FIGURE 19-4

Triggered activities are caused by abnormal cell membrane voltage oscillations, induced by preceding APs. Early afterdepolarizations (EADs) occur in late phase 2 or phase 3 of the AP, before complete cellular repolarization (**a**). When such membrane voltage oscillation reaches the threshold, a second membrane depolarization was induced (**b**). Repetitive EADs may occur with bradycardia or reperfusion injury (**c**). Delayed afterdepolarizations (DADs) occur in late phase 3 or early phase 4 when the membrane potential is fully repolarized (**d**). DADs are thought to be responsible for certain digitalis toxic arrhythmias as well as catecholamine-dependent atrial and ventricular tachycardias (**e**).

heart, most commonly seen in bypass tract-mediated supraventricular tachycardias (SVTs), scar-based ventricular tachycardia, or (3) multiple reentrant circuits (wavelets), as found in atrial and ventricular fibrillation (VF). Understanding the concept of reentry is critical to the understanding how most arrhythmias are initiated and maintained and how antiarrhythmic drugs work.

CLINICAL ASSESSMENT AND MANAGEMENT OF CARDIAC ARRHYTHMIAS

Accurate diagnosis of the arrhythmia is essential for prompt and appropriate treatment. A careful review of the patient's history is important to define the underlying arrhythmogenic substrate, and adequate documentation of the arrhythmia, preferably a 12-lead ECG during the episode, is essential. Close attentions to the morphologic characteristics of the arrhythmia (P, QRS), its mode of initiation or termination, and its response to certain maneuvers and

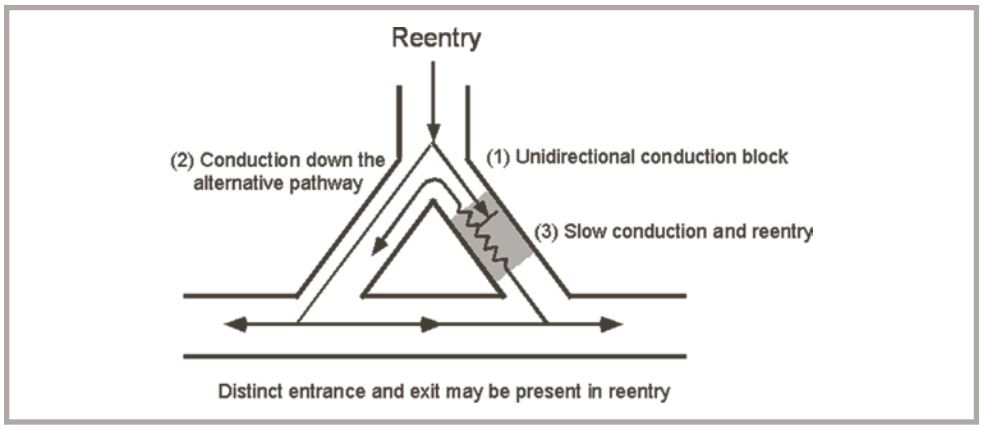

FIGURE 19-5

Basic requirements of reentry include (*1*) multiple pathways (either anatomic or functional) within the reentry circuit, (*2*) unidirectional conduction block in one limb of the circuit, (*3*) The impulse travels down an alternative limb in the circuit. Critical degree of conduction slowing (*shaded area*) allows the area of prior unidirectional block to recover excitability and the impulse to reenter the circuit.

drugs, often provide enough information for a reasonably accurate diagnosis. In addition, symptomatic severity during the arrhythmia, frequency and duration of recurrences, may also influence the diagnostic strategy and therapeutic decision. The physician should be aware of circumstances that immediately preceded or coexist with the arrhythmia such as angina, myocardial infarction, hypoxia, metabolic abnormalities, and the use of inotropic or antiarrhythmic drugs. The goals should include identification and treatment of reversible conditions that may trigger arrhythmias and be the primary targets for intervention.

For instance, in patients with known history of prior myocardial infarction, a wide complex tachycardia (WCT) is far more likely to be ventricular than supraventricular in origin. Palpitations that reproducibly recur during exercise or stress implies a catecholamine-sensitive mechanism and may respond to adrenergic blocking agents. Mode of arrhythmia initiation and termination provides insight into the potential mechanism and differential diagnosis. An automatic arrhythmia usually has a spontaneous initiation and may exhibit a "warm-up" phenomenon. The ECG appearance of the first beat of an automatic tachycardia is often identical to the rest of the beats of the tachycardia. A reentrant arrhythmia is frequently initiated by an "early" premature beat followed by a pause. This corresponds to the premature stimulus, unidirectional block, slow conduction, and then reentry. The ECG appearance of the first beat of a reentrant tachycardia may not be identical to the rest of the tachycardia. Automatic arrhythmias are not terminated by overdrive pacing and may be incessant. Reentrant arrhythmias can usually be terminated by overdrive pacing or introduction of properly timed extrastimuli. The mode of initiation and termination of triggered activity in clinical human arrhythmias has not been well studied.

Vagal cardiac maneuvers may provide important diagnostic information. These include carotid sinus pressure application, the Valsalva maneuver, and administration of IV adenosine.

Noninvasive cardiac maneuvers, often greatly underutilized, may provide important diagnostic information. The Valsalva maneuver and application of carotid sinus massage (CSM) result in increased vagal tone. This slows the rate of sinus nodal discharge, slows AV nodal conduction and prolongs refractoriness producing AV nodal block. Clinically, abrupt termination of a tachycardia with vagal maneuvers implies an "AV nodal-dependent" mechanism is most likely involved.[2] Ventricular tachycardia (VT) shows no response to vagal stimulation. Heart rate response during atrial fibrillation (AF), atrial flutter (AFL), and AT will often slow in response to increasing AVB but is unlikely to terminate the arrhythmia. By slowing the heart rate, vagal maneuvers also allow the underlying atrial activity to be seen and thus establishing the diagnosis.

Other vagal stimuations include breath-holding, cold water immersion, induced gagging (suctioning via an endotracheal tube), or adenosine administration. The Valsalva maneuver should generally be avoided in patients with ischemic heart disease because of the accompanying fall in coronary blood flow. Prior to carotid massage, careful auscultation of carotid arteries for bruits is important because of the possibility of provoking cerebral embolic complication.

The response of SVTs to specific drugs may also be diagnostic. Adenosine is a short-acting potent endogenous nucleoside that slows conduction through the AV node. If the arrhythmia is "AV node-dependent," 6–12 mg of IV adenosine restores sinus rhythm in the majority of cases. If the tachycardia is "AV node-independent," such as an AT, adenosine slows the ventricular response, and rarely will result in termination.[2] Verapamil also has a potent negative dromotropic effect on the AV node. However, verapamil has a longer duration of action and may cause significant vasodilatation and hypotension and should not be used in the setting of a WCT. With either drug, asystole has been observed, thus the capability for temporary pacing should be available whenever these drugs are administered.

Determining the presence of P waves and their relationship to the QRS complexes, as well as analyzing the QRS morphology, is of paramount importance in diagnosing an arrhythmia. No single lead can provide sufficient information to assure a correct diagnosis. Therefore, multiple simultaneous leads must be examined and a 12-lead ECG obtained whenever possible. These tracings should always be compared to a sinus rhythm tracing if available. Continuous telemetry tracings provide opportunities to examine the mode of initiation and termination of the episode, as well the response of the arrhythmia to ectopic beats.

Clinical approach to arrhythmia diagnosis:
1. Determine the rhythm regularity.
2. Assess the A-V relationship.
3. Assess the morphologic characteristics of P and QRS.
4. Assess response to maneuvers or drugs.

ARRHYTHMIA DIAGNOSIS

There are many approaches to arrhythmia diagnosis, but the simplest and most clinically relevant approach is to first categorize the rhythm as slow or fast, then further differentiate according to its regularity, AV relationship, morphologic characteristics, and response to

maneuvers or drugs. Characterization of every arrhythmia is beyond the scope of this text, which will focus only on the more common, clinically relevant arrhythmias.

Bradycardias

Sinus Bradycardia

Sinus bradycardia (SB) in the adult is defined as a sinus rate less than 60 beats/min (bpm). In the general population, this rhythm is normal in the majority of cases, usually reflecting enhanced vagal tone, such as good cardiovascular conditioning/fitness or sleeping during nocturnal hours. In patients with structural heart disease, however, this is often a distinctly abnormal rhythm. Causes include drugs with a negative chronotropic effect (beta-blockers, calcium channel blockers, amiodarone), parasympathomimetic drugs, myocardial infarction (especially inferior), hypothermia, gram-negative sepsis, hypothyroidism, and CNS disorders. Therapy is primarily directed at the underlying cause and to relief of symptoms. Symptomatic patients may require treatment with IV atropine, isoproterenol infusion, or even temporary pacing.

Parasympathetic tone dominates during normal resting conditions. Vagal influences suppress sinus rate and prolong AV nodal conduction and refractoriness. Sympathetic effects increase sinus rate and accelerate AV nodal conduction.

Sinus Node Dysfunction

SND, also called sick sinus syndrome (SSS), is frequently intermittent and is most commonly found in the elderly. SND encompasses a group of disorders that include "inappropriate" SB, sinus arrest, and SA exit block (Fig. 19-6). SND accounts for more than half of all

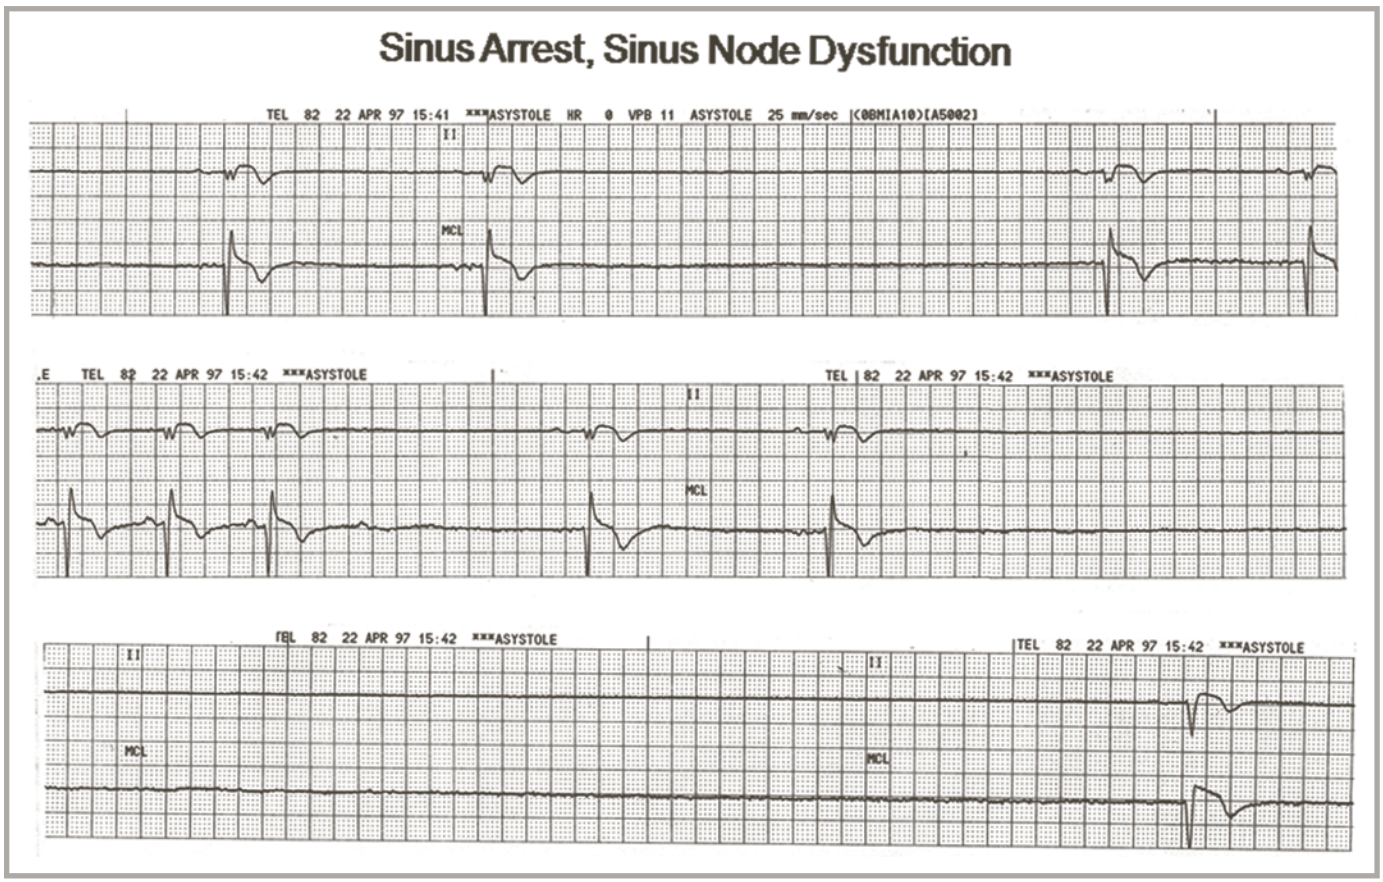

FIGURE 19-6

Sinus node dysfunction (SND). Continuous telemetry recording demonstrated severe sinus bradycardia (SB), sinus arrest with pauses of greater than 13 s duration and failure of an adequate escape rhythm.

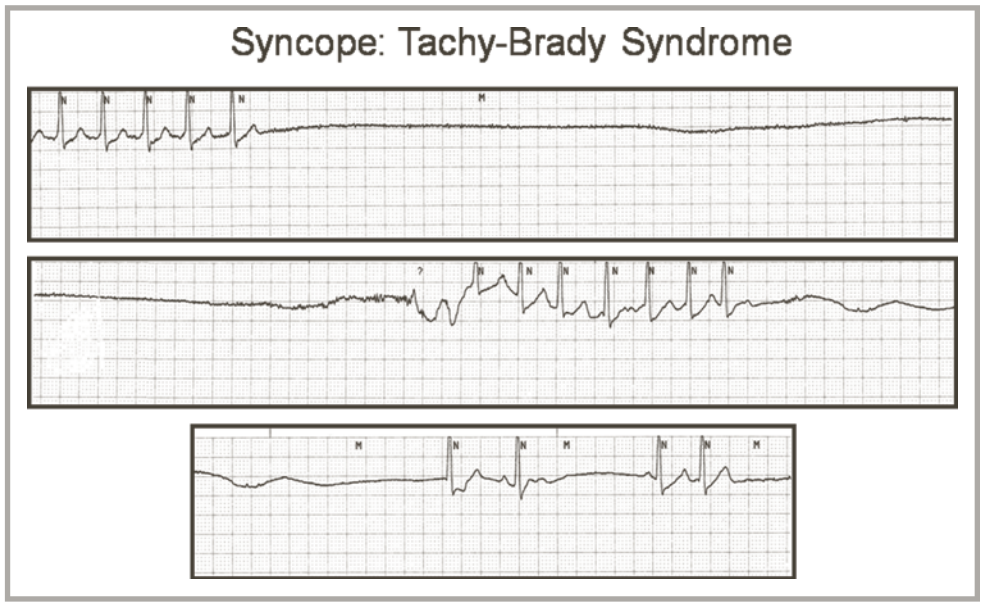

FIGURE 19-7

Tachy-brady-syndrome with SND. Episodes of tachyarrhythmia, most often atrial fibrillation (AF), are followed by periods of severe bradycardia and postconversion pauses. This is a common cause of syncope in patients with paroxysmal AF.

permanent pacemaker implantations in the United States. It is commonly caused by idiopathic degeneration of the sinus node, hypertension, ischemia, infiltrative or inflammatory diseases, or the normal aging process.

Tachy-Brady Syndrome is the most common cause of cause of symptomatic SND and is associated with syncope.

Inappropriate SB refers to a primary rhythm disorder of persistent SB, inappropriate for the physiologic condition of the patient, and is unexplained by other factors such as hypothyroidism or medications. When marked SB (heart rate <50 bpm) occurs, symptoms of fatigue and weakness predominate. Prolonged sinus pauses (>3 s) caused by either failure of sinus node impulse formation (sinus arrest), or conduction block of sinus impulses exiting to the surrounding atrial tissue (sinus exit block), may result in paroxysmal dizziness, presyncope, or syncope. Other manifestations of SND/SSS include the tachy-brady syndrome in which episodes of tachyarrhythmia (most often AF or flutter) is followed by periods of severe bradycardia and pauses (Fig. 19-7). The tachy-brady syndrome is the most common cause of symptomatic SND and is associated with a high incidence of syncope. Tachycardia may also follow bradycardia – the brady-tachy syndrome. AF, for instance, may develop in the presence of bradycardia or pauses.

Asymptomatic patients require no immediate treatment. Symptomatic bradycardia may be treated with atropine, isoproterenol, or temporary pacing. Over time, these patients often require permanent pacemakers.

AV Block (Heart Block)

Abnormal A-V conduction:
1. Prolonged A-V conduction (first-degree AV delay)
2. Intermittent A-V conduction (Mobitz I or II)
3. No A-V conduction (complete heart block).

Abnormalities of the AV conduction system include (1) prolonged AV conduction (first-degree AV delay), (2) intermittent AV conduction (second-degree AVB), and (3) complete heart block (CHB) (third-degree AVB). Causes of abnormal AV conduction include fibrodegeneration of the conduction system, ischemic heart disease, drug effect (beta-blockers, calcium channel blockers, digitalis, antiarrhythmic drugs), cardiac surgery, infectious and infiltrative diseases. First and second degrees of AVB can be seen in normal individuals with heightened vagal tone, especially during sleep.

The P-R interval is predominately determined by the AV nodal conduction time. First-degree AV delay is defined as a P-R interval greater than 0.2 s. P-R interval prolongation may be caused by a delay in impulse conduction in the atria, AV node, or the HPS. A narrow QRS complex and a P-R interval that exceeds 0.26 s strongly suggest a delay in the AV node. The P-R interval is predominately determined by the AV nodal conduction time. P-R interval prolongation (>0.2 s) may be caused by delay in impulse conduction in the atria, AV node, or the HPS (Fig. 19-8). A narrow QRS complex and a P-R interval that exceeds 0.26 s suggest a delay in the AV node.

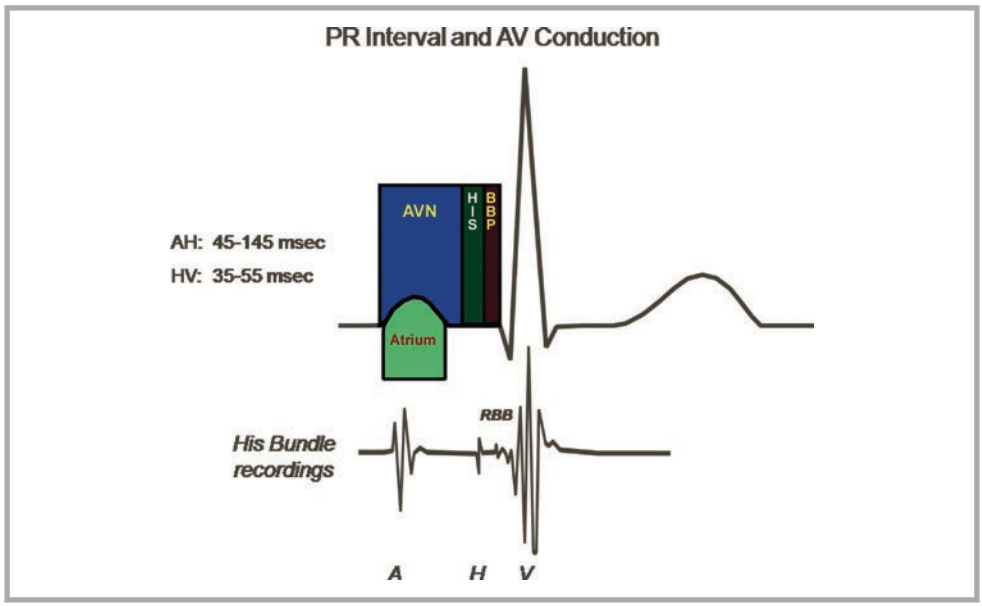

FIGURE 19-8

An illustration of the P-R interval and the intracardiac His-bundle electrogram recordings. Surface electrocardiographic P-R intervals consist of conduction times through (*1*) AVN, (*2*) His-Purkinje system (HIS), and (*3*) the bundle branch-Purkinje system (BBP). Atrial activations generate the P waves. The time interval between the atrial activation (*A*) and the His bundle activation (*H*) represent the AVN conduction. The interval between the His potential and ventricular depolarization (*V*) estimates the HPS conduction time (via the *RBB*). The P-R interval reflects predominantly the AV nodal conduction time.

Second-degree AVB occurs when some atrial impulses fail to reach the ventricles. Mobitz Type I second-degree AVB (Wenckebach) is characterized by progressive lengthening of the P-R interval before block. Wenckebach should always be suspected when "group beating" or a repetitive pattern is seen. The classic ECG pattern of Wenckebach consists of (1) progressive P-R prolongation before the block, (2) lesser degree of AV conduction delay with each cycle such that the R-R intervals are progressively decreasing before the block, (3) the first conducted beat following the block has a shorter P-R interval than that before the block (Fig. 19-9). The level of block for Type I second-degree AVB with a normal QRS complex is almost always at the level of the AV node. Mobitz Type II second-degree AVB occurs when AV conduction intermittently fails without a preceding change in P-R intervals, which is most often caused by disease within the HPS. The Mobitz Type II second-degree AVB is usually associated with a wide QRS and bundle branch pattern. Narrow QRS complexes during the conducted beats suggest the block is above the His bundle level, whereas a wide QRS complex during conducted beats suggests a block below the His bundle (infra-His) and is associated with a high-risk of progressing to CHB.

Differentiation between Type I and Type II second-degree AVB is usually straightforward except in the case of 2:1 AVB. The site of AV conduction block may be suggested by the width of the escape rhythm (Table 19-1). If the escape rhythm has a narrow QRS complex and occurs at a rate of 40–60 beats/min, block within the AV node is likely. If the QRS is wide and the rate is less than 40 beats/min, block usually is distal to the His bundle, although considerable overlap is seen. The response of AV conduction to various maneuvers or drugs may also assist in differentiating the site of block (Table 19-2). Exercise, atropine, and isoproteronol improve AV node conduction whereas vagal stimulation decreases AV node

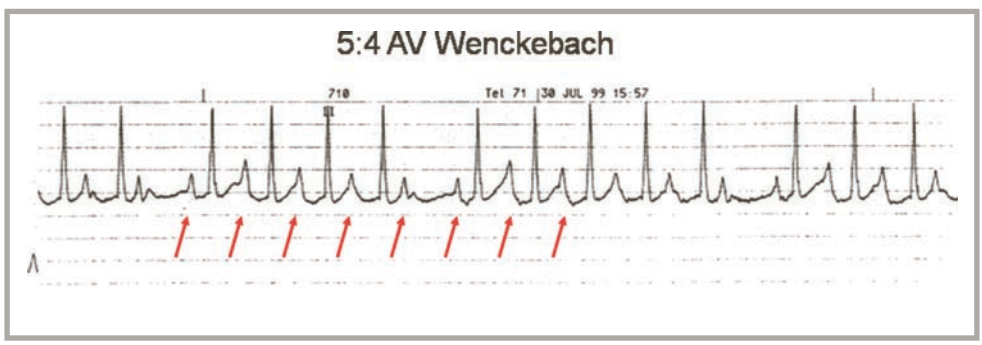

FIGURE 19-9

Mobitz type I, second-degree AV block (AVB) (Wenckebach) during sinus tachycardia (ST) (*arrows*) at a rate of approximately 125 bpm. There is a progressive lengthening of the P-R interval until a QRS complex is dropped. The conduction ratio is 5:4. That is, there are five P waves for four QRS complexes in the Wenckebach cycle.

TABLE 19-1

AV CONDUCTION ABNORMALITIES

ECG	SITE OF BLOCK
First-degree AVB	AVN>>HPS
Second-degree AVB	
Type I-normal QRS	AVN>>>HPS
Type I-wide QRS	AVN>HPS
Type II-normal QRS	HPS≥AVN
Type II-wide QRS	HPS>>>AVN
2:1-normal QRS	HPS≥AVN
2:1-wide QRS	HPS>>AVN
Third-degree AVB	
Normal QRS	HPS≥AVN
Wide QRS	HPS>>AVN

AVN AV node
HPS His-Purkinje system

TABLE 19-2

DIFFERENTIATING THE SITE OF CONDUCTION BLOCK

	AV NODE	INFRA-NODAL
QRS	Narrow	Wide
P-R interval	>0.26	0.26
Wenckebach pattern	Yes	No
Exercise	Improve	Worsen
Atropine	Improve	Worsen

Isoproterenol	Improve	????

conduction. So if exercise, atropine, or isoproterenol improves conduction, the site of block is likely to be the AV node and vice versa for block below the AV node. If vagal maneuvers, such as carotid sinus pressure, worsen AV conduction, the site of block is likely the AV node. Improvement in AV conduction after vagal maneuvers may suggest infra-nodal conduction disease.

Third-degree AVB, also known as CHB, occurs when there is a complete failure of conduction between the atria and the ventricles, with dissociation between the atrial and ventricular depolarizations (Fig. 19-10). CHB is most commonly found in the later decades of life, with 80% of cases presenting after the age of 50, mostly in the presence of structural heart disease, such as age-related fibro-degeneration of the conduction system, surgical trauma, or infarction (particularly anterior myocardial infarction). The escape rhythm often originates below the site of conduction block (usually infra-nodal) and is associated with a slower rate, wide QRS and unlikely to respond to autonomic manipulations. Clinical distinction between atrioventricular dissociation (AVD) and CHB should be appreciated. Although A-V dissociation is present in both conditions, the ventricular rate is faster than the atrial rate in AVD; the anterograde conduction is thus physiologically not possible (such as VT). In CHB, the atrial rate is faster than the ventricular rate; AV dissociation is due to a failure of anterograde conduction.

Management of patients with AVB is usually straightforward. Asymptomatic first-degree AVB and type I second-degree AVB require no specific treatment. Type II second-degree AVB or third-degree AVB associated with active transient problems usually resolve as the underlying problem improves. Such patients may be observed carefully without immediate intervention if a hemodynamically stable and a narrow QRS escape rhythm is present. Symptomatic patients and patients with a wide QRS complex and a slow escape rhythm require immediate attention. If the level of block is at the AV node, IV atropine and isoproterenol infusion may be useful. Transvenous pacing may be required if the site of block is below the AV. Atropine should not be used in the setting of acute myocardial infarction.

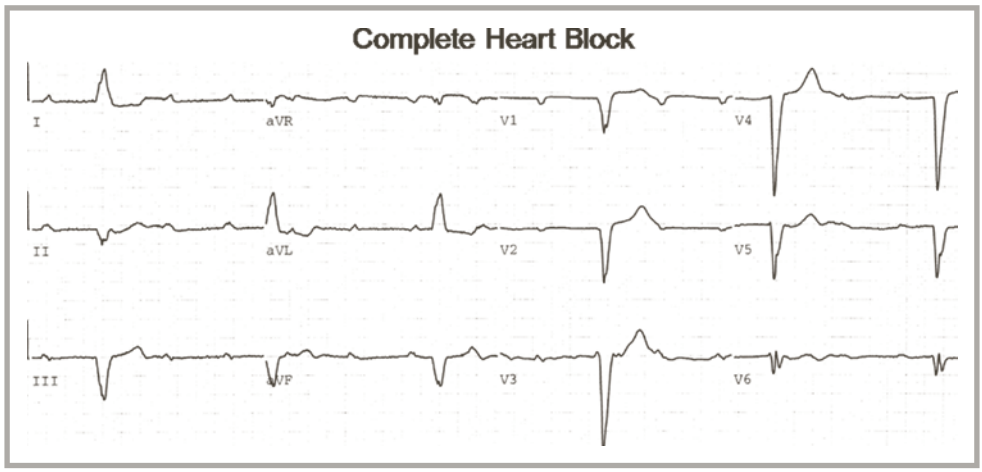

FIGURE 19-10

Third-degree (complete) heart block. The tracing shows sinus rhythm with complete heart block (CHB) with a slow ventricular escape rhythm (wide QRS complexes). Note that the P waves march through the tracing without any association to the QRS complexes. This implies the site of conduction block is at the infra-His level.

Tachycardia

The width of the QRS complex reflects the depolarization time across the ventricles. A narrow (<120 ms) QRS complex suggests a normal ventricular activation via the AV conduction system, whereas a wide QRS (>120 ms) complex implies an abnormal, delayed ventricular depolarization. A narrow QRS complex tachycardia can also be considered a SVT, because the arrhythmia focus/circuit originates above the level of the ventricle. A WCT reflects either a SVT with abnormal aberrant conduction, or a primary ventricular tachycardia (VT), in which the focus/circuit originates in the ventricle or Purkinje fibers.

Sinus Tachycardia

ST in the adult is defined as a sinus rate greater than 100 bpm. The maximal sinus rate is age-dependent but the relationship may not be a linear one. The age-related physiologic maximum heart rate (MHR) can be easily approximated at about 220 bpm minus the age. ST is probably the most commonly encountered arrhythmia in the ICU setting. In the majority of cases, it is an appropriate response to vagal withdrawal with an underlying stimulus such as pain, fever, anemia, respiratory insufficiency, low cardiac output, or hypotension. It is critical to determine and direct therapy at the underlying causes.

The physiologic MHR is age-dependent:
MHR>220-Age,
or MHR>206 − (0.69×Age)

Rarely, "inappropriate" sinus tachycardia (IST) can be observed. This is a primary rhythm disorder caused by an appropriate sinus node response with an enhanced autonomic sensitivity. IST is commonly associated with postural orthostatic tachycardia syndrome (POTS), vasovagal syncope, or other forms of autonomic disorders. Symptomatic control with pharmacologic therapy can be difficult and catheter ablation is usually not indicated.

Atrial Tachycardia

An AT is characterized by an ectopic atrial activation with a uniform abnormal P-wave morphology. It is an "AV node-independent" tachycardia, in which the focus/circuit is located above the level of the AV node. Variable AV conduction or R-R intervals can occur. ATs may be caused by enhanced focal automaticity or reentry. A reentrant AT is commonly associated with underlying structural heart disease, particularly in patients with congenital heart disease or prior cardiac surgeries. A focal tachycardia is often seen in patients with pulmonary hypertension, valvular cardiomyopathy, digitalis toxicity, hypokalemia, amphetamine ingestion, acute alcohol ingestion, and hypoxia. However, it may be observed in patients with apparently normal hearts. Unlike reentrant rhythms, automatic AT cannot be initiated or terminated by premature beats. This arrhythmia typically appears to "warm-up" on its initiation, increasing its rate after the first several beats.

Digitalis increases automaticity within the atria and slows conduction in the AV node; thus, when AVB occurs in the setting of ATs, digitalis toxicity should be suspected.

Multifocal Atrial Tachycardia

MAT is usually seen in the setting of severe pulmonary disease. The treatment is directed toward improving the underlying pulmonary status or correcting other potential causes.

A multifocal atrial tachycardia (MAT) is described as an irregular AT in which ectopic atrial depolarizations originate from multiple foci. At least three distinctly different P wave morphologies are present with varying P-R and R-R intervals (Fig. 19-11). MAT is commonly seen in the setting of severe pulmonary disease, and may precede the development of AF. Treatment is directed at improving the underlying pulmonary status. If slowing of the ventricular rate is desired, verapamil may be of some benefit. Beta-blockers are generally avoided because of the risk of bronchospasm. Digitalis should be avoided as it is unlikely to be of any benefit and exposes the patient to the risk of toxicity. This arrhythmia is also termed wandering atrial pacemaker (WAP) when the heart rate is less than 100 bpm.

Atrial Fibrillation and Atrial Flutter

AF is the most frequently encountered arrhythmia. The prevalence of AF increases with advancing age, occurring commonly in elderly (>60 years of age) population. AF usually develops in patients with structural heart disease, such as mitral valvular disease, pericarditis, ventricular dysfunction/heart failure, hypertension, pulmonary disease, or early after cardiac surgery. AF is also often associated with the Wolf–Parkinson–White (WPW) syndrome, thyrotoxicosis, and alcohol intoxication.

AF is caused by multiple random wavelets of reentry circulating within atrial tissue. It may be triggered by focal ectopy originating from one of the pulmonary veins. Atrial fibrillatory activities appear on the ECG as coarse or fine irregular baseline undulations, and the refractory period and conductivity of the AV node determine the ventricular rate response. The ventricular rate response generally ranges from 130 to 200 bpm, and is characterized by irregularly irregular R-R intervals. The QRS complexes during AF are usually narrow unless aberration occurs. Aberration is a common finding after a long–short cycle (Ashman's phenomenon) as the refractory periods of the conduction system have not yet recovered (Fig. 19-12).

During AF, hemodynamic deterioration with severe symptoms may result from (1) the loss of coordinated atrial contraction (atrial kick) to ventricular filling, (2) rapid ventricular

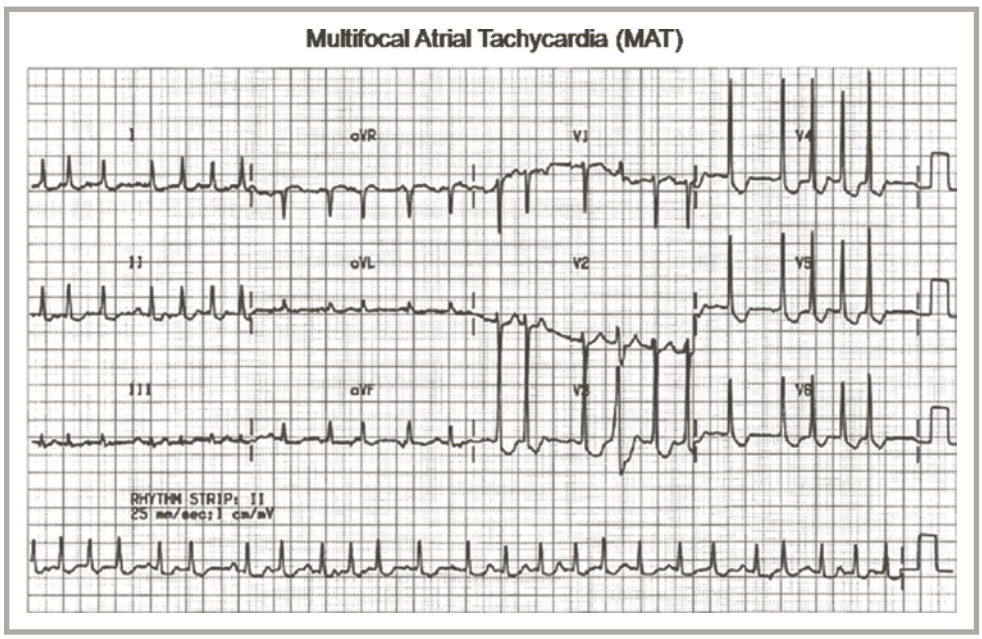

FIGURE 19-11

Multifocal atrial tachycardia (MAT) is characterized by an irregular atrial tachycardia (AT) with ectopic atrial depolarizations from multiple foci. At least three distinctly different P wave morphologies are required with varying R-R intervals.

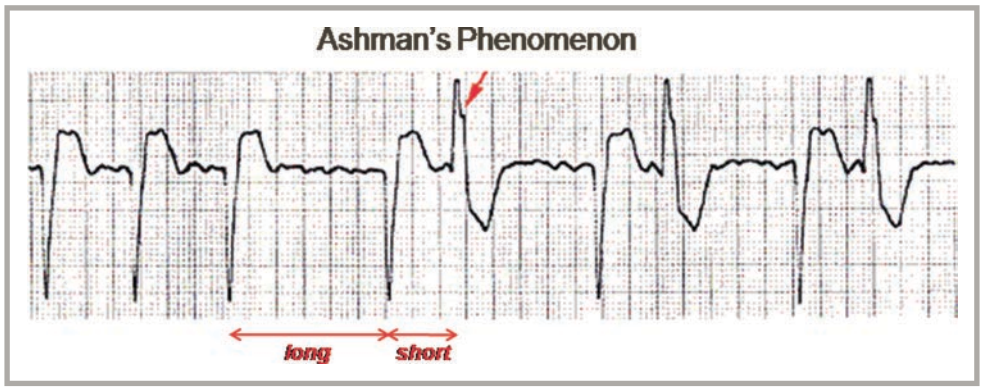

FIGURE 19-12

Ashman's phenomenon describes an aberration of a complex that represents a normal physiologic response. It is commonly observed during atrial fibrillation with widely variable R-R intervals. A wide QRS complex (*arrow*) is usually seen when a long cycle is followed by a short cycle, as the refractory periods of the conduction system have not yet recovered.

rate response, (3) irregular R-R intervals with impaired diastolic filling, and (4) tachycardia-induced cardiomyopathy. AF may be an independent risk factor for mortality and sudden death. AF greater than 48 h in duration predisposes the development of thrombus, particularly in the left atrial appendage. It constitutes a major independent risk factor for stroke and is associated with a three to fivefold increased risk of systemic embolism, especially in patients with valvular heart disease (up to 15-fold increased risk).

In addition, AF is a progressive and self-perpetuating disease. Electrical remodeling induces physiologic and anatomic changes with atrial dilatation, myofibril disarray and fibrosis, and shortening of atrial refractory period. The phenomenon of "AF begets AF" has been well demonstrated in both humans and animal models.[3,4] Without intervention, prolongation of arrhythmia episode duration and development of permanent AF are to be expected. It is therefore imperative to identify the presence of AF and institute therapy early for effective arrhythmia control.

Atrial flutter (AFL) typically occurs in patients with structural heart disease. It may also be seen in the setting of acute pulmonary embolus, hyperthyroidism, pericarditis, and repaired congenital heart disease and in the early days following open heart surgery. "Typical" AFL originates from a macro reentrant circuit within the right atrium in which the impulse travels counterclockwise down the right atrial free wall and up the intraatrial septum.[5] The arrhythmia utilizes the cavo-tricuspid isthmus as the zone of slow conduction and is termed "isthmus-dependent." The ECG characteristically shows negative saw-tooth flutter waves in the inferior leads (II, III, and aVF) and sharply peaked flutter waves in lead V1 (Fig. 19-13). Occasionally, a clockwise reentry involving the cavo-tricuspid isthmus may occur. Untreated, the atrial rate usually ranges from 250 to 350 bpm, with 2:1 AV conduction, giving a regular ventricular rate at approximately 150 bpm. The diagnosis of AFL should always be suspected when a narrow QRS tachycardia at 150 bpm is seen. "Atypical" AFL describes a "nonisthmus dependent" reentrant AT, often originates from reentry circuit(s) in other parts of the atria (such as mitral valve annulus, atrial appendage, surgical scar).

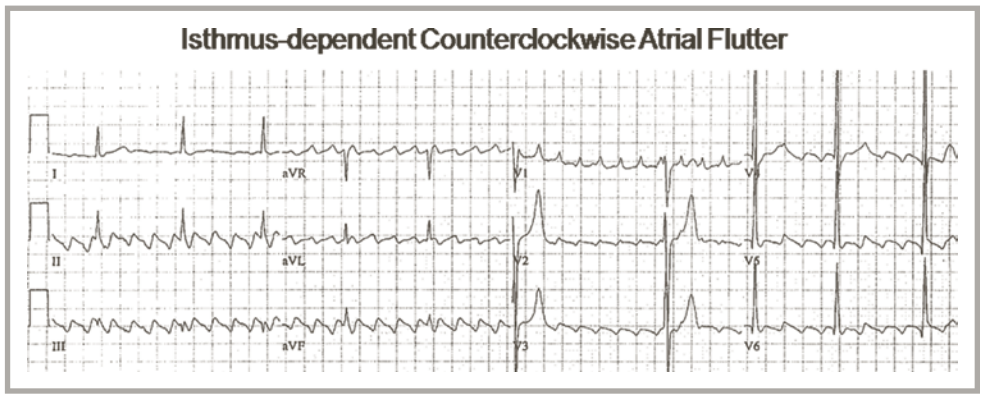

FIGURE 19-13

"Typical" atrial flutter (AFL) with the classic "saw-tooth" flutter waves in the inferior leads. Variable AVB is noted with 4:1–7:1 conductions. The "flutter waves" are characteristically positive in lead V1 and negative in lateral precordial leads, at approximately 300 bpm.

Higher-degree blocks or variable AVB often occur. If the AV conduction ratio varies, the ventricular rhythm will be irregular. Accentuating AVB by vagal manipulation or pharmacologic blockade (Adenosine) may aid in the diagnosis because flutter waves often become better visualized with a slower ventricular rate. A bradycardic ventricular response during AF or AFL, in the absence of drugs, suggests disease of the AV conduction system and may be associated with SND. Postconversion bradycardia or pause may be expected in such patient.

In unstable patients with AF or flutter, emergent cardioversion is needed. In stable patients with flutter or fibrillation, the goals of treatment are to (1) control ventricular rate, (2) restore sinus rhythm, and (3) prevent thromboembolic complications.

In hemodynamically stable patients with AF or flutter, the initial goals of treatment are to (1) control the ventricular rate, (2) restore and maintain sinus rhythm, and (3) prevent thromboembolic complications. AV nodal blocking agents (beta-blockers and calcium channel blockers) should be used preferentially for acute control of the ventricular rate, whereas digitalis should be reserved for rate control in chronic AF. Intravenous calcium channel blocker (diltiazem) or beta-blocker (esmolol or labetalol) can be titrated safely to quickly achieve rate control before switching to oral agents. In unstable patients with rapid atrial tachyarrhythmias, such as patients with aortic/mitral stenosis, diastolic dysfunction, or active ischemia, emergent synchronized direct current (DC) cardioversion is required.

Pharmacologic conversion to sinus rhythm may be achieved using the Vaughan Williams class 1 or class 3 agents (membrane active drugs). Intravenous and oral amiodarone is the most commonly used agent for chemical conversion. Amiodarone can also be used for rate control during AF/AFL where patients are intolerant to calcium channel blockers or beta-blockers. Ibutilide, a new class III antiarrhythmic agent, is effective in rapidly terminating AF and flutter. The efficacy is higher for AFL than fibrillation (63 vs. 31%), especially in patients with a shorter duration of arrhythmia and a normal left atrial size. The major side effect is polymorphic ventricular tachycardia (*torsade de pointes*). It may be considered as an alternative to electrical cardioversion under monitored condition.

Additionally, typical AFL may be terminated by right atrial overdrive pacing whereas atypical AFL and AF are refractory to pacing intervention. Antiarrhythmic drug therapy may be necessary for successful electrical cardioversion or maintenance of sinus rhythm after cardioversion. In patients with chronic, refractory AF or AFL and an uncontrollable ventricular response, radiofrequency (RF) catheter ablation of the AV junction followed by permanent pacemaker insertion can be very effective.

In patients with recurrent, paroxysmal atrial arrhythmias (both AF and AFL), as well as in those with sustained arrhythmia episodes of greater than 48–72 h duration, anticoagulation is recommended to reduce the risk of thromboembolic complications unless specific contraindications are present. A therapeutic anticoagulation (INR 2–3) for 3–4 weeks before and 3–4 weeks after pharmacologic or electrical cardioversion is recommended. A transesophageal echocardiography (TEE) may be used to exclude the presence of left atrial thrombi. "Lone AF" describes AF occurring in young (<60 years old) individuals with structurally normal hearts. These patients are at lower risk for thromboembolic complications and may therefore be safely treated with aspirin alone.

Supraventricular Tachycardias

Differential diagnosis of SVT

AV nodal-dependent:

1. AV nodal reentrant tachycardia (AVNRT).
2. Orthodromic AV reciprocating tachycardia (AVRT) using a bypass tract.

AV nodal-independent:

1. Ectopic atrial tachycardia.
2. Atrial flutter/fibrillation.

SVTs include tachycardias caused by AV nodal reentry tachycardia (AVNRT), orthodromic AV reciprocating tachycardia (AVRT) utilizing an AV bypass tract, and AT.[6] Clinically, SVT can be differentiated into "AV node-dependent" or "AV node-independent" arrhythmias (Fig. 19-14 and Table 19-3). AV node-dependent SVT utilize the AV node as a critical part of the circuit. Interruption of impulse propagation through the AV node (AVB) terminates these reentrant arrhythmias. The prototypes of AV node-dependent arrhythmias include AV nodal reentry (AVNRT) and AVRT utilizing a bypass tract. In AV node-independent SVTs, the arrhythmia substrates are located above the AV node that functions as a bystander during tachycardias. These include all forms of atrial tachyarrhythmias, such as AT, AF or AFL.

AVNRT is the most common form of reentrant narrow complex SVT. AVNRT can occur at any age and is usually unrelated to structural heart disease. The rate is variable but usually ranges from 180 to 200 bpm and should be suspected when there is abrupt onset

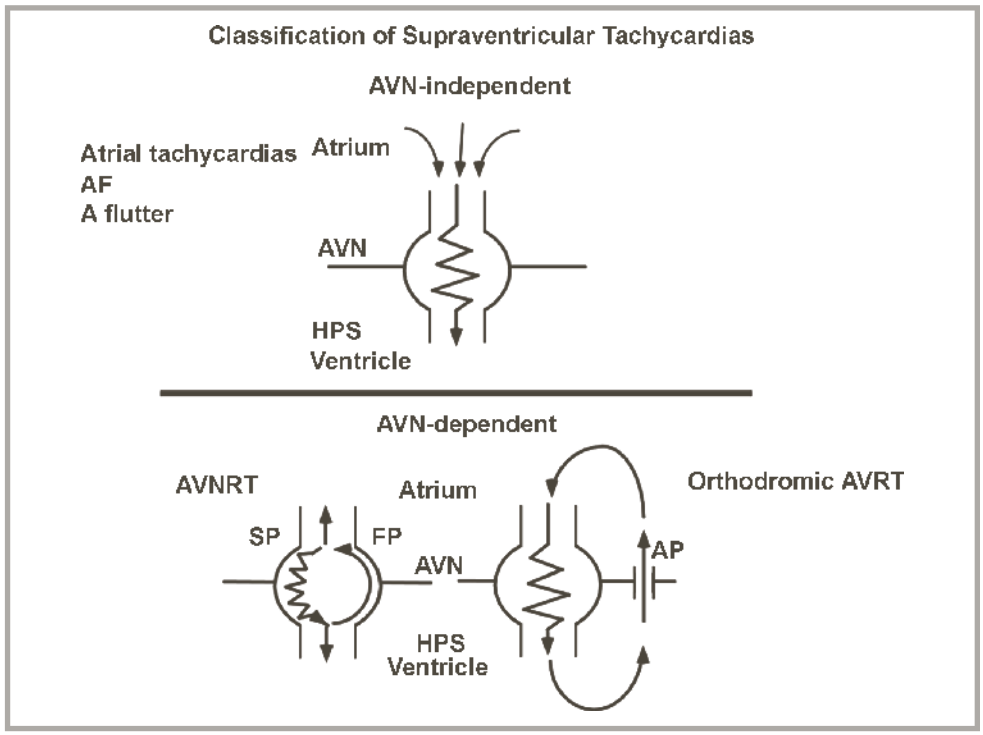

FIGURE 19-14

Mechanistically, reentrant supraventricular tachycardias (SVTs) can be classified into "AV node-dependent" or "AV node-independent" arrhythmias. AV node-dependent SVT utilize the AV node as a critical part of the circuit, and interruption of impulse propagation at the AV node terminates arrhythmias. These include AV nodal reentry (AVNRT) and AV reciprocating tachycardia (AVRT) utilizing a bypass tract. In AV node-independent SVTs, the arrhythmia substrate is located above the AV node. These include all forms of atrial tachyarrhythmias. (SP, slow pathway; FP, fast pathway; AP; accessory pathway; HPS, His-Purkinje system; AVN, AV node).

TABLE 19-3

MECHANISTIC CLASSIFICATION OF SVTs

AV nodal-dependent:
AVN is a part of the circuit and is critical in the maintenance of the SVT. Impulse conduction block at the AVN causes termination of SVT
AV nodal reentrant tachycardia (AVNRT)
Orthodromic AV reentrant tachycardia (AVRT) using a bypass tract
AV nodal-independent:
AVN is a not part of the circuit and the SVT mechanism is located above the AVN
AT Atrial tachycardia (AT)
AFL Atrial Flutter (AFL)
AF Atrial Fibrilation (AF)

and termination. AVNRT is caused by reentry within the AV node along two functionally distinct pathways. Such "dual AV nodal pathway" physiology consists of a fast-conducting (beta) pathway that generally has a longer refractory period and a slower-conducting (alpha) pathway, which has a shorter refractory period (Fig. 19-15). Anterograde conduction normally occurs down the AV nodal fast pathway during sinus rhythm, but an atrial premature depolarization (APD) may find the fast pathway refractory and travel down the alternative slow pathway. If conduction in the slow pathway is sufficiently slow, the fast limb will recover excitability and reentry may occur. During this common/typical (slow–fast) form of AVNRT, retrograde conduction over the fast pathway depolarizes the atria at almost the same time that the impulse reaches and depolarizes the ventricles. The atria and ventricles are activated nearly simultaneously, resulting in an extremely short VA time. Occasionally, the anterograde conduction proceeds down a "slow" AV nodal pathway with the retrograde conduction up the "fast" AV nodal pathway, also called the uncommon/atypical form of "fast–slow" AVNRT.

The electrocardiographic characteristics of typical (common form) AVNRT are marked by a narrow complex, regular tachycardia with nearly simultaneous atria and ventricular activations and a very short VA (RP) interval (Fig. 19-16). The retrograde P wave is often buried within the QRS complex and thus invisible on the surface ECG. Occasionally, the P wave may be seen just prior to or after the end of the QRS, forming a pseudo-S or pseudo-R

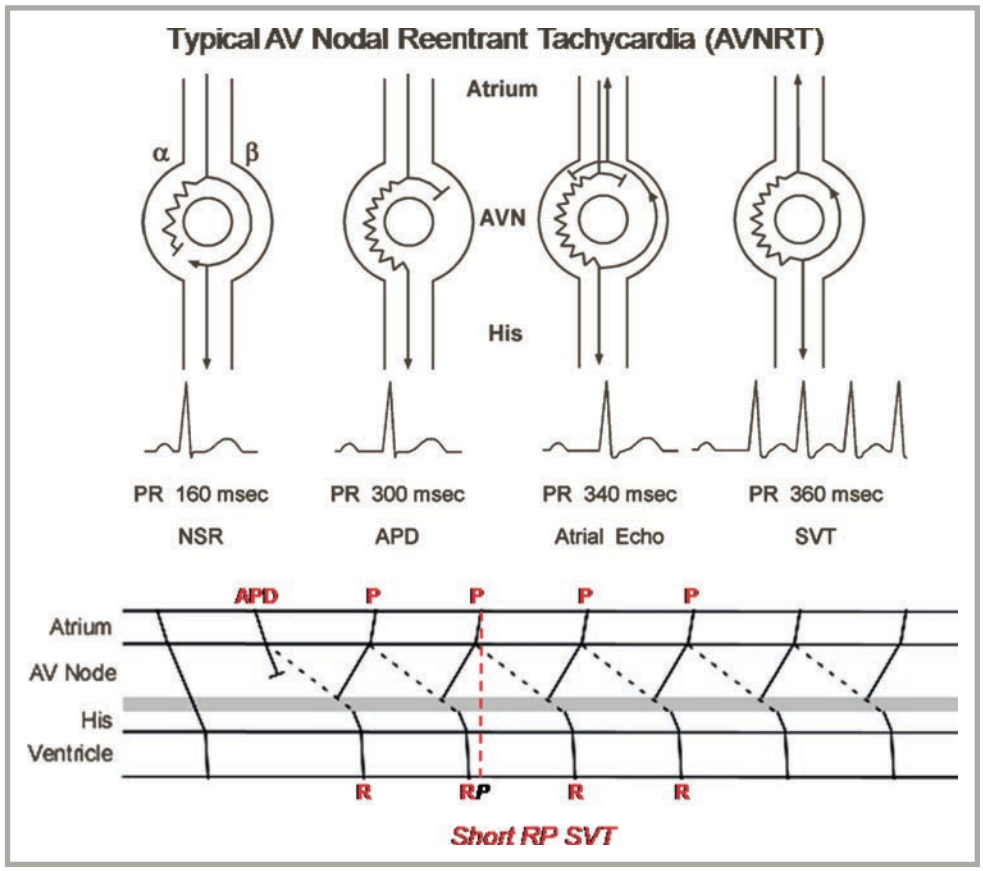

FIGURE 19-15

A graphic representation of the "typical" AV nodal reentry tachycardia (AVNRT). The AV node is schematically divided into dual AV nodal pathways that consist of a slowly conducting α-pathway and a rapidly conducting β-pathway. The refractory period of the β-pathway is usually longer than the α-pathway. During normal sinus rhythm, the impulse preferentially conducts over the β-pathway. An atrial premature depolarization (APD) blocks at the β-pathway and travels down the slowly conducting α-pathway, resulting in a prolonged P-R interval. When a critical degree of slow conduction within the circuit is present (P-R interval reaches 340 ms), a single atrial echo results (single reentrant beat). Further slowing in the circuit may result in sustained reentry. The lower ladder diagram illustrates the RP relationship during AVNRT. During "typical" AVNRT, the impulse propagates down the slow AV nodal pathway and conducts retrograde up the fast AV nodal pathway. The atria and ventricles are activated nearly simultaneously in a "parallel" activation pattern, resulting in an extremely short VA time.

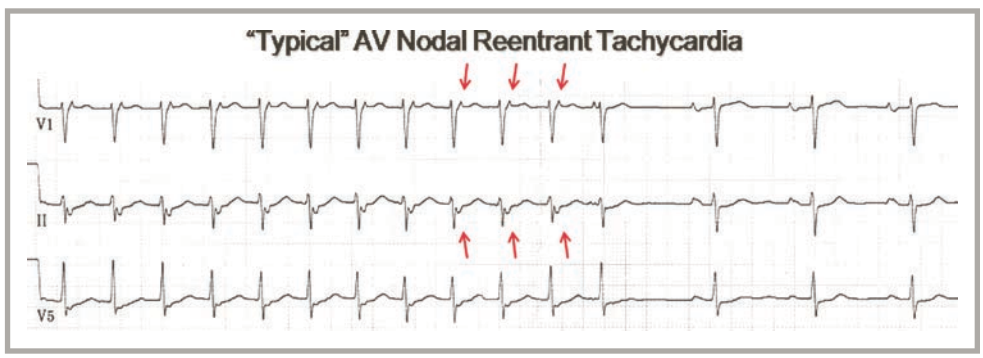

FIGURE 19-16

The ECG characteristics of typical AVNRT are marked by a narrow complex, regular tachycardia with nearly simultaneous atrial-ventricular activations and a very short VA (RP) interval. The retrograde P waves (*arrows*) can be seen as "pseudo-S waves" in the inferior leads Rsr′ patterns in lead V1.

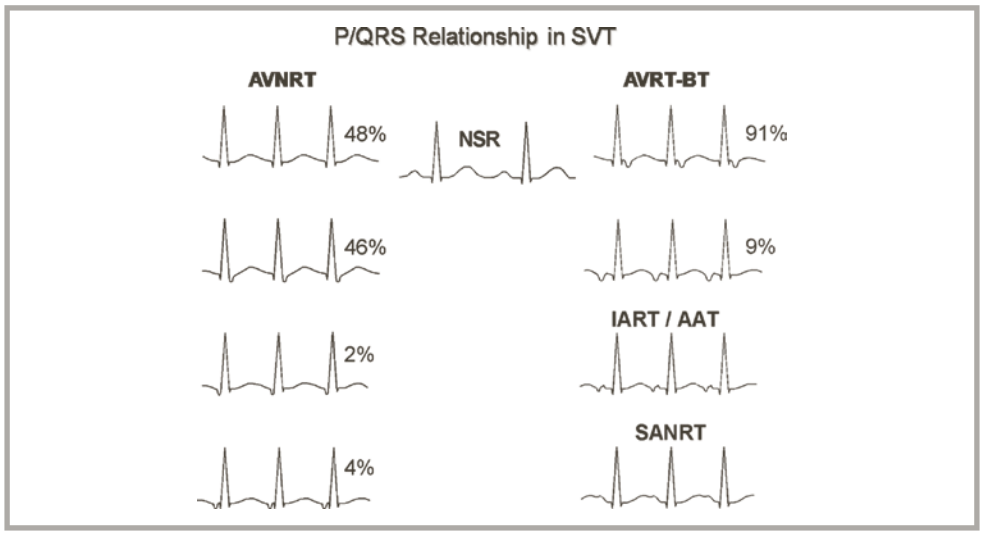

FIGURE 19-17

The P/QRS relationships in SVT are illustrated for normal sinus rhythm (NSR), AVNRT, AVRTs using retrogradely conducting AV bypass tracts (AVRT-BT), intraatrial reentry tachycardia (IART), automatic atrial tachycardias (AAT), and sinoatrial nodal reentry tachycardia (SANRT). The numbers represent relative incidences of these arrhythmias.

wave, best seen in the inferior leads or V1. Various P-QRS patterns are described for different types of SVTs (Fig. 19-17).[2]

Orthodromic AVRT utilizes an accessory AV pathway (bypass tract) as the retrograde limb and the normal AV conducting system as the anterograde limb of the macroreentrant circuit (Fig. 19-18). During orthodromic AVRT, the atria are activated only after the impulse traverses the ventricles and the retrograde limb of bypass tract. The P wave therefore must follow the QRS, producing an obligatory VA delay such that the R-P interval is often shorter than the P-R interval, with the retrograde P wave distinct from the QRS. In 10% of orthodromic AVRTs, the AV bypass tract conducts slowly, producing a long R-P and short P-R interval. The differential diagnosis of a long RP tachycardia includes the uncommon form of AVNRT, orthodromic AVRT utilizing a slowly conducting bypass tract, and AT (Fig. 19-19).[7]

Differential diagnosis of long RP tachycardias:
1. Atypical form of AVNRT.
2. Orthodromic AVRT utilizing a slowly conducting bypass tract.
3. Artrial tachycardia.
4. Incessant form of permanent AV junctional tachycardias (PJRT).

ATs are more commonly observed in elderly patients with structural heart disease. It is caused by either reentry or abnormal automaticity. ATs are "AV node-independent" and may demonstrate variable ratios of AVB, although 1:1 tachycardia can be seen. During ATs, the P waves may be seen anywhere among the QRS complexes. Sinus node reentry tachycardia (SNRT) and intraatrial reentry tachycardia (IART) are generally slower than other forms of SVT, with an average rate of 130–140 bpm. In SNRT, the P wave is very similar to the sinus rhythm P wave, whereas the P wave of IART is frequently bizarre and different.

Diagnostic Approach to Narrow Complex Tachycardias

The stepwise diagnostic approach to a narrow complex tachycardia is summarized (Fig. 19-20), (Table 19-4). First, the tachycardia should be classified as being regular vs. irregular. An irregular QRS during SVT suggests the presence of AF or an SVT with variable AVB. Second, it is important to identify the P waves. If no P wave is visible, the diagnosis of "typical" AVNRT is suspected, in which the P waves may be buried within the QRS complex. If P waves can be identified, we next determine the presence of heart block (atrial rate is greater than the ventricular rate). The presence of heart block suggests an "AV node-independent" mechanism, identifying the rhythm as being AF, AFL or AT. Lastly, the P wave timing during tachycardia is analyzed. The SVTs can be divided into "short RP" or "long RP" tachycardias relative to the P-R interval (Table 19-5). A short RP interval (VA time) of less than 70 ms is almost diagnostic of AVNRT, whereas an intermediate RP interval is more suggestive of an orthodromic AVRT utilizing a retrograde accessory pathway. A variable RP relationship during a tachycardia suggests a lack of temporal dependence of the QRS with the subsequent P

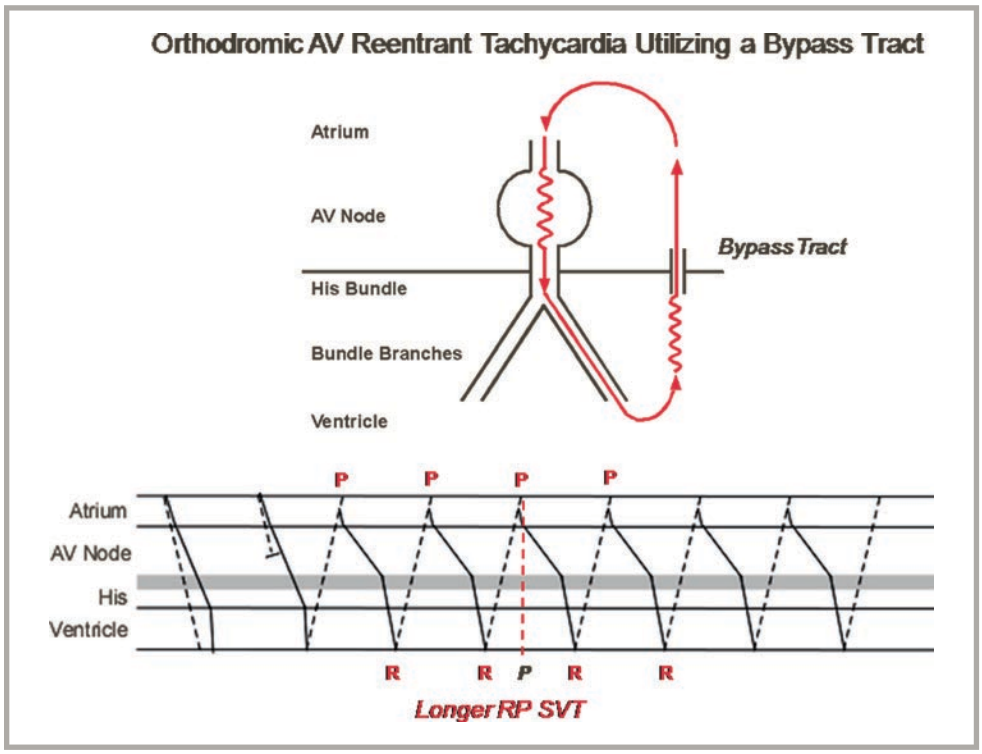

FIGURE 19-18

A graphic representation of orthodromic AVRT utilizing an AV bypass tract. The normal AV conduction system is depicted along with a left lateral bypass tract. Both atrium and ventricle are parts of the macroreentrant circuit during AVRT and are sequentially activated. AVB interrupts the reentry and terminates the arrhythmia. The lower ladder diagram illustrates the RP relationship during orthodromic AVRT. During AVRT, the impulse propagates down the AV node, activating the ventricles *before* conducting up the bypass tract for retrograde atrial activation. The atrium is thus activated *after* the ventricles in a "sequential" pattern, resulting in an obligatory longer VA time.

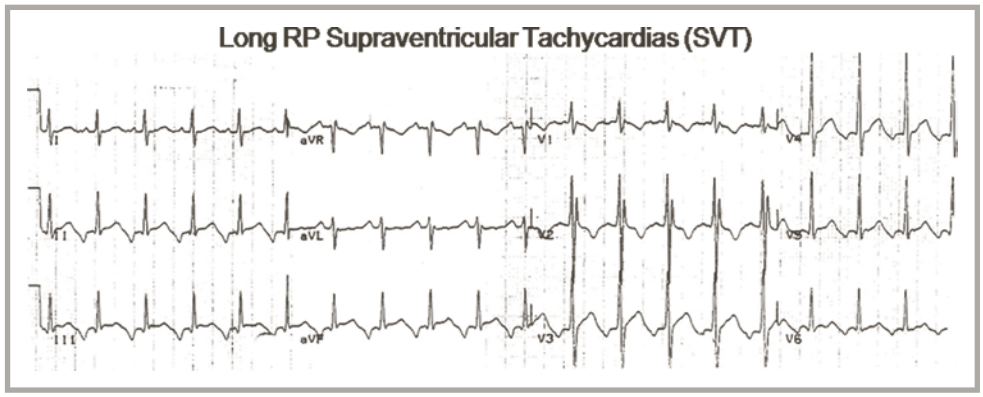

FIGURE 19-19

The differential diagnosis of long RP tachycardias includes (*1*) atypical, slow–fast form of AVNRT, (*2*) orthodromic AVRT utilizing a slowly conducting bypass tract, (*3*) atrial tachycardia, and (*4*) an incessant form of permanent AV junctional tachycardias (PJRT).

waves and favors the diagnosis of AT. During ATs, the RP and P-R relationships are highly variable since variable heart block can occur (P-R intervals) and there is no VA conduction during SVT (RP intervals). As discussed earlier, differential diagnosis of long RP tachycardia includes AT, atypical AVNRT, or orthodromic AVRT utilizing a slowly conducting retrograde accessory pathway.

4. P-waves during atrial tachycardia may be anywhere		

Observation of either spontaneous or induced AVB is critical for the diagnosis of SVT. The presence of AVB quickly distinguishes the arrhythmia into the "AV node-independent" (atrial arrhythmias) vs. the "AV node-dependent" (AVNRT, orthodromic AVRT) varieties. Vagal maneuvers such as Valsalva and CSM, or adenosine, are effective in inducing AVB that either terminates the SVT abruptly or slows ventricular response, which allows better identification of the underlying atrial activities. Orthodromic AVRT requires both atrial and ventricular components in a circuit; the presence of AVB during a persistent tachycardia

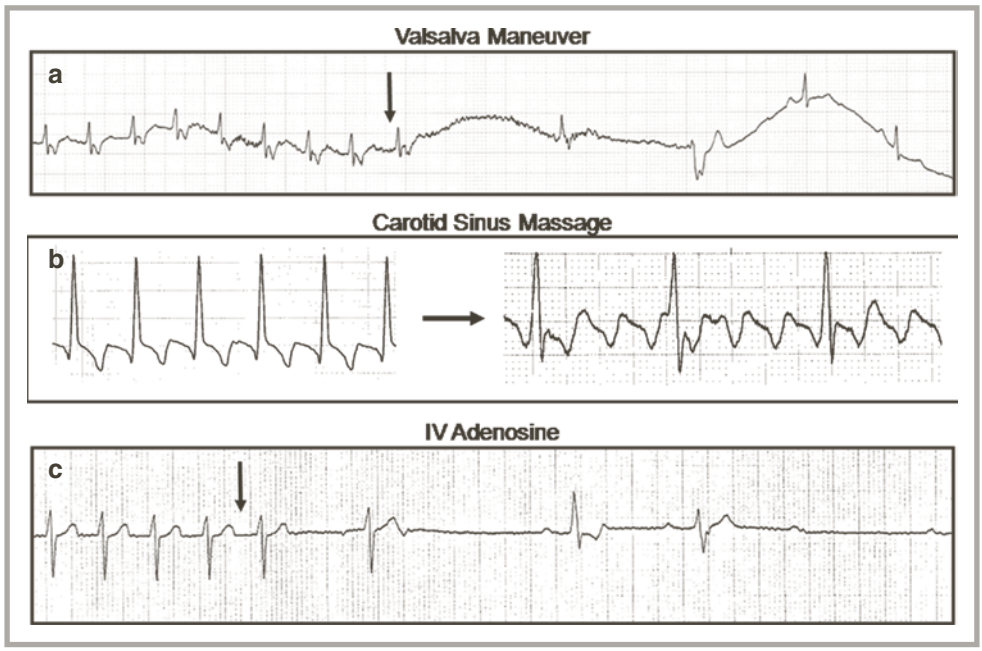

FIGURE 19-21

Various vagal maneuvers in SVT diagnosis include (**a**) Valsalva maneuver that abruptly terminates a short RP SVT after a retrograde P wave, at the AV node level. This is an "AV node-dependent" SVT most consistent with an orthodromic AVRT. (**b**) Carotid sinus massage (CSM) slows ventricular response during a SVT without termination. This allows better identification of the underlying atrial activities in AFL (AV node-independent). (**c**) Adenosine induces transient AVB and termination of "AV node-dependent" SVTs, although it may terminate some ATs that are sensitive to adenosine.

excludes this diagnosis. AVB during AVNRT is extremely unlikely, although rarely observed. The presence of AVB during a regular tachycardia strongly favors the diagnosis of AT (Fig. 19-21).

Finally, the mode of initiation and termination of the SVT also provides diagnostic information. An atrial premature beat can initiate or terminate AT, AVNRT, or orthodromic AVRT. A ventricular premature beat should have no effect on AT and is unlikely to affect AVNRT (small reentrant circuit within the AV node). However, ventricular premature beats can commonly initiate and terminate orthodromic AVRT.

Treatment is guided by the hemodynamic response to the SVT. Unstable patients require prompt electrical cardioversion. Relatively low energies (approximately 50 J) are usually sufficient to restore sinus rhythm. In stable patients, noninvasive vagal maneuvers or adenosine administration should be the first therapy of choice, as this often terminates arrhythmias that utilize the AV node as part of the reentrant circuit (AVNRT and AVRT) and may also slow and terminate ATs. Continuous electrocardiographic recordings should be available during these vagal maneuvers to document the responses.

If antiarrhythmic medications are required, class 1 and class 3 drugs are most useful. Automatic AT is notoriously difficult to treat, often even resistant to electrical cardioversion. If possible, therapy must be directed at the underlying cause. If digitalis toxicity is implicated, digitalis must be discontinued and hypokalemia corrected. RF catheter ablation may be required in management of drug-refractory SVTs.

Ventricular Tachycardia and Ventricular Fibrillation

Most ventricular tachycardia (VT) originates from reentry within the ventricular myocardium, which most often occurs in the setting of structural heart disease with abnormal anatomic substrate. In fact, more than 90% of patients presenting with sustained VT have underlying coronary artery disease (CAD). VT can also occur in patients with nonischemic cardiomyopathies, congenital and valvular heart diseases, long QT syndrome, and less commonly, in structurally normal hearts.[8]

Electrocardiographically, VT appears as a run of ventricular premature complexes with more than three consecutive beats at a rate in excess of 100 bpm. When the tachycardia lasts less than 30 s and is self-terminated, it is termed nonsustained VT (NSVT). It is considered a sustained episode if the tachycardia persists for longer than 30 s or requires intervention for

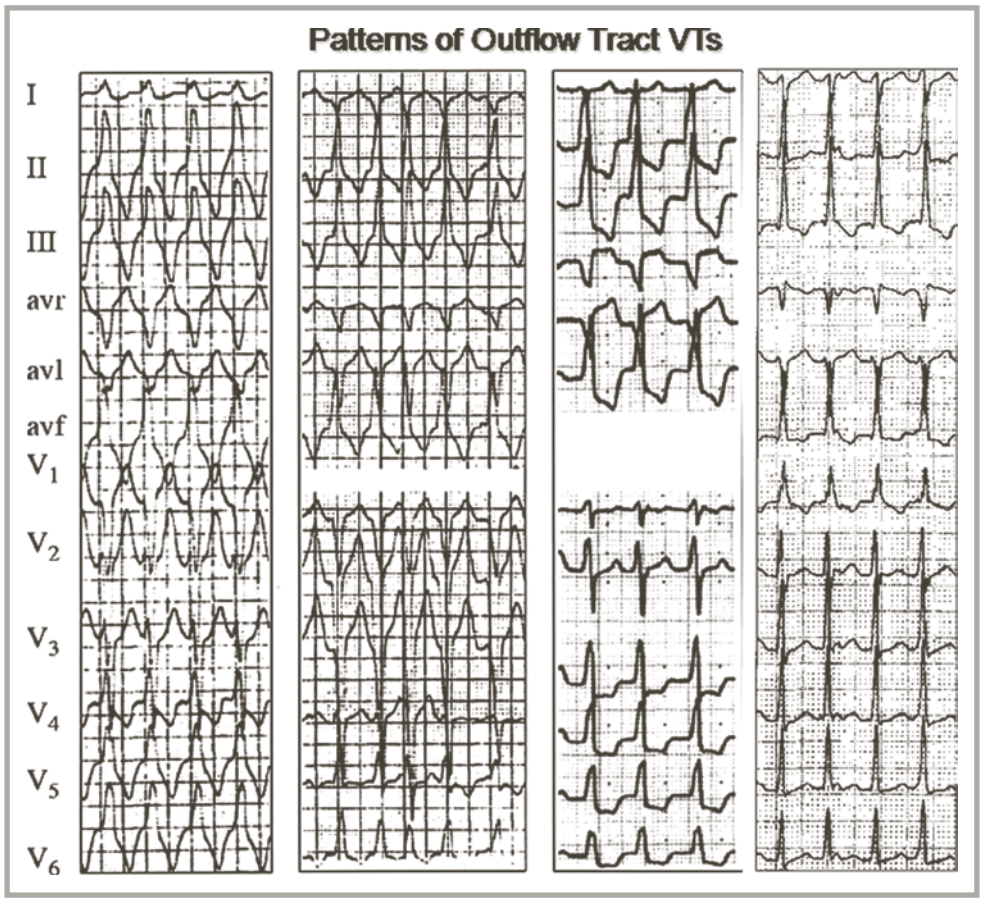

FIGURE 19-22

Electrocardiograpahic patterns of outflow tract VTs are characterized by (*1*) tall, rapid upstroke QRSs in the inferior leads, (*2*) negative avR and avL leads, and (*3*) prominent precordial R wave transition suggesting a basal site-of-origin. Either left bundle branch block (LBBB) or RBBB QRS pattern in V1 can be observed depending on whether the arrhythmia originates from right ventricular outflow tract (RVOT) or LVOT.

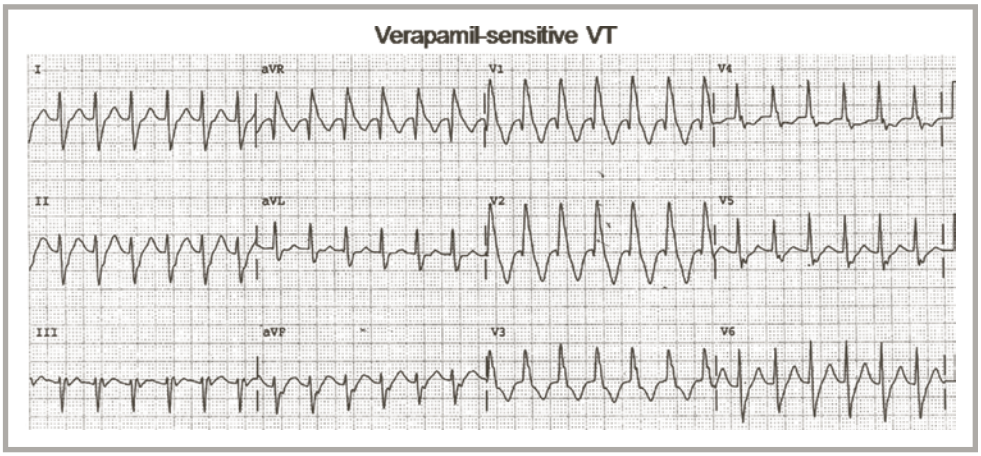
hemodynamic deterioration. This rhythm most often is regular, but irregularity may occur, particularly during nonsustained episodes. Ventricular activation independent of atrial activity (VA dissociation) is the hallmark of VT. However, retrograde atria activation (VA association) can be observed in up to 50% of cases. Thus, the presence of VA association does not exclude VT. "Monomorphic" refers to an arrhythmia with a single stable QRS morphology, whereas "polymorphic" VT has multiple and irregular QRS patterns. Monomorphic VT (MMVT) implies a "fixed" origin of ventricular activation, often associated with scar-based reentry or focal triggers. Polymorphic VT (PMVT) does not require a "fixed" anatomic substrate and is usually associated with long QT syndrome, drug toxicity, metabolic disorders, and active ischemia/infarction. PMVT is frequently faster than 200 bpm and may degenerate into VF. Sustained MMVT most commonly occurs in patients with prior myocardial infarction, caused by scar-based myocardial reentry with multiple morphologies.

Other forms of VTs include bundle branch reentry (BBR), VT from the ventricular outflow tracts, and fascicular VTs involving the Purkinje fibers. BBR VT typically occurs in patients with dilated, nonischemic cardiomyopathy and His-Purkinje conduction disease.[9] The reentry circuit consists of right and left bundle branches and intervening ventricular myocardium. One bundle branch serves as the anterograde limb and the other as the retrograde limb.[10-12] The ECG morphology is typically that of the left bundle branch block (LBBB) pattern. RF catheter ablation of the RBB is very effective in curing BBR VT.

Repetitive MMVT is generally associated with structurally normal hearts in young patients. They typically originate from either the right or left ventricular outflow tracts and present as frequent PVCs or nonsustained repetitive bursts. Although the risk of sudden death is low, symptomatic palpitations, dizziness, syncope, and ventricular dysfunction can result. The majority of these arrhythmias originates from the right ventricular outflow tract (RVOT), while LV outflow tract (LVOT) VTs account in up to 15–20% of the cases.[13]

FIGURE 19-23

The typical ECG patterns of the "verapamil-sensitive VT" originating from the left posterior fascicle near mid-inferior septum: (*1*) a right bundle branch block (RBBB) pattern, (*2*) a superiorly directed QRS axis, (*3*) relatively sharp QRS with rapid ventricular activations.



The outflow tract VTs are focal tachycardias due to abnormal automaticity or triggered activity. They are often exercise induced and catecholamine sensitive and thus tend to respond to beta-blocker therapy. Such arrhythmia typically has left bundle branch (LBBB) morphology with an inferior axis; however, right bundle branch block (RBBB) QRS VTs can occur with LVOT origins (Fig. 19-22).[14]

Fascicular VT describes an idiopathic form of reentrant VT that generally originates from the inferior left ventricular septum producing a QRS pattern of RBBB with left axis deviation (Fig. 19-23). The mechanism is postulated to be reentry involving the Purkinje network or various fascicles (particularly the left posterior fascicle). This form of VT is also frequently observed in young people with structurally normal hearts and usually responds to verapamil, thus being termed "verapamil-sensitive VT."[15,16] RF catheter ablation is an effective therapeutic option for treatment of both outflow tract VTs or fascicular VT and is associated with a good success rate.

VF is characterized by extremely rapid (>300 bpm) erratic ventricular depolarizations. VF is a self-sustaining rhythm based on multiple wavelets of random reentry within a critical mass of myocardium. VF usually develops from sustained monomorphic or PMVT; however, it may also occur during acute myocardial ischemia, metabolic derangement, or drug toxicity. Immediate hemodynamic collapse ensues and if untreated, death quickly follows. Because the defibrillation efficacy is negatively correlated to the duration of VF, emergent DC defibrillation and advanced cardiac life support (ACLS) is critical to terminate this potentially lethal arrhythmia.

The ability of VT to cause hemodynamic deterioration is related to the tachycardia rate, abnormal ventricular contraction pattern, and the underlying cardiovascular compensatory conditioning of the patient. Hemodynamically poorly tolerated WCTs, regardless of cause, require prompt DC cardioversion. Sustained VT that does not cause hemodynamic compromise may be treated with a variety of pharmacologic agents, including IV lidocaine, procainamide, and amiodarone. Lidocaine, however, is often ineffective outside the setting of acute cardiac ischemia. Because beta-blockers have been shown to raise the VF threshold and antagonize the catecholamines that trigger arrhythmia recurrences, it may be an effective adjunct in preventing the recurrence of VT or VF.

Preexcitation Syndrome

Preexcitation refers to ventricular excitation that occurs earlier than would be expected if the atrial impulse had traveled exclusively down the normal AV conduction system.[17] Preexcitation of the ventricles may occur via one of several anatomic connections, known as accessory pathways (AP) or bypass tracts. The bypass tracts/accessory pathways can exist between the atria and ventricles (AV, the Kent bundle), the atria and Purkinje system (atrio-fascicular), the

CASE STUDY: PART 1

A 24-year-old man was referred for evaluation of symptomatic tachycardia. He first noted onset of paroxysmal palpitations at age 16. These episodes occurred mostly with exercise or stress, and could be terminated with Valsalva maneuvers. He had atypical chest pain, rapid palpitations, visual disturbances, and mild lightheadedness without dyspnea. He had a normal stress echocardiogram without inducible arrhythmia. A baseline 12-lead electrocardiogram is shown in case study image 1. An ambulatory Holter monitor recording is shown in case study image 2.

What are the differential diagnoses?

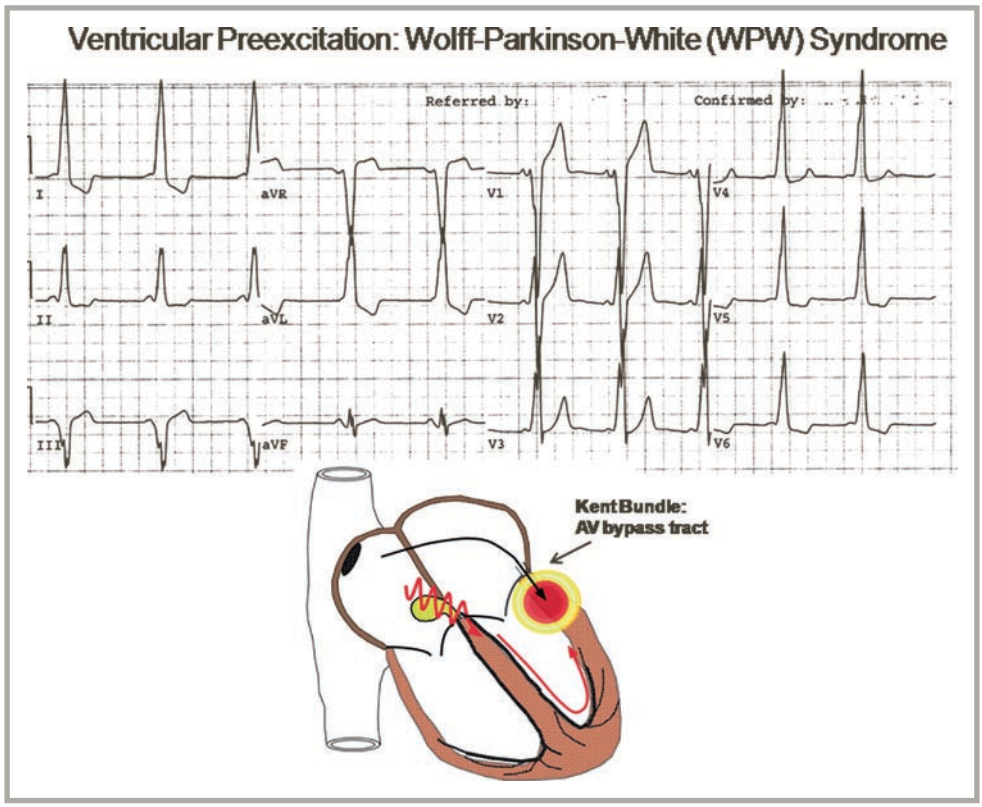
FIGURE 19-24

Wolff-Parkinson-White (WPW) syndrome. The ventricular activation occurs over both the normal AV node-HPS and an AV bypass tract (Kent bundle). Anterograde conduction over the bypass tract preexcites the ventricular myocardium. The hallmarks of WPW preexcitation include (*1*) short P-R, (*2*) abnormally wide QRS with delta wave, and (*3*) repolarization abnormalities.



AV node and Purkinje fibers (nodo-fascicular), the AV node and ventricles (nodo-ventricular), and between the Purkinje system and the ventricles (fasciculo-ventricular). The latter four forms of accessory pathways are collectively called Mahaim fibers.[18,19]

The WPW syndrome is the classic form of preexcitation, caused by the congenital abnormal presence of an accessory pathway (bundle of Kent) between the atria and the ventricles. The prevalence of WPW syndrome is estimated at between 0.1 and 0.4%. Rarely, multiple bypass tracts may exist in the same patient. The classic ECG findings include (1) a short P-R interval (<0.12 s), (2) a wide QRS complex (>0.12 s) with slurring of the initial upstroke of the QRS (delta wave), and (3) abnormal repolarization (T waves) (Fig. 19-24).

The delta wave represents a fusion of ventricular depolarizations, and the degree of preexcitation is dependent on the relative contributions of impulse conduction over the accessory pathway(s) vs. the normal AV conducting system.[20] Greater contribution by the accessory pathway results in wider delta waves. WPW syndrome has been associated with other forms of congenital heart disease such as Ebstein's anomaly and atrial septal defect, as well as mitral valve prolapse.

The clinical significance of the WPW syndrome is related to its associated arrhythmias. Orthodromic AVRT is the most prevalent arrhythmia associated with the WPW syndrome (see SVTs). AF is less common but potentially more dangerous in preexcitation syndrome. AF may be precipitated by orthodromic AVRT. During AF, the rapid atrial impulses may conduct over the accessory pathway and result in extremely rapid ventricular rate response (up to 300 bpm). The "preexcited" AF can precipitate significant hemodynamic decline (Fig. 19-25), and degeneration into VF may also occur. Electrocardiographically, AF in the WPW syndrome is characterized by a rapid, irregular, "preexcited" WCT that may be indistinguishable from PMVT/VF. Antidromic AVRT accounts for less than 5% of cases in which the accessory pathway is the anterograde limb and the AV node-HPS is the retrograde limb of the reentrant circuit.[21] Ventricular activation during antidromic AVRT occurs exclusively over the bypass tract and is characteristically marked by bizarre, wide, complex tachycardia that is indistinguishable from VT. AFL occurs rarely but can be a significant problem if 1:1 conduction over the accessory pathway results.

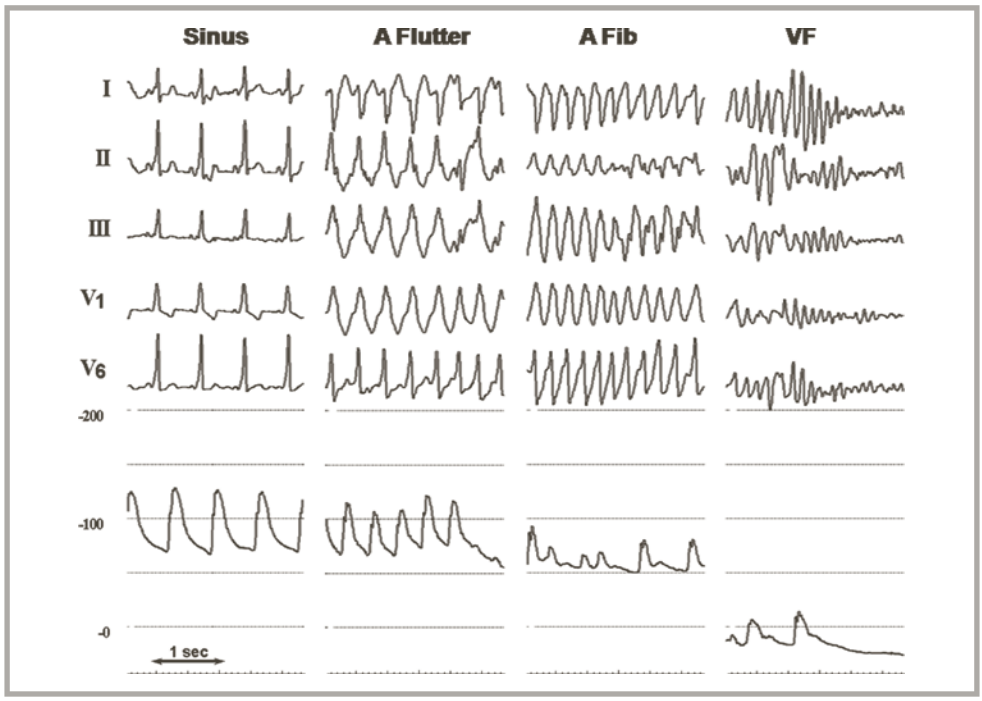


FIGURE 19-25

Risk of sudden death in a patient with WPW. Surface ECG (leads I, II, III, V1, and V6) and arterial blood pressure recordings from a patient with WPW syndrome are displayed. Note the short P-R interval and slurred upstroke of the QRS complex (delta wave) during sinus rhythm. A relatively regular wide complex tachycardia (WCT) is observed during AFL. Rapid AV conduction over the accessory pathway occurs during preexcited AF that resembles polymorphic VT (PMVT). Finally, the rhythm degenerates into ventricular fibrillation (VF) with hemodynamic collapse.

Therapeutic options are determined by the hemodynamic tolerance and the type of arrhythmia encountered. A regular narrow complex tachycardia in a patient known to have WPW can be assumed to be an orthodromic AVRT. AV nodal blockade via vagal maneuvers or IV adenosine often terminates this AV node-dependent arrhythmia. In patients with WPW and AF, IV procainamide or amiodarone is the treatment of choice. Digoxin, verapamil, and other AV nodal blockers must be avoided in patients with WPW and AF because these agents can facilitate conduction over the accessory pathway and accelerate the preexcited tachycardia/AF. Rapid preexcited AF in an unstable patient requires prompt DC cardioversion.

The case study represents a young man with symptomatic palpitations in the absence of structural heart disease. There was no evidence of ventricular preexcitation at baseline. The Holter demonstrated episodes of regular SVT with intermittent delta waves during SB. The patient has a "concealed" WPW syndrome and atrioventricular reeentrant tachycardia (AVRT) utilizing a left lateral accessory pathway. He underwent a successful RF catheter ablation procedure.

Differential Diagnosis of Wide Complex Tachycardias

The width of the QRS complex reflects the depolarization time across the ventricles. A wide QRS (>120 ms) implies an abnormal, delayed ventricular activation, not utilizing the normal AV node, HPS. The differential diagnosis of a WCT includes (1) VT, (2) SVT with functional BBB or aberrant conduction, (3) SVT with preexisting "fixed" BBB or aberrant conduction, and (4) SVT with ventricular preexcitation (Table 19-6). The last category includes SVTs with innocent bystander bypass tract and antidromic tachycardia. In a wide complex SVT with an

Differential Diagnosis of WCTs

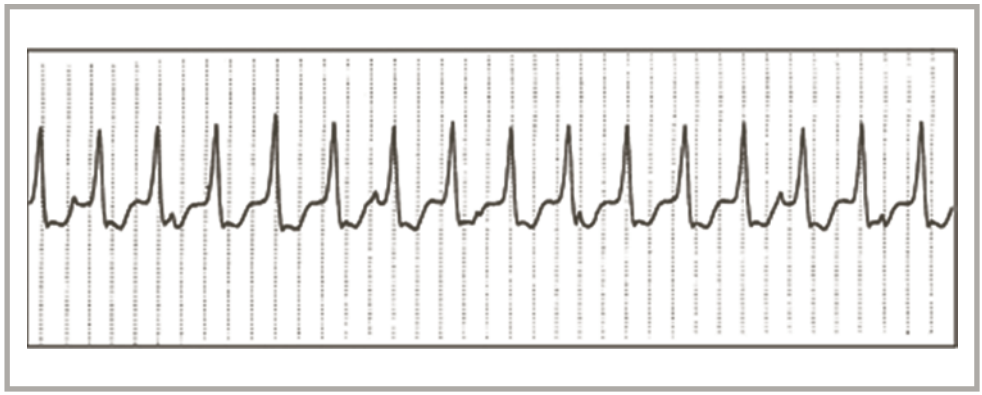
STEPWISE APPROACH TO DIFFERENTIATE WCTs

1. What is the relationship of atrial and ventricular events?
2. What is the width of the QRS complex?
3. What is the axis of the QRS complex?
4. What are the morphologic features of the QRS complex?

FIGURE 19-26

Monomorphic ventricular tachycardia with VA dissociation.



innocent bystander bypass tract, the bypass tract does not participate in the SVT mechanism, but provides passive preexcited ventricular activation. In antidromic tachycardia, the arrhythmia utilizes the bypass tract as the anterograde limb and the AV node as the retrograde limb of the macroreentrant circuit. These preexcited tachycardias can be difficult to distinguish from VT since ventricular "preexcitation" occurs in both scenarios.

To differentiate WCT of supraventricular from ventricular origin, heart rate and hemodynamic responses are usually nondiagnostic. The presence of structural heart disease strongly favors the diagnosis of VT, although SVT can also exist in this population. Certain ECG features may be useful to distinguish VT from wide complex SVT. Table 19-6 outlines a stepwise approach to the differentiation of WCT (Table 19-7).

First and foremost, the AV (P-R) relationship must be defined. The presence of VA dissociation, fusion beats, and captured beats is diagnostic of VT (Fig. 19-26). Unfortunately, these findings occur infrequently and are often difficult to recognize in the presence of a wide QRS tachycardia. Vagal maneuvers may induce AV dissociation for the diagnosis of SVT but has no effect on ventricular arrhythmias. Second, the QRS width should be carefully measured. A wider QRS complex favors a primary ventricular arrhythmia, not using the Purkinje system for ventricular activation. However, significant overlaps of the QRS width between VT and SVT exist. By convention, QRS complexes that are predominately positive in lead V1 are designated as RBBB pattern and QRS complexes that are predominantly negative in lead V1 are designated as LBBB pattern. In the absence of antiarrhythmic drugs, a QRS width greater than 0.14 s with RBBB morphology and a QRS width greater than 0.16 s with LBBB morphology favors VT.

Third, the QRS axis may offer additional diagnostic clues as an extreme right or left axis deviation favors VT. During a WCT, RBBB morphology with a superior axis (negative QRS in leads II, II, and aVF) favors VT, whereas LBBB morphology with a right axis deviation (QRS axis +90°–+210°) favors VT.

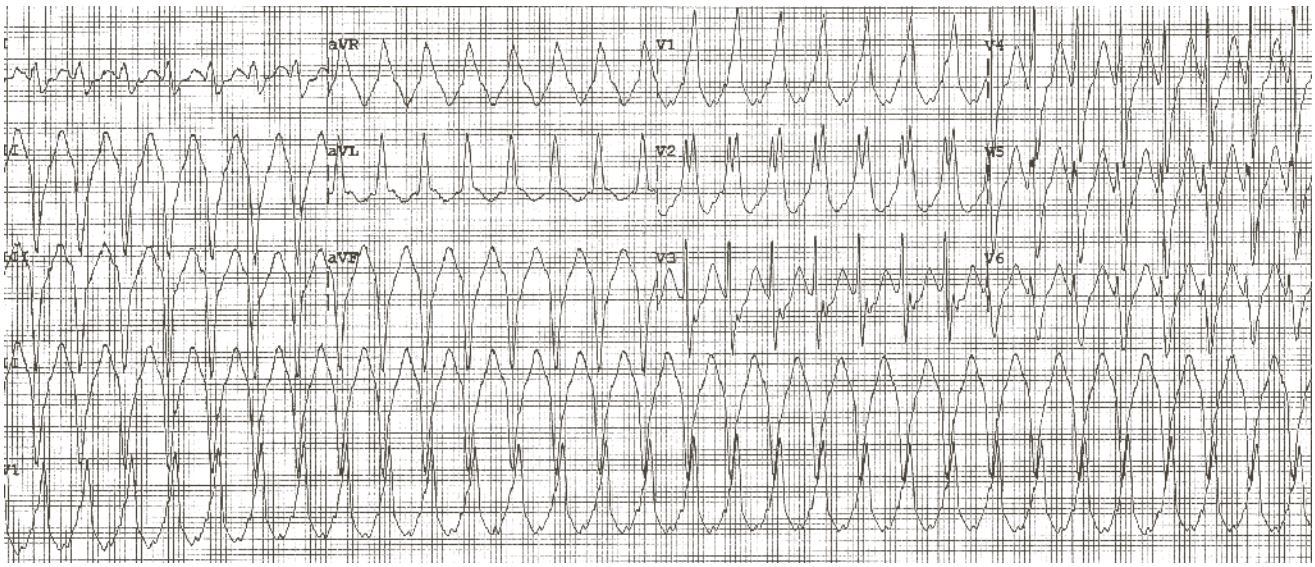
Additional electrocardiographic features that suggest the presence of slow and inhomogeneous conduction are extremely valuable in determining the origin of WCT.[22] The absence of an RS complex in all precordial leads (negative concordance) is highly specific for VT. When an RS complex is present in a precordial lead, an RS duration greater than 100 ms (delayed intrinsicoid deflection) is also highly suggestive of VT. Brugada et al. incorporated these findings with prior ECG criteria developed by Wellens and Kindwall to construct a simple stepwise algorithm for the differential diagnosis of WCTs (Fig. 19-27).[23] For a WCT with RBBB pattern, a monophasic or biphasic QRS in lead V1 and an R/S ratio of less than 1 in lead V6 favor the diagnosis of VT. A triphasic QRS complex (especially a rsR' pattern) in leads V1 or V6 favor SVT.[24] During a WCT with LBBB pattern, an initial R wave greater than 30 ms in duration in leads V1 or V2, an interval greater than 60 ms from the onset of the

CASE STUDY: PART 2

A 76-year-old man presented with syncope and an acute cerebrovascular accident. He was found to be in a sustained WCT and required cardioversion to restore sinus rhythm. He has a history of hypertension, CAD, and AF.

His echocardiogram showed a severe biatrial enlargement with moderately severe mitral and tricuspid regurgitations. While recovering on the Neurology floor, the patient developed recurrent sustained WCT. The 12-lead electrocardiogram is shown in. What is the differential diagnosis of the WCT?

CASE STUDY: IMAGE 3



QRS to the S nadir, and notching of the downstroke of the S wave favor the diagnosis of VT. In lead, V6, the presence of any significant Q wave favors VT (Fig. 19-28) (Table 19-8).[25] The sensitivity of this stepwise analysis was 99% and the specificity was 97%. In addition, when a QRS width during the tachycardia is narrower than the QRS width during sinus rhythm, VT should be considered because it is highly unlikely that aberrant conduction during a tachycardia will result in a narrower QRS.

SPECIAL CONSIDERATIONS

The Long QT Syndrome

The upper limit for the normal duration of the QT interval corrected for the heart rate (QTc) is generally accepted as 0.44 s. QT interval lengthening is due to prolongation of cardiac repolarization. These abnormalities allow the formation of early depolarization- (EAD) related triggered activity and reentry that are responsible for the development of PMVT. *Torsade de Pointes* (TdP, twisting of the points) is defined as atypical PMVT associated with prolonged QT intervals.[26] It is characterized by oscillating QRS axis giving the appearance of twisting along the line (Fig. 19-29). Most often, episodes of TdP are self-limiting and result in syncopal events. Cardiac arrest occurs when TdP becomes persistent that eventually degenerates to VF.

DRUGS REPORTED TO CAUSE QT INTERVAL PROLONGATION AND TORSADE DE POINTES

Antiarrhythmics	Class IA and III
Antifugal	Fluconazole, itraconazole, ketoconazole
Antihistamine	Astemazole, diphenhydramine, terfenadine
Antibiotics	Erythromycin, TMP-sulfa
Antimalarial/antiprotozoal	Chloroquine, mefloquine, pentamidine, quinine
Gastrointestinal	Cisapride
Psychiatric	Haloperidol, lithium phenothiazine, tricyclic antidepressants
Other	Amantidine, chloral hydrate, indapamide, probucol, tacrolimus, vasopression papaverine, cocaine, bepridil

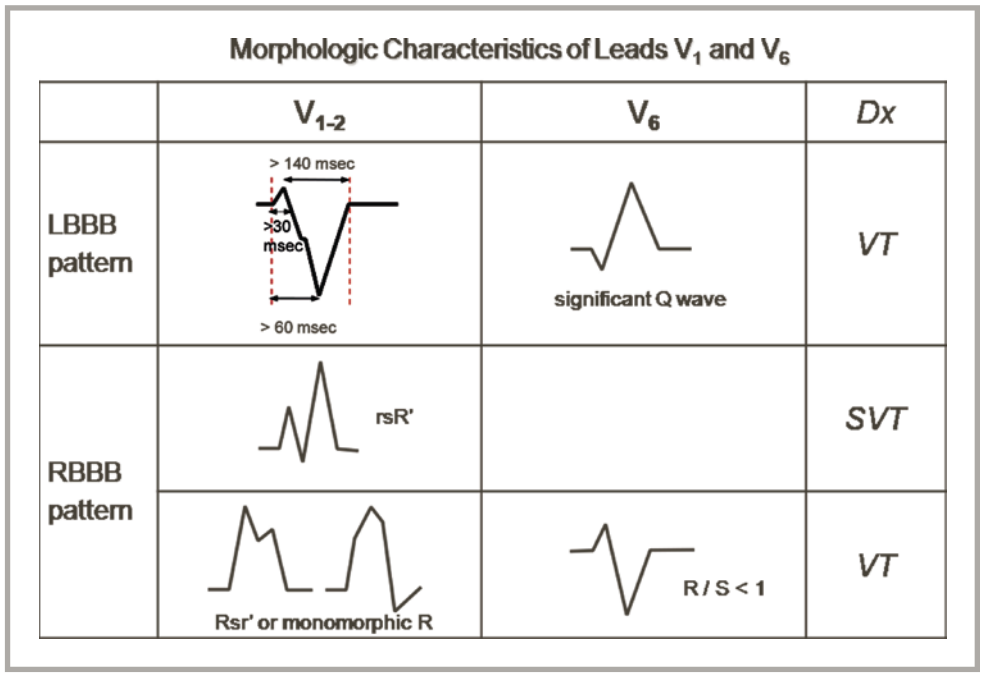

FIGURE 19-28

Morphologic characteristics of ventricular tachycardia. For a WCT with RBBB pattern, a monophasic or biphasic QRS complex in lead V1 and an R/S ratio of less than 1 in lead V6 favor the diagnosis of VT. A triphasic QRS in leads V1 or V6 favor SVT. For a WCT with LBBB pattern, an initial R wave greater than 30 ms in duration in leads V1 or V2, an interval greater than 60 ms from the onset of the QRS to the S nadir, and notching of the downstroke of the S wave favor the diagnosis of VT. In lead V6, the presence of a significant Q wave favors VT.

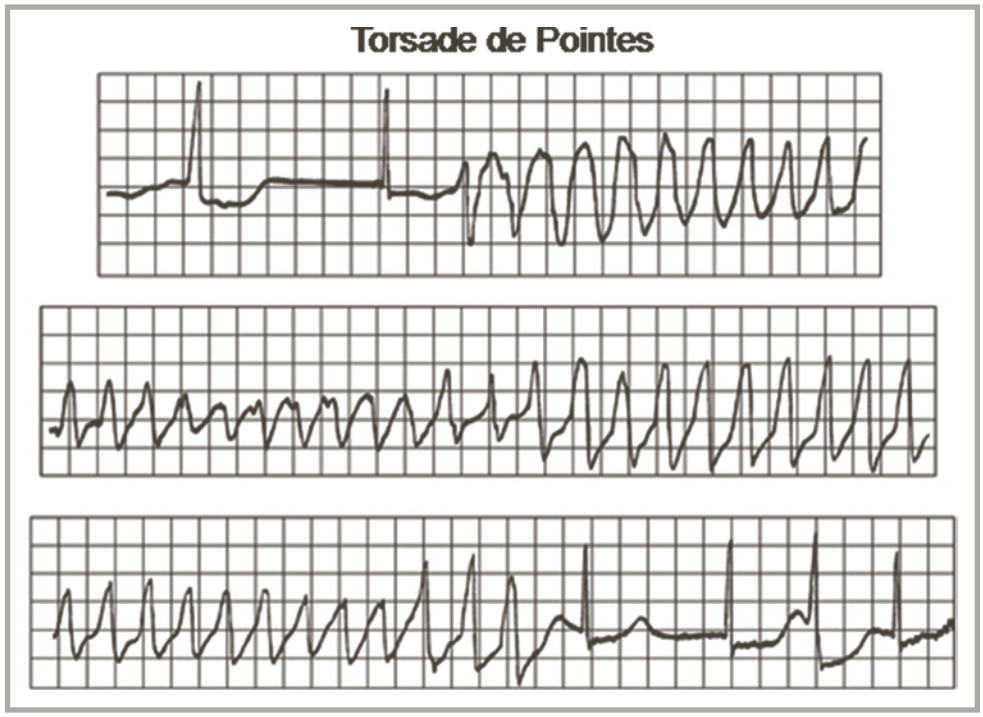

FIGURE 19-29

PMVT (Torsade de pointes) occurring in the setting of long QT interval.

Patients with congenital LQTS typically present with syncope or cardiac arrest, and there is often a family history of sudden death.

The long QT syndromes (LQTS) can be congenital or acquired. Patients with congenital LQTS typically present with recurrent syncope or cardiac arrest, and often associated with a family history of sudden death. The congenital LQTS are phenotypically and genotypically diverse. Ten genotypes have been identified with distinct mutations in at least eight different ion channel genes or protein structures. Mutations in potassium-channel genes, KCNQ1 (LQT1) and KCNH2 (LQT2), and the sodium-channel gene, SCN5A (LQT3), are the most common causes of the long QT syndrome.

Historically, two types of congenital LQTS have been recognized: (1) an autosomal recessive type (Jervell-Lange–Nielsen) associated with congenital deafness, and (2) an autosomal

dominant type (Romano–Ward) with normal hearing. However, recent genetic and molecular findings suggested that all forms of LQTS are autosomal dominant, but with variable penetrance and phenotypic expressions. Risk stratification in such patients using genotype, in conjunction with clinical variables such as sex and the length of the QT interval, may be helpful in identifying high-risk patients.[27-29]

The acquired form is characteristically associated with bradycardic pauses and prominent late diastolic U waves. Clinically, acquired LQTS occurs in association with certain antiarrhythmic drugs (particularly class IA and class III agents), electrolyte disturbances (primarily hypokalemia), bradycardia, psychoactive drugs, and macrolide antibiotics. Other miscellaneous drugs that have been linked to QT prolongation and TdP include terfenadine, probucol, papaverine, ketanserin, cocaine, and bepridil (Table 19-9). Updated information on the drugs to avoid is also available online (www.long-qt-syndrome.com; www.torsades.org).

Management for sustained tachyarrhythmias in LQTS is immediate defibrillation. Magnesium sulfate administered intravenously has been shown to suppress recurrent episodes of PMVT in this setting. Electrolyte imbalances must be corrected, and any potential offending drug must be discontinued. Attempts to shorten repolarization (QT interval) by increasing the heart rate with atropine, isoproterenol infusion, or temporary overdrive pacing may also be effective. Because the risk of sudden death is relatively high even in asymptomatic patients with congenital LQTS, prophylactic treatment with beta-blockers is often recommended. Other chronic therapeutic options include cervicothoracic sympathectomy, and implantable cardioverter-defibrillator (ICD) implantation.

The case study WCT showed a RBBB-Superior QRS morphology, with features consistent with a monomorphic ventricular tachycardia (VT). However, given the patient's history of AF-flutter, valvular regurgitation and atrial dilation, rapid supraventricular/atrial arrhythmia with aberrant conduction should be considered. Careful monitoring during his WCT demonstrated intermittent "breaks" in the tachycardia, with alternating LBBB and RBBB QRS patterns that were at the same rate, suggesting passive aberrant conduction. Underlying atrial activities (arrows) were noted ().

After 12 mg of IV adenosine, underlying AFL (arrows) with variable AVB was revealed. The initial presenting WCT was atria flutter with one-to-one AV conduction ().

Acute Myocardial Infarction

Tachyarrhythmias or conduction defects occur frequently in the setting of an acute myocardial infarction. It is important to distinguish these benign from potentially life-threatening complications. ST is a common and appropriate physiologic response during an acute ischemic event. It can be caused by pain, stress, decreased cardiac outputs, and anxiety. Management should always be targeted at the underlying causes. SB is also not an uncommon occurrence, particularly in early stages of an inferior wall infarction.

Conduction abnormalities associated with IWMI are primarily located at the level of the AV node.

AV conduction disturbances may be observed in up to 30% of patients with acute myocardial infarction.[30,31] Conduction abnormalities associated with inferior wall infarctions (IWMI) are primarily located at the level of the AV node. The AV node usually has a dual-blood supply from the LAD artery, via its septal branches, as well as the AV nodal artery from the RCA. An inferior myocardial infarction with RCA stenosis commonly results in AV nodal ischemia (but not necrosis). In addition, ventricular mechano-sensitive or chemo-sensitive receptors are clustered in the inferioposterior wall, which may be stimulated by stretch, infarct distension or ischemia. Autonomic modulations with cardio-inhibitory baroreflex and vagal activation (Bezold–Jarisch reflex) are thought to be responsible for conduction disturbances in such clinical setting.[32,33]

Temporary pacing is indicated for symptomatic patients; however, permanent pacing is rarely necessary as these conduction disturbances are typically transient and associated with a benign clinical course. However, AVB associated with anterior wall infarction usually results from LAD occlusion with subsequent infra-nodal, His bundle necrosis as infra-nodal structures have only a single blood supply. In this instance, the high-grade AV conduction disturbance tends to be permanent, with a slower infra-nodal escape focus necessitating permanent pacing. Overall, CHB develops in 5–8% of patients with AMI and is associated with increased mortality regardless of the location of infarction.[34]

Approximately 10–20% of patients develop an atrial arrhythmia, mostly AF or flutter, within 24 h of an AMI. These arrhythmias are also often transient although they are associated with a worse prognosis. In postinfarction patients, ventricular ectopy and nonsustained ventricular tachycardia occur frequently, but sustained episodes of VT or VF occur in less than 5% of cases. VT or VF occurring early in the peri-infarction period (within 48 h) is often transient and usually requires only short-term antiarrhythmic drug therapy. Sustained VT occurring after 48 h postinfarction is associated with increased mortality and recurrent arrhythmia.[35] The incidence of VF is highest within the first 4 h of an acute infarction and may occur in up to 5% of patients. Immediate defibrillation followed by intravenous antiarrhythmic drug treatment is indicated. Accelerated idioventricular rhythm can also occur, either as an escape mechanism or as an abnormal ectopic focus that often follows reperfusion or thrombolytic therapy. Prophylactic use of antiarrhythmic agents (except beta-blockers and possibly amiodarone) is not indicated. The American College of Cardiology and the American Heart Association (ACC/AHA) Guidelines on acute myocardial infarction do not recommend antiarrhythmic therapy for nonsustained, low grade ventricular arrhythmias. The recent DINAMIT trial also showed no benefit from ICD therapy within 40 days of an MI.[36] Although there is a reduction in the rate of death due to arrhythmia, this was offset by an increase in the rate of death from nonarrhythmic causes resulting in no difference in all-cause mortality.

SUMMARY

Arrhythmia diagnosis may often appear to be an imposing task. However, a fundamental understanding of cellular electrophysiology, conduction system anatomy, arrhythmia mechanisms, and common clinical scenarios often leads the clinician to the correct diagnosis and treatment. The importance of a systematic analysis and approach to arrhythmia diagnosis cannot be overemphasized. Once a diagnosis is reached with reasonable certainty, therapeutic interventions can be attempted, based on the underlying pathophysiology. This chapter has centered mostly on arrhythmia diagnosis with only a brief overview of therapeutic interventions. A more detailed discussion of antiarrhythmic medications and implantable devices is presented elsewhere in this text.

REVIEW QUESTIONS

1. **Which of the following statements regarding arrhythmia management is/are true?**
   - **A.** Automatic arrhythmias occur when cells undergo spontaneous diastolic (phase 4) depolarizations and induce APs
   - **B.** Arrhythmias caused by triggered activity are initiated by afterdepolarizations
   - **C.** Multiple anatomic or functionally defined pathways are required for reentry to occur
   - **D.** Unidirectional conduction block is required for reentry to occur
   - **E.** All of the above

2. **Interruption of conduction through the AV node terminates AV nodal-dependent tachycardias. AV nodal-dependent tachycardias include which of the following?**
   - **A.** Atrial tachycardias
   - **B.** Orthodromic AV reentry tachycardias utilizing a bypass tract
   - **C.** Atrial flutter
   - **D.** AV nodal reentry tachycardia
   - **E.** B and D
   - **F.** A and C

3. **Which of the following is/are true regarding differentiation of the site of AV conduction block?**
   - **A.** A narrow QRS complex escape rhythm usually indicates block within or above the level of the AV node
   - **B.** Mobitz type 1 AVB (Wenckebach) usually indicates block above the AV node
   - **C.** Mobitz type 2 AVB usually indicates block below the AV node
   - **D.** AVB improves with exercise is indicative of infra-nodal conduction disease
   - **E.** A, B, C

4. **The differential diagnosis of long R-P tachycardias includes which of the following?**
   - **A.** The uncommon (fast–slow) form of AVNRT
   - **B.** Atrial tachycardia
   - **C.** Orthodromic AV reentry tachycardia utilizing a slowly conducting bypass tract
   - **D.** The common (slow–fast) form of AVNRT
   - **E.** A and C
   - **F.** A, B, and C

5. **In the absence of antiarrhythmic drugs that slow myocardial conduction, which of the following during a WCT excludes the diagnosis of ventricular tachycardia?**
   - **A.** Monophasic or biphasic QRS complex in lead V1 and an R:S <1 in lead V6 during an RBBB pattern WCT
   - **B.** Initial R wave duration >30 ms, onset of the QRS to the S nadir >60 ms, and notching of the downstroke of the S wave in leads V1 or V2
   - **C.** AV association
   - **D.** AV dissociation with fusion beats or capture beats
   - **E.** None of the above

ANSWERS

1. The answer is E: All of the above. Automatic and triggered arrhythmias account for a minority of arrhythmias. Arrhythmias due to automaticity are caused by phase 4 diastolic depolarization of cellular membrane potentials that reach the threshold and generate abnormal APs. Arrhythmias associated with triggered activity are caused by cellular membrane potential oscillation that forms afterdepolarizations. Reentry is responsible for most clinically relevant tachyarrhythmias. Prerequisites of reentry include (1) an initiating event, most likely a premature beat that result in unidirectional block; (2) multiple anatomic or functional pathways; and (3) sufficiently slow conduction down the alternative pathway so that the tissue proximal to the block recovers excitability and allows the impulse to reenter the circuit.
2. The answer is E: B and D. AV nodal-dependent SVTs utilize the AV node as a critical path in the arrhythmia circuit. These arrhythmias include AVNRT, which involves a reentrant circuit within the AV nodal region utilizing the dual AV nodal pathway physiology (fast and slow pathways), and orthodromic AVNRT, which is a macroreentrant circuit utilizing anterograde conduction through the AV node and retrograde conduction through bypass tract(s). The mechanism responsible for the initiation and maintenance of AV nodal-independent SVTs reside above the AV node, and interruption of AV nodal conduction does not interfere with these arrhythmias but may slow the ventricular response.
3. The answer is E: A, B, and C. The site of AVB may be suggested by the width and patterns of the conducted QRS. A narrow QRS complex rhythm suggests a junctional escape rhythm and therefore the site of block is within the AV node, proximal to the AV junction. A wide QRS suggests infra-nodal block. Mobitz type 1 AVB (Wenckebach pattern) usually indicates AV node involvement in conduction disease, whereas an abrupt block (Mobitz type 2) AVB usually indicates block below the AV node

   The response of AV conduction to various maneuvers or drugs may also localize the site of the block. Sympathetic stimulation or parasympathetic withdrawal (exercise, atropine, or isoproterenol) improves AV nodal conduction. These maneuvers may worsen infranodal conduction block by enhancing proximal AV nodal impulse propagation and thus stress the distal HPS.
4. The answer is F: A, B, and C. The P-wave location is variable during ATs, but usually has a shorter P-R than RP intervals. The uncommon form of AVNRT utilizes anterograde conduction down the fast AV nodal pathway (short P-R) and retrograde conduction up the slow AV nodal pathway (long RP). During the common forms of orthodromic AVRT, the retrograde conduction up the bypass tract is sufficiently fast that the result is a shorter RP than P-R. A long RP during orthodromic AVRT requires a slowly conducting bypass tract as the retrograde limb, resulting in a longer RP than P-R.
5. The answer is E: None of the above. The differential diagnosis of a WCT includes VT, SVT with aberrant conduction, or SVT with ventricular preexcitation. Certain electrocardiographic morphologic criteria can be useful in distinguishing VT from wide complex SVT. The presence of a monophasic or biphasic QRS complex in lead V1 and an R:S <1 in lead V6 suggests VT in an RBBB pattern WCT. A broad R wave (>30 ms), with a slow and inhomogeneous ventricular conduction (R-to-S >60 ms with notching on the downstroke of the S wave) suggests VT in a LBBB pattern WCT. Although VA dissociation is a hallmark of VT, AV association may be observed in up to 50% of VTs.

CHAPTER 20

HARVEY M. LICHT, FREDRIC JAFFE, AND GILBERT E. D'ALONZO

Gastrointestinal Hemorrhage

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Discuss the differential diagnosis of acute gastrointestinal bleeding.
- Describe the diagnostic and therapeutic maneuvers necessary to identify the cause and control of gastrointestinal hemorrhage in the ICU.
- Understand the role of endoscopy, surgery, and tube placement in upper and lower GI bleeding.
- Appreciate the complications of stress ulceration and how it occurs in the critically ill patient.

ACUTE GASTROINTESTINAL HEMORRHAGE

Acute gastrointestinal hemorrhage is a common emergency that often requires treatment in an intensive care unit. Mortality associated with gastrointestinal hemorrhage is significant and has remained approximately 10% since World War II.[1] Mortality has not changed despite technologic advances, perhaps due to increased patient age and the presence of comorbid disease. Although the upper gastrointestinal tract is the site of origin of most acute episodes of gastrointestinal bleeding, a colonic site of bleeding is also frequently seen.[2] The small bowel rarely causes acute gastrointestinal bleeding. This chapter reviews the evaluation and management of the ICU patient with gastrointestinal bleeding, including differential diagnosis, diagnostic modalities, and treatment options.

DIFFERENTIAL DIAGNOSIS

Gastrointestinal bleeding is a common cause of admission to the intensive care unit and also frequently complicates the course of patients admitted to the ICU for other illnesses.[3] There are a wide variety of conditions that may cause upper gastrointestinal hemorrhage. The most common etiologies are ulcers, gastritis and erosions secondary to nonsteroidal antiinflammatory drugs or alcohol, stress gastritis, and esophageal varices. A report from a Canadian registry for upper gastrointestinal bleeding of nonvariceal etiology found that ulcers were the cause in 56% of cases, erosions in 10%, esophagitis caused 9%, and Mallory-Weiss tears

TABLE 20-1

CAUSES OF UPPER GASTROINTESTINAL BLEEDING

Stress gastritis	Develops in setting of severe systemic physiologic stress, e.g., – sepsis, multiorgan failure, burns. No association with prior ulcer disease. Painless bleeding
Gastric/duodenal ulcer	Usually associated with upper abdominal pain. Bleeding ulcers are more common over the age of 60. Associated with use of ASA/NSAID's and also associated with *Helicobacter pylori*
Esophageal varices (gastric varices/portal gastropathy)	A manifestation of portal hypertension secondary to cirrhosis. Associated with other findings such as ascites, splenomegaly, and hepatic encephalopathy. Variceal bleeding often occurs in decompensated cirrhotic patients with jaundice and coagulopathy
Mallory-Weiss tear	Mucosal tear at esophago-gastric junction induced by vomiting or retching. Presents as painless hematemesis
Erosive gastroduodenitis	Caused by ASA, NSAID's, or alcohol. Risk of bleeding increases with higher doses of medications and with concomitant use of aspirin and NSAID's. Risk also increased with prior history of ulcer
Infrequent causes	Esophagitis, angiodysplasia, Dieulafoy lesion, cancer

accounted for 4% of cases of bleeding.[4] The other causes of bleeding included angiodysplasia, Dieulafoy lesions and malignancy, and other less common causes (Table 20-1)[1].

Upper Gastrointestinal Bleeding

Stress ulcers are common but preventable shallow mucosal lesions that occur in critically ill patients.

A frequent cause of upper gastrointestinal bleeding in the intensive care patient is the stress ulcer or stress gastritis with erosions. Stress ulcerations are small, shallow ulcers in the gastroduodenal mucosa that develop acutely in critically ill patients who experience serious physiologic instability.

The pathophysiology of stress gastritis and stress ulceration is different from that of peptic ulcer disease. It is postulated that in the setting of severe systemic illness, there is arterial vasoconstriction of the mesenteric bed. This leads to shunting of blood away from the mucosa, resulting in a relative ischemia of the gastroduodenal mucosa. This injury makes the mucosa more susceptible to back diffusion of acid from the lumen into the mucosa, which leads to further injury to the mucosa. This occurs in the setting of physiologic stress and is not associated with a history of prior ulcer disease. Bleeding from stress ulceration most commonly develops in patients with respiratory failure who are on mechanical ventilation and in patients with coagulopathy; however, patients with sepsis, burns, and other organ failure and those with acute neurologic events are also at risk.[3] These ulcerations occur chiefly in the gastric fundus but may also occur diffusely throughout the stomach and duodenal bulb.[2] These lesions are generally small, shallow mucosal erosions without significant submucosal penetration. For this reason, these erosions do not progress to perforation. They are usually painless and present with evidence of upper gastrointestinal bleeding such as hematemesis or melena. Many of these erosions do not bleed and remain subclinical.[2] They are usually multiple and may appear within 24 h of admission to the ICU. Fortunately, bleeding from stress ulceration has become much less common because of the widespread use of pharmacologic prophylaxis with proton pump inhibitors to inhibit gastric acid secretion, early enteral nutrition, and greater attention to reestablishment of systemic perfusion and oxygenation.

Peptic ulcer disease is the most common cause of GI bleeding and is associated with melena and hematochezia.

Gastric or duodenal peptic ulceration is responsible for up to 50% of the episodes of acute upper gastrointestinal hemorrhage.[2] In contrast to stress ulcers, most patients with ulcer disease have a history of abdominal pain or dyspepsia; although, approximately 10–15% may present with painless bleeding manifest as melena or hematemesis.[3]

Pain is frequently in the epigastrium and is improved with food or antacids or acid-suppressing medication. Unlike duodenal ulcers, gastric ulcers may also cause symptoms of early satiety and weight loss. Although commonly referred to as peptic ulcers, the ulcer is usually caused by aspirin or nonsteroidal antiinflammatory drugs or by Helicobacter pylori infection. There is no indication to treat Helicobacter infection during the acute ulcer; however, the recurrence rate after ulcer healing can be reduced by eradication of Helicobacter pylori infection.[4]

In a similar fashion, if the ulcer is caused by the use of aspirin or nonsteroidal antiinflammatory drugs, avoidance of these medications will reduce the recurrence rate. If these medications are needed, concomitant treatment with a proton pump inhibitor will effectively reduce ulcer recurrence. It is common for people to be taking nonsteroidal antiinflammatory drugs by prescription and over the counter for arthritis and for other complaints. There is also a very high prevalence of coronary artery disease and cerebrovascular disease, and patients are routinely treated with antiplatelet drug therapy such as aspirin for these diseases and also as part of medical regimens to prevent these illnesses in patients with risk factors. This results in many patients taking both aspirin and nonsteroidal antiinflammatory drugs, often without the physician's awareness. Concomitant use of these medications and higher doses of these medications increase the risk of bleeding from erosions and ulcers of the upper gastrointestinal tract. Patients should be counseled regarding this risk.

The clinical situation frequently arises when a patient with atherosclerotic disease requires antiplatelet therapy but is at an increased risk because of a history of ulcer disease. A study in this group of high risk patients has underscored the role of proton pump inhibitors. The addition of the proton pump inhibitor, esomeprazole, to the regimen with aspirin provided efficacy and greater safety regarding ulcer bleeding as compared to treatment with the antiplatelet drug, clopidogrel, alone.[5]

Another common cause of upper gastrointestinal bleeding is esophageal varices. Varices are a manifestation of portal hypertension caused by cirrhosis. The bleeding associated with esophageal varices is usually abrupt and severe. There is a 30% mortality associated with bleeding varices during the first episode of bleeding. Mortality most frequently is secondary to liver failure; although, rarely bleeding may cause exsanguination. In cirrhotic patients with known varices, upper gastrointestinal bleeding is caused by lesions other than varices in 50% of the episodes.[6] Bleeding is frequently from gastritis, ulcer, Mallory-Weiss tear, or portal gastropathy.[6] Evaluation with endoscopy early in the course of treatment is important to diagnose the cause of bleeding and direct the appropriate management. Patients with cirrhosis and variceal bleeding frequently manifest other findings of portal hypertension such as ascites, splenomegaly, and hepatic encephalopathy. They can have coagulopathy and thrombocytopenia that may complicate treatment. In addition to treating the cause of bleeding, it is important to evaluate for other complications of cirrhosis that often accompany bleeding episodes such as spontaneous bacterial peritonitis, and renal insufficiency. Prophylaxis with antibiotics is indicated to reduce the risk of infection that is associated with bleeding in the cirrhotic.[7]

Variceal bleeding is associated with portal hypertension secondary to cirrhosis.

Varices are enlarged venous channels that are most commonly found in the esophagus and stomach. They are formed by collateral blood flow that is shunted away from the liver as a means of reducing portal hypertension. Variceal bleeding occurs when portal pressure is greater than 12 mmHg. The risk of bleeding correlates with the endoscopic findings of red marks on the varix and the size of the varix, and clinically with the severity of the liver dysfunction as quantified by the Child's-Pugh classification (Table 20-2). The clinical parameters that determine the Child's class include serum albumin, prothrombin time, bilirubin, ascites, and encephalopathy. Patients who are Child's class A have well-compensated cirrhosis, and those with more severe liver disease, as reflected by these parameters, are classified Child's classes B and C. These clinical factors in addition to the endoscopic findings are used to predict the risk of variceal bleeding. When a diagnosis of cirrhosis is made, patients

TABLE 20-2

CHILD'S – PUGH STAGING:
A 5–6;
B 7–9;
C >10 POINTS

Points per finding	1	2	3
Encephalopathy	None	Grade 1–2	Grade 3–4
Ascites	None	Medically controlled	Uncontrolled
Albumin g/dL	>3.5	2.8–3.5	<2.8
Bilirubin mg/dL	<2	2–3	>3
Protime (INR)	<1.7	1.7–2.3	>2.3

should be screened with endoscopy to characterize the varices and determine the risk of a first variceal bleed. Based solely on clinical parameters, those who are Child's class A have a 40% risk and patients with Child's class C have an 85% risk of bleeding from varices within 2 years. The endoscopic finding of large varices carries a 25% risk and cirrhotics with small varices have a 7% risk of variceal bleeding within 2 years.[7] These clinical and endoscopic findings are weighed to determine which cirrhotic patients should be prophylactically treated to reduce the risk of the first variceal bleed. Patients with more advanced Child's class and with large varices should be prophylactically treated with beta blockers or esophageal banding to prevent the first variceal bleeding episode. Therapy with a nonselective beta blocker, when given in a dose to reduce the resting heart rate by 25% or to 60 beats/min, decreases the 2-year risk of variceal bleeding to 15%. This also improves the mortality rate. Prophylactic banding of varices is also efficacious and can be considered for patients who do not tolerate, or are not candidates for, treatment with beta blockers. After the first episode of bleeding, variceal bleeding recurs in 60% of patients within 1–2 years. Banding can reduce this to 33% and beta blockers reduce the rebleeding rate to 40%.

Previous vomiting is an important clue to distal esophageal tearing.

Another common cause of upper gastrointestinal bleeding is a Mallory-Weiss tear. This is a mucosal tear at the esophago-gastric junction, typically above a hiatal hernia. It is induced by vomiting or retching.

The tear is caused by an increase in intraabdominal pressure associated with vomiting or retching that is transmitted into the stomach. The increased intraluminal pressure within the stomach causes a large pressure differential at the esophago-gastric junction as compared to the relatively low or negative intrathoracic pressure outside the wall when the esophago-gastric junction is situated in the chest above a hiatal hernia. The pressure differential causes the tear in the mucosa, which presents as painless hematemesis in the context of retching or vomiting. With more violent vomiting, a deeper tear can occur through the wall of the lower esophagus, leading to a perforation (i.e., Boorhave's syndrome).

Instead of presenting as hematemesis, the patient with Boorhave's syndrome has a transmural tear and presents with severe chest pain, sepsis, hypotension, and shock. There is often evidence of mediastinitis or pleural effusion. This presentation cannot be confused with the mucosal Mallory-Weiss tear. Because the pathogenesis involves vomiting, it is unlikely that a Mallory-Weiss tear would present as melena without hematemesis.

Other common causes of upper gastrointestinal bleeding include gastritis and duodenitis secondary to aspirin, nonsteroidal antiinflammatory drugs or alcohol. These erosive disorders may present as painless bleeding or may have prior symptoms of dyspepsia or upper abdominal discomfort. The risk of bleeding increases with the use of higher doses of aspirin or nonsteroidal antiinflammatory drugs and with the concomitant use of aspirin with nonsteroidal antiinflammatory agents. However, bleeding can also occur with the use of low-dose aspirin, as is frequently given for coronary artery disease. Older women and people with a prior history of ulcer are at a particularly high risk of bleeding.[8]

Esophagitis is another cause of upper gastrointestinal bleeding and most commonly is secondary to gastro-esophageal reflux disease.[8] Bleeding often is accompanied by a history of acid reflux or retrosternal heartburn. Other causes of esophagitis include pill-induced esophagitis, and infectious causes such as Herpes, Cytomegalovirus, or Candida. These infections have been seen more frequently in immunocompromised patients, often with AIDS or patients on chemotherapy. These etiologies of esophagitis are most often associated with symptoms of odynophagia, dysphagia, or chest pain but infrequently can cause gastrointestinal bleeding.

Less common causes of upper gastrointestinal bleeding include angiodysplasia and Dieulafoy lesions. An angiodysplasia is a dilated tuft of capillaries that form arterio-venous communications in the mucosa and submucosal of the gastrointestinal tract. They most commonly occur in the right colon and distal small intestine but can also be found in the stomach and duodenum. They can be sporadic findings or are sometimes found in patients with renal failure on dialysis and in patients with aortic valvular disease. Depending on the site of the lesion, they present with painless upper or lower gastrointestinal bleeding. Dieulafoy lesions are seen in the stomach and represent an ectatic artery just below the surface of the mucosa. These may be very difficult to identify endoscopically unless they are seen when actively bleeding because there is normal mucosa overlying the artery.

A rare cause of upper gastrointestinal bleeding is an aorto-enteric fistula. This occurs in patients with a history of a graft placed for an abdominal aortic aneurysm. A fistula develops most frequently with the duodenum, and massive upper gastrointestinal bleeding may be preceded by a self-limited "herald" bleed. This diagnosis is difficult to establish and requires a strong index of suspicion in the patient with a history of prior graft surgery who presents with bleeding and endoscopy reveals no other cause for the bleed. It is unusual to demonstrate the bleeding fistula endoscopically or angiographically.

Many patients with upper gastrointestinal bleeding present with melena. In contrast, lower gastrointestinal bleeding presents most commonly with red or maroon colored blood per rectum.

The origin of lower gastrointestinal bleeding is usually from the colon. Because of the infrequent occurrence of lesions in the small intestine, this organ is rarely the source of gastrointestinal bleeding. Rapid transit of blood from an upper gastrointestinal lesion can also manifest as red blood per rectum; although as noted, more commonly an upper gastrointestinal site of bleeding will result in black stools. During an episode of upper gastrointestinal bleeding, the slow transit of blood through the colon usually affords adequate time for bacteria in the colon to metabolize blood to a black color. However, if transit through the colon is rapid, as can occur with massive upper gastrointestinal bleeding, there will not be an adequate time of exposure to produce the black color and red or maroon blood will be passed per rectum. In a similar fashion, if bleeding from the right colon is not that profuse and transit is slow through the colon, there can be sufficient time for blood to be turned black by the colonic bacteria. Clinical judgment must be used to assess the site of blood loss. Interpretation of vital signs reflecting intravascular volume status, the hemoglobin, and results of naso-gastric lavage helps to distinguish upper from lower gastrointestinal sites of bleeding. Further evaluation to define the cause of bleeding and consideration of treatment options varies depending upon whether blood loss is from the upper or lower tract.

Lower GI bleeding is associated with hematochezia.

Lower Gastrointestinal Bleeding

Causes of lower gastrointestinal hemorrhage are found in Table 20-3. Rapid bleeding with large amounts of blood loss is usually caused by diverticular disease or angiodysplasia of the colon.

Two major causes of hematochezia are diverticulosis and angiodysplasia.

A variety of conditions are associated with slower and smaller amounts of blood loss, including inflammatory and ischemic bowel diseases, radiation-induced colitis, and hemorrhoids.

Ischemic colitis occurs in older patients with atherosclerosis.

Colonic polyps and cancer rarely cause gross gastrointestinal bleeding. They are more likely to cause occult blood loss and present as iron deficiency anemia. In contrast to upper gastrointestinal bleeding, which is almost always rapidly and accurately diagnosed, the cause of lower gastrointestinal bleeding remains undiagnosed in 10–15% of patients.

Colonic diverticuli are the most common cause of lower gastrointestinal bleeding. Colonic diverticuli are herniations of the mucosa and submucosa through the muscular layer of the colon. This occurs at an area of weakness in the muscular layer that is a consequence of the path the arteriole takes as it penetrates from the serosa through the colonic wall to perfuse the colon. Therefore, diverticuli are always in close proximity to an arteriole. Diverticuli are most common in the sigmoid colon, but bleeding occurs most frequently, although not solely,

TABLE 20-3

CAUSES OF LOWER GASTROINTESTINAL BLEEDING

Colonic diverticulosis	Presents as painless red/maroon blood per rectum. It is the cause of 30–50% of lower gastrointestinal bleeding. It is usually self-limited but recurs in ~20% of patients
Colonic angiodysplasia	Usually found in the right colon. Presents as painless red/maroon blood per rectum. Accounts for 20–30% of lower gastrointestinal bleeding
Upper GI bleed	Rapid transit of a large volume of blood from an upper GI source can present as red/maroon blood per rectum
Less frequent causes	Inflammatory bowel disease, ischemic colitis

from right-sided diverticuli. Bleeding occurs when there is a communication between the diverticulum and the adjacent arteriole. This presents as painless bleeding. This is to be differentiated from diverticulitis, which is an inflammatory disease that is caused by a small, usually walled-off perforation of a diverticulum into the pericolic tissue that presents as pain, fever, and localized tenderness. This is not associated with gross or occult bleeding. Inflammatory diverticulitis is more commonly a complication of left-sided diverticular disease. Because of the differing pathogenesis, diverticular bleeding and diverticulitis do not occur simultaneously.

Colonic diverticuli are rare in people under the age of 40, but increase in frequency with age and are found in 65% of people over the age of 85. Bleeding occurs in 15% of people with diverticuli, but accounts for 30–50% of cases of lower gastrointestinal bleeding. Diverticular bleeding is self-limited in 80% of cases, but may recur in greater than 20% of cases.[9]

Angiodysplasia is common to the right colon and ileum.

Colonic angiodysplasia is the second most frequent cause of lower gastrointestinal bleeding. As previously mentioned, these vascular lesions are found most commonly in the cecum and ascending colon and also in the distal small bowel.

They are found in approximately one percent of people undergoing elective colonoscopy for reasons other than bleeding; although, the true prevalence in the general population is not known. Angiodysplasia of the colon accounts for 20–30% of the cases of lower gastrointestinal bleeding and presents with painless rectal bleeding, similar to diverticulosis. Bleeding is self-limited in 90% of cases but recurrent bleeding is frequent.[10] As explained previously, a brisk upper gastrointestinal bleed may also present with the passage of bright red or maroon blood per rectum and is the third most common cause of "apparent" lower gastrointestinal bleeding.

Briskly bleeding lower GI lesions can be found by arteriography or by tagged red blood cell nuclear scanning.

As with all cases of gastrointestinal bleeding, the primary goal is to return the patient to hemodynamic stability. Following fluid resuscitation, blood transfusion, and correction of coagulopathy if needed, the patient should undergo testing to determine the cause of blood loss. A patient with lower gastrointestinal bleeding should be evaluated with a nuclear medicine bleeding scan.

The technetium pertechnetate labeled red blood cell scan is most useful because of the prolonged time the red cells retain the labeled material. During a bleed, the labeled blood will pool in the lumen and can be identified on the scan. If the initial scan is negative, the prolonged duration of the labeling allows scans to be repeated during the next 12–24 h if bleeding recurs. The scan is sensitive to a rate of blood loss of 0.5 mL/min.[11] The scan is useful in documenting active bleeding but does not identify the cause of bleeding and is poor at localization of the site of blood loss. There is redundancy of the bowel, and nonperistaltic contractions in the colon can propel the labeled blood proximal or distal to the bleeding site, which complicates interpretation of the scan and localization of the bleeding site. However, because a positive scan indicates active bleeding, this suggests that there is likely to be benefit in proceeding with an angiogram to identify the bleeding site and localize it by documenting extravasation of contrast into the lumen. This requires bleeding at a rate of 1–1.5 mL/min.[11]

The angiogram can also reveal radiographic characteristics that establish a diagnosis of angiodysplasia; although, without extravasation of contrast, it cannot be definitively considered the cause of bleeding. Angiography also provides access for treatment of bleeding from diverticuli and angiodysplasia. Infusion of an arterial vasoconstrictor, such as vasopressin, into the artery perfusing the bleeding site can be done. If bleeding is successfully stopped, the infusion is usually continued for another 24 h. If not successful, intra-arterial embolization can be attempted. These interventions carry a risk of infarction of the colon. Other complications associated with angiography include injury to the artery from the access puncture site and along the course of the vessel as the catheter is passed. A tear or aneurysm of the vessel can develop. Atherosclerotic plaques can also be dislodged from the wall of the artery, leading to emboli distal to this site. The radiologic contrast material can also lead to renal insufficiency or allergic reactions. It is because of these risks associated with the arteriogram that a bleeding scan is initially used as a screening test to indicate active bleeding. This increases the likelihood that the angiogram will identify the bleeding site and is weighed into the risk: benefit decision-making process whether to proceed to the arteriogram.

TREATMENT OF ACUTE GASTROINTESTINAL HEMORRHAGE

Patient Assessment

The treatment of acute gastrointestinal bleeding begins with an assessment of the severity of the bleed and its consequences on the function of the major organ systems, e.g., renal function, and ischemia to the brain or heart. Simultaneously, the patient must be resuscitated and intravascular volume and blood losses must be replenished and coagulopathy must be corrected if present. It is helpful to stratify patients for risk of rebleeding and for risk of death. This will help to triage patients and decide who requires treatment in an intensive care unit. The risks for rebleeding include patient age greater than 65, shock at the time of presentation, comorbid illnesses, the hemoglobin level, and evidence of fresh red blood per rectum or per naso-gastric tube.[3]

Some patients with upper GI bleeding have gastric tube aspirates negative for blood, indicating that bleeding has stopped or is from a source distal to the stomach.

Factors associated with an increased risk of death during the hospitalization in addition to the above include sepsis, decreased renal function, and onset of bleeding during a hospitalization for other causes.[3] A study of the mortality from upper gastrointestinal bleeding in England in 1995 demonstrates these points.[12] More than 4,000 patients with upper gastrointestinal bleeding were evaluated and the overall mortality rate was 14%. The mortality for those admitted to the hospital for bleeding was 11% and for those with bleeding complicating a hospitalization for another illness, the mortality was 33%. Sixty-five percent of the deaths in patients younger than 80 years were associated with cancer or organ failure on presentation. In the absence of these factors, the death rate in patients younger than 60 was 0.8%. In addition to clinical parameters, there are also endoscopic findings associated with risk of ulcer rebleeding (Table 20-4).

The risk is less than 5% with a clean ulcer base, approximately 10% with a flat spot on the ulcer base, 20–30% with an adherent clot, 40% with a visible vessel (which is actually a raised clot over an artery on the ulcer base), and 50% with active bleeding from the ulcer. Thus, clinical factors and endoscopic findings help to determine who is at greater risk of rebleeding and of death during the hospitalization. Most rebleeding develops within the first 3 days of admission.[13] These factors should be used to determine which patients with gastrointestinal bleeding would benefit most from admission to an intensive care unit.

Emergent Endoscopy

If a patient presents with shock or evidence of active bleeding as indicated by fresh red blood per rectum or from the naso-gastric tube, then emergency endoscopy should be done after initial resuscitation to diagnose and treat the cause of bleeding. Otherwise, endoscopy can be done within 24 h or later depending upon the patient's clinical condition. Treatment with high-dose proton pump inhibitors can be initiated prior to endoscopy; although, there is no data to show that this affects patient outcome. However, the initiation of early treatment with proton pump inhibitors has been shown to decrease the findings of stigmata for recurrent ulcer bleeding at the time of endoscopy. With early high-dose treatment, the number of patients with a clean-based ulcer is increased, thereby reducing the need for endoscopic treatment.[14]

Upper endoscopy often provides useful prognostic information concerning risk of rebleeding.

TABLE 20-4

ENDOSCOPIC FEATURES SUGGESTIVE OF INCREASED RISK OF REBLEEDING

Peptic ulcer
Arterial spurting of blood or oozing
Visible vessel at the ulcer base
Clot at the ulcer base
Ulcer >2 cm
Esophageal varices
Size of varices
Red spots on varices

There is a broad base of data showing that endoscopic treatment is successful in reducing the rate of rebleeding when applied to ulcers with visible vessels or active bleeding. It is controversial, although suggested, that if a clot is found to be covering the ulcer base it should be removed so that underlying abnormalities could also be treated. Endoscopic treatment often includes initial injection of the ulcer with epinephrine. This maneuver usually stops oozing or active bleeding and also reduces the risk of precipitating bleeding if a visible vessel or clot is treated with thermal coagulation. The injection with epinephrine helps to keep the endoscopic field clear of blood to facilitate further endoscopic treatment. However, epinephrine injection alone is not adequate to prevent recurrent bleeding. It is used as an aid to more definitive endoscopic therapy. Several therapeutic techniques can then be used that are equally efficacious in stopping bleeding and reducing the risk of ulcer rebleed. These include coaptive coagulation with heater probe or BICAP probe, and also noncontact techniques including argon plasma coagulation and laser therapy. Application of endoscopic clips is another modality that can be used to stop acute bleeding. Laser therapy has fallen out of favor because the equipment is expensive and not easily portable to bring to the patient's bedside. In addition to the treatment of ulcers, these endoscopic techniques are also used to treat other lesions that may cause bleeding such as Mallory-Weiss tears, angiodysplasia, and Dieulafoy lesions.

Although all of these techniques reduce the rate of rebleeding, the mortality rate has not been affected. This probably is related to the deleterious results of the initial blood loss and resulting poor perfusion on the function of other organs, especially in the elderly and those with comorbid diseases such as coronary and cerebrovascular disease and renal insufficiency, diabetes, and hypertension. The mortality associated with acute gastrointestinal bleeding is usually secondary to organ failure or stroke or myocardial infarction and not because of exsanguinations.

Pharmacological Therapy

Patients with upper gastrointestinal bleeding are also treated with acid suppression in addition to the endoscopic therapy. H-2 blockers are not effective in raising the gastric pH adequately and also develop tachyphylaxis after 1–2 days of intravenous use.[4] Studies show that their use is not clinically significantly better than placebo in preventing rebleeding.[4] High-dose proton pump inhibitors, when used in conjunction with endoscopic therapy, improve the rebleeding rate and perhaps the need for surgery; although, as already mentioned, there is no mortality benefit. The high-dose treatment can be given for the first few days as an infusion, such as a bolus of omeprazole 80 mg followed by 8 mg/h infusion or as bolus therapy with 40 mg b.i.d. These regimens have been shown to be equally efficacious in preventing repeat bleeding episodes.[15] High-dose treatment has been shown to raise the gastric pH above 6 and theoretically, this may stabilize a clot by improving platelet aggregation and decreasing fibrinolysis.[15]

Assessing Response to Therapy

With the possible exception of varices and ulcers containing visible bleeding vessels, most GI bleeding ceases spontaneously.

Aggressive fluid resuscitation and correction of coagulopathy during acute GI bleeding are essential.

Unlike most causes of acute gastrointestinal bleeding that stop spontaneously approximately 80% of the time, only 50% of episodes of gastro-esophageal variceal bleeding stop spontaneously.[6]

Cirrhotic patients with more severe decompensation, Child's class C, and those with large varices are less likely to stop without therapy. As with all cases of gastrointestinal bleeding, there are three goals to therapy. Foremost is establishing intravascular stability by replacing lost volume and blood products.

The initial treatment is usually with infusion of crystalloid such as normal saline with the goal to stabilize blood pressure. It is useful to also follow the heart rate, which initially increases as a physiologic response to increase cardiac output in the presence of volume depletion. Signs that volume replacement is successful in returning the patient toward a euvolemic state include an increase in blood pressure and decrease in tachycardia. Adequate volume replacement improves cardiac output and perfusion of the body, but additionally it is necessary to transfuse packed red blood cells to maintain a level of hemoglobin adequate to

oxygenate the body organs. This varies with the age and comorbidities of each patient but can be in the range of 9–10 g/dL. Excessive transfusion of blood products can increase the risk of recurrent variceal bleeding by causing an increase in portal hypertension.[16] Transfusion of fresh frozen plasma to correct coagulopathy, often associated with cirrhosis, and transfusion of platelets if needed during active bleeding also must be considered. It is rarely necessary or advantageous to transfuse whole blood.

Complications of Gastrointestinal Bleeding

The second goal of therapy during acute bleeding is to prevent complications secondary to the bleeding. Upper gastrointestinal bleeding can result in aspiration and impair oxygenation. During profuse active bleeding, endotracheal intubation to maintain an adequate airway and prevent aspiration is often necessary. This is especially true if the patient is encephalopathic or has a depressed gag reflex or if he will require large amounts of sedation during endoscopy. In addition to monitoring the patient for consequences of bleeding such as myocardial infarction, stroke or renal insufficiency, a patient with cirrhosis has an increased risk of bacterial infection not seen in noncirrhotic patients. There is an increased risk of bacteremia, pneumonia, urinary tract infection, and spontaneous bacterial peritonitis that is associated with bleeding episodes in cirrhotic patients.[16] Therefore, antibiotic prophylaxis with either a quinolone or cephalosporin is suggested during the treatment of a cirrhotic with bleeding.[16] Other complications seen in bleeding cirrhotic patients include hepatic encephalopathy and renal insufficiency. Hepatic encephalopathy can be precipitated by absorption of the excessive protein load presented to the gut from the digestion of the blood as it passes from the stomach through the small intestine. However, this should not be assumed the cause until other precipitating factors of hepatic encephalopathy are excluded including electrolyte abnormalities; e.g., hypokalemia, alkalosis, and hypo and hypernatremia; and medications, e.g., sedatives and narcotics, and infection. Other causes of altered mental state should also be evaluated including neurologic events such as intracranial bleed. Another frequent complication of bleeding in the cirrhotic patient is renal insufficiency, which can be secondary to acute tubular necrosis caused by hypoperfusion from blood loss as is seen in noncirrhotic patients. Additionally, a cirrhotic patient can develop hepato-renal syndrome as a consequence of the bleeding episode. Renal insufficiency complicating a bleeding episode in a cirrhotic patient is a poor prognostic sign and is associated with a high in-hospital mortality rate[12] (Table 20-5).

Controlling Active Bleeding

The third goal of treatment of the bleeding cirrhotic patient is the cessation of bleeding. Variceal bleeding responds to both pharmacologic and endoscopic treatment. Drugs are used to constrict the mesenteric arterial bed and thereby reduce blood return into the portal venous system. This leads to a reduction in portal pressure and cessation of variceal bleeding in many patients. Intravenous infusion of vasopressin has been successful in stopping variceal bleeding in 60% of patients. However, vasopressin causes diffuse arterial constriction and can lead to myocardial infarction, stroke, renal insufficiency, and limb ischemia. To reduce these risks, intravenous nitroglycerine has been given with vasopressin. However, the treatment of choice is now the intravenous infusion of octreotide, a long-acting analog of somatostatin that leads to vasoconstriction of the mesenteric arterial bed. It is postulated that it

TABLE 20-5

COMPLICATIONS OF GASTROINTESTINAL BLEEDING

Aspiration of blood	Acute hypoxemia, cardio-pulmonary arrest, arrhythmia, chemical pneumonitis
Hypoperfusion of end organs	Acute myocardial infarction, stroke, acute tubular necrosis, mesenteric ischemia
In cirrhotic patient	Increased risk of infection – bacteremia, spontaneous bacterial peritonitis hepatic encephalopathy

TABLE 20-6

CONTROL OF VARICEAL BLEED

Pharmacologic	Vasopressin ± nitroglycerine infusion Octreotide
Endoscopic	Sclerosis Banding
Sengstaken-Blakemore tube	
Trans-jugular intrahepatic portal-systemic shunt (TIPS)	
Surgery	Shunt Esophageal transection

works by decreasing secretion of vasodilatory gastrointestinal hormones such as glucagon. Octreotide is not associated with constriction of other systemic arterial beds and therefore is a safer drug to use than vasopressin. It is successful in stopping variceal hemorrhage in many patients; although, this is a temporizing treatment. It is given as an intravenous bolus of 50 mg and then an infusion at 50-mg/h. The optimal length of treatment is not known but it is usually continued for 2–3 days. During this time, more definitive endoscopic treatment can be done (Table 20-6).

Initially, endoscopic variceal sclerosis was done with an injection needle catheter passed through the endoscope. Various sclerosing agents were used and injected into the varix or para-variceal to obliterate the varices. This was associated with several complications, including esophageal ulceration that could lead to bleeding or stricture formation. Perforation, mediastinitis, and sepsis were also complications. Because of the complication profile, most endoscopists prefer the technique of endoscopic band ligation to obliterate esophageal varices. Endoscopic banding is usually done every 2–3 weeks to allow healing of superficial ulceration. In contrast to the sclerosis ulcers, it is unusual for these ulcerations to cause clinical problems. It usually requires two to three endoscopic sessions to completely obliterate esophageal varices by banding. Because banding does not affect portal hypertension, it is necessary to do surveillance endoscopy to detect the formation of new varices in the future. Endoscopic treatment of bleeding gastric varices is less effective. Injection of sclerosing agents has been tried with limited success.

Esophageal balloon tamponade techniques can be used when endoscopy ligation and sclerotherapy fail to stop variceal bleeding as a temporizing method.

If pharmacologic and endoscopic treatment is unsuccessful or if variceal bleeding recurs, there are three therapeutic options. This includes placement of a Sengstaken-Blakemore tube, placement of a trans-jugular intrahepatic portal-systemic shunt (TIPS shunt), or surgery. The Sengstaken-Blakemore tube is rarely used because of risks of aspiration, necrosis or perforation, or migration of the balloon causing airway obstruction.

The device has a gastric balloon and an esophageal balloon, which can be distended to compress the veins in order to stop variceal bleeding. First the gastric balloon is distended to a particular volume with air after fluoroscopic placement below the diaphragm. The apparatus with the distended balloon is then pulled against the esophago-gastric junction to compress the veins in the gastric cardia and thereby decrease flow of blood into the esophageal varices. If this does not result in cessation of bleeding, then the esophageal balloon is next distended to the indicated pressure to directly compress the esophageal varices in an attempt to stop bleeding. There is a suction port in the stomach and usually a naso-gastric tube is placed proximal to the esophageal balloon to aspirate secretions in the esophagus to reduce the risk of aspiration. Placement of the Sengstaken-Blakemore tube is temporizing and bleeding frequently recurs when the tube is deflated if more definitive treatment has not been done.

More frequently, if variceal bleeding is not controlled by drugs or endoscopic intervention, a TIPS shunt is placed by the interventional radiologist. This creates a fistula between the hepatic vein and portal vein. This technique is done by passing a catheter, under fluoroscopic guidance, through the internal jugular vein to the level of the hepatic vein. A needle is subsequently passed through the hepatic vein and through the liver parenchyma into a branch of the portal vein. This tract is then dilated, and a metallic expandable stent is placed in the liver to create a shunt between the portal and hepatic veins. Blood flows directly from the portal vein through the shunt into the hepatic vein without traversing the sinusoids. This decompresses the portal hypertension and controls variceal bleeding; however, this shunts

blood away from the liver and can result in precipitating hepatic encephalopathy and worsening liver failure. The last option to control variceal bleeding is emergent surgery to create a vascular shunt to decompress portal hypertension or by transection of the distal esophagus, which disrupts the esophageal variceal blood flow. Surgery is associated with a high mortality rate in the critically ill cirrhotic patient and shunt surgery is also associated with complications of worsening liver function and hepatic encephalopathy, similar to the TIPS procedure. Emergency surgery should be avoided if possible. After the variceal bleed is controlled, patients should be evaluated for the possibility of liver transplant.

SUMMARY

The successful management of acute gastrointestinal hemorrhage demands a highly organized and multidisciplinary diagnostic and treatment approach. The intensivist must quickly involve the gastroenterologist and, when necessary, the invasive radiotherapist and surgeon in the diagnostic and treatment process. The intensivist must quickly identify that bleeding is present and with the help of the gastroenterologist determine the site of bleeding. During this diagnostic process, the magnitude of bleeding must be assessed and aggressive resuscitation must occur. The urgency of these processes depends heavily on the severity of the hemorrhage and its etiology. The therapeutic resources that are available must play an important part in this treatment equation. The availability of endoscopic therapy and interventional radiology has diminished the frequency of surgical intervention for upper gastrointestinal hemorrhage. However, surgical intervention is usually necessary for unremitting lower gastrointestinal bleeding.

REVIEW QUESTIONS

1. **All the following are common causes of gastrointestinal bleeding except:**
   - **A.** Gastric ulcer
   - **B.** Esophagitis
   - **C.** Gastritis
   - **D.** Diverticulosis

2. **Peptic ulcer disease is least likely to be associated with:**
   - **A.** Melena
   - **B.** Pain
   - **C.** Hematochezia
   - **D.** Hematemesis

3. **The most important therapeutic intervention during urgent resuscitation of acute GI bleeding is:**
   - **A.** Intravascular volume expansion
   - B. Vasopressor therapy
   - **C.** Correct coagulopathy
   - **D.** Endotherapy

4. **The immediate treatment of choice for bleeding esophageal varices is:**
   - **A.** Liver transplantation
   - **B.** TIPSS procedure
   - **C.** Esophageal balloon tamponade
   - **D.** Endoscopy with band ligation

ANSWERS

1. The answer is B. The most frequent etiology of esophagitis is gastro-esophageal reflux disease. Esophagitis can also be caused by infections such as candida, herpes, and cytomegalovirus. These infections are frequently complications of the immunocompromised state. Esophageal ulceration can also result from mucosal injury caused by some medications. Although esophagitis may cause mucosal erosion and ulceration, gastrointestinal bleeding is an uncommon result. Esophagitis is more frequently diagnosed because of symptoms of retrosternal heartburn, chest pain, or odynophagia or dysphagia.

2. The answer is C. Peptic ulcer disease effects the stomach and duodenum and frequently presents as epigastric pain. The pain of duodenal ulcer classically is improved with food. Gastric ulcer pain may be worsened by eating if it causes delayed gastric emptying. The complication of ulcer bleeding may present as hematemesis or the passage of melena, black stool per rectum. Melena usually is from bleeding proximal to the ligament of treitz; although, it rarely can be from a right colonic source. The rapid transit of a large amount of blood from an ulcer may result in hematochezia; however, the passage of red blood per rectum more commonly is from a colonic source.

3. The answer is A. Intravascular hypovolemia must be quickly corrected to prevent end-organ damage. Blood pressure must be stabilized to assure adequate perfusion of vital organs. Volume resuscitation is initially managed by infusion of crystalloid and, if needed, blood transfusion is given to maintain an adequate hemoglobin level for oxygen delivery. Complications of inadequate volume replacement can result in stroke, myocardial infarction, acute tubular necrosis, and mesenteric ischemia

4. The answer is D. Esophageal varices account for half of the episodes of gastrointestinal bleeding in a cirrhotic patient with esophageal varices. Endoscopy allows accurate diagnosis and treatment with variceal banding. If unsuccessful, balloon tamponade or TIPS shunt can be done, but these procedures are associated with greater risk of complications. Liver transplantation would not be considered in a patient with uncontrolled variceal hemorrhage.

CHAPTER 21

CHAN Y. CHUNG AND WISSAM CHATILA

Acute Liver Failure

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Recognize patients presenting with acute liver failure (ALF).
- Identify different etiologies of ALF.
- Understand the pathophysiology of underlying various organ and system dysfunctions in ALF.
- Monitor and manage patients with ALF.

Acute liver failure (ALF) or fulminant hepatic failure is a rare syndrome of rapidly deteriorating hepatic function characterized by the onset of hepatic encephalopathy (HE) and coagulopathy in a patient without any prior liver disease.[1] With an estimated 2,000 cases per year in the United States, patients with ALF have a high mortality rate and can develop cerebral edema, infections, and multiorgan failure.[2] Before orthotopic liver transplantation (OLT), survival from ALF was only 20%. Currently, with the advent of OLT, overall survival (including patients receiving OLT) rates approach 67%, and spontaneous survival (survival without receiving OLT) rates have risen to 45%. Post-OLT, ALF patients have a 1-year survival rate of 70%. Despite the encouraging results with liver transplantation, patients suffering from ALF are among the most difficult patients to manage while awaiting OLT, and 30% of patients die without receiving OLT.[3] Patients with cirrhosis frequently present to the intensive care unit with hepatic failure; however, they differ from patients with ALF with regard to pathophysiology, management, and prognosis. This chapter is limited to the discussion of patients with ALF.

CASE STUDY

A 43-year-old man presented to the emergency department complaining of severe jaw pain. The patient, with no significant past medical history except for alcoholism, was involved in an altercation at a bar 2 days prior and came to the hospital due to unremitting jaw pain. The patient had normal vital signs and a normal physical examination except for a tender mandible. X-rays of the mandible were consistent with fracture, and the chest x-ray and electrocardiogram were normal. The CBC, BMP, and PT/PTT were all within normal limits. The patient was placed on alcohol withdrawal prophylaxis and acetaminophen+codeine as needed for pain, and the mandible repair was delayed until after the weekend.

Over the weekend, the patient's hospital stay was uneventful except for mild confusion which was thought to be due to alcohol withdraw. On the day of the mandible repair, the patient appeared obtunded and jaundiced in the operating room. The operation was canceled and repeat laboratory data were ordered including liver function tests: ALT 25,356, AST 32,098, total bilirubin 8.5, INR 4.6.

The patient was found to be in ALF and transferred to the intensive care unit. The patient's housemate was contacted. It was found that the patient drank up to a case of beer per day and was taking almost a bottle of acetaminophen tablets for the 2 days prior to hospitalization for the jaw pain and finally came to the hospital when it was just too unbearable. Over the hospital stay, he was given two combination acetaminophen and codeine tablets every 4 h for the jaw pain.

Intavenous *N*-acetylcysteine (NAC) was started, but the patient became severely obtunded and was intubated. The patient quickly became unresponsive with progressive worsening liver function tests, coagulopathy, hypoxia, renal failure, and hypotension. He was not eligible for a liver transplant due to his active alcohol abuse, lack of social support, and extremely unstable medical status. One week after his transfer to the intensive care unit, the patient expired.

DEFINITIONS AND ETIOLOGY

Acute Liver Failure:
Occurs in patients without previous history of liver disease. Is defined as the development of hepatic encephalopathy (HE) and coagulopathy usually within 3 weeks of the onset of jaundice. Is associated with an overall survival of 67% and a spontaneous survival (without orthotopic liver transplantation) of 45%.

ALF has been defined as the development of HE and coagulopathy within 26 weeks of the onset of jaundice (usually <3 weeks) in a previously healthy person.[1] ALF occurs predominantly in younger patients (30–40 year-old) and women except in the case of viral hepatitis (A and B) and indeterminate causes. It is characterized by either a very rapid (less than 1 or 2 days) or a much slower progression of liver dysfunction (up to several months).[4] Hepatic failure occurs as a result of severe liver injury from either hepatocellular necrosis and/or apoptosis depending on the etiology (Table 21-1).[5] Geographic differences determine the most common etiology of ALF. In the United States, acetaminophen (APAP) is the most common etiology of ALF (46%), followed by non-APAP etiologies: indeterminate causes (14%), other drug-induced injury (11%), acute hepatitis B (HBV) (7%), and autoimmune hepatitis (5%) (Fig. 21-1).[4] Acetaminophen is also the most common cause of ALF in the United Kingdom and Scandinavia.[6] In East Asia, indeterminate causes and acute HBV are the dominant causes of ALF, while indeterminate causes and hepatitis E (HEV) are the two most common causes in India, with hepatitis A (HAV) being the most common in South America.[7,8]

Acetaminophen is the most common cause of ALF, followed by non-APAP etiologies. Despite an exhaustive workup, the etiology of ALF remains indeterminate in 15% of patients.

CLINICAL FEATURES

Development of HE is required to diagnose ALF.

The hallmark of ALF is the development of HE in the setting of acute and severe liver injury.[9] The severity of HE, which manifests as neuropsychiatric dysfunction, has been stratified into four stages (Table 21-2).[10] Unlike HE of decompensated cirrhosis, HE of ALF responds poorly to therapy and often masks the development of cerebral edema, a catastrophic complication of ALF. Cerebral edema is characterized by systemic hypertension, hyperventilation, increased muscle tone, decorticate or decerebrate posturing, abnormal pupillary reflexes, and eventually altered brainstem reflexes in the event of uncal or cerebellar herniation. Unfortunately, it is common for cerebral edema to develop in the absence of significant physical findings.[11] Moreover; ALF usually affects all organ function, resulting in cardiovascular instability, hypoxemic respiratory failure, renal insufficiency, coagulopathy, severe malnutrition, and life-threatening infections. Therefore, in addition to the signs of HE and jaundice, patients with ALF have fetor hepaticus (an unusual distinct odor) and present with tachycardia, tachypnea, hypotension, and hypoxemia. The aforementioned signs may also be related

TABLE 21-1

CAUSES OF ALF

Drug toxicity
- Acetaminophen
- Antimicrobials (tetracycline, ampicillin-clavulanate, trovafloxacin, isoniazid)
- Antiepileptics (valproate, phenytoin)
- Anesthetic (halothane)
- Antihyperglycemic (troglidazone)
- Antidepressants (tricyclic antidepressants, monoamine oxidase inhibitors)
- Others: loratadine, pemoline, antabuse, cyclophosphamide, lovastatin

Viral hepatitis
- Hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis E (HEV)
- Herpes simplex virus (HSV)
- Epstein–Barr virus (EBV)

Toxins
- Mushrooms (*Amanita phalloides*)
- Organic solvents
- Ethanol
- Herbal remedies (ginseng, chaparral, pennyroyal oil, teucrium polium)
- Bacterial toxins (cyanobacteria, *Bacillus cereus)*

Circulatory impairment
- Ischemia (hepatic vascular occlusion, shock)
- Septic shock
- Cardiac failure
- Heat stroke

Pregnancy induced
- Acute fatty liver of pregnancy (AFLP)
- Hemolysis-elevated liver enzymes-low platelet (HELLP) syndrome

Malignant infiltration
- Hematologic (leukemia, lymphoma)
- Liver metastasis

Metabolic
- Wilson disease
- Galactosemia
- Hereditary tyrosinemia

Miscellaneous
- Autoimmune hepatitis
- Budd–Chiari syndrome
- Malaria
- Tuberculosis

Coxiella burnettii
- Reye syndrome

Etiologies of acute liver failure (ALF) in United States (n=1,147) (Modified from Lee et al.[4] ©2008 John Wiley & Sons, Inc. Reprinted with permission from John Wiley & Sons, Inc).

TABLE 21-2

STAGES OF HEPATIC ENCEPHALOPATHY (HE)

STAGE	MENTAL STATE
1	Changes in behavior with minimal change in the level of consciousness
2	Gross disorientation, drowsiness, possible asterixis, inappropriate behavior
3	Marked confusion, incoherent speech, sleeping most of the time but arousable to vocal stimuli
4	Comatose, unresponsive to pain, decorticate or decerebrate posturing

SOURCE: Modified from Polson and Lee.[10] Copyright 2005 John Wiley & Sons, Inc. Reprinted with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc

to sepsis or gastrointestinal hemorrhage, which are common complications of ALF.[12] Laboratory abnormalities vary according to the etiology of the hepatic failure, but it is the development of HE rather than specific test results that distinguishes ALF from severe active hepatitis. Common laboratory findings in ALF include an increase in ammonia level, elevated international normalized ratio (INR), and elevation in liver function tests: hyperbilirubinema (much lower in APAP etiology compared to other etiologies), transaminitis (>1,000, in HAV or HBV and ischemic hepatitis and even greater in APAP toxicity; usually <1,000 with other causes) (Table 21-3).[4]

PATHOPHYSIOLOGY OF LIVER FAILURE

Hepatic Encephalopathy and Cerebral Edema

Cerebral edema: Develops in patients with advanced HE (stage 3 or stage 4). Leads to brain death if unrecognized and untreated.

Intracranical hypertension secondary to cerebral edema is one of the primary causes of high mortality and morbidity in the ALF patient. The neural depression and generalized slowing seen on electroencephalography (EEG) associated with HE are thought to be mediated through increased inhibitory neurotransmitters such as γ-aminobutyric acid A (GABA). Ammonia, infection/inflammation, and hyponatremia contribute greatly to the development of cerebral edema. Ammonia, primarily synthesized by gut flora, is detoxified in astrocytes to osmotically active glutamine leading to cerebral swelling. Higher arterial ammonia levels are associated with higher morbidity and mortality in patients with ALF. Infection and inflammation have been associated with worsening HE in ALF.[13] The progression of cerebral edema is accelerated by volume overload, hyponatremia, and a hypo-oncotic state and leads to a significant increase in intracranial pressure (ICP); therefore hyponatremia should be strictly avoided. Ammonia's effect on cerebral edema can be potentiated by hyponatremia. It is unclear whether cerebral edema represents the end-stage of the spectrum of HE or if it constitutes a separate complication. Cerebral edema occurs mostly in stages 3–4 of HE and is one of the principle causes of death in ALF. Three mechanisms may be involved in the pathogenesis of cerebral edema: (1) increase in the cerebral interstitial fluid; (2) increase in fluid transfer across the blood–brain barrier; and (3) cellular edema. Cellular (cytotoxic) edema from astrocyte swelling appears to be the primary etiology of cerebral edema in the ALF patient.[8]

Infections

Infectious complications in ALF are very common and occur early in the course of the disease.

Infectious complications occur early in the course of ALF in up to 80% of patients and are a major cause of mortality. Patients with ALF are predisposed to multiple infections and sepsis because of their compromised immune function (related to complement and opsonin deficiency and impaired neutrophil function) and the use of invasive ICU instrumentation. Bacterial as well as fungal infections have been reported. The lungs, urinary tract, and blood in descending order are the most common sites of bacterial infection. Catheter-related infections are a major source of avoidable infection. Isolated organisms include *Staphylococcus aureus, Streptococcus* species, and gram-negative bacilli. One-third of the patients develop fungal infections, specifically *Candida* species.[14]

TABLE 21-3

ETIOLOGY AND CLINICAL CHARACTERISTICS OF 1,147 ALF (1998–2007)

FEATURE	APAP (*N*=532)	DRUGS (*N*=133)	INDETERMINATE (*N*=161)	HAV (*N*=31)	HBV (*N*=83)	ALL OTHERS (*N*=207)

Death without transplantation (%)	26	31	32	13	28	33

SOURCE: Modified from Lee et al.[4]

Renal Impairment

Renal insufficiency (serum creatinine >2 mg/dL) in ALF, often manifested by oliguria and water retention, can result from hepatorenal syndrome, acute tubular necrosis (ATN), or intravascular volume depletion. Renal insufficiency has been reported to occur in 30–84% of the cases of ALF, some of which progress to end-stage renal failure that requires hemodialysis. The hepatorenal syndrome is a functional renal impairment resulting from an intense renal arterial vasoconstriction caused by a hormonal imbalance (an increase in renin and aldosterone vs. a reduction in prostaglandin). ATN may also result from the same toxic substances that precipitated ALF (e.g., acetaminophen) or from iatrogenic factors introduced in the ICU (hypotension, nephrotoxic drugs, or contrast agents). Typically in hepatorenal syndrome, the urine sodium (U_{Na}) < 10 mEq/L and the urine sediment is unremarkable. By contrast, in ATN, the urine shows the presence of cellular casts and U_{Na} >40 mEq/L. A large intravenous fluid challenge is often given to exclude prerenal azotemia.[15]

Circulatory Impairment

ALF is associated with high cardiac output shock and multiorgan dysfunction.

The hemodynamic changes in ALF are comparable to those of sepsis and are consistent with high cardiac output shock, a state characterized by systemic vasodilatation, high cardiac output, hypotension, and impaired tissue oxygen uptake. Some patients experience a reduction in their cardiac output and heart rate (relative bradycardia), both of which exacerbate the presence of hypotension. Of note, one should be careful to detect infections and hemorrhages, commonly encountered in patients with ALF that can contribute to hypotension and further blur the clinical picture. It has been suggested that this state of systemic vasodilatation is centrally mediated or mediated via circulating endotoxin, increased inflammatory mediators (tumor necrosis factor, interleukin-6), and unregulated production of nitric oxide (NO). Systolic hypertension in a patient with stage 3 or 4 encephalopathy may indicate the development of increased ICP.[16]

Respiratory Failure

Hypoxemia is extremely common in ALF. Noncardiogenic pulmonary edema (pulmonary artery occlusion pressure <18 mmHg) accounts for almost one-third of cases with hypoxemia, but the true incidence of pulmonary edema also varies with the nature of the inciting event.[17] Other causes of hypoxemia include aspiration of gastric contents in encephalopathic patients, nosocomial pneumonia, intrapulmonary hemorrhage, and pulmonary vascular dilatation. Hypoxemia is multifactorial in the majority of patients with ALF. In addition to hypoxemia, a respiratory alkalosis may be observed, except in cases of advanced cerebral edema that results in respiratory depression.[18]

Coagulopathy

Patients with ALF are, by definition, coagulopathic with hypofibrinogenemia and platelet dysfunction, both quantitative and qualitative. The liver is involved in the synthesis of numerous coagulation factors (other than factor VIII) and some of the inhibitors of fibrinolysis. In ALF, the abnormal prothrombin time found in all patients confirms the loss of liver synthetic function and is used as an indicator for the severity of hepatic injury. A high prothrombin time reflects more impaired hepatic synthetic function and more severe liver injury. Moreover, thrombocytopenia (<100,000/mL) and platelet dysfunction have been demonstrated in ALF. A low-grade disseminated intravascular coagulation (DIC) in part due to increased peripheral consumption and fibrinolysis may coexist with impaired hepatic synthetic function, further exaggerating the risk of major hemorrhage (gastrointestinal and intrapulmonary).[19]

Metabolic Disturbances

The liver is the site of glycogen stores, gluconeogenesis, and lactate metabolism. In the presence of severe hepatic necrosis, and despite the hypercatabolic state of patients with ALF,

the liver is rendered ineffective as a source of glucose. Therefore, it is common to observe that such patients have high glucose requirements necessitating continuous intravenous 10% dextrose infusion. Moreover, severe lactic acidosis may complicate the metabolic acidosis associated with renal failure.[20]

PROGNOSIS OF LIVER FAILURE

The prognosis in ALF is related to the etiology and the severity of the liver injury. However, the etiology of liver failure may be the most important predictor of outcome. The highest survival rates have been reported in acetaminophen toxicity and Hepatitis A Virus (HAV) infections. Acetaminophen toxicity, HAV, pregnancy, and ischemic hepatitis (shock liver) have a better prognosis with a 60–70% survival without OLT. ALF from drug-induced liver injury, indeterminate causes, HBV, and Wilson's disease have a poor prognosis with a 20–30% survival without OLT. The timing of the onset of HE has a major impact on prognosis. Generally, there is a better outcome in patients with hyperacute ALF with a quick onset of HE (<1 week), e.g., APAP toxicity and HAV, compared to patients with slower onset HE. The level of HE also has prognostic implications. Higher mortality is seen in patients with severe HE who undergo emergent OLT compared to those with mild encephalopathy. In addition, persistent deterioration of HE and coagulopathy despite aggressive supportive therapy also indicate a poor prognosis.[4]

With ALF from APAP toxicity, hypoglycemia is a poor prognostic sign, pointing to the inability of the liver to conduct gluconeogenesis and mobilize glycogen. Also, a continually rising prothombin time (PT) after 3–4 days is associated with mortality as high as 93%. However, approximately 70% of patients with APAP toxicity recover from ALF by 4–14 days.[21] There is no one good standardized method of determining prognosis, but many transplant centers use the King's College Hospital prognostic criteria. Patients are divided into APAP and non-APAP hepatic injury patients (Table 21-4).[18] Refractory increases in ICP, factor V, factor VIII/factor V ratio, liver histology, hepatic volumetry (by computed tomography [CT] scanning), arterial ketone body ratio, and plasma Gc protein have been proposed to have prognostic significance; however, some variables require further validation, and others are more difficult to obtain (e.g., liver biopsy or CT scans).

MONITORING AND MANAGEMENT

The search for the etiology and an initial evaluation for prognosis should begin immediately in the ALF patient. A thorough history should be obtained as to the timing of exposure or ingestion of a toxin, onset of jaundice, and/ or onset of HE. A detailed medication history, including prescription, nonprescription, herbs, and dietary supplements should be obtained. Radiologic imaging of the liver such as a right upper quadrant ultrasound should be obtained to rule out vascular causes. The management of patients with ALF consists of treating the etiology of ALF, if possible, and early evaluation for OLT. Due to the possible rapid neurologic deterioration, patients with ALF should be transferred to an intensive care unit at

TABLE 21-4

KING'S COLLEGE CRITERIA FOR ORTHOTOPIC LIVER TRANSPLANTATION (OLT)

APAP TOXICITY	NON-APAP TOXICITY
Arterial pH<7.3 or all of the following: Grade 3–4 encephalopathy PT>100 s (INR>6.5) Creatinine >3.4 mg/dL	PT>100 s (INR>6.5) or any three of the following: Non-A, non-B hepatitis/drug etiology Jaundice to encephalopathy >7 days PT>50 s (INR>3.5) Bilirubin >17.5 mg/dL Age <10 or >40 years

TABLE 21-5

ETIOLOGY-SPECIFIC THERAPY OF ALF

ETIOLOGY	THERAPY
APAP	*N*-acetylcysteine (NAC) oral or IV
AFLP/HELLP	Delivery of fetus
Amanita phalloides	Penicillin G and NAC (as for APAP overdose)
Autoimmune hepatitis	Methylprednisolone
HBV	Lamivudine or Adefovir
Herpes simplex	Acyclovir

the first sign of encephalopathy. Because of multiorgan involvement, frequent complications, and rapid deterioration in patients with ALF, optimal supportive care cannot be delivered without appropriate monitoring performed by medical and surgical teams familiar with the management of such patients. Therefore, acknowledging that the only effective therapy is OLT, the closest OLT center should be contacted early in the course of care for possible OLT and timely transfer. Patients with ALF should have frequent monitoring of pulse oximetry, serum glucose levels, serum electrolytes, and evaluation of encephalopathy. Due to sampling artifact and risk of complications, liver biopsy is usually not helpful in determining the etiology or prognosis of ALF and is generally not recommended.[10]

Currently available measures or antidotes that are used to minimize hepatic injury are limited to specific types of liver failure. With APAP toxicity, the administration of NAC has been well-studied and is recommended even if there is uncertainty as to the timing, ingested dose, or serum concentration of APAP. NAC should be given ideally at 8–10 h after ingestion, but should not be withheld even after 48–72 h at first presentation. Either oral or intravenous NAC treatment should be continued until there is improvement of hepatic function, e.g., decreasing transaminases, resolution of HE, decreasing INR, but not by declining serum APAP levels.[22] Although not readily available, serum APAP-protein adducts can be measured to detect latent APAP hepatotoxicity.[23] For women with acute fatty liver of pregnancy (AFLP) and hemolysis-elevated liver enzymes-low platelet (HELLP) syndrome, prompt delivery of the fetus is the only non-OLT treatment that can rapidly reverse ALF. Other etiology-targeted treatments for ALF are not well-studied, but recommended: penicillin G and silymarin for Amanita phalloides; acyclovir for herpes simplex virus (HSV); methylprednisolone for autoimmune hepatitis; and lamivudine for HBV (Table 21-5).[18]

There is no specific treatment to reverse the hepatic injury in ALF. The only effective therapeutic intervention is OLT. Early transfer to a liver transplant center is paramount.

There may be a new breakthrough in the pharmacologic approach to reversing existing hepatic injury. A recent preliminary double-blind randomized study compared the use of intravenous NAC for 72 h vs. placebo in 173 patients with ALF from non-APAP etiology other than from pregnancy, malignancy, and shock. There was a significant spontaneous survival benefit (survival without OLT) in patients with mild HE (stage 1–2). Due to its good safety profile and easy availability, IV NAC may be recommended in all ALF patients with mild HE (stage 1–2), but future studies will need to confirm its effectiveness.[24] Because of the scarcity of available organs for donation, many nonpharmacologic approaches for liver replacement are under investigation (bioartificial liver support including hepatocyte transplantation, xenotransplantation, and bioreactors; artificial liver support including sorbent dialysis, large volume plasmapheresis, and albumin dialysis).[25] Until the efficacy and safety of nontraditional approaches are established, the management of patients with ALF consists of aggressive supportive care along with the recognition and treatment of complications while awaiting liver transplantation or until spontaneous liver function recovery occurs. Many of the following management strategies and recommendations are from the United States Acute Liver Failure Study Group.[18]

Hyperammonemia

Although higher arterial ammonia levels have been associated with increased morbidity and mortality, there is insufficient evidence to recommend lactulose or nonabsorbable antibiotics in the treatment of ALF. Neomycin is not recommended because of the risk of ototoxicity

and nephrotoxicity. If lactulose is to be administered, the development of intravascular depletion, aspiration, and gaseous abdominal distention leading to possible megacolon should be monitored.[18]

Infection

Although underpowered, studies on prophylactic antibiotics have not been shown to decrease mortality in patients with ALF and are not recommended in patients with early HE.[26] Because patients with ALF do not frequently show signs and symptoms of infection, daily surveillance cultures and chest X-rays are recommended for early detection of infection. Empiric broad-spectrum antibiotics are recommended for ALF patients that have positive cultures, worsening HE, and refractory hypotension.[8] Both antibacterial and antifungal empiric treatment are recommended for patients listed for OLT.[18]

Sedation and Analgesia

Sedation should be avoided in early HE (stage 1–2) to more accurately assess changes in mental status. However, pain and psychomotor agitation, especially in advanced HE (stage 3–4), can increase ICP.[27] Benzodiazepines and propofol are the two most commonly used sedative agents. Although these two agents can worsen HE by increasing GABA neurotransmission, careful sedation and analgesia should be used particularly prior to invasive procedures, e.g., endotracheal intubation, central line placement, ICP devices. Propofol appears to be more beneficial secondary to shorter recovery time and its benefit in decreasing ICP by decreasing cerebral blood flow. A shorter half-life opiate infusion such as fentanyl is also recommended to prevent and treat patient discomfort rather than morphine or meperidine that can decrease seizure threshold by accumulating active metabolites with renal failure.[18]

Coagulopathy

Spontaneous bleeding rates are low (<10%) and prophylactic correction of coagulopathy is not recommended.[28] Attempts to correct coagulopathy prior to invasive procedures, e.g., central line placement, are recommended. Cryoprecipitate can be given with significant hypofibrinogenmia (<100 mg/dL). When fresh-frozen plasma cannot correct the INR to safe levels (≤1.5), recombinant factor VIIa (rFVIIa) can be administered immediately prior to very invasive procedures, e.g., ICP measurement device placement. If rFVIIa is contraindicated, e.g., thrombus, pregnancy, stroke, myocardial infarction, plasma exchange can be considered to correct the coagulopathy. Vitamin K deficiency may contribute to the coagulopathy, and parenteral vitamin K administration is recommended.[29] Intravenous histamine-2-receptor blockers have been shown to decrease upper gastrointestinal bleeding rates and should be administered. Proton pump inhibitors are an acceptable alternative. Platelet transfusion is recommended when there is thrombocytopenia (<50,000/mm^3) with clinically significant bleeding or prior to an invasive procedure.[18]

Nutrition

High caloric density enteral nutrition is recommended in patients with ALF due to their hypercatabolic state and to avoid hypoosmolality that may exacerbate cerebral edema.[30] Total parenteral nutrition should be administered only when enteral nutrition is contraindicated. With hypoglycemia, intravenous glucose infusion is recommended with tight glucose control avoiding both hypoglycemia and hyperglycemia that can increase ICP.[18]

Seizure Prophylaxis and Surveillance

Although silent seizure activity has been seen in a large proportion of ALF patients with high grade HE (stage 3–4), there are conflicting results in the use of prophylactic anticonvulsants, and its use is not recommended.[31,32] The use of EEGs are recommended for high grade HE

(stage 3–4), abrupt deterioration in neurologic examination, myoclonus, or to titrate barbiturate coma therapy in the management of cerebral edema.[18]

Circulatory Dysfunction

Hemodynamically unstable patients may require arterial cannulation and pulmonary arterial catheterization to titrate fluid resuscitation and vasopressor support to maintain adequate tissue perfusion pressure and to minimize organ dysfunction. After the correction of volume status with intravenous crystalloids, vasopressors may be used with systolic blood pressure <90 mmHg, mean arterial blood pressure <65 mmHg, or to maintain cerebral perfusion pressure (CPP) to 50–80 mmHg. Although dopamine and norepinephrine are recommended, norepineprhine is preferred due to its more consistent and predictable increase in CPP.[33] Low-dose dopamine is not effective in preventing renal failure and is not recommended. Epinephrine is not recommended due to its possible effect on decreasing the hepatic blood flow. Vasopressin can directly cause cerebral vasodilation leading to increased ICP and is not recommended. Patients with ALF frequently have relative adrenal insufficiency, and hydrocortisone has been shown to improve norepinephrine response to hypotension.[18] Hydrocortisone administration should be considered in patients with persistent hypotension despite intravenous volume challenge and norepinephrine.[34]

Cerebral Edema and Intracranial Hypertension

Any patient who progresses to high grade HE (stage 3–4), undergoes an acute deterioration of mental status, or prior to placing an ICP monitor should undergo a head CT to rule out intracranial hemorrhage. The head CT may detect cerebral edema, but is not sensitive in detecting intracranial hypertension.[35] Monitoring of cerebral hemodynamics (ICP, CPP, cerebral blood flow, and cerebral oxygen consumption) is not universally accepted for all patients with ALF, but many transplant centers strongly advocate its early use in patients with advanced HE because this allows early identification and treatment to minimize risks of significant brain injury. On the other hand, ICP monitoring is essential for diagnosis as well as for guiding therapy in patients with deteriorating neurologic status who are suspected to have intracranial hypertension. The placement of an ICP monitor has been very controversial due to the lack of randomized, controlled studies, but nonrandomized studies have shown to improve survival. Placement of ICP monitors have a 10–20% risk of bleeding complications and is not recommended in patients with low-grade HE (stage1–2), severe brain herniation, or severe hypotension.[36] However, ICP should be considered in patients listed for OLT with severe HE (stage 3–4) and in non-OLT candidates with a reasonable likelihood of spontaneous survival.[18]

The management of cerebral edema first starts with interventions to avoid increasing ICP. The patient with cerebral edema from ALF should be in a quiet environment with limited stimulation, and interventions that can increase ICP such as tracheal suctioning and chest physiotherapy should be minimized. A patient's positions such as the Trendelenburg position, head flexion, head rotation, and sudden change of position to the supine position can increase ICP and should be avoided. The head of the bed should be elevated to 30° to decrease ICP and to avoid aspiration.[37] Fever can increase ICP and should be treated aggressively with cooling blankets or fans, but not with nonsteroidal antiinflammatory drugs or APAP due to the risk of nephrotoxicity and potentiating hepatotoxicity, respectively.[38]

Aggressive central and cerebral hemodynamic monitoring is required to guide the therapy for complications.

Osmotic diuresis administered in boluses has been shown to be effective in reducing ICP. Mannitol (0.25–0.5 g/kg) in boluses are usually given as needed (as long as serum osmolality remains <320 mOsm/L and with a normal osmolar gap) to maintain an ICP < 25-mmHg or a CPP of 50–80 mmHg.[39] Hypertonic saline can be given in boluses (7.5% at 2.0 mL/kg) or infused (30% at 5–20 mL/h) to maintain a serum sodium of 145–155 mmol/L to decrease ICP along with frequent monitoring of serum sodium. Rapid increases of serum sodium should be avoided in the hyponatremic patient due to the risk of osmotic demyelination.[40] Some liver transplant centers also induce a state of hypothermia and/or barbiturate coma to reduce ICP in patients refractory to mannitol and hypertonic saline to bridge them to OLT.[18] Moderate hypothermia (32–33°C) has been shown to decrease ICP and can be considered

when treatment is refractory to mannitol, but is not recommended as prophylaxis. Shivering can increase ICP and should be treated with meperidine or increased sedation.[41] Intravenous indomethacin (25 mg over 1 min), by inducing cerebral vasoconstriction, can be used as salvage therapy to acutely decrease ICP and increase CPP.[18] If hemodialysis is required, continuous hemodiafiltration is preferred due to intermittent hemodialysis causing increases in ICP. Reduction of blood volume with hemodiafiltration can be effective in decreasing ICP.[42] Corticosteroids have not been shown to decrease ICP in the ALF patient and are not recommended. Ventilatory management is also considered to reduce ICP (see below).[18]

Respiratory Failure

Mechanical ventilation is recommended not only for the management of acute hypoxemic respiratory failure, but also for ICP monitor placement and severe encephalopathy (stage 3–4) to protect the patient from aspiration. To prevent increasing ICP, induction anesthesia and constant sedation should be used during intubation and mechanical ventilation, respectively.[18] Hyperventilation may decrease ICP secondary to hypocapnia-induced cerebral vasoconstriction. However, prophylactic hyperventilation has not been shown to effect cerebral edema and may even decrease cerebral oxygen utilization due to vasoconstriction.[43] Acute hyperventilation can be used as emergency rescue therapy in brain herniation. A stable pCO_2 (30–40 mmHg) should be maintained to avoid hypercapnia that can increase ICP. A high positive end-expiratory pressure may increase ICP and decrease hepatic blood flow; thus a lower positive end-expiratory pressure is recommended.[18]

SUMMARY

Patients with severe liver dysfunction are extremely difficult to manage because of the nature of multiorgan involvement during the course of their illness. However, successful outcome is possible with aggressive monitoring and management in tertiary care transplant centers. Early recognition of ALF allows expedited transfer of high-risk patients to specialized centers where sophisticated supportive therapy is instituted while patients await their only curative therapy, liver transplantation. Delivering prompt, appropriate and meticulous care to these patients, such as recognizing infections and cerebral edema, are paramount.

1. Urgently identify and remove the etiology of hepatic injury.
2. Optimize the patient's condition for hepatic recovery.
3. Anticipate and prevent the complications of ALF.
4. Urgently identify and transplant candidates for OLT.

REVIEW QUESTIONS

1. In ALF:
- **A.** The slower the progression the better the outcome
- **B.** Liver failure caused by drug toxicity has the worst prognosis
- **C.** The most common viral etiology is HBV virus
- **D.** Patients always need liver transplant because of the associated high mortality

2. The signs of cerebral edema:
- **A.** Include hypotension, hyperventilation, and worsening mental status
- **B.** Should prompt insertion of ICP monitoring before initiating therapy
- **C.** Can be exacerbated by stimulation of the patient such as during tracheal suctioning
- **D.** Occur most commonly in stage 2 HE

Questions 3 and 4 refer to the following:
A 32-year-old woman, previously healthy, was admitted to a small community hospital because of acetaminophen overdose after a suicide attempt. In the emergency room, she was alert and oriented, in no distress, and without complaints. Her laboratory results revealed toxic acetaminophen levels, AST 4,509, ALT 5,745, INR 5.2, total bilirubin 4.5 mg/dL, pH 7.35, PaO_2 112 mmHg, and serum creatinine 3.0 mg/dL. The patient was started on intravenous hydration and NAC, and transferred to the four-bed intensive care unit. On the second day, she became lethargic, but still appropriate when aroused, and her laboratory studies showed lower acetaminophen levels, AST 4,202, ALT 4,897, total bilirubin 4.3 mg/dL, INR 5.3, pH 7.30, PaO_2 99 mmHg, and serum creatinine 3.2 mg/dL. The closest tertiary care center, where liver transplant can be offered, is approximately 5 h away by ambulance.

3. **Based on the current history and present illness, the next step in the patient's management should be**
   - **A.** Continue NAC and start transfusion of fresh-frozen plasma
   - **B.** Transfer to the tertiary care center
   - **C.** Perform a liver biopsy
   - **D.** Obtain blood cultures and start broad-spectrum antibiotics

4. **Over the next day, the patient became comatose, without any focal neurologic deficit; her systolic blood pressure dropped to 80 mmHg, requiring aggressive intravenous fluid resuscitation and norepinephrine; and her laboratory studies were essentially unchanged compared with the previous day. The next step in her management should be**
   - **A.** Transfer to the tertiary care center
   - **B.** Obtain a head CT scan to exclude cerebral edema
   - **C.** Intubate and initiate hyperventilation to treat cerebral edema
   - **D.** Transfuse with packed red blood cells, investigate for possible blood loss, and treat with broad-spectrum antibiotics

ANSWERS

1. The answer is C. Among the viral infections, HBV is the most common cause of ALF. A more rapid progression of liver failure portends a better prognosis compared to slower deterioration, and acetaminophen overdose has a high likelihood of spontaneous recovery. Although a high percentage of patients may need liver transplant to salvage them, some have spontaneous recovery; prognostic factors help differentiate which patients need liver transplantation the most.
2. The answer is C. Hypertension, rather than hypotension, is one of the signs of cerebral edema, which occurs mostly in stage 3 or 4 HE. Once suspected, intracranial monitoring is recommended but should not delay initiation of therapy; patients who sustain prolonged increase in ICP have the worst prognosis.
3. The answer is B. Patient is not improving and is actually showing evidence of progression to stage 2 HE, despite conservative and supportive therapy. The best plan of action is to transfer her, while she is stable, to the transplant center where aggressive monitoring and therapy can be offered should she continue to deteriorate. Until she is transferred, supportive therapy should continue, but due to a low risk of spontaneous bleeding, prophylactic fresh-frozen plasma is not recommended. A liver biopsy is a high-risk procedure, and current data to support such practice are limited.
4. The answer is D. If the patient was not transferred to a transplant center, she should be stabilized before taking a 5-h trip. First, the reason for her hypotension should be identified and treated. The patient has progressed to stage 4 HE, and causes of hypotension include major hemorrhage and sepsis; hypotension is not among the early signs of cerebral edema. Therefore, treatment with antibiotics and transfusion should be started. Although intubation is recommended in comatose patients for airway protection, hyperventilation is not advised unless cerebral edema is suspected.

Acute Renal Injury

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the pathophysiology of acute kidney injury (AKI).
- Recognize factors associated with the development and worsening of AKI.
- Elicit a concise, pertinent history and conduct a targeted physical exam in patients with acute kidney disease.
- Interpret urinary sediment and urinary index results.
- Formulate a differential diagnosis of AKI based upon history, physical findings, and laboratory data.
- Recognize the types of current treatment modalities and their limitations in AKI.

INTRODUCTION

Despite considerable advances in critical care medicine and renal replacement therapy (RRT), the presence of acute renal failure (ARF) continues to be highly associated with morbidity and mortality in intensive care unit (ICU) patients.[1] Even after statistical adjustment for concurrent illnesses, ARF remains strongly linked to an elevated ICU mortality. However, it remains uncertain whether to consider ARF as directly contributory toward patient mortality or as simply present in sicker patients, those with intrinsically higher mortality. This chapter reviews ARF in the critically ill patient specifically: pathophysiology, diagnostic methods, and treatment.

CASE STUDY: PART 1

Mr. J.P. is a 64-year-old patient with a past medical history significant for hypertension, coronary artery disease, ischemic cardiomyopathy with an ejection fraction of 20%, benign prostatic hypertrophy, chronic cigarette smoking (1 pack/day for 35 years), and chronic obstructive pulmonary disease (COPD). He was admitted to the hospital with a 1-week history of cough productive of discolored sputum, fever, chills, and progressively worsening shortness of breath. He denied chest pain and leg swelling and other signs of heart failure. His vital signs upon admission were oral temperature, 39.1°C; respiratory rate, 24 breaths/min; heart rate, 116 beats/min; blood pressure, 100/55 mmHg; and oxygen saturation, 91% on room air by pulse oxymetry.

On examination, he was sitting in bed in mild respiratory distress. His neck had an easily seen jugular venous pulse. His heart was regular with a soft ejection murmur along the left sternal border. Lung examination was remarkable for crackles in the right base and diffuse wheezing. The abdomen was slightly tender to palpation over the suprapubic region. Extremities showed mild edema but no clubbing or cyanosis. Rectal examination revealed a large prostate.

DEFINITION

AKI has replaced the term ARF.

Currently the RIFLE Criteria is used to define AKI.

The term "acute kidney injury" (AKI) is rapidly replacing the term "acute renal failure" (ARF) to denote a rapid deterioration in kidney function. "Kidney" substituting for "renal" creates parallel terminology with regard to the stages of CKD (chronic kidney disease). Refining "injury" from "failure" underscores the reversible nature of renal damage. Therefore, for the remainder of this chapter, AKI will be used exclusively.

AKI is usually detected by a rise above baseline in a patient's plasma creatinine (Cr) level, a rise above baseline in the blood urea nitrogen level (BUN), or a decrease in urine output (UO).

Historically, disagreement has existed in the most useful criteria for diagnosing established AKI. Commonly used definitions of AKI have included a rise in serum creatinine by 0.5 mg/dL above baseline, a doubling of serum creatinine, a 50% reduction in calculated creatinine clearance, and a deterioration in renal function requiring dialysis. In 2004, this heterogeneity led to the creation and dissemination of the RIFLE (risk, injury, failure, loss, end-stage) Criteria (see Table 22-1) intended to standardize the definition. In an early study to evaluate the validity of RIFLE, Abosaif et al evaluated its sensitivity and specificity in ICU patients.[2] ICU mortality was greatest among patients classified as RIFLE class "F" (failure) with a 74.5% mortality compared to 50% among those classified as class I (injury), and 38.3% in those classified as RIFLE class R (risk). Hoste et al[3] evaluated RIFLE as a predictive tool in 5,383 critically ill patients. AKI occurred in an astounding 67% of ICU patients with 12% achieving a maximum "R" class, 27% a maximum "I" class, and 28% a maximum "F" class. Among 1,510 patients who at some point reached "R" class, 56% progressed to either "I" or "F" classes. This finding highlights the high frequency with which patients with high kidney risk progress

TABLE 22-1

RISK, INJURY, FAILURE, LOSS, END-STAGE (RIFLE) CRITERIA FOR ACUTE RENAL DYSFUNCTION

CATEGORY	GFR CRITERIA	URINE OUTPUT (UO) CRITERIA	
Risk	Increased creatinine × 1.5 or GFR decrease >25%	UO<0.5 mL/kg/h × 6 h	High sensitivity
Injury	Increased creatinine × 2 or GFR decrease >50%	UO<0.5 mL/kg/h × 12 h	High specificity
Failure	Increase creatinine × 3 or GFR decrease >75%	UO<0.3 mL/kg/h × 24 h or anuria × 12 h	
Loss	Persistent AKI=complete loss of kidney function >4 weeks		
ESKD	ESKD (>3 months)		

GFR glomerular filtration rate; *AKI* acute renal failure; *ESKD* end-stage kidney disease; *UO* urine output

to kidney damage. Patients with a maximum score of "R" had a mortality rate of 8.8%, compared to 11.4% for "I" and 26.3% for "F" classes. Patients with no evidence of renal dysfunction had a mortality rate of only 5.5%.

Regardless of the definition used, creatinine is still the main muscle end-product of creatine phosphate. In healthy individuals, creatinine and other uremic toxins are cleared from the circulation, by first-order kinetics almost exclusively via renal function. Due to its inert chemical structure and simplicity of measurement, serum creatinine is used as the core laboratory determinant of kidney function. Yet, serum creatinine is far from being a perfect indicator. First, there exists a considerable delay between the onset of actual renal injury and a rise in serum creatinine. Current investigations of biomarkers such as serum cystatin C and Urinary Kip-1 may eventually be clinically useful as earlier markers of renal injury. Earlier identification of AKI should allow ICU physicians to treat AKI earlier. Second, at elevated serum creatinine concentrations, the renal tubular secretion of creatinine contributes significantly to total body creatinine excretion. Hence, urinary creatinine clearance measured by 24 h urine collection may overestimate glomerular filtration rate (GFR) by as much as 30% when serum creatinine exceeds 5 mg/dL. Third, all equations estimating GFR assume that the serum creatinine concentration is stable. Significant errors in calculation are introduced when serum creatinine is either rising or falling. When serum creatinine concentrations rise, the GFR calculated from the serum creatinine clearance overestimates the true GFR. For example, anuric patients have a true GFR of zero regardless of the value obtained by calculating a creatinine clearance based upon serum creatinine (see Fig. 22-1).

Serum creatinine is a poor indicator of renal function during ARF.

Both to assist in the diagnosis of AKI and in predicting clinical outcomes (requirement for dialysis), stratification of individual patients by severity of AKI has known value. AKI may be classified as "nonoliguric AKI" when urinary output is greater than 400 mL/24 h, "oliguric AKI" when urinary output is less than 400 mL/24 h (but greater than 100 mL/min), or "anuric AKI" if urinary output is less than or equal to 100 mL/24 h. Patients with lower UO are less likely to recover renal function and prove more difficult to manage clinically with regards to both volume status and avoiding hyperkalemia. Causes of anuria include complete urinary obstruction, vascular catastrophe (e.g., stent occluded in the renal artery in a patient with a single kidney), severe acute tubular necrosis (ATN), and bilateral cortical necrosis or rarely acute glomerulonephritis (AGN). A well-worn but still relevant framework to discuss AKI is to distinguish the type of AKI by the dominant anatomic location where it originates, namely, prerenal, postrenal, or intrinsic renal injury. Further separating the intrinsic renal causes of AKI into its four functional components further helps to conceptualize the causes of AKI: glomeruli (glomerulonephritis [GN]), tubules (ATN), vessels (vasculitis), and interstitium (interstitial nephritis) (Table 22-1).

The Cockcroft – Gault formula is the historic standard for drug dose calculations.

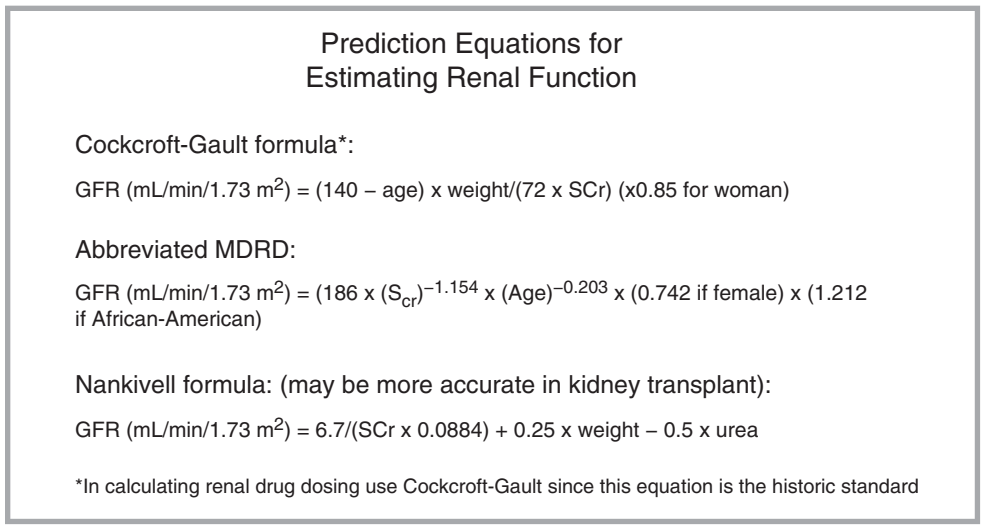

FIGURE 22-1

Predicting equations for estimating renal function.

EPIDEMIOLOGY

Incidence

Currently, AKI severe enough to require dialysis occurs in approximately 5% of general ICU patients. The exact proportion varies by the particular ICU cohort under examination, i.e., medical ICU vs. cardiac surgery ICU, but overall appears to be uniform around the globe. Yet, over a period of 20 years, the incidence of AKI treated with RRT has more than doubled. The rising incidence of ICU patients requiring RRT suggests that sicker patients may now survive long enough to receive dialysis instead of dying at an earlier point in care. Recent data from 2002 report an incidence rate of 270 patients per million population.[4] In comparison, the incidence of acute lung injury was estimated at 112–320 patients per million population.[5] AKI requiring RRT therefore has a comparable incidence to that of acute lung injury.

Risk Factors

ICU patients will often have multiple risk factors for the development of AKI.

Compared to patients without CKD, those with preexisting CKD are most predisposed to developing AKI from exposure to iodinated radiocontrast agents, aminoglycosides, nonsteroidal antiinflammatory agents (NSAIDs), atheroembolic events, and following cardiovascular surgery. Contrast-induced nephropathy (CIN) increases the odds ratio for death up to 5.5.[6] Patients with the combination of baseline renal insufficiency and diabetes mellitus are particularly susceptible to AKI due to CIN.[7] These patients should always receive some form of contrast prophylaxis before contrast exposure unless of course the radiologic study is emergent and there is no time for prophylaxis. Additional important factors associated with the development of AKI in ICU patients, notably include hypotension, sepsis, advanced age, and hyperbilirubinemia. Each additional risk factor increases the chance for developing AKI.

Mortality

The presence of AKI in a seriously ill patient increases the risk of dying and is an independent risk factor for death.

Most contemporary studies demonstrate a modest improvement in mortality, related to the increasing use of hemodialysis and more successful supportive ICU measures. ICU mortality in AKI correlates well with both the number and severity of comorbidities present. Among nonICU patients, in the absence of comorbidities, mortality rates specifically attributable to AKI vary widely, from 7 to 23%. In the ICU, mortality in patients with AKI rises to range from 50 to 70%. As mentioned earlier, it is controversial whether AKI is merely a surrogate for patient severity or intrinsically contributes to an elevated mortality. In one study, 16,000 relatively healthy patients exposed to iodinated radiocontrast agents were monitored for the development of AKI; 189 patients eventually developed AKI. Age-matched patients who also developed AKI not due to CIN were 5 times more likely to die. Because these were relatively "healthy" patients with minimal comorbidities, this study emphasizes the role of AKI as an independent risk factor for mortality. Yet, failure of intensive dialysis (including continuous dialysis or daily dialysis) to markedly improve survival suggests that patient substrate rather than uremia per se predicts survival.

PATHOPHYSIOLOGY

AKI in ICU patients is most often caused by either prerenal azotemia, ATN, or a combination of both factors. While prerenal azotemia may completely reverse with only correction of the effective circulating volume, ATN is characterized by renal injury that requires time for organ repair and recovery. Specifically, there is currently no pharmacologic treatment that makes ATN recover quicker. The most important intervention is to discontinue the offending agent. ICU patients developing ATN may have multiple simultaneously coexisting etiologies

of AKI, making the precise determination of the dominant cause of AKI often impossible. These insults include hypoperfusion secondary to a prolonged prerenal state (hypotension), renal vasoconstriction, and a variety of nephrotoxins (both endogenous and exogenous). The end result is renal ischemia with necrosis of tubular cells and a subsequent reduction in GFR.

Prerenal azotemia is caused by decreased renal blood flow, which leads to an elevation of ADH and angiotensin II levels. This in turn causes increased sodium reabsorption in both the proximal and distal convoluted tubules. When blood volume or blood pressure decreases, baroreceptors located in the aortic arch and carotid sinuses are activated. This baroreceptor reflex leads to sympathetic nerve activation, resulting in renal afferent arteriolar vasoconstriction and renin secretion through β_1-receptors.[8] Constriction of the afferent arterioles causes a decrease in the intraglomerular pressure, reducing GFR proportionally. Renin cleaves circulating angiotensinogen into angiotensin I and eventually (after conversion to Angiotensin II) stimulates aldosterone release. Increased aldosterone levels also result in sodium and water absorption in the distal collecting tubule. The net result is a decreased UO and a decreased urinary sodium level, classically less than 20 mEq/L.[8]

In critically ill patients, even timely correction of renal hypoperfusion (prerenal azotemia) may result in ATN. It has been shown that substances such as endotoxin, tumor necrosis factor, and other inflammatory molecules are directly toxic to the renal endothelial and tubular cells.[9] Concurrent insults of prerenal azotemia and any of the above factors are additive in terms of inducing AKI.

The pathophysiology of AKI is a complex interaction of vascular, cellular, and immunologic events that propagates inflammation.

Prolonged prerenal azotemia can lead to kidney ischemia and ATN.

The time course of ATN has been divided into clinical phases: initiation, maintenance, and repair[10] (see Fig. 22-2). During these phases, there are ongoing changes at the cellular level with different levels of inflammation. It is early in the initiation phase where GFR is profoundly decreased.

Initiation

The tubules in the renal medulla are at the greatest risk to ischemic injury.

During the early initiation phase, hypoperfusion results in renal injury due to oxygen delivery below the threshold to maintain normal tubular cell structure and function.[11] This is seen first in the medulla where blood flow is low under normal circumstances because of the need to concentrate urine. Reabsorption of sodium by the thick ascending limb of Henle requires a relatively hypoxic environment under normal circumstances. The normal condition leaves the medulla (including deep segments of the proximal convoluted tube) at greatest risk to ischemic injury when decreased oxygen delivery occurs. This hypoxemia leads to tubular apical cell brush boarder loss. Disruption of the actin cytoskeleton, cell–cell tight junctions, and membrane transport proteins results in a loss of cell polarity and directional solute transport. It is in this phase that adhesion molecules, i.e., integrins, redistribute and result in shedding of the cells into the lumen, which then are able to bind because of the redistributed integrins.[12] These shed cells result in the classical muddy brown cast formation seen in ATN.

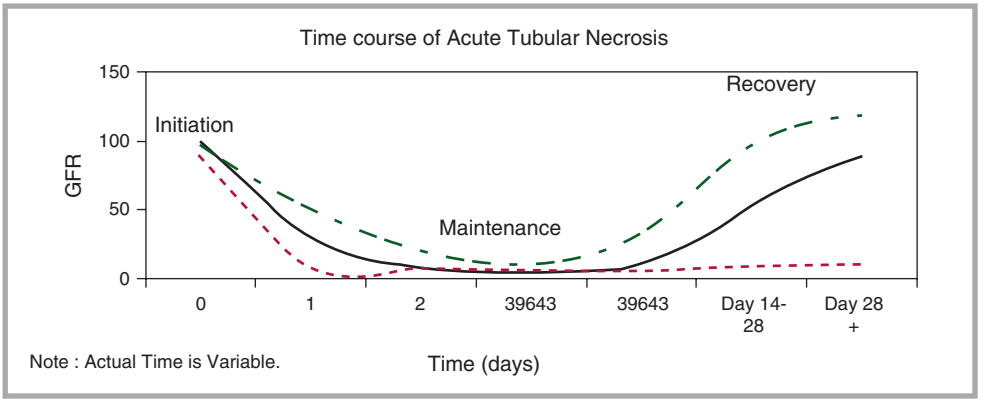

FIGURE 22-2

Time course of acute tubular necrosis (ATN).

Early in AKI from ATN, GFR is profoundly reduced. There are three known mechanisms for the decrease. The casts described above lead to intratubular obstruction and an increased intratubular pressure that results in decreased GFR. The shed cells also expose the tubular basement membrane and allow backflow of filtrate, also decreasing GFR.[12] It is proposed that the GFR is reduced by up to fifty percent because of this backleak. The tubuloglomerular feedback is also severely deregulated. There is an increased NaCl concentration delivery to the macula densa, which results in decreased glomerular permeability. Renal vasoconstriction is also seen in this initiation phase and leads to decreased plasma flow with a resultant decrease in GFR.[12] This process is at least partly mediated through adenosine. Currently, clinical investigations are underway using adenosine receptor antagonists to reverse abnormal tubular glomerular feedback that is observed in ATN.

Extension and Maintenance

Ischemic injury to vascular myocytes and endothelial cells during the initiation phase of renal injury results in microvascular changes that contribute to the subsequent extension and maintenance phases of renal injury and repair. Inflammatory mechanisms emerge as ATN progresses. Renal endothelial and epithelial cells produce multiple cytokines and chemokines.[13] The balance of vasodilators (nitric oxide, prostacyclin) and vasoconstrictors (endothelin, thromboxanes) is altered in favor of the vasoconstrictors, propagating further ischemia.

Endothelial activation promotes leukocyte infiltration with further inflammation and injury. These leukocytes increase the obstruction and hypoperfusion of the renal microcirculation. They also release more cytokines, reactive oxygen species, and enzymes.

Ongoing apoptosis continues during the maintenance phase. Remaining viable renal cells de-differentiate, proliferate, and migrate across the basement membrane to reestablish epithelial continuity (Fig. 22-2).

Recovery

During the recovery phase, these new de-differentiated cells reestablish normal epithelial polarity and transportation functions.[14] There is also repair of renal endothelial injury and restoration of normal tissue perfusion. These de-differentiated cells given enough time without further insult regain their differentiated character. During the re-differention phase, the tubular cells are unable to concentrate urine and the patient experiences a post ATN diuresis, which can lead to the creation of a new problem, namely, volume depletion and ATN, if not prevented.

DIAGNOSIS

The diagnosis of AKI, especially in the ICU, requires a careful, stepwise approach. Figure 22-3 depicts such an approach, the different components of which are discussed in the following sections.

The diagnosis of AKI should follow a careful stepwise approach (see Fig. 22-3).

History and Physical Examination

It cannot be overstated that the history and physical evaluation yields important clues in the successful diagnosis of the cause of AKI. A detailed history should include questions regarding exposure to nephrotoxic agents, history of sinus problems, pulmonary hemorrhage in order to consider pulmonary–renal syndromes, fever or purpura suggesting vasculitis, the presence of bone pain in the elderly to evoke multiple myeloma, history of trauma (pigment nephropathy), and recent radiocontrast exposure (i.e., cardiac angiography). The physical examination may reveal signs of volume depletion such as tachycardia and hypotension, which would raise the suspicion of a prerenal etiology for AKI. A rash can accompany allergic interstitial nephritis. Livedo reticularis can be seen in patients with atheroembolic

The history and physical examination can provide important clues to the etiology of AKI.

White blood cell casts are found in the urine sediment of patients with interstitial nephritis, and red blood cell casts are found in GN.

FIGURE 22-3

AKI and signs of embolism to the legs. Rhabdomyolysis should be suggested by signs of ischemia to the limbs and evidence of muscle compartmental syndrome associated with trauma or vascular occlusion.

Urine Analysis

The analysis of urine indexes and sediment is an important part of the diagnostic evaluation of patients with AKI. The analysis of sediment, when casts are present, is particularly helpful. Pigmented granular casts are seen in ischemic and toxic AKI; white cell casts are typical of interstitial nephritis, and red cell casts are sometimes found in GN. The finding of heme positive urine, in the absence of red cells, suggests myoglobinuria or hemoglobinuria. Eosinophils may be discovered in the sediment of patients with allergic interstitial nephritis, but may also be present in patients with atheroembolic disease as well as in acute pyelonephritis. The detection of eosinophils in the urine is improved by using staining methods such as the Hansel stain. To diagnose acute interstitial nephritis (AIN), we prefer cytologically testing the urine for eosinophils due its high diagnostic sensitivity.

Analysis of urine indexes and sediment is an important part of the diagnostic evaluation of patients with AKI.

Urine electrolyte indexes are useful in patients with oliguria. Their usefulness decreases during the use of diuretics. Parameters that are commonly measured are urine-specific gravity, urine osmolality, urinary concentration of sodium (Na), and urinary concentration of creatinine. From these parameters, fractional excretion of sodium (FENa) can be calculated as follows:

$$\text{FENa} = \frac{\text{urine Na concentration / plasma Na concentration}}{\text{urine creatinine concentration / plasma creatinine concentration}}$$

Measurement of the fractional excretion of urea (FEurea) may be useful in some patients with AKI, with FEurea being 50–65% in ATN and usually below 35% in prerenal azotemia. Yet, inconsistent results have been reported.[15] A later prospective study confirmed that FENa is diagnostically superior to FEurea only when diuretics have not been administered, casting doubt on the utility of FEurea as an alternative after diuretics are used because of the lower specificity reported in most recent trials.[16] FEurea should not be used in isolation; rather, it may be used in conjunction with the history and other laboratory tests to discriminate between prerenal azotemia and ATN.

Urea handling almost entirely occurs in the proximal convoluted tubule and therefore, the fractional excretion of uric acid (FEurea) is not affected by loop diuretics. In one study, values below 12% suggested the presence of prerenal disease (sensitivity 68%, specificity 78%), while values greater than 20% suggested the presence of ATN (sensitivity 96%, specificity 33%).[17]

$$\text{FEurea} = \frac{\text{urine concentration / plasma Na concentration}}{\text{urine creatinine concentration / plasma creatinine concentration}}$$

Table 22-2 shows urinary indexes for different conditions.

Blood Tests

In addition to the measurements of serum creatinine and BUN, other laboratory tests may aid in the differential diagnosis of AKI. Elevated serum calcium and serum uric acid levels may be encountered in tumor lysis syndrome. To avoid this complication in patients with leukemia or lymphoma receiving chemotherapy, prophylaxis with allopurinol is highly recommended. Serum creatine phosphokinase is markedly elevated in patients with rhabdomyolysis, and myeloma kidney should be suspected when an abnormal protein spike is found on serum or urine protein electrophoresis. Eosinophilia may be discovered in patients with acute allergic interstitial nephritis. Positive antiglomerular basement membrane antibodies confirm the presence of Goodpasture's syndrome, and perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) are associated with polyarteritis nodosa syndromes, whereas cytoplasmic antineutrophil cytoplasmic (c-ANCA) antibodies are usually found in patients with Wegener's granulomatosis (Table 22-3). The presence of an osmolar gap

TABLE 22-2

URINARY INDICES IN PATIENTS WITH ARF

	PRERENAL	ATN	AGN	OBSTRUCTION
Urine Osm	>500	<350	300–500	300–500
Urine Na	<20	>40	<40	>40
FENa	<1	>1	<1	>1

ATN acute tubular necrosis; *AGN* acute glomerulonephritis; *Osm* osmolarity; *FENa* fractional excretion of sodium

TABLE 22-3

ANTIBODIES IN RENAL DISEASE

DISEASE	ANTIBODY	TARGETED PROTEIN
Wegener's	c-ANCA	Granulocyte serine protease
Polyarteritis nodosa	p-ANCA	Granulocyte myeloperoxidase
Goodpasture's syndrome	Anti-GBM	Alpha-3 chain of type IV collagen

c-ANCA cytoplasmic antineutrophil cytoplasmic antibodies; *p-ANCA* perinuclear staining antineutrophil cytoplasmic antibodies; *anti-GBM* antiglomerular basement membrane antibodies

(difference between measured and calculated osmolarity), suggests the presence of a low molecular weight nephrotoxin such as ethylene glycol.

ETIOLOGY

Postrenal Azotemia

In any ICU patient with AKI, urinary track obstruction must be considered and excluded. Prompt diagnosis and intervention can result in rapid resolution and complete recovery of renal function. Obstruction may be the cause in 5% of hospitalized patients with AKI.[8] Though ultrasonography is greater than 95% sensitive to detect urinary obstruction, simple palpation of the lower abdomen and pelvis is often diagnostic.

The kidney in obstructive uropathy maintains its clearance capacity. An increase in serum creatinine requires either obstruction of urine flow between the external urethral obstruction or unilateral urethral obstruction in patients with only one functional kidney. Obstruction of the bladder neck is the most common cause.[8] Ultrasound or CT scan genitourinary imaging is essential to the diagnosis and should be obtained in any ICU patient with AKI when feasible. This usually results from prostatic disease with hyperplasia being more common than neoplasia, however, gross hematuria with large "clots" is also common. Other common obstructive disease entities include neurogenic bladder or anticholinergic drug therapy, including anesthesia and/or narcotics. Ureteral obstruction can occur with intraluminal obstruction, for example calculi, surgical misadventure, infiltration of the ureteral wall from a neoplastic process, or external compression from a retroperitoneal or intraabdominal process, for example intraabdominal compartment syndrome in trauma patients.

Urinary tract obstruction should be considered in patients with poor urinary output and previous pelvis surgery radiation or a history of prostate disease.

The majority of obstructive uropathy patients are treated by relief of the obstruction and the diagnosis carries a good prognosis. Foley catheter placement, percutaneous nephrostomy tube, or stent placement are indicated regarding the type and level of obstruction. It is prudent to monitor patients closely once the obstruction is relieved. Patients may rapidly undergo a profound diuresis with greater than 4 L of urine per day. The volume status and serum electrolytes should be monitored and if necessary, vigorous intravenous replacement fluid administered. Ultimate treatment will depend on the underlying pathology which led to the initial obstruction (Table 22-4).

CASE STUDY: PART 2

His laboratory work showed a white blood cell count of 16,000 with a left-shift and a hemoglobin of 14 g/dL. Creatinine was 1.6 mg/dL and BUN was 44 mg/dL; potassium, bicarbonate, calcium, phosphorus, and magnesium were normal; creatine kinase was 125 mg/dL. A chest radiograph showed a right lower lobe consolidation consistent with pneumonia.

The patient was admitted with a diagnosis of community-acquired pneumonia and was started on cefotaxime. During the first 12 h in the hospital, his urinary output was found to total 10 mL; he also complained of worsening suprapubic pain. A Foley catheter was placed with difficulty, and 2,500 mL of urine was obtained. On hospital day 2, the patient's serum creatinine improved to 1.3 mg/dL and BUN decreased to 31 mg/dL.

SPECIFIC ETIOLOGY/MANAGEMENT

Prerenal Azotemia

Prerenal azotemia can be found in both volume-depleted and total body volume overloaded patients; it results from poor perfusion to the kidneys. Poor perfusion can be caused by decreased intravascular volume (as in dehydration), poor forward flow (as in heart failure), or vascular obstruction generating poor perfusion (renal artery stenosis). Importantly, any cause of hypotension is a cause of prerenal azotemia. The most common causes of prerenal azotemia are volume depletion and hypotension. Causes include vomiting, diarrhea, nasogastric suction, and protracted hemorrhage. Elderly patients are particularly susceptible to prerenal disease as a result of their predisposition to hypovolemia and the increased prevalence of renal vascular disease. Prerenal states are usually reversible if the underlying cause is quickly corrected. The pathophysiology has been covered earlier in this chapter.

Certain drugs have been associated with prerenal azotemia. The combination of angiotensin converting enzyme inhibitors (ACEI) and diuretics can induce prerenal azotemia, particularly in patients with renal vascular disease. ACEI decrease resistance in the efferent arterioles with a concomitant decrement in GFR. Non-steroidal anti-inflamatory agents (NSAIDs) inhibit vasodilatation of afferent arterioles, thereby decreasing GFR and renal flow. Cyclosporin and tacrolimus (especially intravenous administration) may cause vasoconstriction and induce a prerenal state. Among hospitalized patients, prerenal azotemia is usually caused by cardiac dysfunction, liver failure, septic shock, and accumulation of fluid in body cavities (such as the peritoneum). A delay in treating any significant hypotension increases the risk of prerenal azotemia and ATN.

Patients with prerenal AKI should be treated with aggressive fluid resuscitation (if not total body volume overloaded). Inotropes and afterload reduction may also be used if poor forward flow or low cardiac output is suspected (heart failure, cardiomyopathy, etc.), or by relief of renal artery stenosis via percutaneous angioplasty or renal artery bypass surgery. Early and aggressive intervention can quickly correct this disease state and prevent progression to ATN.

Prerenal azotemia can be found in both volume-depleted and total body volume overloaded patients; it results from poor perfusion to the kidneys.

Acute Tubular Necrosis

ATN is the most common form of intrinsic AKI. It is usually associated with ischemia or nephrotoxic agents (Table 22-5).

ATN typically presents with an oliguric phase, associated with worsening serum creatinine, azotemia, and a progressive decrement in GFR. This oliguric phase can be followed by a diuretic phase, marked by the presence of electrolyte abnormalities and volume depletion. Some patients never develop a decrement in urinary output; this is termed nonoliguric ATN. Patients with nonoliguric ATN have a better prognosis than patients with oliguric AKI, the latter have a greater likelihood of requiring hemodialysis and a significantly higher mortality. In the past, the use of diuretics and osmotic agents has been advocated to revert oliguric AKI. However, there is no evidence that patients who convert from an oliguric to a nonoliguric state after a pharmacologic intervention have an improvement in their prognosis.

CASE STUDY: PART 3

On the second hospital day and after relief of postrenal obstruction, the patient developed a brisk spontaneous diuresis. His blood pressure dropped to 85/45 mmHg and he became tachycardic. Because of poor intravenous access, a central line was placed and the patient was given 3 liters normal saline intravenously over several hours. Subsequently, the patient developed acute shortness of breath and chest pain. Chest radiography was consistent with pulmonary edema. The patient responded to aggressive diuresis with intravenous furosemide and topical nitrates. On hospital day 3, his creatinine increased to 1.9 mg/dL.

Dopamine

Dopamine does not aid renal recovery.

Despite overwhelmingly negative clinical studies including a randomized, double-blind, placebo-controlled trial,[18] dopamine is unfortunately still sometimes tried as an agent to induce renal recovery. Dopamine is a selective renal vasodilator that can induce natriuresis and an increase in GFR and urinary output. The dopamine dose at which mainly dopaminergic receptors are activated is 1 μ/kg/min to 3 μg/kg/min. Lauschke et al[19] studied the renovascular effects of low-dosage dopamine(2 μg/kg/min) vs. placebo in a randomized, double-blind, placebo-controlled, crossover study in 40 ICU patients, 30 of whom had AKI. Dopamine infusion did not alter UO or systemic hemodynamic parameters. Dopamine does not improve survival or delay dialysis.[19] Rather, patients receiving "renal dose" dopamine are at elevated risk for developing supraventricular tachycardia. The lack of evidence and potential risks of dopamine even at low doses should argue for the abandonment of its use for "renoprotective" reasons. Recent unpublished data suggest that intravenous fenoldopam delivered directly into renal arteries may be beneficial in speeding recovery from ATN.

Diuretics and Mannitol

Diuretics are sometimes still used to treat oliguric AKI. Furosemide is a loop diuretic and a vasodilator that may decrease oxygen consumption in the loop of Henle by inhibiting sodium transport, which may lessen ischemic injury. Furosemide works on the thick ascending limb of the nephron and increases flow, possibly allowing removal of casts and decreasing toxins such as myoglobin or hemoglobin. Historically, furosemide has been tried to "convert" oliguric AKI to nonoliguric renal failure.[20-22] Patients who convert from an oliguric to a nonoliguric state are able to tolerate more liberal fluid intake and total parenteral nutrition. However, it must be stressed that patients who convert need to be monitored closely for prerenal volume depletion. Hypotension must be avoided to further renal damage. Diuretics should be stopped if there is no response. There is no data in support of using furosemide as a prophylactic agent to prevent AKI. In fact, clinical trials of contrast-induced renal failure

CASE STUDY: PART 4

On hospital day 5, the patient had a rise in temperature to 39.2°C; blood cultures were obtained. On day 6, methicillin-sensitive *Staphylococcus aureus* was detected. He was started on oxacillin. On day 7, the patient developed chest pain with electrocardiographic changes consistent with ischemia. He underwent cardiac angiography, evidencing a subtotal occlusion of the left anterior descending coronary artery. A coronary artery stent was placed; 2 days later his creatinine was found to be 2.4 mg/dL and it continued to increase over the next several days.

have shown harm in using furosemide. Ho and Sheridan[23] performed a meta-analysis of nine randomized furosemide studies to prevent ($n=3$) or treat ($n=6$) AKI. Furosemide had no significant effect on in-hospital mortality, risk for requiring RRT, number of dialysis sessions, or even the proportion of patients with persistent oliguria.

Mannitol is an osmotic diuretic that also appears to also scavenge free radicals, decrease cell swelling, and cause renal vasodilatation by inducing intrarenal prostaglandin production.[24] It has been used in organ preservation solutions for renal transplant, when it appears to have beneficial properties. Mannitol also may be useful when given very early in the course of rhabdomyolysis, although this remains controversial. Other than these selected instances, its role in the prevention or treatment of AKI has not been proven, and current evidence does not support its use in either the prevention or treatment of AKI.

Natriuretic Peptides

Atrial natriuretic peptide (ANP) vasodilates the afferent arteriole and constricts the efferent arteriole, thereby increasing GFR. It also inhibits the tubular absorption of sodium. The net result of these actions is an increase in urinary output. In preliminary studies, ANP appeared to increase GFR and decrease the need for dialysis. In a randomized, placebo-controlled trial of critically ill patients, ANP did not improve 21 day dialysis-free survival, mortality, or change in plasma creatine concentration.[25] A subsequent randomized trial of oliguric patients with AKI found no difference between the placebo-treated and the ANP-treated group.

Use of natriuretic peptides has not led to improved renal outcomes.

Brain natriuretic peptide (BNP) was approved for use in acute, decompensated heart failure in 2001. It has been shown to decrease pulmonary capillary wedge pressure and dyspnea more quickly than nitroglycerin or placebo alone.[26] Subsequent studies have led to controversy on its clinical use. Multiple trials have shown an increase in 30-day mortality and worsening renal function.[27] For now, BNP is best avoided.

Contrast Nephropathy

The overall risk for contrast-induced nephropathy (CIN) for AKI is low in the general population, but the risk increases up to 30% in patients with chronic renal disease, diabetes mellitus, or heart failure. The volume of contrast used is also important. CIN accounts for up to10% of hospital cases of AKI.[13] The pathogenesis of CIN is possibly related to a reduction in renal medullary blood flow. An increment in creatinine can be seen as early as 24–48 h after the procedure with radiocontrast material. The creatinine typically peaks in 3–5 days and returns to baseline within 10–14 days. Only a small percentage of the patients develop oliguric AKI.

Hydration with isotonic saline solution should be used as prophylaxis in high-risk patients. Hypotonic solutions provide less volume expansion than isotonic solutions, but they have been shown to increase prostaglandin excretion; this, in turn, has been associated with improved medullary blood flow.[28] The recommended dose is 1 mL/kg/min for 12 h before and after the procedure. Low-osmolar or nonionic contrast agents are an option for reducing toxicity in patients who are at high risk. The use of nonionic contrast agents is not indicated in patients at low risk for CIN.

Recently, the use of intravenous bicarbonate has become more popular in prevention of CIN. The method of prevention is not known. A recent meta-analysis[29] concluded hydration

with sodium bicarbonate decreases the incidence of CIN in comparison to hydration with normal saline without a significant difference in the need for RRT and in-hospital mortality. In this analysis, twelve trials (1,854 participants) were included. Sodium bicarbonate significantly decreased the risk of CIN without a significant difference in need for RRT, in-hospital mortality, or congestive heart failure compared with controls. Similar results were seen for the risk of CIN when sodium bicarbonate was compared with normal saline alone, but not when sodium bicarbonate/*N*-acetylcysteine combination was compared with *N*-acetylcysteine/normal saline combination. Despite these recent findings, bicarbonate remains controversial and should be used with caution.

The risk of CIN is highest in patients with advanced age, CKD, diabetes mellitus, and heart failure.

N-Acetylcysteine is a potent reducing agent that has been postulated to help prevent CIN by reactive oxygen species scavenging. The first positive study was published in 2000. Since then there have been a number of trials with mostly negative or equivocal results.[30] Based on available data, it is not possible to make strong recommendations regarding its use to prevent CIN. Because of its overall low cost and low side effect profile, it continues to be used until an ideal study can define its true role.

Atheroembolic Disease

Atheroembolic disease causing AKI occurs mainly in the elderly, usually heavy smokers. It is more likely to occur in patients with atheromatous disease who undergo procedures such as cardiac angiography, intra-aortic balloon placement, and vascular surgery. Atheroembolic disease has been reported to occur spontaneously and, rarely, after the institution of anticoagulation. Its presentation soon after an invasive procedure can often be confused for CIN. Clinical manifestations are a consequence of cholesterol crystal migration and atheromatous debris in the circulation. AKI may ensue and it is frequently associated with visual disturbances and with cerebral and intestinal ischemia. Physical examination can reveal the presence of refractive plaques in the retinal arteries (Hollenhorst bodies), rash, petechiae, livedo reticularis, and bluish discoloration of the toes. Eosinophilia, eosinophiluria, and hypocomplementemia can be seen; these features can also be associated with AIN, vasculitis, allergic reactions, and some of the entities causing rapidly progressive GN. Definitive diagnosis can be made by muscle, skin, or renal biopsy showing characteristic biconcave crystals. The course of AKI in these cases is highly variable, but renal dysfunction usually occurs 3–8 weeks after the initial insult. No treatment has been shown to be effective in these cases, and therapeutic measures are usually aimed at removing anticoagulation and preparing the patient for hemodialysis.

Rhabdomyolysis

Rhabdomyolysis (RML) has been described in a variety of settings, including crush injuries, strenuous exercise, peripheral arterial embolism, alcoholism, cocaine use, protracted seizures, heat-induced disorders, and viral infections. Most cases of rhabdomyolyis are subclinical, manifested only by elevations of CPK. Pigmenturia, hyperkalemia, hyperphosphatemia, and elevation of lactate dehydrogenase and creatine kinase characterize RML.

The development of AKI in patients with RML has been attributed to various mechanisms, including (a) the direct toxic effects of myoglobin or its by-products, such as ferrihemate, (b) disseminated intravascular coagulation, (c) obstruction of renal tubules with myoglobin or uric acid crystals, and (d) renal ischemia caused by release of vasoconstrictor substances. The risk of developing AKI is not uniform among patients who present with RML.

Clinical factors that increase the risk of developing RML include liver dysfunction, hypotension, seizures, severe muscle damage, disseminated intravascular coagulation, and dehydration.

Clinical factors that increase the risk of developing RML include liver dysfunction, hypotension, seizures, severe muscle damage (manifested by high muscle enzyme levels), disseminated intravascular coagulation, and dehydration.[31] It has been recommended that patients with crush injuries immediately receive IV fluids on the accident scene and then in the hospital to achieve a urinary output of 200–300 mL/h.[32] It is apparent that early volume resuscitation and intensive IV fluid administration may reduce the incidence of AKI. The use of solutions containing bicarbonate has been recommended to maintain a urinary pH greater than 6.5.[33] Urine alkalinization prevents heme-protein precipitation with Tamm-Horsfall

protein, and therefore intratubular pigment cast formation. Maintaining an alkaline urinary pH may also reduce the conversion of myoglobin to ferrihemate, an iron compound that can cause vasoconstriction and local production of toxic oxygen radicals. An alkaline urinary pH may also prevent the precipitation of uric acid crystals in the tubules. Alkalinization can worsen the symptoms of hypocalcemia by a direct membrane effect and to a lesser degree by increasing binding of calcium to albumin, which reduces ionized calcium levels. Alkalinization can also increase calcium phosphate precipitation in the tissues.

Acute Interstitial Nephritis

The first cases of AIN were described in patients with diphtheria and scarlet fever. Among patients with AKI of undetermined origin, 11% have AIN by biopsy. Today, AIN is most often caused by medications. Other causes of AIN are shown in Table 22-6.

Clinical manifestations include fever, rash, and eosinophilia. This triad suggests AIN, but its absence does not rule out the disorder, because the triad is only present in 10–40% of patients. Renal impairment manifests 5–25 days after initial exposure to the etiological agent. Recovery of renal function after discontinuation of the offending drug is frequent. Patients who develop AIN after exposure to NSAIDs tend to have worse RF and only a partial recovery of renal function. There is only limited evidence in the literature to support the use of steroids in patients with medication-induced AIN.[34]

Drug-Related Nephrotoxicity

Medications are a common cause of nephrotoxicity. This risk is especially high in the elderly. Aminoglycosides are a common cause of hospital-acquired AKI.[35] Patients who are elderly, volume depleted, or have preexisting renal disease are at higher risk. Other risk factors for toxicity from aminoglycosides include preexisting liver disease, shock, female gender, and high peak and trough levels.

Tubular cells and cells in the pars recta are predominantly affected. Tubular abnormalities are usually seen in the early phases of renal injury; they are marked by glycosuria, aminoaciduria, and proteinuria.[36] Electrolyte abnormalities such as potassium and magnesium wasting can be seen, and polyuria and nephrogenic diabetes insipidus may be present.[36] Nephrotoxicity caused by aminoglycoside administration usually results in nonoliguric AKI.[37] It can be seen at any time 1–2 weeks after starting treatment, although the time to onset of renal dysfunction may be shortened in patients with predisposing factors. Treatment is supportive with discontinuation of the drug. Recovery of renal function is slow, usually 4–6 weeks.[36] In some patients, especially those with previous renal disease, recovery of renal function is incomplete; this is possibly related to residual interstitial fibrosis. Penicillins, cephalosporins, and quinolones have also been associated with AKI, but they are usually associated with interstitial nephritis.

TABLE 22-6

CAUSES OF INTERSTITIAL NEPHRITIS

Infectious
Immunologic diseases
Hypercalcemia
Idiopathic
Drugs
Antibiotics (penicillins, cephalosporins, sulfa drugs, quinolones)
Proton pump inhibitors
Nonsteroidal antiinflammatory medications
Diuretics
Allopurinol
Cimetidine
Interferon alpha
Rifampin
Phenytoin

Another antibiotic of increasing significance is colistin. This agent has a very narrow therapeutic window. AKI is reported in up to 20% of patients.[36] The nephrotoxicity of colistin has been primarily associated with its chemical structure. The d-amino acid and fatty acid components of the colistin molecule represent the parts responsible for toxicity. The mechanism by which colistin induces its nephrotoxic effects, including ATN, is closely related to its mechanism of action against gram-negative bacteria. Specifically, colistin increases the tubular epithelial cell membrane permeability, resulting in an increased influx of cations, anions, and water, leading to cell swelling and lysis.

Amphotericin B is a polyene antifungal agent that interacts with membrane sterols and causes cell membrane disruption and an increment in cell wall permeability. Lesions have been noted in several different places in the nephron, such as the tubules and the medulla.[38] The nephrotoxic effect of amphotericin is initially manifested as a loss of urine concentration, distal renal tubular acidosis, hypokalemia, and hypomagnesemia. Most patients receiving amphotericin experience a rise in serum creatinine. AKI due to amphotericin B is usually nonoliguric, slowly progressive, and dose related.[39] Renal function usually returns to baseline after a short interruption of the drug or a reduction in the dose administered. The most important risk factor for development of nephrotoxicity due to amphotericin is volume and salt depletion; therefore, prevention of toxicity includes volume and sodium repletion. Newer formulations of amphotericin, such as lipid complex formulations and liposome-encapsulated amphotericin B, are less likely to cause renal dysfunction and may be an option in patients with previous renal disease.[39]

NSAIDs alter intrarenal hemodynamics by inhibiting the synthesis of the vasodilatory prostaglandins that counteract angiotensin-2 mediated constriction of the afferent arteriole.[39] In patients with underlying CKD or volume depletion, they can induce the onset of prerenal azotemia.

Acyclovir can induce ATN in 10–30% of treated patients. Nephrotoxicity becomes evident 24–48 h after treatment is initiated. Acyclovir crystals precipitate in the distal tubules and cause intratubular obstruction.[40] Treatment consists of volume repletion and discontinuation of the drug.

Indinavir is another antiviral drug associated with AKI. Crystaluria is seen in approximately 20% of patients treated, but clinical nephropathy necessitating discontinuation of therapy is required in 0.5% of patients.[41] Indinavir therapy should be accompanied by daily intake of at least 2–3 L of fluid to maintain high urinary flow rates to minimize the risk of crystal deposition.

Cyclosporine and tacrolimus are agents commonly used to provide immunosuppression in patients with solid organ and bone marrow transplantation. These agents are associated with vasoconstriction causing nonoliguric AKI and have also been implicated in the development of thrombotic microangiopathy (thrombi deposition in small vessels) in the kidney.[42]

Medications are a common cause of AKI and therefore medication dosages should be adjusted.

Cisplatin is a chemotherapeutic agent, frequently used in the treatment of ovary, testicular, and lung cancer; it can cause damage to the proximal and distal tubules.[43,44] Initially, it causes polyuria with preserved GFR. Reduction in GFR and nephrogenic diabetes insipidus can be seen after 3–4 days of treatment. Recovery of renal function usually is seen 2–4 weeks after discontinuation of the drug, but may not be complete.

Urate Nephropathy

Urate nephropathy is caused by the deposition of urate crystals in the tubules. It is seen most often in patients with lymphoproliferative disorders and hematologic malignancies, although it has also been described to occur with solid tumors. Hyperuricemia occurs spontaneously with tumor cell lysis; more often, it is the consequence of chemotherapy or radiotherapy. AKI is usually associated with release of other ions from neoplastic cells, resulting in hyperphosphatemia and hyperkalemia.[45] In the setting of acidic urine, the elevated uric acid concentration exceeds its solubility, leading to precipitation of crystals in the tubules, obstruction of tubular flow, and AKI. When urate nephropathy is suspected, a urine uric acid to creatinine ratio is helpful. A ratio >1 highly suggests the presence of uric acid nephropathy. A value <0.6 suggests another etiology is responsible for ongoing AKI. Prevention is accomplished by administering allopurinol and volume expansion before chemotherapy.

Keeping the urinary pH above 7.0 using sodium bicarbonate is controversial. Excessive urinary alkalinization should be avoided to decrease the risk of calcium phosphate deposition in the kidney and other organs. Serum electrolytes are followed carefully. Patients with AKI frequently require dialysis, but in general the prognosis is good.

Glomerulonephritis and Other Intrinsic Renal Diseases

GN can present as acute or subacute renal failure. When this time course is quick, the disease is referred to as rapidly progressive glomerulonephritis (RPGN). This may account for up to 5% of hospital-diagnosed AKI. Rapid diagnosis using serologic markers is important to institute treatment rapidly. Immunosuppressive therapy, plasma exchange, or both can reduce morbidity and eventual progression to end-stage renal failure.

Wegener's granulomatosis is an idiopathic disorder characterized by the presence of granulomatous vasculitis in the kidney and upper and lower respiratory tract.[46] Diagnosis can be made by serologic detection of c-ANCA or biopsy. Standard therapy for Wegener's consists of a combination of cyclophosphamide (2 mg/kg) and prednisone (1 mg/kg).[47] This regimen achieved remission in 75–91% of patients. The role for plasma exchange is less clear.

Anti-GBM-mediated disease is an entity characterized by the deposition of antibodies directed toward the glomerular basement membrane (GBM).[48] These antibodies can also be seen in the alveolar basement membrane. The syndrome usually presents as RPGN. Renal biopsy shows proliferative GN with crescent formation.[49] It can present with or without hemoptysis; smokers are more likely to present with hemoptysis. Therapy for anti-GBM-mediated GN consists of early administration of immunosuppressive drugs and plasmapheresis.[49]

Hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) are two closely linked entities associated with AKI, hemolytic microangiopathic anemia, and thrombocytopenia. TTP is also associated with fever and central nervous system abnormalities. Prothrombin time (PT) and activated partial thromboplastin time (PTT) are normal in these entities. HUS and TTP likely represent different spectra of the same disease.[50] Other manifestations of the disease include neutrophilic leukocytosis, bowel perforation, and normal coagulation profile. Treatment consists of supportive therapy and early plasmapheresis.[51]

RENAL REPLACEMENT THERAPY

Dialysis is required in high number of patients with oliguric AKI and some patients with nonoliguric AKI. In the setting of AKI, patients who undergo hemodialysis have improvement in morbidity and mortality over patients who do not receive this therapeutic modality. Hemodialysis carries important risks. Bleeding from the access site, hemorrhage, and infection are a few of the complications that can be seen. Hypotension and arrhythmias can be induced by changes in compartment volumes and electrolyte disturbances.

There is a risk that dialysis actually prolongs or worsens AKI, likely the result of microinfarcts worsening ischemia or the activation of an inflammatory reaction by the blood–dialyzer interface. Dialysis with biocompatible membranes results in less complement activation, better survival from sepsis, and fewer dialysis sessions. RRT and dialysis are discussed at length in Chap. 21.

SUMMARY

AKI is frequently diagnosed in the ICU setting and is associated with a high mortality. In most cases, early diagnosis results in an improved renal and survival outcome. A stepwise diagnostic approach to AKI (see Fig. 22-3) in the critically ill patient, including a detailed history and physical examination, along with urine analysis and serum tests, assists in determining the etiology of AKI and instituting appropriate care.

REVIEW QUESTIONS

1. **A 56-year-old with hypertension, diabetes, and CKD stage III with a baseline reatinine of 2.0 mg/dL is admitted to the Cardiac Care Unit by his cardiologist for a NSTEMI (nonST segment elevation myocardial infarction). He is to undergo Cardiac Catheterization the next day. He is currently stable and without chest pain. There are no physical stigmata of heart failure. Which ONE of the following recommendations is most likely to reduce his risk for CIN?**
   - **A.** Use gadolinium instead of iodinated contrast
   - **B.** Evaluate ventricular function echocardiographically rather than with a fluoroscopic ventriculogram
   - **C.** Administer intravenous fenoldopam before and after the procedure
   - **D.** Administer isotonic saline intravenously for volume expansion before contrast exposure
   - **E.** Administer *N*-acetylcysteine orally before and after the procedure

2. **A 45-year-old woman presents to a local ER with a 3-day history of fevers, shortness of breath, and productive cough. Upon admission to the ICU, her oral mucosa appeared dry and her skin showed decreased turgor. Her blood pressure was 86/45 and her heart rate 120; serum creatinine was 2.3 mg/dL and BUN 62 mg/dL. Analysis of her urine electrolyte indexes is likely to reveal:**
   - **A.** Urine osmolarity of 200, urine sodium > 40, FENa > 1
   - **B.** Urine osmolarity of 600, urine sodium < 20, FENa < 1
   - **C.** Urine osmolarity of 500, urine sodium > 40, FENa > 1
   - **D.** Urine osmolarity of 300, urine sodium > 30, FENa < 1

3. **A 25-year-old woman has been hospitalized for treatment of a *Staphylococcus aureus* abscess of her left thigh complicating a puncture wound. The wound is incised and drained and she receives antibiotic therapy. Her hospital stay is complicated by severe sepsis requiring ICU transfer. After 1 week she develops a new fever. On physical examination, her temperature is 38.1°C and there is a diffuse erythematous skin rash of her trunk and extremities. A urinalysis shows specific gravity of 1.020, pH 6.5, 1+ blood, 1+ protein, no glucose, and no ketones. There are 10–20 WBCs/hpf and 1–5 RBCs/hpf, on microscopic examination. Which of the following is the most likely diagnosis?**
   - **A.** Acute Tubular Necrosis
   - **B.** Drug-induced interstitial nephritis
   - **C.** Hemolytic uremic syndrome
   - **D.** Postinfectious glomerular nephritis
   - **E.** Pyelonephritis

4. **A 75-year-old man with a history COPD is admitted for fevers, malaise, and shortness of breath for more than 1 week. In the emergency department, his blood pressure is 80/42 and his chest X-ray shows multifocal infiltrates. He remains hypotensive despite 5 L of NSS. He is started on vasopressors and transferred to the ICU. A foley catheter is placed and his UO is approximately 30 mL/h. His baseline serum creatinine is 0.9 mg/dL. His creatinine is now 3.2 mg/dL and BUN is 32 mg/dL. What are the most likely findings on microscopic examination of the urinary sediment?**
   - **A.** White cell casts
   - **B.** Pigmented granular casts
   - **C.** Red blood cell casts
   - **D.** Waxy casts
   - **E.** Bland urine sediment

5. **A 68-year-old patient was admitted to the hospital for an acute myocardial infarction. Cardiac catheterization revealed severe three vessel atherosclerotic disease requiring emergent bypass surgery. His course was complicated by a prolonged ICU stay for cardiogenic shock, requiring the placement of an intra-aortic balloon pump. His creatinine at admission was 1.0 mg/dL. The patient was hemodynamically stable after a week in the ICU. His creatinine, however, began to rise, despite the administration of IV fluids. After 10 days his creatinine reached 2.3 mg/dL. His urine sediment appeared bland by light microscopy. Hansel's stain did reveal the presence of urinary eosinophils. The peripheral eosinophil count was 600 cells/μL and his c3 and c4 were low. His serum creatinine continued to rise despite attempts and volume expansion, and the patient required RRT within 3 weeks of admission. What is the likely cause of his renal failure?**
   - **A.** ATN from hypotension
   - **B.** Acute interstitial nephritis
   - **C.** Cholesterol emboli
   - **D.** Prerenal azotemia
   - **E.** CIN from the cardiac catheterization

ANSWERS

1. The answer is D. The most effective mechanism to reduce the risk of CIN is volume expansion with isotonic saline. *N*-acetylcysteine may have a positive effect, but should not be given in place of saline infusion. Minimizing the volume of iodinated contrast is also important, but again volume expansion remains most important.
2. The answer is B. The patient in this case is suffering from prerenal azotemia. The clinic manifestations of hypovolemia are low blood pressure, tachycardia, dry mucous membranes, and decreased urinary output; this results in a prerenal state marked by elevated serum creatinine and BUN. The set that better depicts a prerenal state is B (see Table 23.2); set A is consistent with ATN, set C is consistent with postrenal obstruction, and set D is consistent with AGN.
3. The answer is B. This question illustrates the presentation of AIN. While pyelonephritis is certainly a possibility and must be ruled out, AIN is more likely. Discontinuation/changing of the antibiotics should lead to improvement with the patient.
4. The answer is B. The microscopic examination will reveal pigmented granular casts or muddy brown casts consistent with ongoing ATN. White cell casts are more consistent with interstitial nephritis. Red Cell casts may be found in GN. Waxy casts are found in CKD. Bland urine sediment is consistent with prerenal azotemia and would be corrected by aggressive volume expansion.
5. The answer is C, Cholesterol emboli. This patient has multiple risk factors for this disorder. The time frame is also consistent with cholesterol emboli rather than in ATN where the creatinine often

plateaus then improves. CIN cannot be the answer because the renal failure occurred too far from contrast exposure. Often urinary sediment is bland, but may contain urine eosinophils on Hansel's stain. The atheroemboli often lead to progressive dysfunction despite appropriate care. Treatment is supportive and may require RRT.

CHAPTER 23

DAVID E. CICCOLELLA AND MICHAEL S. LAGNESE

Sepsis Syndromes

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Name the different sepsis syndromes.
- Understand how dysfunction of the host immune system contributes to development of the sepsis syndromes.
- Identify the hemodynamic and oxygen utilization abnormalities observed in septic patients.
- Recognize the clinical presentation and progression of the sepsis syndromes.
- Describe the intensive care unit (ICU) management of the sepsis syndromes.

SEPSIS SYNDROMES DEFINED

Sepsis results when invasion of the body by microorganisms (including bacteria, fungi, viruses, and parasites) causes alterations in the normal homeostatic balance maintained by the human host in health. Patients with sepsis or septic shock may present with a constellation of variable symptoms and signs, including fever or low body temperature, tachypnea, tachycardia, low blood pressure, low urine output, mental status changes, and multiple laboratory abnormalities such as high white blood cell counts, hyperglycemia, and hypoxemia.[1] The number and severity of these clinical manifestations represent a spectrum of clinical

Clinical conditions may progress along a disease continuum from sepsis to septic shock.

CASE STUDY: PART 1

A 50-year-old man presented to the emergency department with a 4-day history of high fevers, chills, left-sided pleuritic pain, and productive cough with thick yellow sputum. He also had a small amount of blood-tinged sputum the day before presentation. He reported that 4 days ago he felt unusually fatigued and had a sore throat. By the next day, he had developed fevers to 103.5°F, taken orally, and associated chills. His fever persisted, and anorexia and nausea and vomiting developed 1 day before presentation. His past medical history was significant for noninsulin-dependent diabetes mellitus and hypertension (usual BP, 130/85), both controlled with medications. He had a 30 pack-year smoking history and drank alcohol rarely. He had worked as a bus driver for many years.

conditions, which may progress along a disease continuum from sepsis to more severe sepsis and septic shock. The frequency of these clinical conditions is rising as a result of changing population risk factors,[2] and the mortality rate has remained high, ranging between 25 and 30%[3] for severe sepsis and 40–70%[4] for septic shock.

Some of the risk factors for the development of sepsis include diseases such as diabetes mellitus, acquired immunodeficiency syndrome, liver failure, kidney failure, and cancer, being among the very old or very young, and the use of invasive technology from urinary and vascular catheterization to cardiac mechanical-assist devices.

The definitions used in this chapter were originally recommended in the American College of Chest Physicians (ACCP)/Society of Critical Care Medicine (SCCM) consensus statement of 1992[1] and then modified by these and two other societies in an International Sepsis Definitions Conference in 2001.[5] These definitions are important from a research and practical perspective as they may determine the level or type of treatment administered to the patient (e.g., recombinant human activated protein C). *Systemic inflammatory response syndrome (SIRS)* is present when two or more of the following are present: (1) leukocytosis, white blood count (WBC) >12,000, or leukopenia, WBC<4,000, or significant band forms (>10%); (2) hyperthermia (>38°C) or hypothermia (<35°C); (3) hypocapnia ($PaCO_2$<32 mmHg) or respiratory rate >20 breaths/min; (4) heart rate >90 bpm. The presence of infection is not required for the diagnosis of SIRS because it can be caused by noninfectious diseases such as trauma, pancreatitis, tissue ischemia, and hypovolemic shock. *Sepsis* is present when the SIRS is caused by infection. *Severe sepsis* is sepsis associated with organ hypoperfusion, dysfunction, or hypotension. Examples of hypoperfusion and perfusion abnormalities are oliguria, mental status alterations, or lactic acidosis. These abnormalities have been more functionally defined for the practicing intensivist.[6] *Septic shock* is a subset of sepsis associated with hypotension (i.e., mean arterial pressure [MAP] <60 or <80 mmHg if underlying or history of hypertension) refractory to fluid resuscitation and signs of organ hypoperfusion and dysfunction. *Refractory septic shock* is functionally defined as maintenance of a MAP>60 mmHg (or >80 mmHg if underlying hypertension) via the administration of dopamine >15 μg/kg/min or norepinephrine > 0.25 μg/kg/min or epinephrine >0.25 μg/kg/min in addition to adequate fluid resuscitation. The term *sepsis with hypotension* has been used to describe sepsis states that are responsive to intravenous fluid resuscitation. Finally, *bacteremia* refers to the presence of bacteria in the blood, documented either by growth on blood culture or by visible microorganisms seen on Gram stain.

SIRS can result from both infectious and noninfectious insults.

SIRS caused by infection is sepsis.

Severe sepsis with low blood pressure is referred to as septic shock.

Multiple organ dysfunction syndrome (MODS) can be primary (e.g., acute respiratory failure due to pneumonia) or secondary (e.g., acute respiratory failure due to acute respiratory distress syndrome [ARDS]), depending on it being a direct or indirect cause of organ failure. Although there are no specific, commonly accepted criteria for MODS, organ system dysfunction has been defined in various intensive care unit (ICU) severity of illness scoring systems (Multiple Organ Dysfunction Score), and is associated with increasing ICU mortality.[7]

In general, these definitions have prognostic and therapeutic implications as there is a stepwise increase in mortality from SIRS to sepsis, severe sepsis, and septic shock,[8] and a response to more specific treatments such as activated protein C in severe sepsis or septic shock.[3]

CASE STUDY: PART 2

On physical exam, the patient appeared lethargic but was easily aroused. He was in moderate respiratory distress and was just able to complete sentences without pausing to catch his breath. There was prominent use of accessory respiratory muscles. His rectal temperature was 104.5°F, heart rate was 118, respiratory rate was 28, blood pressure was 98/60 mmHg, and O_2 saturation by pulse oximetry was 92% on a nonrebreather facemask with a FiO_2 of 1.0. His skin was cool and moist. There were inspiratory crackles and some wheezing over the left lower lung field on auscultation. Except for these findings, the cardiovascular, abdominal, and neurological examination results were normal.

During the initial evaluation and treatment in the emergency department, laboratory studies were obtained. Arterial blood gas revealed hypoxemia, despite high supplemental oxygen, and a mixed acid–base disorder with hypocapnia and metabolic acidosis. The electrolytes showed a sodium of 142 mmol/L and an elevated anion gap. Serum glucose was elevated at 180 mg/dL. Creatinine and blood urea nitrogen were 1.4 and 36 mg/dL, respectively. The complete blood cell count showed a white blood cell count of 22,800 cells/mm^3 with increased band forms, a hematocrit of 42%, and a platelet count of 200,000 cells/mm^3. Sputum Gram stain showed no epithelial cells, many Gram-positive diplococci, and many white blood cells, some containing intracellular bacteria. The chest X-ray showed a dense left lower lobe consolidation with a very small pleural effusion. The cardiac silhouette appeared normal.

The patient continued to receive bronchodilators, supplemental oxygen, and intravenous fluids and was started on broad-spectrum intravenous antibiotics; a third-generation cephalosporin and a macrolide. The patient was admitted to the ICU with a diagnosis of community-acquired pneumonia with sepsis and respiratory distress.

In sepsis or septic shock, infection may occur in a variety of sites but lung, abdomen, and urinary tract appear to be the most common.[9] However, the source of infection cannot be identified in approximately 20–30%[9]of patients. Blood cultures may be positive in only 30%[9]of patients.

The clinical manifestations of sepsis result from the interaction between the defenses of the human body and the microbial infection. Through a complex cascade of cellular and humoral defenses, the human immunologic system provides the means by which infection is attenuated and eliminated. Although it is usually carefully contained and regulated, the immune system has great potential to become harmfully uncontrolled, as occurs with the sepsis syndromes. This chapter presents an overview of the pathophysiologic processes responsible for sepsis and sepsis-related syndromes.

PATHOPHYSIOLOGY

The host defense system has three components: the most basic being the physical barrier of skin and mucous membranes with its indigenous microbial flora; there are also innate and adaptive immune systems.[10,11]

The innate immune system requires no prior exposure to a pathogen and responds nonspecifically but rapidly to microbial threats. It functions to recognize, contain, and destroy pathogens and their toxins, as well as limit tissue injury and promote repair.[11] Its defenses include phagocytic leukocytes and a large number of mediators derived from the coagulation and complement systems: eicosanoids, highly reactive nitrogen and oxygen species, cytokines, acute phase reactants, and the recognition receptors.[11] The recognition of pathogens occurs through at least four families of innate immune receptors, including Toll-like receptors (TLRs), nucleotide-binding oligomerization domain-like receptors, C-type lectin receptors, and triggering receptors present on myeloid cells.[11] The TLR family is comprised of 11 immune receptors that involve a complex mechanism for recognizing conserved molecular patterns characteristic of bacteria and viruses.[11] The TLR recognition system is not specific for pathogens but is a general response to danger. It utilizes a small number of receptors to detect a small number of molecules and produces similar cellular responses regardless of how it is activated.[11]

The adaptive immune response is the most sophisticated component of the host defense system. It includes specific antibody formation by B cells and instruction of cytotoxic T cells. It is a second line of defense that has a delayed response but demonstrates high speci-

ficity for its microbial targets and therefore results in little collateral damage to the host.[11,12] The various components of the host-response system are as follows.

Cellular and Inflammatory Mediators

Both locally active and circulating mediators play a role in coordinating immune response.

Normally protective cellular mediators released during sepsis can also cause tissue damage if not attenuated.

Many of the clinical signs seen in sepsis are manifestations of systemic host protection.

The host defense system involves the interaction of a variety of cells and humoral systems. As part of the host immune reaction, a series of both local and systemic soluble factors are released. Their primary coordinated function is to identify, limit, and eliminate the infecting organism and its products from the body. Analysis of bronchoalveolar lavage fluid has demonstrated that a large number of biologically active molecules or mediators can be found in the alveoli of patients with sepsis. Many of these inflammatory mediators have been identified and their function characterized (Table 23-1), but many more likely exist and remain unknown. A fundamental concept in sepsis pathophysiology is that the cellular mediators and hormones released can be just as harmful to normal human tissue as they are to the invading organism. For this reason, the defense cascade is usually under tight homeostatic control. Many of the systemic effects of the circulating immunologic mediators produce clinical changes that play a role in resolving infection.

Cellular Elements

The stimulated macrophage is the initiator of much of the immunologic cascade.

Recognition of bacterial antigens by the host macrophage initiates the immune response.

To understand the abnormalities encountered in the sepsis syndromes, it is important to first review some of the basic mechanisms involved in normal immune function following microbial invasion. The tissue mononuclear phagocytes (also known as macrophages) are found in abundance at potential sites of pathogen entry and are the primary cells that initiate much of the early local and systemic immune response (Fig. 23-1). These cells can be found in most body tissues and secretions, and in many organ systems; these cells have highly specialized organ-specific subpopulations. Specific microbial antigens act as a stimulus to mononuclear phagocytes and cause them to release a variety of humoral factors that in turn act on various other tissues and organ systems. These antigens generally are microbial proteins and have variable ability to activate the host immune system.

One of the most important of these microbial antigens is lipopolysaccharide (LPS), otherwise known as Gram-negative endotoxin. LPS is a large, complex cell membrane component necessary for bacterial growth and survival. A LPS fragment is first recognized and complexed to a lipopolysaccaride binding protein (LBP) circulating in the plasma. It is then transferred to a CD14 receptor on a host cell membrane. The CD14 host

TABLE 23-1

SELECTED INFLAMMATORY MEDIATORS AND THEIR FUNCTIONS

MEDIATOR	SELECTED FUNCTIONS
TNF-α	Stimulates polymorphonuclear neutrophils (PMNs) Increases vascular permeability Stimulates IL-1, IL-6, IL-8, IL-9 Stimulates PAF Stimulates cyclooxygenase production
Platelet-activating factor (PAF)	Stimulates platelet degranulation Attracts eosinophils Stimulates neutrophil activity
Interferon-γ	Stimulates macrophage protein synthesis Stimulates monocyte maturation
Interleukin-1	Stimulates mononuclear phagocyte function Stimulates IL-2 Stimulates fibroblast and endothelial proliferation
Interleukin-2	Stimulates T-lymphocyte production and activity
Interleukin-5	Stimulates eosinophil production and activity
Interleukin-6	Stimulates B-lymphocyte production and activity Decreases TNF production

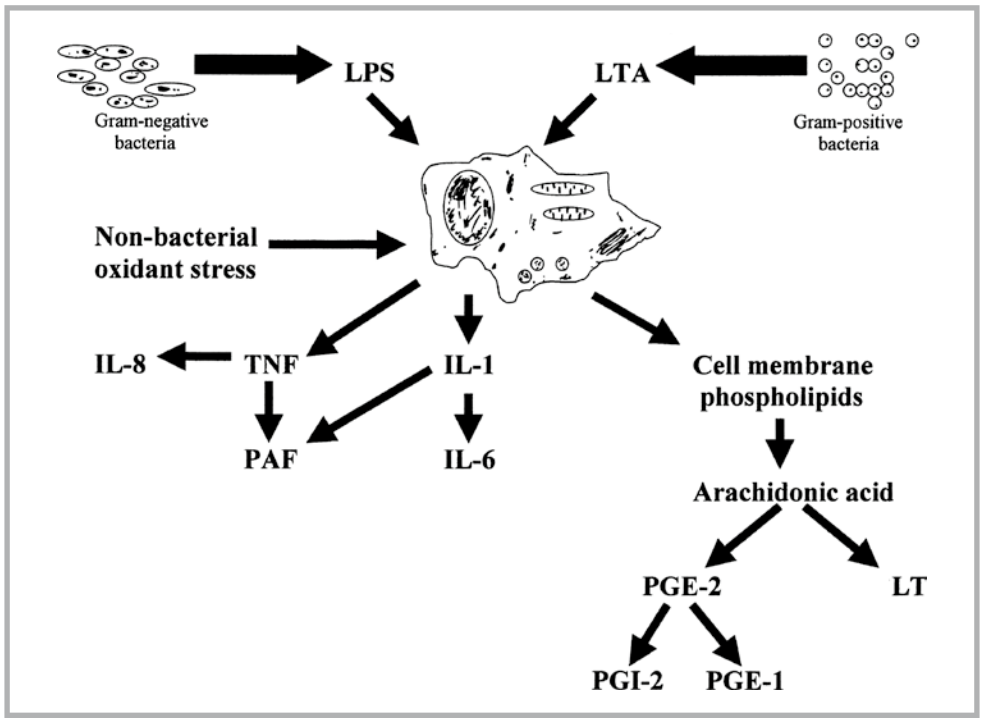

FIGURE 23-1

Schematic diagram of interactions of several common macrophage stimuli and potential subsequent macrophage activity. *LPS* lipopolysaccharide; *LTA* lipoteichoic acid; *TNF* tumor necrosis factor; *PAF* platelet-activating factor; *IL* interleukin; *LT* leukotriene; *PG* prostaglandin.

receptor protein that recognizes and interacts with LPS is found primarily on the macrophage cell membrane. The LPS fragment is then transferred from the CD14 receptor to the transmembrane Toll-like receptor 4 (TLR4), which recognizes the pathogen-associated molecular pattern, LPS, and with the addition of other proteins such as MDR2 forms an LPS-host recognition protein complex.[11] The LPS recognition signal is then transmitted by TLR4 intracelluarly and the activated signaling pathway cascades and amplifies, resulting in the production and release of inflammatory mediators such as cytokines and chemokines. These responses are initiated within just a few minutes and may be profound as LPS exposure to healthy subjects causes a time-dependent expression of several thousand genes in circulating leukocytes.[13] The binding of LPS to the host macrophage CD14 receptor initiates the production and release of many of the elements involved in this immune cascade. Several soluble forms of CD14 have also been identified and have been shown to bind with LPS. These circulating LPS–CD14 compounds are able to activate the immune response and initiate sepsis syndromes independent of primary macrophage involvement. The LPS–CD14 interaction is both complex and incompletely understood; there appear to be several proteins that have the ability to alter the binding properties of these two compounds at the molecular level.

LPS is a bacterial cell wall constituent that interacts with the macrophage membrane protein CD14.

Circulating CD14 can also bind with LPS and trigger the immunologic response.

Cytokines

Macrophages and other inflammatory cells produce cytokines, which are large molecules that have the ability to modulate the function and secretory response of other host cells by interacting with specific cell membrane receptors. The cytokine–cell membrane interaction results in altered cell gene expression and, ultimately, altered cellular function. These effects take place locally at a cellular level causing, among other things, chemotaxis, which results in the migration of more phagocytic cells to the areas of infection. A systemic effect also occurs, with many cytokines acting as hormones and circulating to areas distant from the site of secretion. It is this systemic release of dozens of inflammatory cytokines that is responsible for the clinical features of sepsis.

Cytokines induce and alter target cell secretory function. They are released from inflammatory cells.

Cytokines released from host immune cells have both local and systemic effects, resulting in many of the clinical signs of sepsis and septic shock.

Many cytokines have been well characterized in terms of their structure and specific function. Tumor necrosis factor (TNF) is one of the most important cytokines with both local and systemic effects (Table 23-2). In the immediate area of infection, TNF can cause direct damage

TNF, a cytokine, causes local tissue destruction and tissue edema and promotes intravascular coagulation.

TABLE 23-2

CLINICAL EFFECTS OF TNF-α, IL-1, AND IL-6

MEDIATOR	CLINICAL EFFECTS	SOURCE
TNF-α	Hypotension	Polymorphonuclear lymphocytes
	Fever	
	Cachexia	Mononuclear phagocytes
	Capillary leak syndrome	
	Capillary thrombosis	
Interleukin-1	Hypotension	Endothelial cells
	Fever	T lymphocytes
	Skeletal muscle breakdown	B lymphocytes
		Mononuclear phagocytes
Interleukin-6	Fever	Endothelial cells
		T lymphocytes
		B lymphocytes
		Mononuclear phagocytes

to endothelial cells. Upon systemic release, it causes intravascular coagulation, leading to tissue ischemia, gross increase in capillary permeability leading to tissue edema, and fever. It is also a potent stimulator of other cytokines and other mediators of inflammation, including cyclooxygenase species and several molecules in a class of cytokines known as the interleukins (IL), including interleukin-1 (IL-1). IL-1 causes fever through its stimulatory effects on the preoptic nucleus of the hypothalamus, which is why it is also referred to as the endogenous pyrogen. It is also the primary mediator of skeletal muscle catabolism observed in severe sepsis. IL-1 release from the macrophage occurs independent of TNF stimulation, as when phagocytic cells are stimulated by LPS. IL-1 also stimulates neutrophil and lymphocyte activity, causing production and release of cellular products and cellular replication and migration. Many other cytokines (including many other interleukins) are released by the macrophage upon microbial stimulation (see Fig. 23-1).

Interleukin-1 (IL-1) causes fever, stimulates muscle breakdown, and attracts and stimulates host immune cells.

Arachidonic acid is a substrate for production of many other inflammatory mediators and regulatory hormones and is itself liberated from the macrophage cell membrane.

Platelet-Activating Factor and Leukotrienes

PAF has both local and systemic effects, including platelet chemotaxis and bronchoconstriction, and contributes to hypotension as seen in septic shock.

The stimulated macrophage also releases membrane phospholipids that are converted to arachidonic acid. Arachidonic acid, in turn, is the biochemical substrate for conversion to various other mediators of inflammation by cyclooxygenases and lipoxygenases. These end products are mediators of many cellular processes, including alteration in vascular permeability and immune cell chemotaxis. Among the more important of these membrane phospholipid derivatives are platelet-activating factor (PAF) and leukotriene B4 (LTB4). PAF is secreted by many host cells in response to interaction with LPS and has a number of local cellular effects, including stimulation of other immune mediators and initiation of platelet chemotaxis. It also plays a role in stimulating further release of other mediators of inflammation, including TNF, and IL-1. Clinically, PAF causes pulmonary hypertension, bronchoconstriction, and profound systemic hypotension and is likely a key factor in the development and progression of septic shock, which, as noted above, is characterized by profound and refractory systemic hypotension. LTB4 is biosynthesized from membrane-derived arachidonic acid in the lipoxygenase pathway. LTB4, a potent chemotactic factor for neutrophils, promotes vascular fluid leakage at the capillary, contributing to tissue edema, and ultimately to gas exchange abnormalities in the lung.

Nitric Oxide and Oxygen Radicals

Improvement in tissue DO_2 is a major goal of therapy for septic shock.

As hypotensive shock progresses during sepsis, so does tissue hypoxia and subsequent ischemic injury. A major goal of therapy in septic shock is improvement and maintenance of the tissue oxygen supply. However, if oxygen delivery (DO_2) can be restored, several species of reactive oxygen radicals are produced as a result of normal cellular respiration. Under physiologic conditions, an adequate supply of local defense antioxidants is present to absorb the chemical reactivity of these potentially harmful oxygen radicals. However, when previously

ischemic tissue is reoxygenated, release of oxygen radicals can overwhelm any antioxidant defense species available. Endogenously produced nitric oxide (NO) is the substrate for production of the highly reactive free radical peroxynitrite, which is involved in microbial destruction. But, like other elements in the inflammatory cascade, peroxynitrite has also been shown to cause direct tissue damage when present in substantial amounts. This process is referred to as NO-induced reperfusion injury and can affect any tissue.

NO is produced endogenously and is converted to highly reactive free radicals that are involved in microbial destruction.

Again, the entire defense cascade is of necessity under careful autoregulation and homeostatic control. The numerous redundant inflammatory cascade pathways underscore the complexity of both the inflammatory response itself and the regulatory pathways that initiate and control it. Most of these regulatory mechanisms involve modulation of either the cytokine receptor function or number or cytokine production itself. To a variable extent, all the sepsis syndromes involve at least some initial dysfunction of these normal control mechanisms. Furthermore, as sepsis progresses, these control mechanisms become increasingly dysfunctional and perpetuate the disease state.

NO can also induce direct tissue damage if homeostatic control is not maintained.

Oxygen Consumption and Delivery

During sepsis or septic shock, microvascular abnormalities (especially vasoconstriction) can occur, leading to decreased perfusion and a mismatch of O_2 delivery to O_2 demand. This results in tissue hypoxia, and cellular ischemia manifested in part by increased lactate levels. Some investigators have postulated an alteration in the normal relationship between DO_2 and consumption in sepsis. Normally, DO_2 does not affect oxygen consumption until DO_2 falls below a critical level, resulting in a linear relationship between DO_2 and consumption designated as physiologic oxygen supply dependency.

Some of the basic and specific relationships between oxygen delivery and consumption as related to sepsis are as follows. Systemic DO_2 is defined as the product of cardiac output (CO) and arterial oxygen content, or, more simply:

$$DO_2 = Q \times CaO_2, \tag{23-1}$$

where Q is CO and CaO_2 is the arterial oxygen content. Systemic oxygen consumption ($\dot{V}O_2$) is defined as the product of the CO and the difference between the arterial and venous oxygen contents, or

$$\dot{V}O_2 = Q \times (CaO_2 - C\bar{v}O_2), \tag{23-2}$$

where $C\bar{v}O_2$ is the mixed venous oxygen content. In the healthy state, the relationship between DO_2 and $\dot{V}O_2$ is a biphasic one (Fig. 23-2), in which the normally perfused organs are able to maintain a constant $\dot{V}O_2$ independent of the DO_2 over a wide range. This effect is primarily accomplished by altering the percentage of oxygen that is extracted from the capillaries. In other words, as DO_2 decreases, the oxygen extraction ratio (O_2ER) increases. The result is physiologic maintenance of $\dot{V}O_2$, referred to as physiologic independence of $\dot{V}O_2$ on DO_2. Below a certain critical DO_2, however, cellular metabolism reaches a point of maximal oxygen extraction and $\dot{V}O_2$ can no longer be maintained; this point is referred to as DO_{2crit}. Oxygen consumption below the DO_{2crit} is linearly related to the DO_2 (see Fig. 23-2).

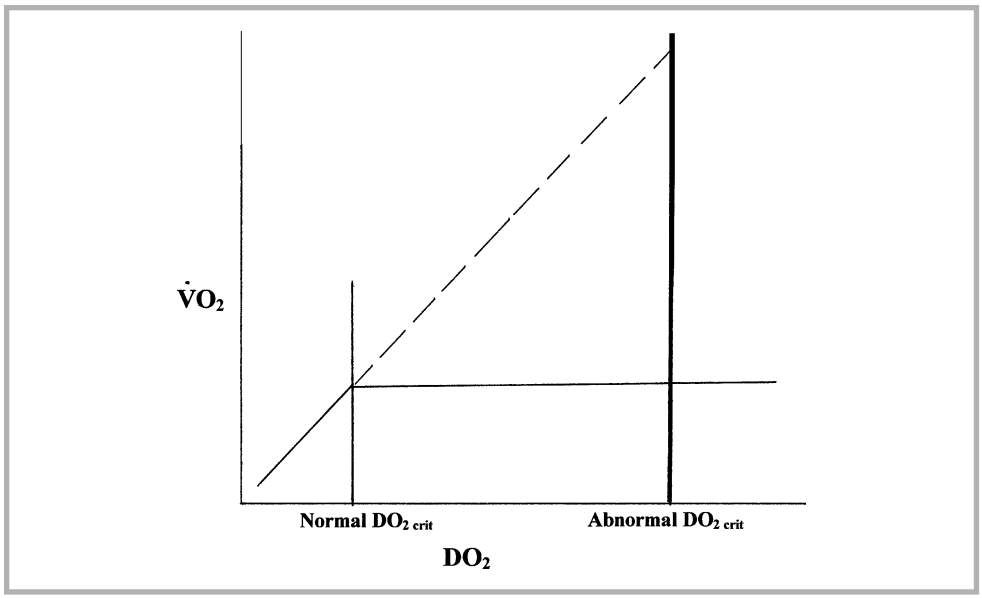
Early studies suggested that, in sepsis, cellular metabolism was altered in such a way that DO_{2crit} was increased, resulting in a pathologic dependence of $\dot{V}O2$ on DO_2. A progressive, linear decline in oxygen consumption was thought to be directly related to lower systemic DO_2. It was postulated that occult tissue hypoxia resulted and that this, in turn, was a possible explanation for the development of SIRS and multiple organ dysfunction syndrome (MODS). However, closer examination of the data has subsequently revealed several mathematical and statistical errors common to many of these studies, which lead to the flawed original conclusions.[14-16] Thus, studies in which DO_2 was increased to supernormal levels have either not been associated with positive outcomes, or if positive, have had methodological flaws; some studies have revealed potentially detrimental effects.[17] In practice, DO_2 should be increased to above the critical DO_2 by normalizing blood pressure and tissue perfusion.[17]

CASE STUDY: PART 3

Soon after admission to the ICU, the patient developed signs of septic shock and respiratory failure. He became mildly confused and more lethargic, systolic blood pressure (SBP) decreased to 75 mmHg and respirations were labored. His urine output had decreased. He was intubated and ventilated and rapidly given further intravenous fluids and vasoactive drugs for circulatory support. Placement of a pulmonary artery (PA) catheter revealed a pulmonary capillary wedge pressure (PCWP) of 12 cm H_2O, a high CO of 10 L/min, and a calculated systemic vascular resistance (SVR) of 700. The PA catheter was used to further optimize his hemodynamic status.

FIGURE 23-2

In the healthy state, there is physiologic independence of $\dot{V}O_2$ on DO_2 beyond the DO_{2crit} (*solid line*), primarily because of the alteration of the cellular extraction ratio as DO_2 varies. It had been postulated that, in the septic patient, the DO_{2crit} could be greatly increased and the O_2ER could be unable to compensate for significant changes in DO_2; this is thought to result in a supposed physiologic dependence of $\dot{V}O_2$ on DO_2 (*broken line*).



Dysfunctional oxygen metabolism is common in the sepsis syndromes.

Normally, the rate of oxygen uptake from the tissues is constant despite variable DO_2.

Cellular and organ oxygen demand is increased in hypermetabolic states such as sepsis.

To date, there is no clear evidence that a pathologic dependence of $\dot{V}O_2$ on DO_2 exists in patients with sepsis. On the other hand, there is general acceptance that sepsis does alter oxygen metabolism significantly at both the cellular and organ system level, and that this disturbance plays a role in the development of the more severe manifestations of the disease, such as SIRS and MODS. Specifically, it has been shown that in hypermetabolic states such as sepsis, cellular oxygen demand is increased, resulting in a net increase in tissue and organ oxygen demand. This demand and subsequent consumption may outpace the ability of the cardiorespiratory system to compensate. Although invasive monitoring and testing and bedside diagnosis allow for such systemic manifestations of this oxygen derangement to be identified, there is currently no reliable way to identify it at the cellular level.

CLINICAL ASPECTS

Sepsis must be considered early in the differential diagnosis because it can be rapidly progressive and fatal.

Clinically, there is much overlap among the sepsis syndromes. For this reason, it is important to be able to recognize the broad, cardinal manifestations of sepsis. The clinical progression of the patient with sepsis can be acute and rapidly fatal, and early consideration of the diagnosis and institution of appropriate therapy are essential. Multiple organ systems are usually involved with variable degrees of acute dysfunction. In fact, in late-phase severe septic shock with MODS, it is rare to find an organ system that has been spared.

Cardiovascular Effects

The cardiovascular effects present the most immediate and life-threatening danger to the patient with sepsis. The most prominent cardiovascular effect is peripheral vasodilatation of

the arterial and venous beds and decreased responsiveness to vasoconstrictors.[18] Several mechanisms are responsible for this, including phospholipase-mediated release of endothelial prostaglandins (PG) and leukotrienes (LT). The hyporesponsiveness occurs in the presence of a marked elevation of serum catecholamines and activation of the renin-angiotensin system which is seen in all types of vasodilatory shock.[18] Common mechanisms that have been implicated in vasodilatory shock include activation of plasma membrane ATP-sensitive potassium channels, NO (inducible form), and a deficiency of the pituitary peptide hormone, vasopressin.[18] NO metabolites are increased in septic shock[19] and NO is thought to be an important mediator causing vasodilatation and vascular hyporesponsiveness[18] in septic shock.[20] Vasopressin is a pituitary peptide hormone with multiple physiological effects, including vasoconstriction via V1 receptors on vascular smooth muscle. Its level is markedly reduced in patients with septic shock as compared to those with cardiogenic shock with a similar blood pressure.[21] Vasopressin treatment has been shown to have a strong vasoconstricting effect in patients with septic shock in several studies.[22–26]

Cardiovascular dysfunction is responsible for many of the common signs and symptoms observed in the septic patient.

An initial physiologic response to the peripheral vascular dilation is increased cardiovascular sympathetic tone resulting in early tachycardia, increased pulse pressure and warm, red skin as peripheral capillary beds dilate. Hypotension resulting from decreased SVR and decreased intravascular volume is a hallmark of septic shock and is usually seen later in the course of sepsis. Pale, cool skin at this stage reflects the underlying tissue hypoperfusion. Also, as released PGs and LTs increase vascular permeability, large molecular weight proteins pass more readily into the extravascular space, resulting in a decreased total blood volume. Additionally, other cytokines inhibit tissue cells from releasing fluid into the extracellular matrix. This altered fluid balance results in a net loss of intravascular volume, contributing to inadequate tissue perfusion. TNF is another well-known mediator of increased vascular permeability in the sepsis syndromes. A third mechanism responsible for impaired cardiovascular function is decreased cardiac contractility.[27] In severe sepsis and septic shock, approximately 50% of patients develop cardiac dysfunction[28-30] despite normal or increased coronary blood flow.[29] There are a number of possible circulating myocardial depressants that have been implicated as causes of decreased cardiac contractility. Myocardial depressant compounds such as TNF-α, interleukin 6 and interleukin 1β probably play a major role in decreased contractility.[29,31]

Decreased cardiac inotropy contributes to hemodynamic compromise during sepsis.

Cytokine-mediated alterations in vascular permeability and tone result in many of the clinical cardiovascular signs of sepsis.

Hemodynamic Changes and Pulmonary Artery Monitoring

The continuous monitoring of multiple systems, such as the respiratory, cardiovascular, metabolic, and central nervous systems (CNS), is important during septic episodes. The PA catheter allows comprehensive monitoring of the hemodynamic function of the body at the bedside. However, routine monitoring of hemodynamics with a PA catheter is probably not required as it has not been shown to improve outcome.[32-34] Details of PA catheter insertion and function are given elsewhere in this text (see Chap. 4 on hemodynamic monitoring).

Hemodynamically, the sepsis syndromes progress through a series of stages due to the effects of hypovolemia, cardiac dysfunction, vascular abnormalities, inflammatory mediators, and tissue hypoxia.[17,35–38] Early sepsis is characterized by a hyperdynamic cardiovascular pattern. The vascular system is diffusely dilated as a result of the systemic effects of numerous circulating mediators. If PA monitoring is used, it will reveal a decreased SVR and PCWP. Reflexive tachycardia usually ensues, and this can be one of the earliest signs of systemic infection. CO is elevated at this stage as the heart rate increases. Increased cardiac contractility generally is not a feature of early sepsis.[29] Although several catecholamines function to increase contractility, a net decrease in systolic and diastolic ventricular function is characteristic.

Early sepsis is characterized by increased CO and decreased SVR.

As the septic process continues, hemodynamic compensations begin to fail. CO appears to normalize as cardiovascular function deteriorates. The PCWP begins to increase and the SVR also moves toward a more normal range. As further systemic collapse continues, the late sepsis hemodynamic profile becomes similar to that seen in cardiogenic shock.

Late sepsis is characterized by deteriorating cardiovascular function.

Respiratory Changes

Tachypnea is the most common respiratory finding in early sepsis.

Hypercapnia generally is not observed in septic patients.

In early sepsis, tachypnea is a common finding. Although incompletely understood, the mechanism may be partly explained by cytokine stimulation of respiratory centers in the brainstem. Significant alveolar hypoventilation can occur at this stage, especially if preexisting pulmonary reserve is already low. Hypercapnia, however, is generally not a feature of early sepsis. Likewise, usually only modest (if any) hypoxemia is present in sepsis unless there is significant underlying pulmonary disease. However, in more advanced sepsis, the lungs themselves may be primarily affected with severe, refractory hypoxemia being a manifestation of this involvement. This is primarily the result of abnormalities in the pulmonary vasculature endothelial membrane permeability, leading to extravasation of fluid and ultimately resulting in ARDS.

Renal Effects

Decreased urine output in the septic patient dramatically worsens prognosis.

An early goal of volume resuscitation in sepsis is maintenance of urine output.

Acute renal failure occurs in about 20% of patients with moderate or severe sepsis and in approximately 50% of patients with septic shock associated with positive blood cultures.[39] Renal dysfunction may occur as the functional intravascular volume decreases and normal compensatory mechanisms fail to maintain adequate organ perfusion. The renal vascular supply has an integrated humoral autoregulatory mechanism that allows the glomeruli to maintain perfusion adequate to produce urine over a wide range of varying volume states. However, as these autoregularoty mechanisms fail, renal blood flow decreases. Prerenal oliguria results and eventually anuric renal failure can occur. In early sepsis, volume expanders such as crystalloid and colloid solutions may improve renal blood flow and increase urine output. This effect is important prognostically because increased urine output generally has been associated with a more favorable outcome.

Neuromuscular Effects

Some degree of neurological dysfunction is almost always observed in severe sepsis.

The nervous system is almost always affected in sepsis; the CNS,[40] peripheral[41] and autonomic nervous systems, and neuromuscular function may be altered. The most common CNS effects are varying degrees of mental status change. These can range from mild confusion or agitation to complete obtundation and even coma. It is usually thought to be acute and reversible but sepsis can also induce focal CNS lesions.[40] Mental status correlates poorly with the degree of sepsis, and even mild early disease can present with profound alterations in higher neurological functions. There are validated scoring systems available for assessment of delirium for medical ICU patients and those specifically on mechanical ventilation.[42-44] The pathophysiology of CNS dysfunction in the sepsis syndromes is unclear; however hemodynamic alterations, neurotoxic substances, and inflammatory mediators all affect the CNS.[40] The multiple systemic immune products released from the macrophage probably play a key role in affecting glial cells, neurons, and endothelial cells causing alteration of blood–brain barrier, cellular metabolism, and cell death.[40] Also, low circulating blood volume in more severe cases can result in decreased cerebral perfusion, contributing to the toxic encephalopathy.

The critical illness effects on the peripheral nervous system and muscles may manifest as generalized weakness and be associated with decreased deep tendon reflexes and a failure to wean from ventilation. These are categorized as critical illness neuromuscular abnormalities, CINMA.[41] Its overall prevalence was estimated at 46% in a review of 24 studies of patients with sepsis, multiorgan failure, and prolonged mechanical ventilation.[41] Though its mechanism is not clearly defined, a number of studies support its association with sepsis and SIRS.[41]

Cytokines and other mediators of the host immune response probably contribute to the CNS dysfunction observed in patients with sepsis.

Alterations in patients' thermoregulatory function are common. Hyperthermia reflects macrophage release of IL-1 and TNF. Hypothermia is also a common sign, usually seen in chronically ill or elderly patients. Patients with septic shock and hypothermia have a significantly increased mortality of 80% compared to a mortality of 50% with fever.[45]

Hematologic and Coagulation Effects

Sepsis can affect all three hematologic cell lines (leukocytes, red blood cells, and platelets) and activate the coagulation cascade.[10] There is typically a leukocytosis, usually with neutrophilia, but occasionally a leukemoid reaction may occur with counts >50,000 per deciliter.[10] The neutrophilia is due to several mechanisms; demargination, and increased production and release of neutrophils.[10] Cytokine-mediated release of immature polymorphonuclear neutrophils (PMNs) is reflected in the leukocyte differential as a left-shift. Unless there is underlying bone marrow pathology that would otherwise result in a decrease in liberated white blood cells, most patients demonstrate such a shift. Patients with normal bone marrow who fail to mount such a response have a poorer prognosis.[46] As noted earlier, activation of circulating neutrophils and monocytes will result in the release of multiple inflammatory mediators including cytokines, increased tissue factor expression, and increased blood cell-endothelial interactions.[10] These responses will contribute to the destruction of the invading microorganism as well as to the inflammation-induced host injury.

Altered production and function of white cells, red cells, and platelets is common in patients with sepsis.

Anemia is seen in most sepsis patients and may develop from hemodilution due to early volume resuscitation, direct blood loss (e.g., phlebotomy, GI bleeding, invasive procedures, or surgery), and anemia of inflammation (decreased erythropoietin production, decreased bone marrow response to erythropoietin, and decreased RBC survival).[10] Suppression of normal hematopoiesis may also be seen and is likely secondary to the actions of endogenous and exogenous inflammatory mediators released during the systemic inflammatory response.

Anemia in patients with sepsis is caused by both hematopoietic suppression and hemodilution following aggressive volume resuscitation.

Circulating platelets are particularly sensitive, both quantitatively and qualitatively, to local and systemic infection. Mild to moderate thrombocytopenia is evident in less severe sepsis, but more profound and clinically significant thrombocytopenia is found in intractable disease and septic shock.

DIC is commonly observed in sepsis syndromes.

In sepsis, coagulation abnormalities occur frequently. The coagulopathy may vary from subtle activation of coagulation factors to marked disseminated intravascular coagulation (DIC) characterized by concurrent intravascular thrombosis and resultant tissue ischemia, abnormal bleeding, and accelerated breakdown of fibrinogen.[47,48] Fifty to seventy percent of these patients will have clinically important coagulation abnormalities of which about a third will have actual DIC.[9,48,49] A modified version of a scoring system[50] developed by the ISTH (International Society on Thrombosis and Haemostasis) for diagnosis of DIC, which uses platelet count, PT, fibrinogen, and d-dimer, is a robust predictor of mortality in sepsis.[48] The depression in platelet count, which also correlates with the severity of sepsis,[51] may be due to the multiple processes of impaired production caused by infectious agents, toxic substances, or inflammatory mediators.[52] Increased consumption, destruction, and sequestration through the spleen and extensive endothelial cell-platelet interactions also plays a role.[48,53,54] These effects on the coagulation system result in laboratory abnormalities such as increased prothrombin time and activated partial thromboplastin time in 14–28%,[48,55,56] elevated fibrin split products (FSP) in 99%,[3,48,57,58] and low levels of protein C and antithrombin in 90% of patients.[3,48,59]

This results in a procoagulant–anticoagulant imbalance manifested as an increase in procoagulant factors and a decrease in anticoagulant factors.[60] In sepsis, the tissue factor–Factor VII(a) system is the main initiator of coagulation and thrombin formation, resulting in conversion of fibrinogen to fibrin, and development of microvascular thrombi[60] and organ dysfunction.[48] Tissue factor is a transmembrane protein present on a number of cells in tissues not normally exposed to blood; unless there is disruption of vascular integrity or production by circulating blood cells.[48,61,62] Endotoxin- and cytokine-challenge studies in humans[63,64] support the principal role of the tissue factor–Factor VII(a) pathway in thrombin generation.[48] Moreover, administration of endotoxin[65,66] to chimpanzees and treatment using monoclonal antibodies directed against tissue factor or factor VIIa completely block thrombin generation.[48]

Three major anticoagulant pathways that may be impaired in sepsis are antithrombin, the protein C system, and the tissue factor pathway inhibitor (TFPI).

There are three major anticoagulant pathways that may be impaired in sepsis: antithrombin, the protein C system, and the TFPI, the main inhibitor of tissue factor–factor VIIa complex.[48]

In sepsis, antithrombin, the major inhibitor of thrombin and of Factor 10a, is reduced due to consumption, decreased production, and degradation.[48] The protein C system, which is normally activated by the binding of thrombin to thrombomodulin on the endothelial cell membrane, is also impaired in sepsis. The binding of thrombin to thrombomodulin on the endothelial cell membrane increases activated protein C 100 times, blocks fibrinogen conversion to fibrin, inhibits thrombin binding to platelet and inflammatory cell receptors, and increases the activation of an important fibrinolysis inhibitor.[48] The activation of protein C helps to control coagulation by degrading clotting cofactors Va and VIIIa. The protein C system is impaired due to decreased production, probable elastase-mediated degradation, and cytokine-induced down-regulation of endothelial cell-associated thrombomodulin and protein C receptor, and decreased protein S level. Lastly, the role of TFPI in the activation of coagulation is unclear.[48]

Gastrointestinal, Hepatic, Endocrinologic, and Metabolic Processes

In addition to the multiple roles of IL-1 already discussed, IL-1 and TNF also influence several metabolic and hepatic processes that are often quite prominent in the septic patient. However, fulminate hepatic failure is usually not a common feature of sepsis. In septic shock, the low circulating flow states and resultant decreased organ perfusion can manifest as a relatively mild elevation in the liver enzymes, AST and ALT, with a disproportionately higher bilirubin.[67] In sepsis associated with a right lower lobe pneumonia, the proximity of the site of infection, and its direct inflammatory effects, may result in markedly abnormal liver enzymes.

Liver failure is usually not a feature of sepsis syndromes.

Less well-understood factors contributing to liver failure in sepsis are the direct effects of the various inflammatory mediators released as part of the systemic inflammatory response.

Muscle mass loss is mainly a result of the catabolic effects of IL-1 and cachectin.

Loss of gross muscle mass has been shown to begin very early in the course of sepsis, primarily as a result of increased muscle protein catabolism mediated by IL-1 and cachectin.

Blood glucose metabolism is altered in sepsis. Hyperglycemia is common[68] and has been attributed to increased levels and activity of endogenous glucocorticoids and catecholamines.[69] Heightened glucagon activity and production also impair glucose metabolism and contribute to clinical hyperglycemia.

SIADH is particularly common when sepsis is caused by infection of the lower respiratory tract.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a common feature in critical illness, including sepsis, especially when the underlying etiology of the sepsis is a bacterial lower respiratory tract infection. The result can be hyponatremia due to impaired renal water excretion.

Multiple Organ Dysfunction Syndrome (MODS)

When more than one organ system is affected by sepsis, MODS is present.

As systemic infection progresses and affects a particular organ system, basic function of the organ will begin to fail. Maintenance of homeostatic stability requires coordination of multiple organ systems and subsystems for survival. Disruption of the primary functions of more than one organ system as related to sepsis is referred to as the MODS. This syndrome usually reflects uncontrolled and advanced disease and can develop rapidly. The prognosis for patients at this end-stage of disease is extremely poor and has not improved in recent years, despite advances in the knowledge base of the pathogenesis of sepsis and the introduction of evolving and novel treatments.

MODS portends a poor prognosis for recovery.

THERAPY

Initial management of these syndromes is supportive and should focus on assessment and treatment of respiratory and hemodynamic impairment and treatment of identified or suspected infections with appropriate antimicrobials. However, more recent studies show that administration of recombinant human activated protein C reduces mortality in patients with severe sepsis; this therapy may be associated with an increased risk of bleeding.[3,70] Initially, broad

CASE STUDY: PART 4

In our previous evaluation of the patient, a rapid and profound deterioration was seen in his respiratory and cardiovascular status. The patient developed respiratory failure despite maximum therapy and was intubated and placed on mechanical ventilation. At the same time, the patient was rapidly given more intravenous fluids with minimal improvement in his arterial blood pressure. He was started on a dopamine drip but despite increasing dose titration, there was only a small improvement in circulatory support. Initiation of a norepinephrine drip significantly improved the shock state and the dopamine was tapered; his BP increased to 92/50 mmHg. Measurements obtained by the PA catheter revealed a hyperdynamic shock state. The PA catheter was used to further optimize his cardiovascular hemodynamics. His sputum and blood cultures revealed Gram-positive diplococci later identified as Streptococcus pneumoniae, and antibiotic therapy was simplified accordingly.

empiric antimicrobial therapy allows coverage for most possible causative infections. As sepsis progresses, and systemic involvement becomes more evident, therapy is directed more toward hemodynamic and organ system support. Furthermore, definitive antimicrobial therapy can be instituted as infectious sources are identified.

Patients with chronic obstructive pulmonary disease (COPD) have an increased risk of developing resistant Gram-negative lower respiratory infections.

Antimicrobial Therapy

The identification of the source of the infection and its prompt treatment is very important. The most important part of the evaluation is a very thorough history and physical examination to determine the source of the infection. After the history and physical examination, potential sites of infection should be evaluated and appropriate Gram stain and cultures of urine, sputum, and blood culture should be quickly obtained. Based on the clinical presentation, cultures of other bodily fluids such as pleural, ascitic, and cerebrospinal fluids and wound cultures should be obtained. Moreover, various foreign bodies (e.g., central venous catheters, PA catheters, arterial lines, other vascular access devices, and indwelling catheters) should be investigated as possible sources of infection.

Antimicrobial therapy is imperative in the initial management of sepsis, even when no obvious source of infection is identified. Appropriate antibiotics should be started immediately after necessary cultures have been obtained, based on specific patient characteristics such as underlying disease(s), immunosuppression, medication allergies, recent stay at a medical facility or nursing home, prior antibiotic treatment, community and hospital antibiotic resistance patterns and site of infection; delays or inappropriate selection of antibiotic treatment have been associated with less optimal outcomes.[71-74] It is recommended to start antibiotics within 1 h of the recognition of severe sepsis or septic shock[75]. In addition, the chances of making a diagnosis are increased by starting antibiotics immediately after obtaining cultures.

When the source of infection is unknown, the initial antimicrobial choice is necessarily empiric. Often there may be clinical findings or patient complaints that suggest a potential source of infection, allowing a more focused regimen. However, even when a source is suspected or known, broad initial coverage is still indicated in addition to directed antimicrobial coverage until the culture and sensitivity results are available. Studies have shown wide variation in terms of outcome, from specific combinations of empiric antimicrobials, and the timing of administration of directed antimicrobials when a source of infection is identified. Nonetheless, early, broad antimicrobial therapy is essential to successful management of sepsis.

In general, severe infections of unknown source as seen in the sepsis syndromes require empiric broad-spectrum antibiotic coverage. Several regimens have been suggested, all with common features. Initial therapy should be directed toward Gram-positive cocci, aerobic bacilli, and usually anaerobes as well. Bactericidal drugs are preferred to those that are bacteriostatic. For empiric coverage, some possible regimens that may be considered are vancomycin with the addition of an extended-spectrum penicillin/beta-lactamase inhibitor, a carbapenem, or a third- or fourth-generation cephalosporin in the ICU. The regimen can be adjusted depending on patient clinical situation, subsequent cultures, and underlying source. Augmented

antipseudomonal beta-lactamase-susceptible penicillins such as ticarcillin/clavulanate or piperacillin/tazobactam or other beta-lactams such as imipenem have also been used as single agent alternatives. If serious beta-lactam allergy is present, a fluoroquinolone such as ciprofloxacin can be used in combination with either clindamycin or metronidazole.

At times, clinical clues may suggest a possible source of infection. In these circumstances, antimicrobials are used in the foregoing regimens. For example, if there is any suspicion that methicillin-resistant *Stapholococcus aureus* (MRSA) is the causative organism, vancomycin should be used. Such might be the case if the patient has an indwelling venous catheter that appears red, edematous, or has a purulent discharge. Likewise, if there is a recent history of surgery and the surgical wound appears to be infected, treatment for MRSA should be added to the regimen. When there is a suspected intraabdominal or pelvic infection, anaerobic and Gram-negative coverage is necessary. Clindamycin or metronidazole should definitely be added in these situations. For patients that may be infected with vancomycin-resistant enterococcus, we would add linezolid.

For patients with septic shock and pneumonia, a third-generation cephalosporin and either a fluoroquinolone or macrolide may be used. Patients with underlying respiratory disease, such as COPD, are predisposed to developing lower respiratory tract infections caused by Gram-negative organisms such as *Hemophilus influenzae* and *Moraxella catarrhalis.* Pneumonia caused by these organisms can result in sepsis and should be treated with either a second- or third-generation cephalosporin.

When community-acquired meningitis is suspected and without an organism on CSF, high-dose ampicillin, a cephalosporin (ceftriaxone or cefepime) plus vancomycin should be included in the empiric antibiotic management.

Early, empiric use of intravenous antibiotics is mandatory as part of the initial therapy of sepsis.

Selection of antibiotics should be guided by a logical assessment of the potentially infecting organisms.

Bactericidal antibiotics are generally preferred in the treatment of sepsis.

Directed antibiotic therapy should be added to the initial regimen if a particular invading organism is suspected, based on the history and physical exam.

Definitive surgical drainage and debridement of any suspected infected fluid or tissue is imperative.

Patients who have been confined to a hospital or other long-term care facility for more than 72 h are typically colonized with antimicrobial-resistant Gram-negative bacteria and MRSA. When they develop sepsis syndromes, initial antibiotic regimens should reflect these modifying circumstances by including coverage with vancomycin or extended-spectrum beta-lactams, such as imipenem, or fluoroquinolones, such as ciprofloxacin. Patients who are neutropenic following therapy for malignant disease represent a well-defined, specific subpopulation who have been documented to benefit from early semi-empiric antibiotic therapy directed toward aerobic Gram-positive cocci (*Streptococcus, Staphylococcus, Enterococcus,* and *Corynebacterium*) and toward certain Gram-negative organisms (*Escherichia coli, Pseudomonas, Klebsiella*).Combination therapy has been recommended for patients with severe sepsis suspected or known to have Pseudomonas and in those with neutropenia, and then subsequent focusing of the regimen once further data is available.[75]

Regardless of the initial broad antibiotic therapy chosen, the regimen should be tailored to the specific organisms as microbiologic culture and sensitivity data become available. In addition to antimicrobial therapy, removal of infected foreign bodies, debridement of devitalized tissue, and drainage of closed spaced infection or abscesses are important source control measures. Surgical or percutaneous drainage of any localized, potentially infected fluid collections should be performed promptly.

Supportive Therapy

Although there is no known specific therapy for the severe sepsis syndromes, vital organ support is essential and requires the level of care and continuous monitoring that only the ICU environment can provide. The initial supportive therapy is directed at identifying and treating hypoxemia and respiratory insufficiency with oxygen supplementation, noninvasive ventilation or intubation and mechanical ventilation. For rapid sequence intubation, it has been recommended to avoid the use of etomidate as an induction agent as it has been associated with relative adrenal insufficiency due to its inhibitory effect on glucocorticoid production.[76,77] However, a recent prospective observational study found no difference in hospital length-of-stay or mortality between septic patients receiving etomidate or other induction agents.[78]

The patient should be assessed for tissue hypoperfusion for which cool skin, mental status changes, oliguria, lactic acidosis, and hypotension are the most obvious clinical indicators.

A central venous catheter can be placed in patients with severe sepsis and septic shock to monitor central venous pressures and to deliver fluids, medications, or blood products. Patients should be quickly resuscitated - initially with intravenous fluids and then with vasopressor agents, blood products, and inotropic agents as necessary. The Surviving Sepsis Campaign International Guidelines[75] recommends protocolized early goal-directed therapy (EGDT) for sepsis-induced shock during the initial 6 h based on reduction in 28-day mortality rate in the original randomized emergency department study[79] and improved outcomes in several studies of protocolized therapy.[80-83] Since the first EGDT study, multiple peer-reviewed studies have confirmed the original findings of improved mortality with a relative and absolute risk reduction of 34 and 16%, respectively.[35,79] In the 11 peer-reviewed publications totaling 1,569 patients, the relative and absolute risk reduction were slightly lower but greater than 25 and 9%, respectively.[35]

In the original EGDT study ($n=263$), emergency department patients with severe sepsis and septic shock were randomized into either a standard therapy protocol with goals of CVP of 8–12 mmHg, MAP ≥ 65 mmHg, and urine output ≥ 0.5 mL/kg/h or to an early goal-directed protocol with the additional goal of $S\bar{v}O_2 \geq 70\%$ using fluid, blood to a hematocrit of ≥30%, and dobutamine[79] for 6 h prior to ICU admission (Fig. 23-3). At 6 h, the EGDT group had significantly higher fluid volume received, higher CVP (13.8 vs. 11.8 mmHg),

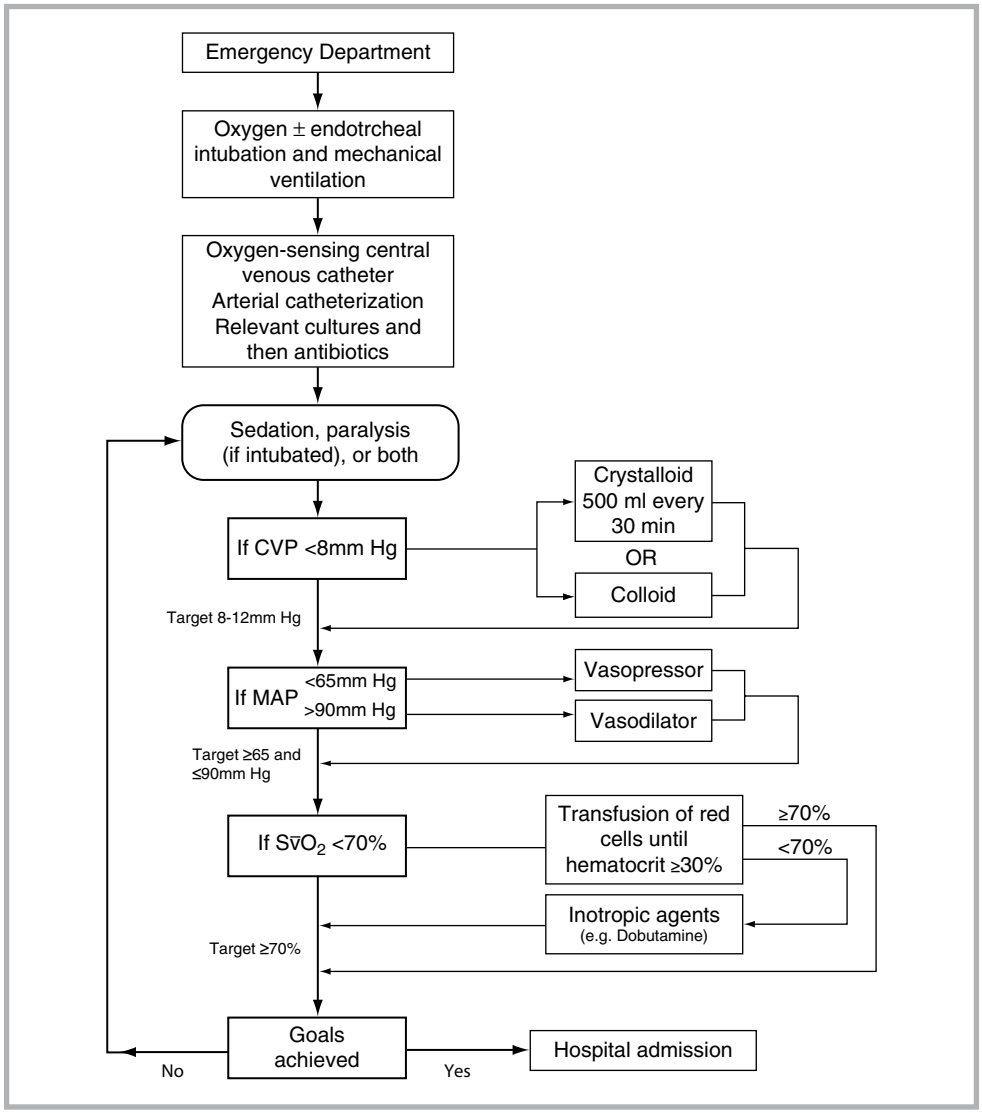


FIGURE 23-3

Early goal-directed therapy protocol. Inclusion criteria: two of the four criteria for SIRS and systolic BP no >90 mmHg (after a crystalloid-fluid challenge of 20–30 mL/kg over a 30-min period) or blood lactate ≥ 4 mmol/L. See exclusions. If CVP<8 mmHg, then a 500-mL crystalloid bolus (or comparable colloid) was given to patients every 30 min to meet a target CVP of 8–12 mmHg. If MAP≤65 mmHg, vasopressors were administered and if >90 mmHg, vasodilators were administered. If $S\bar{v}O_2$ was <70%, blood was transfused to meet a minimum hematocrit of 30%. If the $S\bar{v}O_2$ was still less than 70%, dobutamine was started at 2.5-μg/kg/min and increased by 2.5 μg/kg/min every 30 min until $S\bar{v}O_2$ goal was achieved or reached a maximum of 20 μg/kg/min. If MAP <65 or heart rate >120 beats/min, dobutamine was decreased in dose or discontinued. Patients not hemodynamically optimized were treated with mechanical ventilation and sedatives. *CVP* central venous pressure; *MAP* mean arterial pressure; *$S\bar{v}O_2$* central venous oxygen saturation (illustration by Alice Chen).

higher MAP (95 vs. 81 mmHg), higher $S\bar{v}O_2$ (77.3 vs. 66.0%), and lower lactate levels.[79] Although the EGDT group received significantly more fluid during the first 6 h (5 vs. 3.5 L), there were no differences between groups in total fluid administration at 3 days. Moreover, in the EGDT group, more patients received blood transfusions (64.1 vs. 18.5%) during the first 6 h. Despite more volume at a more rapid rate, there were no differences in the frequency of mechanical ventilation at 6 h, but at 3 days, significantly more patients required mechanical ventilation in the standard therapy group (70.6 vs. 55.6%).

A later study of biomarkers in patients treated with EGDT show that distinct patterns appear as early as 3 h.[84] Lower levels of IL-1RA, ICAM-1, TNF-α, caspase-3, and IL-8 were found at different times within the first 12 h compared to standard therapy. Higher biomarker levels occurred with worsening global hypoxia as reflected by lactate and $S\bar{v}O_2$[84] and higher organ dysfunction and mortality.

According to the international guidelines, these early resuscitation goals should form one part of the treatment protocol and include a CVP of 8–12 mmHg, MAP ≥ 65 mmHg, urine output ≥0.5 mL/kg/h, and $S\bar{v}O_2 \geq 70\%$.[75] A higher target CVP of 12–15 mmHg is recommended for patients on mechanical ventilation and prior decreased ventricular compliance,[85] and possibly in those with increased abdominal pressure[86] or diastolic dysfunction because of the increased pressure needed for ventricular filling.[75] The use of PA catheters has not shown a clear treatment benefit and may not be necessary in the routine management of septic shock.

Fluid resuscitation can be performed with either crystalloid or colloid[75]; there have been no differences in outcome in several studies.[87-89] In particular, the recent SAFE study, which evaluated almost 7,000 ICU patients, showed that using 4% albumin for resuscitation was as safe and effective as saline.[89] However, studies have shown that it requires a greater volume of crystalloid than colloid to reach predetermined resuscitation goals[87] and colloid is more expensive. Most clinicians use predominantly crystalloids.

Volume resuscitation is best done before vasopressors or inotropic agents are added, but frequently vasoactive agents are often needed early in cases of severe shock.[75]

Fluid therapy is recommended to initially achieve the aforementioned CVP goals and then continued as long as there is hemodynamic improvement to fluid challenges, as measured by clinical parameters such as blood pressure, heart rate, and urine output.[75] Depending on your assessment of cardiac status and volume status, fluid challenges may be initiated with volumes of 500–1,000 mL over 30 min with parameters measured before and after each challenge. Recent studies have shown that static pressures from CVP and PCWP are not very accurate predictors of responsiveness to fluid boluses,[90,91] which may lead to under or over resuscitation with fluid, and that dynamic measurements are more accurate predictors.[92,93] In the presence of pulmonary hypertension or changes in right or left ventricular compliance, the central venous pressure may not be a dependable reflection of left ventricular pressures. The Surviving Sepsis Campaign recognizes that there are limitations to the use of static ventricular filling pressures in determining fluid need or predicting fluid responsiveness[94] but note that it is the most easily obtainable measurement available to clinicians.[75] Although the Surviving Sepsis Campaign 2008 cites several overall resuscitation goals using CVP pressures, MAP, $ScvO_2$, urine output, some have recommended that the $S\bar{v}O_2 > 70\%$ be the main target for fluid resuscitation in the first 6 h of severe sepsis management.[93]

Vasopressors

Since septic shock is defined, in part, by systemic hypoperfusion that is refractory to volume resuscitation (or blood lactate concentration of ≥4 mmol/L), vasopressors are frequently used to support hemodynamic and cardiac function. Patients who are supported hemodynamically earlier in the disease course have better outcomes than patients whose therapy is delayed. Patients that required vasopressors later during treatment had a higher mortality at 28 days.[95] Once vasopressors are started, adjusting the MAP goal to 65 mmHg has not been shown to be significantly less effective than 85 mmHg as reflected by systemic oxygen metabolism, skin microcirculatory blood flow, urine output, or splanchnic perfusion.[96] However, the MAP goal may be modified by prior comorbidities such as a history of poorly controlled hypertension and by adequacy of regional and global perfusion when the MAP goal is attained.[75]

At this time, the evidence for best initial choice of vasopressor is limited[97] but human and animal studies suggest that norepeinephrine and dopamine have potential advantages over epinephrine or phenylephrine[78]; recent guidelines recommend starting with either intravenous norepinephrine or dopamine. Epinephrine, phenylephrine, and vasopressin are not recommended to be used as the initial vasopressors due to their various pharmacologic properties and physiological effects.

Norepinephrine exerts its effects predominantly through α_1- and α_2-adrenergic vascular smooth muscle receptors and cardiac β_1-ARs. It produces vasoconstriction and augments MAP via its major α-AR activity, but it is a weaker inotrope. At doses less than 30 ng/kg/min, it typically stimulates the β_1-ARs and at higher doses, has increasing α-adrenergic receptor effects.

The effects of norepinephrine include increased SVR and increased systolic and diastolic pressures. Its vasoconstrictor action is much more potent than its effect on cardiac contractility, which could lead to increased afterload and a reduced CO. However, its vasoconstrictor effects also act on venous capacitance vessels to increase preload and CO, producing little net effect on CO. Norepinephrine is more potent than dopamine in reversing hypotension in septic shock.[98,99] Norepinephrine is beneficial in septic shock because it reverses vasodilatation and improves myocardial function with an unchanged or increased CO, increased coronary blood flow, and a small decrease or no change in cerebral blood flow.

Norepinephrine has long been thought to cause renal, splanchnic and pulmonary vascular vasoconstriction. However, the effect of norepinephrine on splanchnic blood flow in clinical studies of patients with septic shock has shown variable results.[100] Although norepinephrine (and other α-adrenergic agonists) may impair renal perfusion in the setting of hypotension and hypovolemia, recent clinical data indicate that it can be used safely in vasodilatory shock states in association with adequate fluid resuscitation without compromising renal function.[101,102] It should be used with caution in the presence of PA hypertension.

Dopamine is a catecholamine-like agent that has direct effects on three types of receptors: the β-ARs, (β_1 and β_2), α-ARs(α_1 and α_2), and the dopaminergic receptors (DA1 and DA2) in a dose-dependent manner. The cardiovascular response of dopamine is dependent on the dose. The actual dose at which these effects occur varies widely between patients and therefore titration is required. Low rates of infusion produce vasodilatation in the renal, mesenteric, coronary and cerebral vascular beds with minimal effect on other blood vessels or on the heart. At moderate doses, approximately 5–10 μg/kg/min, dopamine increases the rate and force of contraction of the heart, thus increasing CO. The increased CO is mainly due to an increase in SV and less so by an increased HR. Dopamine predominantly increases SBP without affecting diastolic blood pressure (BP). At higher doses, 10–20 μg/kg/min, dopamine produces α-receptor mediated vasoconstriction, increasing MAP, SVR and pulmonary vascular resistance. Furthermore, venous capacity is reduced through vasoconstriction, which increases PCWP, especially at higher dopamine doses. However, it is causes more tachycardia and may be more arrhythmogenic than phenylephrine or norepinephrine.[98]

It has been suggested that epinephrine should be the first alternative agent in patients with septic shock not responding to dopamine or norepinephrine.[98] Epinephrine binds and activates β_2-, β_1-, and α-AR in a dose-dependent manner. The effects of epinephrine at lower doses are mediated via the β-AR, causing vasodilatation, whereas higher doses primarily affect the α-AR causing vasoconstriction. It is one of the most potent vasoconstricting drugs available. It increases myocardial contraction, electrical activity, automaticity, and oxygen requirements. In sepsis, the increase in MAP primarily results from a direct effect on myocardial contractility (increased SV) with only moderate increases in HR and SVR. Although dopamine and norepinephrine have similar hemodynamic effects, epinephrine may increase tachycardia and impair the splanchnic circulation in severe septic shock.[103]

Epinephrine may increase myocardial oxygen demand, ischemia, and angina secondary to an increased HR and BP. It may also increase lactate concentrations either by reduction of organ perfusion or its hypermetabolic effects. The main concern with the use of epinephrine is its potential to decrease regional blood flow, specifically in the splanchnic circulation.[99,104,105] However, a recent study comparing norepinephrine plus dobutamine vs. epinephrine for the management of septic shock showed no difference in efficacy and safety

between the two regimens.[106] More serious reactions include cerebral hemorrhage, tachycardia, arrhythmias, hyperglycemia, angina, and poor cutaneous perfusion.

Phenylephrine has been studied minimally in septic shock,[107] and thus it is difficult to state with certainty its role in septic shock treatment. Phenylephrine is a rapid-acting, selective α_1-adrenergic agonist that acts as a powerful arterial vasoconstrictor.[108] Therefore, phenylephrine elevates MAP mainly through an increase in SVR. The elevated MAP may produce a reflex bradycardia and a small decrease in CO, which may be more marked in patients with preexisting cardiac dysfunction; renal perfusion may also decrease. It has also been reported to reduce splanchnic blood flow and DO_2 in septic shock patients.[109] The main disadvantage of phenylephrine is its pure alpha agonist property that increases afterload without any direct inotropic effects, leading to decreased stroke volume and CO. This disadvantage may be magnified in hypodynamic states, in the setting of unrecognized cardiomyopathy (such as sepsis-induced cardiomyopathy) or with associated valvular heart disease. As a result, phenylephrine is recommended as a third-line therapy in the treatment of septic shock.[98] However, it has no beta-adrenergic stimulation, which makes it a more desirable vasopressor in patients with tachycardia due to catecholamine vasopressors, underlying intrinsic cardiac disease or inadequate intravascular resuscitation, and in patients with cardiac arrhythmias.

Vasopressin, otherwise known as antidiuretic hormone (ADH), is a small peptide hormone released from the posterior pituitary that has several physiologic actions. It plays a major role in water balance and in regulation of the cardiovascular system. It is a potent vasoconstrictor that is released in the presence of hypovolemia or hypotension. The vasoconstrictor effects are mediated through direct stimulation of the vascular smooth muscle V_1 receptors. These receptors are found in multiple tissues of the body such as vascular smooth muscle, bladder, liver, spleen, kidney, CNS, testes, and platelets. In supraphysiologic doses, vasopressin causes powerful vasoconstrictor effects that are more potent than norepinephrine and are not reduced by acidosis.

In septic shock, it was found that vasopressin plasma levels were inappropriately low and it was felt that this decrease could contribute to the hypotension seen in vasodilatory shock.[21] Observational studies involving the use of a vasopressin infusion at doses less than 0.1 U/min in patients with vasodilatory shock have shown improvement in blood pressure. The VASST trial compared norepinephrine alone to norepinephrine and vasopressin at 0.03 U/min, in patients with septic shock and found no difference in outcome.[26]

Vasopressin can produce multiple adverse effects related to smooth muscle constriction in vascular, gastrointestinal, uterine, and bronchial smooth muscle. At supraphysiologic levels (>0.04 U/min), potent vascular smooth muscle constriction may cause coronary artery constriction resulting in cardiac ischemia. The incidence of adverse events was as high as 10% in the VASST trial with no difference between norepinephrine with or without vasopressin.[26] However, the investigators did exclude patients with acute coronary syndrome or severe heart failure that would be most likely to experience an adverse event.[26] Vasopressin may also cause platelet aggregation and increase the potential for small vessel occlusion.

Inotropic Support

Dobutamine produces a strong inotropic effect through stimulation of both β_1- and α_1-ARs in the myocardium. In addition, it produces mild vasodilatation because the effect of β_2-AR stimulation on the peripheral vasculature, and cardiac musculature, is more potent than the vasoconstrictor response produced by α_1-AR stimulation. Dobutamine does increase renal and mesenteric blood flow through increases in CO.

The indications for the use of dobutamine in patients with septic shock are poorly defined; there is concern that the vasodilatory effects of dobutamine may augment the hypotension. In septic shock, cardiac index is usually maintained in fluid-resuscitated patients although cardiac contractility function is impaired.[110] Severe cardiac dysfunction may develop in a small percentage of patients and if filling pressures are elevated, dobutamine may be efficacious. However, there is no benefit to increasing CI to achieve supranormal levels of O_2 delivery.

Dobutamine is best used in septic shock patients with left ventricular dysfunction, as indicated by a CI < 2.5 L/min/m^2 in association with elevated filling pressures.[75] Because of its vasodilatory effects, it is commonly used in conjunction with other vasopressors in the management of septic shock. The conventional infusion rate of dobutamine is 2–20 μg/kg/min and should be titrated according to desired response; tachycardia may be a limiting factor. At doses between 5 and 15 μg/kg/min, there is a greater inotropic effect than chronotropic effect, which characteristically lowers PCWP and CVP with only a mild effect on vascular resistance. Avoid dobutamine if the systolic BP < 100 mmHg and there is evidence of shock. It is contraindicated in obstructive cardiomyopathies, atrial fibrillation or flutter. Adverse effects of dobutamine include arrhythmias and tachycardia, which may produce myocardial ischemia. However, dobutamine infusion rates between 2 and 20 μg/kg/min are less likely to produce tachycardia than dopamine. Hemodynamic monitoring is recommended.

During the initial resuscitation of severe sepsis or septic shock, if an $S\bar{v}O_2 \geq 70\%$ or an $S\bar{v}O_2 \geq 65\%$ is not met after volume resuscitation and initiation of vasopressor therapy, then blood transfusion to a hematocrit greater than or equal to 30% should be considered.

In general, initial vasopressor support, when needed, should be instituted with either norepinephrine or dopamine as the first-line agent.

After the initial phase of EGDT resuscitation, which may have included fluids, vasopressors, and blood, patients may still exhibit evidence of inadequate tissue perfusion, such as persistent hypotension or decreased urine output. Some patients will respond to additional fluid administration with clear evidence of improved tissue perfusion or hemodynamic indices.[93] However, a volume challenge in a patient who is unresponsive to fluid administration may lead to pulmonary edema or cor pulmonale.[111] To determine the patient who is fluid-responsive, static or dynamic measures have been used but static measures of CVP or PAOP are not usually helpful predictors.[93] In patients with sepsis, the positive predictive value or the accuracy of CVP < 8 mmHg or PAOP < 12 mmHg of predicting a 15% change in CO with a fluid bolus is only about 50%.[91,93]

However, dynamic measures of fluid responsiveness are possible without using a fluid bolus, which can be useful when the risk of a direct fluid challenge is not small.[93] Short-term changes in cardiac preload can be induced by either tidal ventilation variation, end-expiratory occlusion,[112] or passive leg raising to 45°.[113,114] During these maneuvers, practitioners can measure changes in CO or surrogates of stroke volume.[93,94,111,112] In these studies, the various surrogates of CO or stoke volume used to predict fluid responsiveness have included pulse pressure variation (PPV), systolic pressure variation, peak aortic blood flow velocity, and echocardiographic variation in vena cava diameter. For example, fluid responsiveness was predicted to a 500-mL bolus by a respiratory induced change in PPV of 13% with a sensitivity of 94% and a specificity of 96%.[115] However, dynamic measures for predicting fluid responsiveness also have limitations. The PPV induced by tidal ventilation requires that the patient not have cardiac arrhythmias or spontaneous breathing but must be sedated (possibly in association with muscle paralysis) and on mechanical ventilation.[115] Moreover, tidal volume must be 8 mL/kg or more to produce a change in stroke volume that can be measured as PPV.[93] On the other hand, the end-expiratory occlusion maneuver method has had similar reliability but can be used in patients having mild spontaneous breathing or cardiac arrhythmias.[112] Accordingly, fluid responsiveness was predicted using a change in pulse pressure of ≥5% or cardiac index ≥5% in response to end-expiratory occlusion with a sensitivity and specificity of 87 and 100% and 91 and 100%, respectively.[112]

Epinephrine, phenylephrine, or vasopressin are not recommended as the initial vasopressors in septic shock.

If hypotension is refractory to dopamine or norepinephrine, epinephrine has been recommended as the first alternative agent.[75]

Recombinant Human Activated Protein C

A number of coagulation abnormalities occur in sepsis causing a procoagulant–anticoagulant imbalance. The protein C system may also affect inflammatory mediators in sepsis. As indicated earlier, the protein C system pathway is affected at several points, and results in low protein C and free protein S levels, and down-regulation of thrombomodulin and the protein C receptor on endothelial cells. Based on the knowledge that there is a deficiency of components of the protein C system, its potential contribution to DIC, and studies showing favorable effects on patients with severe infections who were treated with activated protein C,[116,117] a trial of activated protein C supplementation in sepsis was initiated.[118]

The PROWESS study treated patients with sepsis, beginning within 24 h of presentation, with a 96-h infusion of recombinant human activated protein C (drotrecogin alpha) or placebo.[3] There were exclusions for patients with an increased risk of bleeding and those with chronic renal failure. A reduction in the 28-day mortality rate was noted for the activated protein C treated group (24.7%) compared to placebo (30.8%), translating into a relative risk reduction of 19.4%. Further analysis of the data revealed greater benefit for the more severe patients with an APACHE II score ≥25. Those treated with drotrecogin alpha had a lower frequency of multiple organ dysfunction and faster resolution of cardiac and pulmonary dysfunction.[119]

The overall results of the study were positive but there were FDA Advisory committee concerns due to a change midway through the trial in the subject recruitment protocol and drug manufacturing process.[120] The drug was licensed by the FDA for patients with severe sepsis and a high risk of death and further studies of the drug were requested in adults with a low risk of death and in children.[120] Subsequent studies, both stopped prematurely, confirmed the lack of benefit in adults with low risk of death (ADDRESS trial)[121] and in children (RESOLVE trial).[122] In the ADDRESS trial, mortality rates for a small number of subjects ($n=321$) with APACHE II scores >25 were analyzed and 28-day mortality was found to be 29.5% for patient receiving drotrecogin alpha compared to 24.7% for those receiving placebo. A subsequent randomized placebo-controlled trial, the PROWESS-SHOCK trial, is planned to further define the patient populations and benefits and risks of drotrecogin alpha treatment.[120] The drug was found to be cost-effective in two types of analyzes for patients with more severe disease i.e., APACHE II scores ≥25.[123,124]

The most frequent serious adverse reaction of drotrecogin alpha is bleeding. Since the drug affects a physiologic anticoagulant pathway, it is not surprising that complications of significant bleeding were seen; these included fatal intracranial hemorrhages.[3] A subsequent study, ENHANCE, showed that treatment within 24 h of initial organ dysfunction had a lower associated mortality than seen in those patients treated later.[125] Although mortality was similar in this study to the PROWESS study, there was a higher frequency of intracranial hemorrhage.[125] A recent small, retrospective, medical record review of 73 patients showed a higher frequency of serious bleeding events in patients who had a bleeding risk factor (7 of 20 patients) compared to those without bleeding risk factors (2 of 53 patients).[126,127] When the decision to administer drotrecogin alpha is being considered, the *Warnings and Precautions* sections of the package insert should be carefully reviewed. This agent should be used with caution in patients with sepsis and bleeding risk factors.

Glucocorticoids

The benefits and role of corticosteroids in septic shock remain unclear. Early randomized trials in the late 1980s using high-dose corticosteroids did not show any mortality benefit.[128-130] Recent studies have focused on more physiologic-dose or low-dose corticosteroid (hydrocortisone 200–300 mg daily) treatment based on observations that patients who had a reduced response (<9 μg/dL) to ACTH had higher mortality and that hydrocortisone improves blood pressure response to norepinephrine.[130] Several small studies and a larger trial that showed favorable effects have lead to use of low-dose steroid in septic shock.

The Surviving Sepsis Campaign[75] and American College of Critical Care Medicine[131] currently recommend corticosteroid treatment for patients with hypotension not responsive to fluids and vasopressor treatment. Additional studies are needed to further define the use of corticosteroids in the treatment of septic shock.

SUMMARY

Patient mortality from severe sepsis remains excessive despite advances in our knowledge of the pathophysiology of the disease and novel new therapies. This reflects the fact that there still remains no specific treatment for sepsis, and thus management is largely supportive. Because hemodynamic collapse represents the fulminant stage of this illness, supportive interventions are directed toward maintenance of cardiovascular, respiratory, and hemodynamic integrity. However, many patients with sepsis already have preexisting and sometimes

CASE STUDY: PART 5

After continued antibiotics directed toward Streptococcus pneumoniae and supportive treatment, the patient's vital signs, including blood pressure, gradually improved. His mental status, cardiovascular hemodynamics, and urine output improved over the next 2 days and PA catheter monitoring was discontinued. Over the next 10 days, his pneumonia improved and he was weaned from mechanical ventilatory support. He was later evaluated as an outpatient and was found, as expected, to have COPD.

multisystem disease, and are unable to sustain the derangements imposed by systemic infection, even with aggressive and intensive support.

Important concepts include early consideration of occult infection, and rapid identification of the offending organism, if possible. If a source of infection is found, primary treatment must include both surgical and medical interventions; delay in either approach can be catastrophic. If a source cannot be identified, rapid, empiric antibiotic therapy is the rule. Unfortunately, the septic process may continue unattenuated despite all direct and supportive therapy, even when such therapy is guided by invasive hemodynamic monitoring.

Clinicians need to maintain a state-of-the-art approach to the management of this complex and potentially lethal disease process. With new data and novel therapies being investigated at a vigorous pace, the management of sepsis will undoubtedly advance rapidly.

REVIEW QUESTIONS

I. Multiple choice questions

1. Which one of the following is *not* one of the criteria required for diagnosis of the SIRS, as established by the American College of Chest Physicians/SCCM?
- **A.** Tachycardia greater than 90 beats/min
- **B.** Elevated white blood cell count
- **C.** Low white blood cell count
- **D.** Peripheral edema
- **E.** Low $PaCO_2$ on arterial blood gas analysis

2. Which one of the following statements is *false*?
- **A.** Sepsis is diagnosed when SIRS is found to have an infectious etiology
- **B.** At least two blood culture samples need to be positive for bacterial growth for the SIRS to be present
- **C.** Hypotension is NOT the main criteria required for a diagnosis of septic shock to be made
- **D.** Septic shock is associated with signs of organ hypoperfusion and dysfunction
- **E.** A $PaCO_2$ of 22 torr on arterial blood gas analysis would be one of the criteria needed for SIRS to be diagnosed

3. All the following are true concerning inflammatory mediators released during sepsis syndromes except:
- **A.** They are tightly regulated during sepsis and therefore pose no threat to normal host tissue
- **B.** Their release from the macrophage results in both local and systemic immune responses
- **C.** Bacterial LPS is recognized by the host immune system and can result in activation of the immune response
- **D.** Interleukin-1 (IL-1) can mediate fever in the host through its activity in the hypothalamus
- **E.** TNF is a potent stimulator of several interleukins and can also cause local tissue destruction directly

4. Which one of the following statements is *false*?
- **A.** Systemic release of TNF has been shown to have a stimulatory effect on host intravascular coagulation
- **B.** Both TNF and interleukin-1 (IL-1) can cause fever in the host
- **C.** Interleukin-1 release from the macrophage does not occur unless first stimulated by TNF
- **D.** Arachidonic acid release from the host cell membrane is a common feature of the sepsis syndromes
- **E.** Interleukin-1 (IL-1) is a potent stimulator of phagocytes and lymphocytes

II. True/false questions

5. Interleukin-1 release from the macrophage occurs after stimulation by TNF and also after stimulation by Gram-negative cell membrane LPS.

6. PAF causes platelet degranulation and pulmonary hypertension but has no effect on platelet chemotaxis.

7. Peroxynitrite is produced from endogenously liberated NO and has been shown to cause direct host tissue damage.

8. In the healthy state, the relationship between oxygen uptake and DO_2 is biphasic, with tissue metabolism able to maintain a constant oxygen uptake over a variable degree of DO_2.

9. In the septic state, occult tissue ischemia has been shown to be caused by a pathologic dependence of oxygen uptake on DO_2, thus inciting the ARDS.

10. Antibiotics are an essential element of early treatment of the critically ill septic patient.

ANSWERS

1. The answer is D. The American College of Chest Physicians and the SCCM have jointly established consensus criteria, which should be applied when considering the diagnosis of SIRS in a patient, as an attempt to standardize diagnostic, therapeutic, and investigational efforts. By these criteria, SIRS is present when at least two of the following findings are present: (1) leukocytosis or leukopenia; (2) hyperthermia or hypothermia; (3) hypocapnia or tachypnea >20 breaths/min; or (4) tachycardia >90 beats/min. Peripheral edema is not one of the established criteria required to define the presence of SIRS.
2. The answer is B. Consensus definitions have been established for sepsis and the sepsis syndromes. By these definitions, if SIRS is caused by infection, sepsis is present. Although infection is a common cause of SIRS, noninfectious causes are recognized as well; therefore, bacteremia is not required for the diagnosis to be made. Although the diagnosis of septic shock has previously focused on relative or absolute hypotension, this finding has recently been deemphasized in favor of the more conceptual theory of relative or absolute tissue ischemia, reflected clinically as gross organ dysfunction. Hypocapnia is one of the established criteria that may define SIRS in combination with other consensus criteria.
3. The answer is A. Mediators involved in the inflammatory response are subject to complex and integrated control under homeostatic conditions. Because they function to influence host cells both locally and systemically, any abnormal propagation or acceleration of the immune response has systemwide potential to alter gross host function and result in the clinical syndrome of SIRS, with sepsis being SIRS caused by infection. Many stimulants of the immune cascade are recognized, both exogenous and endogenous. Bacterial LPS is a common exogenous macromolecule that results in mediator release and activation of the immune cascade. Endogenous stimulants, such as IL-1 and TNF, cause effects on host hypothalamic thermal regulation and activation of other mediators, respectively. Additionally, TNF has been shown to cause biochemical tissue damage directly. A fundamental concept in sepsis physiology is that abnormal proliferation of the normally activated immune response results in ultimate host damage.
4. The answer is C. Mediators such as TNF and IL-1 that are released on activation and propagation of the immune cascade work to influence or modify the activity of host cells and organ systems distant to the site of their secretion. TNF has many effects on host cells. For example, TNF is a potent stimulator of the coagulation cascade, which can manifest clinically as a syndrome of DIC, involving inappropriate activation of the blood coagulation factors in the vascular pool. The result is formation of capillary microthrombi that can cause tissue ischemia or infarction. TNF also plays a role in mediation of IL-1 release. Macrophage stimulation by TNF will elicit IL-1 production and secretion but it is not required. Cell membrane phospholipid liberation and subsequent bioconversion by increased phospholipase activity can be caused by both IL-1 and TNF in sepsis. The result is an increase in the arachidonic acid pool, making the precursor metabolite available for further inflammatory mediator generation. One of the first descriptions of IL-1 described its efficiency as a phagocytic and lymphoid cell stimulator.
5. The answer is true. There are many potential stimulators of IL-1 release, including both endogenous mediators such as TNF and exogenous mediators such as the Gram-negative bacterial cell membrane constituent LPS.
6. The answer is false. PAF, like most other inflammatory mediators released during sepsis, has systemic effects, such as pulmonary hypertension, as well as local effects on platelets, including chemoactivation and chemoattraction.
7. The answer is true. Peroxynitrate, an oxygen species free radical, has been shown to cause profound tissue damage local to its release. Basic sepsis physiology describes both an increase in the liberation of these free radicals and attenuated host clearance mechanisms.
8. The answer is true. By adjusting the fraction of oxygen extracted from perfused blood at the cellular level, normal host tissues are able to maintain a constant intracellular supply of oxygen needed to support the metabolic demands of respiration; this is referred to as physiologic independence of oxygen uptake on DO_2.
9. The answer is false. Since first postulated and following intense investigation and academic debate, this theory of oxygen dysmetabolism, known as physiologic dependence of oxygen uptake on DO_2, has largely been abandoned. The exact nature of the oxygen metabolism disturbance observed in sepsis remains to be fully described.
10. The answer is true. There is no cure for sepsis, which is defined as SIRS caused by infection. Therapeutic intervention is largely supportive and is organ or system targeted. Although the infecting organism responsible is rarely identified initially, and is relatively infrequently identified at all, early empiric antibiotic coverage is mandatory. Broad coverage is preferable, with directed antibiotic therapy added if clinically indicated.

CHAPTER 24

RONALD N. RUBIN AND KALYANI NARRA

Bleeding Diathesis

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Know the history, physical examination, and laboratory tests useful in assessing the bleeding patient.
- Be aware of the disorders of vascular and tissue components and platelet dysfunction as they relate to bleeding diathesis.
- Evaluate patients with disorders of platelet immune destruction.
- Diagnose hereditary and acquired coagulation disorders found in intensive care unit patients.

BLEEDING DYSCRASIAS

Normal hemostasis requires an intact interrelating mechanism composed of vascular and tissue components, platelets, and coagulation proteins. Deficiency or disease of any of these components may cause either spontaneous or trauma-related hemorrhage. The intensive care setting, by definition, involves a population that is characterized by multiorgan failure, polypharmacy, and multiple wounds of both accidental and iatrogenic variety. Such pathophysiology significantly stresses even an initially normal hemostatic mechanism. It is not surprising, then, that bleeding is a frequent complication encountered in the intensive care setting. A thorough history, physical findings as well as a broad battery of laboratory tests, often serves to differentiate the different bleeding dyscrasias.

History

A thorough history, physical findings as well as a broad battery of laboratory tests, often serves to differentiate the bleeding dyscrasias.

A carefully taken history provides clues to the pathogenesis of bleeding dyscrasias. Immediate bleeding in mucocutaneous areas (nose, mouth, bladder, skin) suggests vascular or platelet abnormality, whereas delayed deep tissue bleeding such as internal hematoma formation suggests coagulation protein deficiency. Genetic transmission of bleeding disorders, such as the hemophilias and von Willebrand's disease (vWD), also can be elicited by history, as will the ingestion of drugs (e.g., warfarin, aspirin, nonsteroidal antiinflammatory drugs [NSAIDs]), which can profoundly affect hemostasis. Similarly, a history of no hemostatic difficulties during past hospitalizations or surgeries, or during the time period before arrival in the intensive care unit (ICU) suggests that any bleeding dyscrasia is an acquired one, and investigation of recent events and medications often yields an etiology.

Physical Findings

Mucocutaneous petechiae or purpura suggests platelet disorders; spreading hematomas suggest coagulopathy.

A thorough examination often yields clues to the underlying derangement in hemostatic pathophysiology resulting in a bleeding diathesis. Mucocutaneous petechiae and purpura suggest platelet disorders, whereas spreading hematomas suggest coagulopathy.

Laboratory Testing

Laboratory tests are vital to the evaluation of bleeding disorders. Because single tests rarely provide conclusive results, various batteries of tests have been developed. The coagulation cascade is shown in Fig. 24-1. The interpretation of common tests of hemostasis and blood coagulation is shown in Table 24-1, with the diagnosis of common bleeding disorders based on commonly used tests. These studies provide a basis upon which a proper differential diagnosis and reasonable attempts at therapy can then be formulated.

DISORDERS OF VASCULAR AND TISSUE COMPONENTS

On occasion, bleeding may result from pathology involving the vessel area itself, with secondary leakage of blood. When the skin is a dominant target area (as with vasculitic disease), these disorders have palpable skin lesions as their hallmark. Testing performed on patients with these bleeding disorders shows normal coagulation testing and platelet counts and, occasionally, increased bleeding times. A history of exposure to drug allergens or the presence of an infection by appropriate pathogens is very important in arriving at a diagnosis. When clarification of this mechanism is deemed vital to alterations in therapy, skin biopsy and culture are indicated.

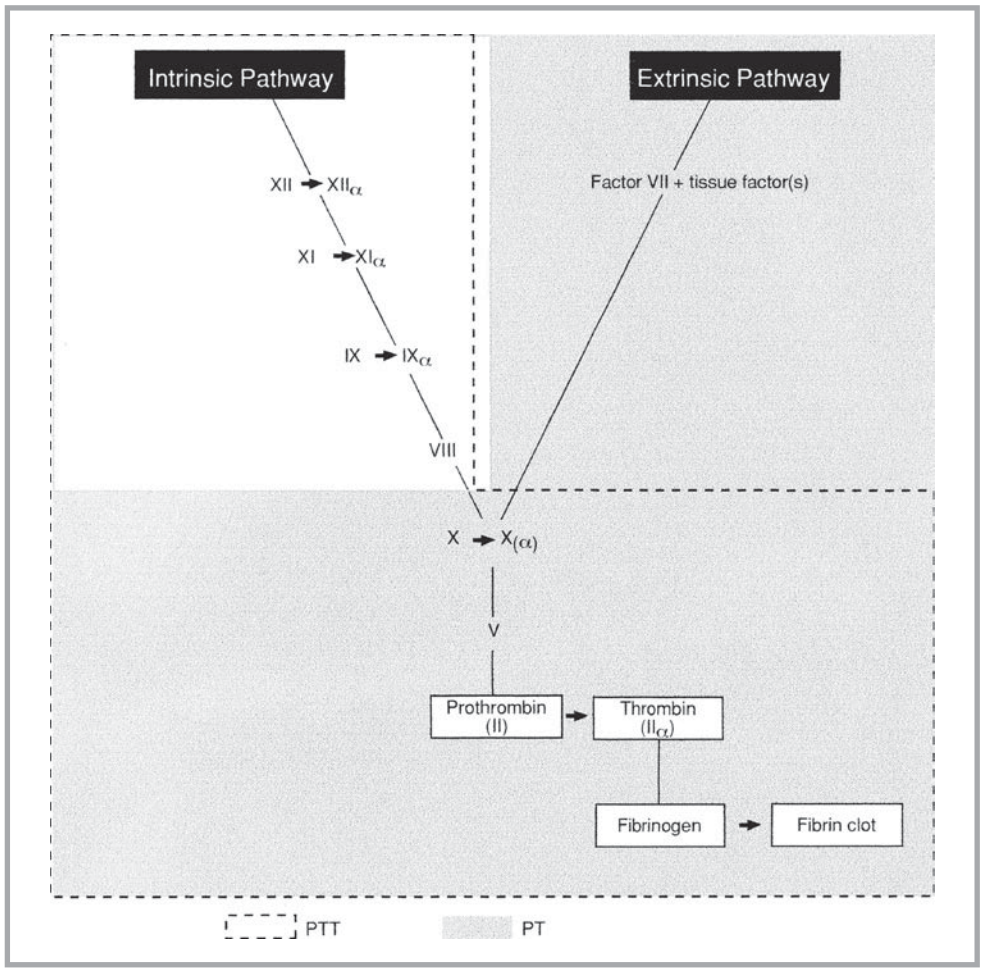

FIGURE 24-1

The blood coagulation cascade has two pathways, intrinsic and extrinsic, involving multiple factors. The integrity of the intrinsic pathway is tested by a partial thromboplastin time (PTT) assay and the extrinsic pathway measuring prothrombin time (PT).

TABLE 24-1

COMMONLY USED TESTS OF HEMOSTASIS AND ASSOCIATED DIAGNOSES

TEST	NORMAL RANGE	IMPORTANT ASSOCIATED CONDITIONS
Essential screening tests		
Platelet count	150,000–450,000/μL	Thrombocytopenias
Template bleeding time	2.0–7.5 min	Thrombocytopenias Vascular disorders (scurvy) von Willebrand's disease (vWD) Platelet dysfunction
Partial thromboplastin time	25–40 s	Intrinsic factor protein deficiencies Anticoagulant overdose
Prothrombin time (PT)	12–17 s	Liver disease Warfarin overdose Vitamin K deficiency
Secondary tests		
Fibrinogen assay	150–400 mg/dL	Severe liver disease Fibrinolytic drugs Disseminated intravascular coagulation (DIC)
Fibrinogen/fibrin digest product assays and D-dimer assays	–	Fibrinolytic agents DIC

Autoimmune Purpura

Autoimmune purpura is a vasculitis of small vessels with associated IgG deposits.

Autoimmune (allergic) purpura is a prototype lesion, also known by its eponym, Henoch–Schönlein purpura. It is a vasculitis of small vessels with associated IgG deposits caused by allergy, most classically to infectious agents such as streptococci and to drugs such as penicillin. Palpable, symmetric, often pruritic lesions are most commonly seen on the extremities. Lesions can occur in the bowel, causing gastrointestinal bleeding, in the kidney, causing hematuria, and in joints, causing clinical arthritis. Biopsy reveals perivascular inflammatory lesions with leakage of plasma and blood into the skin, mucosa, and serosa. Therapy requires recognition, cessation of the offending agent, or treatment of the infection causing the reaction. Recognition is important because this is a vascular lesion and not a true coagulopathy or platelet defect; thus therapies directed at those types of hemostatic disorders will be ineffective. The prognosis is good, however 5–10% of patients develop chronic glomerulonephritis.

Infectious Purpura

These conditions can also cause formation of a palpable purpuric lesion that is often also painful. These lesions may be symmetric and in classical distributions, as with *Rickettsia* infections, or be quite random, as with bacterial infections such as endocarditis. The lesions are caused by actual endothelial damage by the infectious agent (*Rickettsia*) or by embolic occlusion of the microvasculature (endocarditis). Biopsy and culture of lesions can be particularly helpful in these patients, because such procedures demonstrate that the lesions are not primarily coagulopathic or platelet-related, and in addition can actually demonstrate and identify a specific infection.

Structural Malformations

A variety of structural malformations are associated with friability of blood vessels with resulting hemorrhagic tendencies.

A variety of structural malformations are associated with friability of vessels with a resulting hemorrhagic tendency. Hereditary hemorrhagic telangiectasia (HHT), also known as Osler-Weber-Rendu syndrome, is an autosomal dominant trait that causes mucocutaneous telangiectasia resulting in epistaxis, gastrointestinal bleeding, and is associated with pulmonary, hepatic and cerebral arterio-venous malformations. Even though it is a hereditary condition, clinically significant bleeding is not seen until patients are young adults. Acquired aberrancy in blood vessels lead to angiodysplasia (blood vessels are lined by endothelium with a thin layer of smooth muscle only), gastric vascular ectasia, and Dieulafoy's lesions, which can lead to massive hemorrhage.

Scurvy

Scurvy patients respond well to vitamin C.

Scurvy is caused by vitamin C deficiency, which impairs collagen synthesis in vessel walls. These vessels are thus friable because of a lack of collagen support; they rupture very easily and, once ruptured, do not vasoconstrict and thus allow excess bleeding. Classical sites are perifollicular petechiae, gum bleeding, and periosteal hemorrhages. This syndrome is most frequently seen today in severe alcoholics who are malnourished. Laboratory study of such patients usually reveals a prolonged bleeding time. Scurvy patients respond well to vitamin C at 1 g/day.

Steroid Purpura

Steroid therapy causes vascular fragility and increased skin bleeding that often mimics a true platelet dysfunction.

Steroid therapy also results in impaired collagen synthesis, involving particularly the dermal layer of the skin. These patients manifest a vascular fragility and increased skin bleeding that can often mimic a quantitative or qualitative platelet problem.

Miscellaneous Conditions

Paraproteinemias, including cryoglobulinemias and amyloidosis, are associated with skin bleeding and prolonged bleeding times.

Surgical Bleeding

Profuse bleeding in a single area of the body in the absence of an abnormality of platelet or coagulation testing is frequently observed in the ICU.

Profuse bleeding from a single area of the body, in the absence of any abnormality of platelet or coagulation testing, is not an infrequent situation in the ICU. When no other obvious or subtle lesion involving the vasculature, platelets, or coagulation proteins is found, one must consider the possibility of inadequate surgical hemostasis or damage to a vessel severe enough to require exploration and ligature, rather than hemostasis therapy. Classic and common examples include tearing of a vein when placing a central catheter, tearing of an artery during cardiac catheterization, or profound bleeding from a chest tube after thoracotomy and/or cardiac surgery. This problem is discussed later with specific common bleeding situations and entities.

DISORDERS OF PLATELETS

Platelet Structure and Function

Platelets are small (2–3 μm) cells that circulate in the blood. They do not possess a nucleus but do have mitochondria and other organelles that are critical to proper platelet function. Most important are the systems of granules evident using the electron microscope (see Figs. 24-2 and 24-3). Three granule types are identified: (1) dense granules that contain ATP, ADP, serotonin, and calcium; (2) alpha granules that contain many proteins, including trace amounts of plasma proteins (albumin, fibrinogen, von Willebrand's factor [vWF]) and platelet-specific proteins (beta-thromboglobulin, platelet-derived growth factor); and (3) lysosomal granules. All of these proteins are released during the platelet release reaction.

Platelet Physiology During Coagulation

A series of events occurs when platelets are stimulated in vivo. The usual physiologic stimulants are exposure of the platelet membrane to damaged endothelium and exposure of platelets to biologically active substances such as thrombin, which is present in the area of a thrombosis. When these events occur, the platelets first undergo a shape change that is mediated by the membrane. The oblong disks become stellate forms with pseudopod-like structures, these coincide with the phenomenon of platelet adhesion, wherein platelets with the help of glycoprotein Ib/V/IX receptor adhere to vascular endothelium exposed by injury. vWF is the main cofactor in this step. After the platelets adhere to the damaged

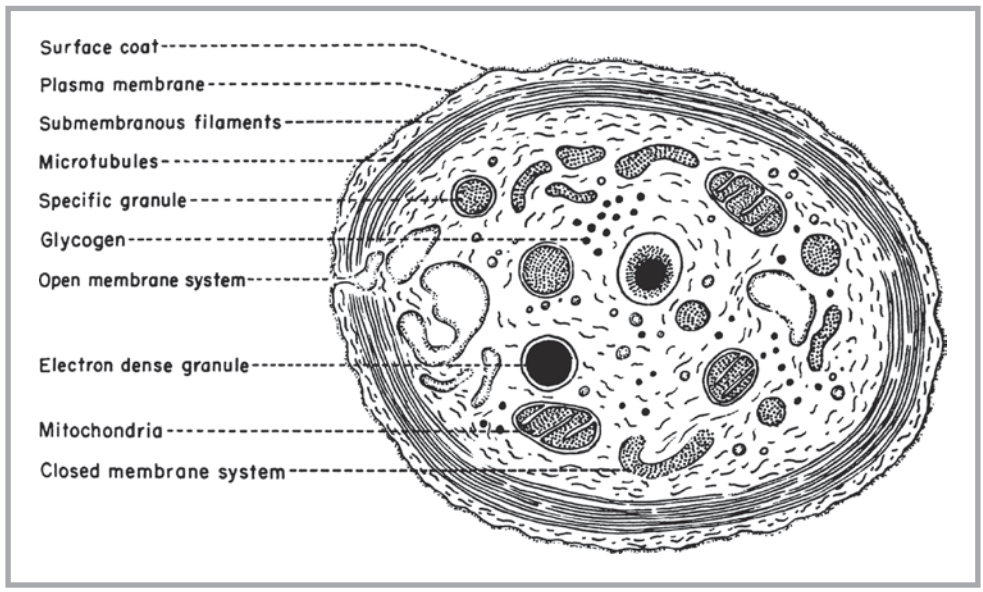

FIGURE 24-2

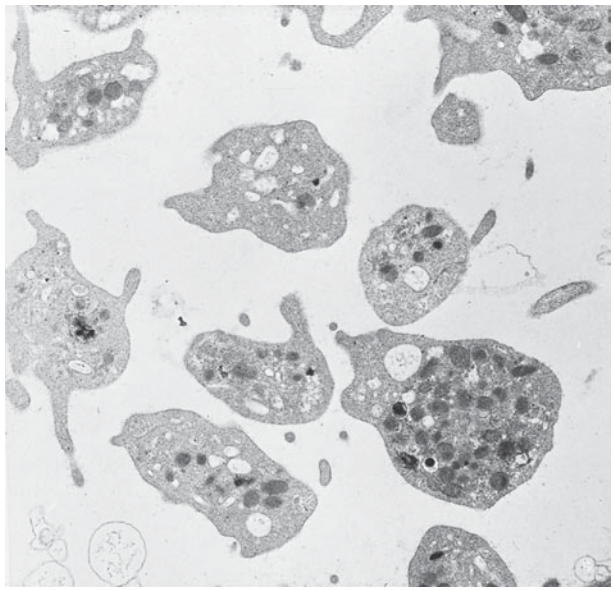
Diagram of an intact platelet shows numerous organelles but no nucleus.

FIGURE 24-3

Electron photomicrograph of numerous intact platelets.



endothelium, they generate mediators like ADP, thrombin, epinephrine, thromboxane A2. These mediators help to recruit more circulating platelets to the site of vascular injury and are responsible for activation of the platelet glycoprotein IIb/IIIa. The next reaction is clumping of platelets to each other, or platelet aggregation, in which platelets adhere to each other with fibrinogen serving as the adhesive molecule cofactor. The vascular endothelium controls platelet reactivity by means of three pathways: arachidonic acid-prostacyclin pathway (aspirin and NSAIDs affect this pathway), the L-arginine nitric oxide (NO) pathway (uremia affects this pathway), and the endothelial ectoADPase pathway. Also at this time, the platelets begin to secrete and release the substances contained in their granules. When sufficient release has occurred, the release reaction is irreversible with total degranulation of platelet granule substances, loss of distinct membranes, and formation of a platelet syncytial mass that is, in essence, the primary hemostatic plug. These reactions are summarized in Fig. 24-4.

TESTS OF PLATELET FUNCTION

The two major tests of platelet integrity as a component of normal hemostasis are platelet counts and the template bleeding time of platelet function.

Platelet Counts

Normal platelet count ranges between 150,000 and 400,000 cells/mm^3.

The normal range of platelet counts is between 150,000 and 400,000 cells/mm^3. Platelets can be counted easily and accurately using current Coulter technology. A series of clinically significant platelet counts has been recognized (Table 24-2).

Bleeding Time

A normal bleeding time requires a platelet number of at least 50,000 cells/mm^3.

In this test, a small iatrogenic wound is made on the patient's arm under standardized conditions and the time for hemostasis in minutes is measured; normal time is 2–7 min. The bleeding time tests platelet function but also requires normal vascular tissue and can indeed be abnormal because of vascular diseases such as scurvy. In addition, a normal bleeding time requires a platelet number of at least 50,000/mm^3 and, in fact, can be prolonged whenever a platelet count is less than 100,000/mm^3. Thus, a Coulter platelet count should be performed before ordering a bleeding time. If the number is less than 100,000/mm^3, the test cannot

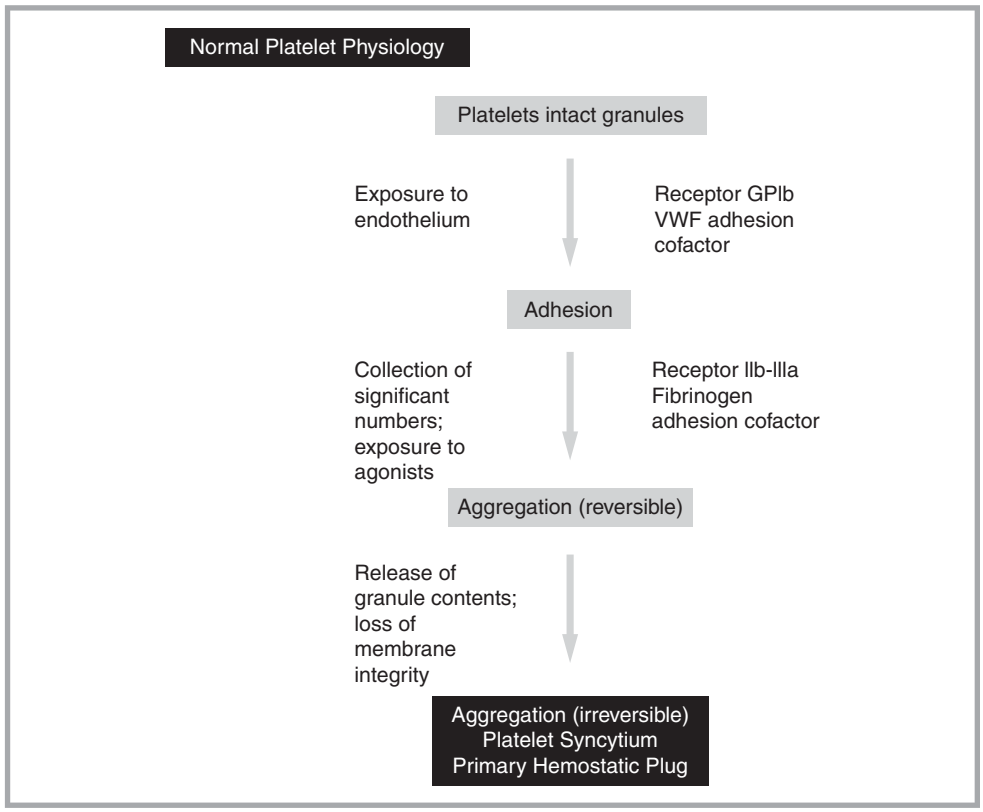


FIGURE 24-4

When an intact platelet membrane is exposed to damaged endothelium, a series of events leads to the formation of a primary hemostatic plug.

discriminate between thrombocytopenia and abnormalities caused by platelet function, and should be deferred. Only when there is a normal platelet count and a prolonged bleeding time, can a defect in platelet function be deduced.

Thrombocytopenia is the most common disorder of hemostasis.

Specific Tests of Platelet Function

A variety of tests are available to directly test platelet function, including platelet aggregometry, in which various known platelet agonists such as ATP and thrombin are added to platelet-rich plasma and the extent of aggregation is measured, and platelet secretion assays wherein known platelet granule contents are measured in plasma after the platelets have been induced to aggregate and degranulate. It should be noted that, unlike the platelet count and bleeding time, special coagulation laboratory facilities and technical knowledge and expertise are required for these tests. Further, they are labor intensive and have a slow turnaround time by ICU standards. Thus, they are often done "after the fact" in bleeding situations and have limited utility in the acute setting of bleeding.

TABLE 24-2

CLINICALLY SIGNIFICANT PLATELET COUNTS

PLATELET COUNT (mm^3)	CLINICAL SIGNIFICANCE
>100,000	Normal hemostasis and testing Tolerate trauma and surgery
100,000–50,000	Bleeding time affected Risk of hemorrhage with trauma/surgery
50,000–20,000	Bleeding time prolonged Bleeding expected with trauma/surgery Signs of skin bleeding on exam
20,000–10,000	More serious (GI, GU) spontaneous bleeding
<10,000	Life-threatening hemorrhage, such as CNS

QUANTITATIVE PLATELET DISORDERS

Thrombocytopenia

Thrombocytopenia is by far the most common disorder of hemostasis. The condition is suspected when the classical immediate and mucocutaneous bleeding pattern is encountered in a patient, and is confirmed by the easily measured Coulter platelet count. Finding a lowered platelet count is only the initial diagnostic step in such patients, however. The more important question is why the thrombocytopenia is occurring; this can be answered very effectively by identifying the mechanisms that resulted in thrombocytopenia.

Decreased Production

Hematopoietic stem cells in the bone marrow become committed to megakaryocytic lineage. Megakaryocytes develop into platelets. Decreased production of platelets results if there is marrow failure (i.e., aplastic anemia), that is, marrow invasion and replacement by tumor, leukemia, or fibrosis, or marrow injury, as with drugs such as benzene, chemotherapy, alcohol, and infectious agents. Thrombopoeitin (TPO) supports the maturation of megakaryocytes into platelets. TPO is predominately produced by the liver in the hepatocytes. Platelet production is also decreased if there is liver damage, for example cirrhosis, as TPO is decreased in this condition. Platelet count in cirrhosis is usually in the range of 50,000–75,000/mm^3.

Abnormal Distribution

Seventy-five percent of the total body platelets circulate; the remaining 25% are sequestered in the normal spleen.

In humans, approximately 75% of the total body platelets circulate while the remaining 25% are sequestered in the normal spleen. These platelets are alive and normal but are not immediately available in the circulation (in contrast, in dogs and cats these platelets can be immediately mobilized when needed). In the presence of pathologically enlarged spleens as with chronic leukemias, lymphomas, and cirrhosis of liver with secondary portal hypertension, the ratio of circulating to sequestered platelets can invert with a resulting thrombocytopenia that is clinically significant. Such spleens should be readily apparent on physical exam or routine imaging studies.

Increased Platelet Destruction

Increased platelet destruction is the most common pathophysiologic mechanism for thrombocytopenia.

Increased platelet destruction is the most common cause of thrombocytopenia. In these abnormal conditions, platelets are utilized, consumed, or destroyed in the circulation faster than even a normal marrow, with its ability to become hyperplastic by roughly a factor of six, can compensate. Again, a convenient and effective classification schema can be structured on the basis of whether the enhanced destruction is immune- or nonimmune mediated (Table 24-3).

TABLE 24-3

DISORDERS CAUSED BY PLATELET DESTRUCTION

Immune disorders
Idiopathic (ITP)
Drug induced: quinidine, heparin
Infections: HIV infection, *H pylori*, hepatitis C, sepsis-related thrombocytopenia
Autoimmune disorders: systemic lupus erythematosus (SLE)
Nonimmune disorders
Thrombotic thrombocytopenic purpura (TTP)
DIC: septicemias, massive trauma, obstetric emergencies
Dilutional: massive trauma, prolonged surgeries, CABG
Microangiopathy: malignant hypertension, cardiac valve dysfunction

THROMBOCYTOPENIA CAUSED BY PLATELET IMMUNE DESTRUCTION

The forms of thrombocytopenia caused by platelet immune destruction have, as a common mechanism, the accelerated destruction of platelets mediated by antiplatelet antibodies. There is almost always a brisk marrow response, although this may take up to 7 days to manifest (see following section). A marrow exam reveals either normal or increased numbers of megakaryocytes.

Autoimmune Thrombocytopenia

Autoimmune thrombocytopenia or immune thrombocytopenic purpura (ITP) is the most common form of thrombocytopenia and is also the most common serious bleeding disorder. Platelets coated with auto-antibodies are rapidly removed from the circulation by macrophages present in spleen and liver. This has been thought to be the entire mechanism causing ITP. However, in the recent years, it has been shown that platelet underproduction from a relative decrease in TPO is also an etiologic factor.

Autoimmune thrombocytopenia (ITP) is the most common form of thrombocytopenia and the most common serious bleeding disorder.

The diagnosis of ITP is based on the finding of an essentially isolated thrombocytopenia, examination of a peripheral smear without evidence for other hematologic abnormality, and an appropriate history and physical examination.[1] Thus, other causes of thrombocytopenia should be excluded, such as drugs (e.g., quinidine, procainamide, and heparin), other immune diseases (e.g., systemic lupus erythematosus, SLE), and other hematologic diseases such as leukemia or lymphoma. Abnormalities such as the presence of splenomegaly, profound changes in other blood counts, and other abnormal forms on smear strongly suggest another diagnosis. The presence of HIV-positive status or the presence of antiretroviral drugs also excludes the diagnosis of idiopathic, classic ITP, although HIV patients commonly manifest an immune-mediated thrombocytopenia, especially very early in their natural history. Other infections like hepatitis C and Helicobacter pylori (especially in certain populations) must be excluded as well.

The diagnosis of ITP is based on finding isolated thrombocytopenia, a peripheral smear that shows no evidence of other hematologic abnormality, and an appropriate history and physical examination.

The presentation of ITP can be explosive, with profound, life-threatening thrombocytopenia (<5,000/mm^3 range) causing profuse mucocutaneous bleeding. Often melena and oral blood blisters are the reason for presentation to the ICU setting. More subtle, lesser degrees of thrombocytopenia, in the range of 30,000–50,000 cells/mm^3, complicating a surgical situation or some other serious medical condition may also require therapy for bleeding. One must note that the coincident occurrence of symptomatic ITP with another serious condition requiring ICU intervention should be an uncommon event.

Therapy

The various treatments for ITP require judgment dependant on the overall clinical situation, the platelet counts, and the bleeding symptoms. An important principle is the excellent functional status of ITP patient platelets. Because of rapid turnover and short half-life, the platelets are young and retain much of their metabolic capacity, such as membrane integrity and granule content. This condition translates into enhanced functional physiology, such that these patients can perform hemostatically at much lower platelet counts than normal patients. Therapy is thus usually considered for patients with platelet counts less than 20,000–30,000/mm^3 and for those less than 50,000/mm^3 who are at risk for bleeding from surgery, peptic ulcer disease, or related situations. If a patient with ITP is already bleeding in a worrisome fashion, higher counts may be preferred in the ICU setting. Therapies are all designed to slow either antibody synthesis or reticuloendothelial destruction or both. A course of high-dose steroids (1 mg/kg) remains the basic therapy. Frequently, a response is seen within several days. If immediate responses are deemed necessary, reticuloendothelial system (RES) blockade methods are used that include either intravenous immunoglobulins or anti-RhD immunoglobulin, frequently resulting (e.g., 80%) in rises in platelet counts within 24–48 h and sustained elevations for 2–3 weeks. This method can be a very effective emergent

In extremely dangerous and urgent settings, emergency splenectomy must be considered for ITP.

maneuver in an acute ICU setting. In extremely dangerous and urgent settings, such as intracranial hemorrhage in an active, thrombocytopenic ICU patient, emergency splenectomy must be considered. The prognosis overall, however, is quite good, with a 5-year mortality rate of about 3–4% from intercurrent bleeding events. Rituximab has been shown to be effective in ITP as well. Several TPO-mimetic peptides, a third-line therapy, that bind to TPO receptors, have been shown to promote a good platelet response. These include Romiplostim (AMG 531), given as weekly subcutaneous dose, and Eltrombopag, taken as a daily oral dose; 80% of ITP patients had acceptable platelet responses to these agents.[2,3] Although these novel agents are exciting, the precise role of this mechanism and usage requires further investigation.

Drug-Immune Purpura

In drug-immune purpuras, a drug usually acts as a hapten, creating a neoantigen with either plasma proteins or the platelet membrane. An antibody is then formed that is capable of reacting with the neoantigen and causing innocent bystander immune complex or complement-mediated platelet destruction. The classic and still most common medicine reported to be causing this condition is quinidine/quinine.[4] Other common drug etiologies include procainamide, sulfa, high doses of penicillins as seen with endocarditis therapy, phenytoin, and INH. ICU patients are usually on multiple antibiotics; vancomycin and linezolid have been shown to cause thrombocytopenia. Because vancomycin is so commonly used, it is difficult to determine the incidence of thrombocytopenia caused by vancomycin. These thrombocytopenias are often explosive and acute, leading to a platelet count less than 10,000/mm^3 and associated mucosal bleeding. They can be caused by a single dose of drug in sensitive patients, though usually the drug needs to be taken for 6 days to cause thrombocytopenia. Fortunately, platelet counts rise quickly, usually within 48 h after the drug is stopped.[5] There is anecdotal evidence that the immune maneuvers discussed earlier (IV immunoglobulin and anti-Rho D) also have some efficacy in this setting, but when a drug is suspected, the medicine must be stopped. Any immune therapies are merely adjunctive.

Heparin-Induced Thrombocytopenia

HIT is the most common drug-associated thrombocytopenia.

Heparin-induced thrombocytopenia (HIT) is a special case of drug-related ITP. Because of the ubiquitous use of heparin in the general hospital and ICU settings, HIT has now become the most common drug-related thrombocytopenia. The incidence of HIT depends on the patient population; incidence of HIT in orthopedic surgery patients is the highest at 3–5% and in patients undergoing cardiac surgery, the incidence is 1–2%; heparin-PF4 antibodies by ELISA (described below) are seen in 14 and 25–50%, respectively.[6] It can be seen therefore that clinical syndrome does not uniformly follow the formation of ELISA antibodies. Lower rates occur for prophylaxis, flush and other heparin regimens, but the denominator of these is so large that cases will still be seen. The other special aspect of HIT is the unique immune mechanism. In this syndrome, heparin combines with platelet factor 4 (PF4), which is normally stored in platelets in their alpha granules and released upon activation, to form heparin-PF4 complexes. These heparin-PF4 complexes generate auto-antibodies, which combine to form immune complexes. These immune complexes are responsible for platelet activation, thrombocytopenia, and generation of procoagulant platelet-driven microparticles leading to thrombin generation. Endothelial cell injury caused by these immune complexes leads to expression of endothelial tissue factor (TF), which generates more thrombin. This mechanism seems to explain the presence of arterial as well as venous thrombosis (HIT with thrombosis).

If vascular pathology is present, particularly as in coronary artery procedures and peripheral vascular surgery cases, platelet thrombi with life- and limb-threatening thrombosis of arteries and veins ensues, with mortality rates in this subgroup ranging from 20 to 50%. The syndrome usually occurs within 5–10 days of heparin exposure, although in patients with prior heparin exposure, 24–48 h may suffice. Due to the potential morbidity and mortality of the lesion, heparin must be stopped in any suspected case.

ELISA can detect heparin-PF4 antibodies; it is highly sensitive but has many false positives. Serotonin release assay, an activation assay that tests whether the heparin-PF4 antibodies

can release radio-labeled C-14 serotonin, avoids this problem of false positives but the turnover time is at least a few days.[7] Thus, HIT remains a clinical diagnosis and, in the urgent setting, unexplained thrombocytopenia in patients on heparin is an indication for stopping the drug. The clotting risk is highest in the first 2 weeks of development of thrombocytopenia and antibodies. It subsequently decreases but anticoagulation is recommended for at least 4 weeks in thrombocytopenia and 3–6 months with HIT and thrombosis.

Warfarin monotherapy is contraindicated in the first 2 weeks, but it can be overlapped with either heparinoids or direct thrombin inhibitors once platelet counts have recovered. Lepirudin and argatroban are direct thrombin inhibitors approved for the treatment of HIT and HIT with thrombosis. Dose adjustments for lepirudin are needed in renal failure while argatroban needs to be adjusted in liver dysfunction. Patients should not be reexposed to heparin except in the case of cardiac surgery when the relatively long half-life of direct thrombin inhibitors poses more bleeding risk. In these situations, heparin can be given during the procedure if heparin-PF4 antibodies are cleared from the body as shown by negative ELISA. Heparin-PF4 antibodies are cleared from the body and undetectable in about 100 days.

Other Immune-Mediated Thrombocytopenias

Infectious ITPs result when either cross-reactive antibodies or nonspecific immune reactions result in platelet destruction. In HIV infection, two mechanisms have been found: immune complex formation with typical innocent bystander-type pathophysiology and the more common true cross-reactive antiplatelet antibody resulting from shared antigens between the HIV virus and the platelet IIb-IIIa receptor. This ITP responds to classical ITP therapy as well as to antiretroviral therapy against the HIV virus.[8] Other infectious thrombocytopenias include septic thrombocytopenia, a usually moderate (50,000–90,000/mm^3) thrombocytopenia associated with sepsis physiology and positive blood cultures. The precise role of circulating immune complexes and inflammatory cytokines remains unclear. This thrombocytopenia responds to therapy of the underlying sepsis. Up to 20% of medical ICU and 35% of surgical ICU patients have thrombocytopenia, although in tertiary care hospitals, the incidence may be higher. In sepsis, the primary mechanism is nonimmune destruction of platelets from binding of platelets to endothelium, but an immune mechanism also contributes. Thrombocytopenia is a predictor of mortality in ICU patients with severe sepsis. Once the platelet count decreases to lower than 100,000, mortality progressively increases whereas the risk of bleeding does not increase.[9] In the absence of confounding factors, patients should probably receive transfusions when the platelet count is less than 10,000–15,000/mm^3.

Infectious ITP results when cross-reactive antibodies cause platelet destruction.

Helicobacter pylori has been shown to cause ITP. CAG A antibodies cross react with a peptide specifically expressed by platelets of patients with ITP. Eradication of H. pylori is accompanied by a platelet response in approximately half the patients. The diagnostic methods are noninvasive using either the urea breath test or stool antigen test. The compliance rate with eradication therapy using a triple antibiotic regimen is high. Testing for H. pylori and its eradication in the initial work up of ITP patients should be considered.[8]

Hepatitis C can cause thrombocytopenia by sequestration in spleen, inadequate production of TPO from advanced stage liver disease causing maturation arrest of megakaryocytes, and also by an immune mechanism by innocent bystander phagocytosis of platelets.[8] ITP related to Hepatitis C is usually not very responsive to steroids or IVIg, but improvement is seen in about half the patients treated with combination Interferon therapy. Therapy with TPO agonist, Eltrombopag, increases platelet count in patients with thrombocytopenia due to Hepatitis C related cirrhosis.[10]

NONIMMUNE DESTRUCTIVE THROMBOCYTOPENIAS

Nonimmune destructive thrombocytopenias are caused by abnormalities in the circulation that result in some type of enhanced usage or destruction of otherwise intrinsically normal platelets. Such usage or destruction is more rapid than marrow production. If a marrow exam

is performed, the hyperplasia will be evident and manifest as at least normal and usually increased numbers of megakaryocytes. There are three main causes; each occurs frequently in the critical care setting.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is defined by a pentad of findings.

TTP is an important syndrome that has been long recognized and classically is defined by a pentad of findings: (1) thrombocytopenia, (2) microangiopathic hemolytic anemia, (3) renal failure or dysfunction with hematuria, (4) fever, and (5) neurologic manifestations such as seizures. We now recognize that the full-blown syndrome is a rather late development. Microangiopathic hemolytic anemia (supported by schistocytes, reticulocytosis, high LDH, high indirect bilirubin, and negative Coombs test) and thrombocytopenia without an apparent alternative cause (sepsis, disseminated cancer, and malignant hypertension) is sufficient for diagnosis.[11] ADAMTS 13 (an acronym for a disintegrin and metalloprotease with thrombospondin-1 like domains) cleaves the large vWF multimers that are synthesized and secreted by endothelial cells. When ADAMTS 13 (previously called von Willebrand factor cleaving protease) is not present or when there are auto-antibodies to ADAMTS 13, the resulting abnormally large vWF multimers in plasma have a greater ability to react with platelets and cause the disseminated platelet thrombi characteristic of TTP.[12] The latter likely result from microthrombi in cerebral and glomerular microvasculature.

The preferred therapy for TTP is plasmapheresis.

Plasma-based maneuvers have become the mainstay of therapy in TTP and have within a decade or so changed the prognosis from >90% mortality to >80% remission rates.[13] The preferred therapy is plasmapheresis for at least 7 days, followed by cautious weaning from plasmapheresis in responders. Plasma exchange removes the ADAMTS 13 auto-antibodies and replaces normal ADAMTS 13 activity. In urgent situations (off-hours), the infusion of plasma is a good temporizing measure pending plasma exchange. Steroids 1–2 mg/kg of prednisone daily until remission is achieved or methylprednisolone 1 g/day for 3 days iv is given to cause durable response. A similar pathophysiologic picture is encountered in the eclampsia of pregnancy and in the vasculitis syndromes of SLE and other collagen vascular diseases.

Disseminated Intravascular Coagulation

The basic abnormal pathophysiology in disseminated intravascular coagulation (DIC) is an abnormal presence of thrombin in the systemic circulation.

In DIC, the basic abnormality is the presence of thrombin in the systemic circulation. The thrombin can be generated by a variety of mechanisms but results in abnormal fibrin deposition in the microcirculation. This fibrin mesh acts as a sieve through which the blood will flow. As this occurs, a microangiopathy ensues and platelets are consumed. The key here is to be aware of the variety of mechanisms that can precipitate this process, because the therapy is indirect and involves addressing the trigger mechanism (see full discussion of DIC later in this chapter).

Dilutional Thrombocytopenia

Dilutional thrombocytopenia occurs if the patient is transfused with large volumes of blood products devoid of functioning platelets.

Dilutional thrombocytopenia disorders are most frequently iatrogenic. The disorders occur when patients have a loss of blood/platelets and repletion with blood products that are volumetrically correct, yet do not contain adequate clotting factors or platelets. This is the situation in massive transfusions and in cardiac bypass surgery where there are large blood losses, either intraoperatively or in the bypass circulation. In vivo, this situation results in an acute depletion of platelets. If the platelets are not replaced, as in the case with many blood recirculation devices, this acute thrombocytopenia will register in vivo and initiate first the formation of thrombopoietin and then hyperplasia of megakaryocytes. However, this process takes about 5–7 days and an immediate, often significant, thrombocytopenia will be seen postoperatively and in the early days after surgery. This finding is usually easily recognized but can be confirmed by a relatively normal presurgery platelet count, a prolonged procedure, and the use of large amounts of platelet-poor transfused blood. If the postoperative

thrombocytopenia, usually in the 30,000–60,000/mm^3 platelet count range, is homoeostatically inadequate for the critically ill patient, therapy is transfusion of platelets pending marrow response, as noted above.

Other related thrombocytopenias caused by nonimmune destruction include abnormally functioning prosthetic valves and malignant hypertension. Both disorders show a microangiopathic smear. Correction of the blood pressure ameliorates the malignant hypertension, whereas valve angiopathy is almost always a sign of dysfunction or infection that requires repair or replacement of the malfunctioning valve.

Abnormally functioning prosthetic valves and malignant hypertension are also associated with nonimmune destruction of platelets.

In all of these entities, the basic pathology is platelet destruction in excess of marrow ability to compensate for losses. In theory, transfused platelets will suffer the same fate and are therefore expected to be of limited efficacy. Correction of the primary abnormal lesions, as discussed above, is the main goal of therapy. Nonetheless, in difficult situations, when a patient is bleeding and has a dangerously low platelet count, platelet transfusions should be considered. TTP is an exception because transfused platelets have been shown to worsen the situation in some cases. In the other entities, assuming that therapy based on the primary insult has been put into place, platelet transfusion should not be withheld.

QUALITATIVE PLATELET DISORDERS

Qualitative platelet disorders share common abnormalities in platelet function (i.e., adhesion, aggregation; see preceding section). Platelet counts are usually within normal limits but the bleeding time, a test of intrinsic platelet function when platelet count is normal, is prolonged. Although characterized by the typical mucocutaneous and immediate-type bleeding pattern found with platelet disorders, the severity and clinical features vary more than seen with the thrombocytopenias. These disorders may be acquired or congenital, but for this chapter, which is concerned with intensive care medicine, the acquired type is discussed at greater length. Acquired platelet disorders are more common, in any setting, than congenital forms, and even more so in the critical care setting.

The prototype congenital disorder platelet qualitative function is von Willebrand's Disease.

The prototype congenital disorder of platelet function is von Willebrand's Disease (vWD). Recall that the large portion of factor VIII, or vWF, is a required cofactor for adhesion of platelets to the subendothelium. vWD is a clinical disease caused by the absence, or at least lowered levels, of vWF on a genetic basis, such that the amount is inadequate to support normal platelet adhesion, with resultant platelet-type bleeding diathesis. A variety of forms of vWD exist, some being caused by abnormally low amounts of vWF and others by an abnormally functioning vWF. Unlike the classical hemophilias, which are sex-linked recessive and thus found in males, vWD in almost all its forms is genetically transmitted autosomally and thus is seen in both males and females. Clues to its presence are platelet-type bleeding in the presence of a normal platelet count, a prolonged bleeding time, and, frequently, a prolonged partial thromboplastin time (PTT), resulting from a general lowering of the coagulant function of factor VIII with the platelet tropism function of that molecule.

Most cases of vWD are mild and respond to the use of DDAVP.

Laboratory confirmation is readily available once the diagnosis is suspected and consists of specific platelet function abnormalities (normal aggregometry, excepting nonreaction with ristocitin as the agonist), the finding of a lowered level of the factor VIII molecular complex, and testing of factor VIII multimers for abnormalities of amounts, molecular mixtures, and function. Most cases are moderate-to-mild and respond to 1-desamino-8-D-arginine vasopressin (DDAVP), which elicits increased factor VIII secretion from endothelial cells and is usually adequate to raise levels to normal or at least to a minimally effective hemostatic point.[14] In more severe cases in which the VIII and vWF levels are profoundly low, this maneuver is not adequate and transfusion of vWF-containing blood products is required. Such products include fresh-frozen plasma (FFP), or concentrates such as cryoprecipitates and related products that have been prepared by methods, which enrich the amounts of factor VIII-vWF in relation to their volume; often an important consideration in critical care patients. Humate P, which is a concentrate of factor VIII, contains larger amounts of vWF than it does factor VIII. Alphanate contains similar relative amounts of factor VIII and

ristocetin cofactor activity of vWF. Recombinant factor VIII should not be used because it does not have vWF activity.

Acquired von Willibrand syndrome is seen in association with autoimmune disorders and cancers, especially myeloproliferative disorders. This is due to increased clearance of vWF from plasma because of its absorption on the surface of abnormal cells. Aortic stenosis has also been associated with acquired von Willibrand syndrome. In this case, the stenotic aortic valve induces structural changes in large vWF multimers due to a shearing effect. These abnormal multimers undergo accelerated proteolysis by ADAMTS-13, leading to decrease in vWF levels. Treatment of the underlying condition leads to resolution of the bleeding disorder.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Coagulation disorders are usually classified as being hereditary or acquired.

A broad variety of conditions can and do cause platelet dysfunction[15,16] (Table 24-4). The proposed mechanism, clinical setting, and treatment principles of these disorders share the findings of platelet-type bleeding diatheses; prolonged bleeding times in the presence of essentially normal (or at least >100,000/μL) platelet counts and theoretical or actual demonstration (in vitro platelet testing) of lesions interfering with the normal and required platelet physiology (i.e., adhesion, aggregation, secretion of granule contents). Therapy involves reversing, if possible, the causative lesion (i.e., discontinuation of aspirin or NSAIDs; dialysis to remove toxic molecules that are deaggregating vWF). Transfusion of normal platelets may be required to temporize bleeding in patients whose platelets are dysfunctional. However, if the causative lesion is not properly addressed, such as stopping drugs or dialysis for uremia, the transfused platelets will quickly experience the same lesions, and become hypofunctional, and hemostasis will not be effective.

TABLE 24-4

ACQUIRED DISORDERS OF PLATELET FUNCTION

AGENT/DISORDER	PATHOGENESIS	THERAPY
Aspirin	Permanent acetylation of platelet cycloxygenase 1(COX-1) interferes with production of agonist thromboxane A2 (TXA2)	Stop ASA Recovery may require 3–7 days
Nonaspirin NSAIDs	Reversible inhibition of platelet COX-1	Stop agent Fully reversible in 24 h after drug withdrawal
Clopidogrel	Irreversible binding to purinergic receptor P2Y on platelets causing inhibition of ADP	Stop clopidogrel Recovery may require 7 days
Glycoprotein IIb/IIIa antagonists abciximab tirofiban eptifibatide	Inhibit platelet aggregation by preventing fibrinogen and von Willebrand's factor (vWF) binding to gpIIb/IIIa	Stop agent. Abciximab effect is mostly gone in 12 h, others only take few hours
Uremia	Toxic molecules, especially nitric oxide (NO) impair platelet interaction with vessel wall. Also anemia decreases platelet-vessel wall interactions due to more platelets in the circulation and less platelets displaced to the vessel wall	Dialysis (removes toxic molecules), DDAVP (releases vWF from endothelial stores), conjugated estrogens, RBC transfusions and erythropoietin(by increasing hematocrit)
Cardiac bypass or exposure to foreign surfaces	Activation and degranulation of platelets in the extracorporeal circuit, so when platelets are back in the patient, they are unable to function well	Reversible within hours of removal from apparatus

DISORDERS OF THE COAGULATION SYSTEM

The third component of normal hemostasis physiology is the coagulation protein system (see the coagulation cascade in Fig. 24-1). This series of proteins acts as a biologic amplifier system, wherein proteases and cofactors are generated with the ultimate product being a powerful serine protease, thrombin, which cleaves a soluble plasma protein, fibrinogen, which then polymerizes into insoluble fibrin, the basic meshwork of a thrombus. Table 24-5 lists and describes the proteins of the coagulation system, which are quite arbitrarily named according to their discovery sequence. The table also lists the coagulation disorders associated with hereditary deficiency in these proteins.

Coagulation disorders are usually classified as being hereditary or acquired. The hereditary types result from gene mutations that render the corresponding proteins either qualitatively or quantitatively deficient. The acquired types are almost always complex disorders in which the pathophysiology is so deranged that multiple deficiencies or defects in the normal hemostatic pathways ensue.

COAGULATION TESTING IN COAGULATION SYSTEM DISORDERS

Coagulation testing and proper interpretations are vital in the diagnosis and therapy of bleeding. A relatively easy initial strategy is to perform a PT and PTT. In performing a PT, a TF (usually brain extract) is added to plasma to quickly activate factor VII, which then fires down the common pathway of coagulation (factors C, V, thrombin, and fibrinogen). This portion of the coagulation cascade is referred to as the extrinsic pathway. The PTT test introduces surface-active substances, such as kaolin, to the plasma; this reaction activates factors XII and XI and proceeds, more slowly than with the PT, to activate factors VIII and IX, which then fire down the common pathway. This portion of the coagulation cascade is referred to as the intrinsic pathway. These tests are excellent screens because if either one is normal, then the common pathway must be intact and any prolongation found can be isolated to the extrinsic or intrinsic wings of the pathway, allowing relatively simple diagnostic corroboration by specific factor assays.[17] Almost all the congenital diseases (i.e., the hemophilias) have this mechanism and result from a single gene defect leading to a single protein deficiency. On the other hand, when both the PT and PTT are abnormal, this finding usually suggests an acquired and complex disorder with multiple defects in the coagulation pathways being simultaneously present. In addition to being able to provide such a bleeding abnormality with a classification and name, proper utilization of this coagulation testing schema leads to the correct diagnosis and proper therapy.

Coagulation testing and proper interpretations are vital in the diagnosis and therapy of bleeding.

The only blood product containing all the coagulation factors is FFP. If one tried to treat all lesions this way, volume considerations would limit efficacy and potentially increase morbidity and mortality. However, excellent specialized plasma derivatives are available that are rich in specific proteins or groups of proteins (i.e., cryoprecipitates for fibrinogen, factors VIII and V) and are much more volumetrically appropriate and factor enriched. To use these correctly, one must know where the deficiencies are and what factors are needed: thus, accurate diagnosis is needed before initiating definitive treatment. Refer again to Fig. 24-1, which shows the extrinsic and intrinsic coagulation protein pathways with tests for each, that is, the PT for the extrinsic pathway and the PTT for the intrinsic pathway. Modern thinking about the coagulation cascade puts TF as the main starting point. TF is released after vascular damage to subendothelium. TF along with factor VIIa activates factor X directly. TF can also activate factor X through factor IX (which needs factor VIIIa as a cofactor). Activated factor X (Xa) converts prothrombin (factor II) to thrombin; this step needs cofactor Va. Thrombin converts fibrinogen to insoluble fibrin. Finally, a clot is formed after polymerization of fibrin; this step needs factor XIII.

The prothrombin time (PT) test examines the extrinsic pathway of clotting and the common pathway.

The PTT tests the intrinsic pathway and the common pathway.

TABLE 24-5

PROTEINS OF THE COAGULATION SYSTEM AND THEIR DISORDERS

FACTOR	BIOCHEMISTRY	BIOSYNTHESIS	BIOLOGIC HALF-UFE (H)	SERUM	ADSORBED PLASMA	FUNCTION	HEREDITARY CONDITION
Fibrinogen	Multimeric glycoprotein; three paired peptide chains; MW 340,000	Liver	72–120	Absent	Unchanged	Precursor of fibrin and common pathway	–
Prothrombin	Monomeric glycoprotein; MW 69,000	Liver: vitamin K dependent	67–106	Absent	Absent	Proenzyme, precursor of thrombin, and common pathway	–
Factor V	Multimeric glycoprotein; MW 200,000–400,000	Liver	12–36	Absent	Unchanged	Cofactor and common pathway	–
Factor VII	Monomeric glycoprotein; MW 63,000	Liver: vitamin K dependent	4–6	Increased	Absent	Proenzyme and extrinsic pathway	Rare, but seen; requires ≥20% activity for adequate hemostasis; fresh-frozen plasma (FFP) source
Factor $VIII_{vWF}$ complex	Multimeric glycoprotein; MW ~1,200,000; functionally heterogeneous subunits	–	–	Absent	Unchanged	Cofactor, intrinsic pathway, and platelet adhesion	vWD; autosomal inheritance; treated with DDAVP, cryoprecipitate
Factor VIII C	Monomeric glycoprotein; MW 267,000	Unknown	10–14	Absent	Unchanged	Cofactor, intrinsic pathway and "carrier" molecule for VIIIC	Hemophilia A, sex-linked inheritance; severe delayed bleeding with surgery, requires ≥50% levels for surgery hemostasis
Factor IX	Monomeric glycoprotein; MW 55,000	Liver: vitamin K dependent	18–40	Increased	Absent	Proenzyme and intrinsic pathway	Hemophilia B; sex-linked inheritance
Factor X	Two-chain glycoprotein; MW 55,000	Liver: vitamin K dependent	24–60	Unchanged	Absent	Proenzyme and common pathway	–
Factor XI	Two-chain glycoprotein; MW 160,000	Liver	48–84	Unchanged	Slightly decreased	Proenzyme and intrinsic pathway	Common in Ashkenazic Jews; autosomal inheritance; variable bleeding risk
Factor XII	Monomeric glycoprotein; MW 80,000	Unknown	52–60	Unchanged	Unchanged	Proenzyme and intrinsic pathway	
Prekallikrein	Monomeric Y globulin; MW 88,000	Liver	Unknown	Unchanged	–	Proenzyme, kinin system, and intrinsic pathway	–
Factor XIII	Multimeric glycoprotein; two paired peptide chains; MW 320,000	Megakaryocytes, liver	72–168	Decreased	Unchanged	Proenzyme and common pathway	Fibrin-stabilizing protein; wound- healing problems in newborns

HEREDITARY COAGULATION DISORDERS

Encountering an occult hereditary coagulation disorder in the critical care setting should be an unusual event. These conditions in their milder forms may not cause any spontaneous bleeding history or symptoms, yet may result in morbid hemorrhage with severe hemostatic stress (i.e., surgery). The author diagnosed mild forms of hemophilia A and B 4 times during a 2-year experience in the Army. The prototype example of hereditary coagulation disease is hemophilia A, which is discussed in some detail below; other less common hereditary coagulation diseases are summarized in Table 24-5.

Hemophilia A

The prototype example of hereditary coagulation disease is hemophilia A, the most common hereditary deficiency.

Hemophilia A, the most common hereditary deficiency, results from a genetic defect in the factor VIII gene that causes deficient amounts (or, less commonly, deficient functioning) of factor VIII. Many different genetic defects have been described, ranging from deletion of the gene with essentially no factor VIII protein in the circulation to more subtle single base mutations that result in intact antigenic amounts but hypofunctional factor VIII.[18] The former defect tends to result in severe variants whereas the latter results in milder forms. However, there is no mild hemophilia with trauma or surgery. All affected patients will bleed severely in such instances. Aspects of clinical severity and levels of factor VIII in hemophilia are correlated and summarized in Table 24-6. It should be noted that hemophilia A and its variants can now be diagnosed by genetic mapping. All hemophilia A subtypes as well as hemophilia B subtypes are transmitted on the X chromosome and display sex-linked heredity with male subjects and female carriers. Factor IX, or hemophilia B, has similar genetics. The other hereditary disorders most often display autosomal recessive heredity.

Clinical Features

Bleeding in hemophilia is not immediate but rather delayed.

Hemophilia, like most of the other coagulation protein diseases, results in a bleeding pattern somewhat different from platelet disorders. The bleeding may not be immediate, but rather delayed. Thus, the trauma physician or surgeon may not detect any undue bleeding initially, but later in the recovery room or ICU, hematoma formation or body cavity bleeding ensues. Joint bleeding or hemarthrosis is the diagnostic hallmark of these conditions, but for critical care specialists, it will be the bleeding with surgery or trauma that is problematic. It cannot be overemphasized that all hemophiliacs, whether defined as mild or severe, will display a dangerous and potentially life-threatening hemorrhagic diathesis with major trauma or surgery. Diagnosis in most cases comes with the patient, for example, a young male with severe hemorrhage at surgery and a sex-linked positive family history, although fully one-third of cases arise de novo genetically. Conversely, in any male, particularly with a positive past history of stress-related hemorrhage, who displays unexpected delayed, deep tissue bleeding with trauma or surgery, the presence of a variant of hemophilia should be suspected. Both hemophilia A and B show marked prolongation of the PTT (but usually the PTT is never longer than 110 s) with normal PT, thus localizing the lesion to the intrinsic arm of coagulation. The PTT corrects with the addition of normal plasma, thus indicating deficiency of a protein. Analysis of specific intrinsic pathway coagulation factors then isolates with precision which factor, VIII or IX, is deficient. The time required for such testing in a coagulation

TABLE 24-6

CLINICAL AND LABORATORY SEVERITY IN HEMOPHILIA

FACTOR LEVEL	CLINICAL SEVERITY	MANIFESTATIONS
<1% (0–1 μm/mL)	Severe	Spontaneous hemorrhages Morbid arthropathy
2–5% (2–5 μm/mL)	Moderate	Spontaneous hemorrhage, including joints, but infrequent
>5%	Mild	No spontaneous bleeds, but life-threatening hemorrhage with trauma or surgery

laboratory is quite reasonable, no more than several hours being required for factor levels. Recombinant factor VIII and factor IX are the replacement therapies of choice for hemophilia A and B, respectively.[18]

Management

Management of all the hereditary disorders of coagulation is dictated by: (1) the required level of factor needed for hemostasis, (2) the distribution space of the clotting factor, (3) the plasma half-life of the factor, and (4) the time needed for firm hemostasis for the particular event involved.[19] Table 24-7 presents these facts and therapeutic principles for the more common hereditary bleeding disorders. It should be emphasized that this is a quite specialized aspect of coagulation medicine, and consultation with physicians experienced with the care of such patients is highly recommended.

ACQUIRED COAGULATION DISORDERS

Acquired coagulation disorders are commonly seen in the ICU and are characterized by multiple and mixed deficiencies of the coagulation cascade, as well as platelet dysfunction.

The acquired coagulopathies are more commonly seen in the critical care setting because they often are the result of other organ failures and therapeutic side effects frequently encountered in this difficult population. These disorders are characterized by multiple and mixed deficiencies, involving not only different parts of the coagulation cascade but often other aspects of hemostasis. These disorders manifest a diffuse effect on coagulation tests, prolonging many of them and crossing the extrinsic–intrinsic–common pathway boundaries. Clinical acumen as to which entities complicate specific conditions (i.e., liver disease, anticoagulant misadventures, and disseminated intravascular coagulopathy with sepsis) and the ability to properly perform and interpret a more complex and comprehensive array of coagulation tests are needed to accurately diagnose and provide effective therapy for these conditions. In all but the latter, an activated factor VIIa recombinant preparation has been used with variable success. Its hemostatic therapeutic potential must be weighed against its significant thrombotic risks. Its precise role in coagulation disorders requires further study.

COAGULOPATHY ASSOCIATED WITH CARDIOPULMONARY BYPASS AND MASSIVE TRANSFUSIONS

Coagulopathy associated with cardiopulmonary bypass and massive transfusions is complex and involves several different factors.

A very common and at times clinically significant coagulopathy is observed in the setting of cardiopulmonary bypass, in the setting of prolonged surgery with massive transfusion, and with cell-saver techniques. Bleeding incidence in these settings has been estimated to be in the 2–5% range. The pathogenesis is complex but basically involves only a few key elements.

TABLE 24-7

BASIC PRINCIPLES OF COAGULATION FACTOR REPLACEMENT

CONDITION (FACTOR DEFICIENCY)	PHARMACOLOGY	CLINICAL ASPECTS
Hemophilia A (VIII)	$T_{1/2}$ 8–12 h 90% plasma compartment No loading dose	Surgery usually requires 5–7 days Activity ≥50%
Hemophilia B (IX)	$T_{1/2}$ 24 h 50% plasma compartment Requires loading dose	Identical
Fibrinogen	$T_{1/2}$ 3–4 days >50% plasma compartment	Levels ≥125 mg% needed for hemostasis
Factor VII	$T_{1/2}$ 6–8 h 50% plasma compartment	Activity ≥25% required for hemostasis

First, the use of massive amounts of transfused blood results in a dilution of coagulation proteins and platelets. The stability of these components in banked blood is quite poor, and within days the amounts in a stored unit are minimal. Because the red cell storage time is 35 days, much banked blood given for hemoglobin support in the OR is essentially devoid of platelets and coagulation factors. Cell-saver technology also is designed for RBC salvage, and the material reinfused in the OR is essentially devoid of platelets and clotting proteins. Thus, a patient with prolonged surgery and large transfusion requirements often is deficient in clotting proteins and platelets. If these deficiencies are not noted and the patient does not receive adequate FFP and platelets, hemostatic function deteriorates and a bleeding diathesis ensues. This condition is a complex bleeding diathesis that is clinically associated with surgical bleeding (i.e., chest tube) as well as diffuse bleeding at other sites. As one should surmise from the pathophysiology, multiple aspects of hemostasis and attendant coagulation tests are abnormal. Thus, there is thrombocytopenia as well as a prolonged PT and PTT. The diagnosis should be suspected when a hemostatically normal patient manifests a bleeding diathesis and diffuse laboratory abnormalities intraoperatively or postoperatively, in association with cardiopulmonary bypass or other extensive surgery requiring large amounts of transfused blood. When this diagnosis is suspected, "resuscitation" with blood and blood products, FFP, platelets, and, if significantly hypofibrinogenemic, cryoprecipitates will stop the bleeding. A value of fibrinogen of <125 mg/dL can be used as indication for cryoprecipitate. Over time, normal synthesis replaces the deficiencies and the situation normalizes. However, this may take days to occur and ongoing blood bank support may be needed in the first postoperative days.

A patient with prolonged surgery and large transfusion requirements often is deficient in clotting proteins and platelets.

A special situation is cardiopulmonary bypass, where in addition to the dilution discussed above, an acquired, transient platelet dysfunction (in addition to the dilutive thrombocytopenia) occurs. This disorder has been shown to result from a qualitative platelet defect related to activation of platelets with release of granule contents. It is elicited by hypothermia, exposure to synthetic surfaces of the cardiopulmonary bypass circuitry, and exposure of platelets to the membrane oxygenator.[20,21] Immediately postoperatively, these platelets are hypofunctional and patients display prolonged bleeding times even with normal platelet counts. If postoperative bleeding is associated with this lesion, platelet transfusions will temporize the situation while normal endogenous platelet function is being restored.

A special situation in cardiopulmonary bypass is an acquired transient platelet dysfunction.

COMPLICATIONS OF ANTICOAGULANTS

Another acquired, iatrogenic bleeding diathesis in critical care medicine is related to the administration of anticoagulants. The most common anticoagulants are heparins and warfarin. Less common are problems related to newer agents such as plasminogen activator and hirudin.

Heparin

Heparin is a commonly used polysaccharide anticoagulant that, via an allosteric interaction with plasma antithrombin III, potently inactivates thrombin and thus inhibits the coagulation protein cascade from forming a fibrin thrombus. Heparin-antithrombin III complex inactivates Xa, IXa, Xia, and XIIa also, but thrombin (factor IIa) is more sensitive.[22] This effect is seen as prolonged PTT (recall that PTT measures the intrinsic and common pathway). As heparin inhibits thrombin, which is in common pathway, ideally PT should be prolonged as well. To overcome the effect of heparin on PT, heparin neutralizers are added to PT testing, so overall only PTT is prolonged with heparin. When excessive heparin is in place, or when a patient with therapeutic levels of heparin is bleeding from a pathologic or iatrogenic lesion, serious and life-threatening hemorrhage will result until the effect of heparin is reversed. The diagnosis is entertained when a patient on heparin has abnormal bleeding. Heparin overdose is defined as a PTT in excess of 2–2.5 times control. PTT > 110 is strong clue for

heparin effect, as level this abnormal rarely, if ever, occurs in factor deficiencies like hemophilia A or B. The coagulation laboratory will perform a mixing study to confirm that the PTT is caused by heparin inhibition rather than factor depletion due to dilution or decreased synthesis. Protamine sulfate is a heparin antidote in these instances and can reverse the heparin effect within minutes.[23] A reasonable initial dose is 1 mg/kg. Some authorities use an empiric lesser dose of 50 mg; this is effective in most patients and utilizes less protamine, which has its own intrinsic anticoagulant effect.

Low Molecular Weight Heparin (LMWH)

LMWHs are generated from heparin; they have about one-third the molecular weight of heparin. LMWHs have more antifactor Xa activity compared to inhibition of thrombin; they do not prolong PTT (PTT effect of heparin is mainly due to its effect on thrombin). Enoxaparin, Dalteparin, and Tinzaparin are commercially available. The half-life of LMWHs is much longer than heparin and they are principally cleared by renal route. Usual dosing is 40 mg subcutaneously for prophylaxis. Therapeutic dose is 1 mg/kg twice daily or 1.5 mg/kg daily. However, dosing in obese and renal failure patients requires measurement of antifactor Xa levels. Protamine is only able to neutralize 60% of LMWHs activity.

Warfarin

Warfarin is a commonly used oral anticoagulant that, via competitive antagonism of vitamin K, interferes with the gamma-carboxylation of clotting proteins II, VII, IX, and X.[24] The functional levels of these proteins is thus titrated lower with an anticoagulant effect. If excessive doses are used, the lowering of clotting proteins becomes excessive and a situation very similar to hereditary coagulation factor deficiency results. This complication can result in spontaneous bleeding, bleeding from surgery or trauma, or bleeding from pathologic sites such as gastric erosions. The patient usually will have a history of warfarin use and demonstrate an excessively prolonged PT and International Normalization Ratio (INR in excess of 3.0). Because many coagulation factors are involved, the PTT is also prolonged. Laboratory testing shows correction with mixing, and factor analysis shows concordant lowering of factors II, VII, IX, and X. Treatment depends on clinical severity and requires judgment. In uncontrolled situations, the factors must be replaced quickly, and this is done by giving FFP. In less urgent situations, if the liver synthetic function is intact, vitamin K acts as an antidote. Daily doses vary between 1 and 10 mg depending on the clinical situation. The preferred route is oral when the clinical situation allows. When parenteral administration is required, cautious (risk of anaphylaxis with intravenous vitamin K) intravenous administration is more dependable compared to variable subcutaneously absorbed route. Response usually occurs within 12 h, but ongoing vitamin K may be needed because the half-life of warfarin exceeds that of vitamin K.

Direct Thrombin Inhibitors

Lepirudin, Argatroban, and Bivalirudin are direct thrombin inhibitors.[25] These agents do not require antithrombin III to bind to thrombin and cause its inactivation. The major indication for the use of these agents is in HIT. Lepirudin is a recombinant analog of hirudin, protein present in leeches. In patients treated with lepirudin, thrombotic event occurred in 4% compared to 15% in historical controls but is associated with higher rate of bleeding and anaphylaxis. It is contraindicated in renal failure and cannot be given more than once because of the problem of sensitization. Argatroban is a small synthetic compound, which also decreased the rate of thrombotic events in HIT. Argatroban increases both PTT and PT/INR; careful monitoring of its rate using coagulation parameters to achieve therapeutic effect, dose reduction in liver dysfunction, and overlapping with warfarin have to be done following the guidelines set by the manufacturer. Bivalirudin is approved for percutaneous coronary intervention in patients who have or are at risk for HIT.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide that causes an antithrombin III-mediated selective inhibition of factor Xa. Neutralization of factor Xa interrupts the blood coagulation cascade and inhibits thrombin formation and thrombus development. It is indicated for prophylaxis of venous thromboembolism after orthopedic surgery and also for treatment of DVT and PE.

PLASMINOGEN ACTIVATORS

Plasminogen activators actually lyse already formed fibrin thrombus. Bleeding from these drugs is usually transient as the half-life of tissue plasminogen activator (tPA) is measured in minutes. However, a more sustained coagulopathy can result from the lysis of fibrinogen and other coagulation factors by the tPA. In such instances, the PT and PTT are usually prolonged and in addition, there is a profound hypofibrinogenemia. Such patients benefit from replacement of factors, particularly fibrinogen in the form of transfusions of cryoprecipitates.

VITAMIN K DEPLETION

A frequent coagulopathy encountered in the ICU is vitamin K depletion.

A coagulopathy frequently encountered in the ICU is vitamin K depletion. As already discussed, this fat-soluble vitamin is required for posttranslational gamma-carboxylation of the vitamin K-dependent clotting proteins II, VII, IX, and X. This step results in the formation of a carboxyl-rich group whose negative domain is required for adsorption of the proteins and hence for function. Vitamin K has two sources in humans: dietary, from green leafy vegetables, and endogenously, from vitamin K made by colonic flora that is subsequently absorbed. The common manifestation of deficiency occurs in the patient not ingesting anything by mouth for reasons of surgery or other morbid conditions who also is being treated with broad-spectrum antibiotics, which obliterate normal bowel flora and thus impair the endogenous source of vitamin K. The condition presents itself most often as a gradual prolongation of, first, the PT (because the shortest half-life for the vitamin K family is factor VII, a protein of the extrinsic pathway and therefore PT), and later, in extreme cases, of the PTT. Diagnosis is suspected by the coincident findings of poor oral intake and broad-spectrum antibiotics and confirmed by demonstrating correction of the PT in laboratory mixing studies with lowered vitamin K family clotting proteins on assay. These patients respond quickly to parenteral vitamin K, and supplements can be placed into their nutrition, either enterally or parenterally, to prevent recurrence.

Vitamin K depletion most commonly occurs in patients that are not ingesting anything by mouth and are being treated with broad-spectrum antibiotics.

LIVER DISEASE

The coagulopathy of liver disease is one of the most frequent bleeding diatheses seen in the ICU.

The coagulopathy of liver disease is one of the most frequent bleeding dyscrasias in critical care medicine. Review of Fig. 24-1 and Table 24-5 reveals the ubiquitous extent of hepatic synthesis of coagulation proteins in all pathways, suggesting that derangements in liver function should result in a variety of disturbances of clotting function. The major defect is deficiency of synthesis of clotting factors.[26] Newer data have revealed that there is a hierarchy of resistance to disease in factor synthesis. Thus, the earliest, least specific, and least prognostic change is defects in the gamma-carboxylation pathways already discussed. The very same factors II, VII, IX, and X are depressed, again with the PT laboratory test being affected first because of the short half-life of VII. As liver disease worsens, the ability to properly synthesize fibrinogen is affected next, with the finding of hypofibrinogenemia and even dysfibrinogenemia (an abnormal fibrinogen molecule). These findings suggest more serious clinical liver disease (i.e., childs' class B or C) and a worse prognosis. Finally, in the most serious and advanced situations, the usually resistant factor V synthetic mechanism

Many hepatologists now use factor V levels as a trigger for liver transplantation.

fails, with lowering of that factor. This finding is an ominous prognostic sign, both for acute survival and for reversibility. Many hepatologists now use factor V levels as a trigger for candidacy for liver transplantation.

Coagulation profiling is now acquiring an important role in the management of liver patients. On routine testing, prolonged PT and PTT result from the diffuse lowering of many factors. Further testing of fibrinogen specific factor levels, especially VII and V, can reveal a more complete prognostic picture with therapeutic value as well (i.e., need for transplantation). Management of bleeding patients is extremely difficult and problematic, and this is among the most difficult bleeding diatheses to treat. Initial attempts involve replacing the extensive array of deficient factors with FFP (plus cryoprecipitates for profoundly hypofibrinogenemic patients <125 mg%) as the standard of care. However, as the half-life of the factors is short, especially VII, this therapy has fleeting or negligible benefit. The volumes involved become prohibitive and bleeding in these cases carries a high mortality.

In addition to the coagulopathy, other events in liver failure significantly add to bleeding diathesis and morbidity. As portal hypertension increases, there is enlargement of the spleen with a degree of hypersplenism, sequestration of platelets, and thrombocytopenia. The degree is usually moderate in the 50,000–100,000 range, but enough to contribute to serious hemorrhage in these cases, especially because platelet transfusions will be similarly sequestered and less efficacious than in normals. Portal hypertension raises the venous pressures in the abdominal wall, as well as in the portal circulation, further increasing the tendency to bleed with surgery or from comorbid gastrointestinal lesions such as the varices or erosions so frequent in these patients. As previously discussed, liver failure, especially cirrhosis, may become an important indication for use of TPO agents such as Eltrombopag.[10]

As portal hypertension increases in patients with liver disease, splenic enlargement promotes further sequestration of platelets and thrombocytopenia.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is, along with hepatic coagulopathy, one of the most frequently encountered bleeding diatheses in critical care medicine. DIC is the end result of an intermediary syndrome that has, as its basis, the abnormal generation and presence of the serine protease thrombin in the systemic general circulation, usually in the microcirculation. In fact, DIC can result from any disease process that activates either the intrinsic pathway (i.e., infections, Gram-negative sepsis) or the extrinsic pathway (i.e., introduction of TFs via obstetric complications, carcinomatosis, massive trauma). Figure 24-5 presents an overview of these pathophysiologic models with the clotting pathways. Once either of these pathways is activated, the common pathway fires, with the diffuse, systemic production of thrombin and fibrin formation. This process in due time, therefore depletes the plasma of its clotting moieties, which are consumed in this process. Paradoxically, this microvascular consumptive storm then causes a profound bleeding diathesis.

The clinical features of DIC are heterogenous and depend on levels and balance of diffuse microclotting and clotting factor depletion.

The clinical features of DIC are quite heterogeneous and depend on the levels and balance of diffuse microclotting and clotting factor depletion. Three arbitrary patterns are described. (1) In acute hemorrhagic DIC (e.g., abruption of placenta), the coagulopathy overwhelms the microthrombus aspect of the syndrome; these cases demonstrate the most profound derangement of coagulation testing and clinically evidence severe bleeding. (2) In laboratory DIC (common in infections), the process is less explosive such that there is sufficient factor depletion for laboratory findings to become manifest but not so severe as to result in serious bleeding; in the author's experience, this is the most common situation. (3) In subacute and chronic forms of DIC, most typical of malignancy, the microthrombosis aspect dominates and even evolves into grossly evident thrombi (e.g., Trousseau's syndrome). Laboratory evaluation, as is typical of the acquired coagulopathy states, utilizes a battery of tests that demonstrate the presence of consumption of clotting proteins and platelets by the process and the presence of microvascular clotting. For the former, PT is measured as a surrogate for the clotting cascade proteins, the fibrinogen and platelets. For the latter, the presence of fibrin clots is deduced by measuring their physiologic digestion products, fibrinogen degradation products, and/or D-dimers. Until a valid assay for thrombin levels is available, which would be a more specific test of this condition, we continue to use this classical battery (Table 24-8).

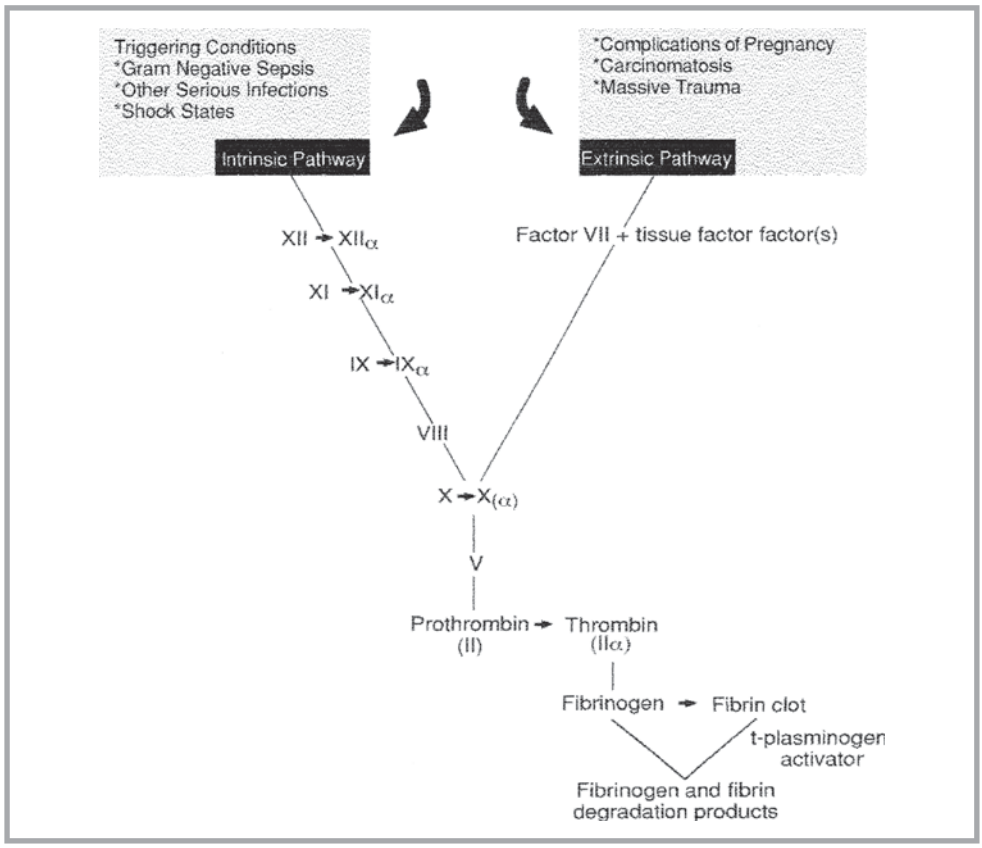

FIGURE 24-5

Numerous clinical conditions have been associated with the development of disseminated intravascular coagulation (DIC).

Management of DIC is difficult and controversial. A variety of schemas have been proposed. All authorities agree, however, that the keystone of therapy is removal of the initiating process.[27] Regardless of what else is done, this maneuver is primary and no amount of other treatment will be effective if the trigger process is not addressed. Thus, surgery to drain an abscess must not wait for correction of the DIC lab abnormalities. Conversely, draining the abscess will indeed reverse and correct the abnormalities. Sometimes the removal of the trigger is relatively easy, as with evacuating the uterus, draining an infection, or giving antibiotics. Other situations, such as carcinomatosis or refractory hypoperfusion and shock, are much more problematic. Supportive therapy may be needed in coagulopathic patients with severe depletion of clotting moieties and uncontrolled hemorrhage. Blood products should not be withheld from these patients, especially if maneuvers targeting the trigger process are in place or at least attempted. A broad mixture of coagulation support is used: plasma, platelets, and cryoprecipitates depending on the degree and specifics of the laboratory abnormalities encountered. When an overt thrombosis such as acral gangrene is present, the microcirculatory thrombosis may require the judicious use of heparin as well. Fortunately, many patients have only laboratory manifestations with

Management of DIC is difficult and controversial.

TABLE 24-8

LABORATORY DIAGNOSIS OF DIC[a]

LABORATORY TEST	NORMAL	MEAN VALUES IN DIC (%)[b]
Platelets	150–400,000/μL	52 (93)
PT	11–14 s	18 (90)
Fibrinogen	150–400 mg/dL	137 (71)
Fibrin degradation products/D-dimers	–	High titer (92)

[a]Clinical diagnosis of DIC required at least three tests abnormal
[b]Percentage of cases with autopsy-confirmed DIC in author's trial who manifested an abnormal value

DIC is a serious disease. A 1-month mortality of 66% has been reported, regardless of mechanism.

little clinical bleeding. In these cases, reversal of the initiating process is the only therapy required. It must be mentioned that the presence of DIC in a critical care patient is an ominous prognostic. In the author's series, a 1-month mortality of 66% was associated with the presence of DIC regardless of mechanism.[28]

SUMMARY

Bleeding diathesis is a common problem facing the ICU practitioner in caring for critically and complexly ill patients. Fundamentals of a good history and physical examination along with appropriate laboratory testing enable the critical care practitioner to approach the patient with a logical differential diagnosis and appropriate treatment plan.

REVIEW QUESTIONS

1. **Which of the following statements about DIC is true?**
   - **A.** The prognosis is good, especially if heparin is administered
   - **B.** A good screening test is examination of peripheral smear for microangiopathy
   - **C.** The keystone of therapy is to effectively address the underlying cause
   - **D.** Thrombocytopenia is the most useful laboratory finding
   - **E.** Transfusion support should be avoided as it may worsen the situation ("fuel on the fire")

2. **Which of the following is a true statement regarding TTP?**
   - **A.** Microangiopathy in the setting of thrombocytopenia is the most useful initial diagnostic tool
   - **B.** TTP patients frequently respond well to platelet transfusions
   - **C.** Corroborative lab findings include prolonged PTT and PT
   - **D.** There is no effective therapy without plasma exchange
   - **E.** Despite therapy, the prognosis is poor

3. **Which of the following is true in the setting of HIT?**
   - **A.** LMWH is an excellent therapeutic alternative
   - **B.** The major morbidity of the syndrome is thrombotic rather than hemorrhagic
   - **C.** Most cases of HIT remain ELISA positive indefinitely
   - **D.** Most cases can safely receive heparin again by 3 months
   - **E.** If platelets decrease below 50,000, platelet transfusions should be administered

4. **Which clinical scenario is most likely to be associated with mucocutaneous, immediate bleeding problems?**
   - **A.** A 16-year-old boy with hemophilia A
   - **B.** A 47-year-old patient on Coumadin
   - **C.** A 56-year-old patient with advanced cirrhosis of the liver
   - **D.** A 61-year-old patient with coronary artery disease on Aspirin and Plavix
   - **E.** A 29-year-old man with sickle cell anemia and chest syndrome

5. **Which of the following therapeutics inhibits clot formation by interfering with vitamin K metabolism?**
   - **A.** Aspirin
   - **B.** Heparin
   - **C.** Lepirudin
   - **D.** Fondaparinux
   - **E.** Coumadin

ANSWERS

1. The answer is C. A wide variety of conditions can activate the coagulation cascade and initiate the pathophysiology of DIC. Common examples include infection and trauma. Supportive therapy has a role in bleeding patients and should be offered. There is no convincing evidence for a "fuel on the fire" phenomenon. Anticoagulants such as heparin have been tried but do not impact outcome. What is effective is resolving the inciting cause (e.g., antibiotics, drainage), which will result in resolution of the coagulopathy. Microangiopathy can be found in a minority of DIC cases and thrombocytopenia alone is much too nonspecific a finding to confirm the diagnosis.
2. The answer is A. It is now known that principal pathophysiology of TTP involves abnormal factor VIII multimers with subsequent abnormal platelet adhesion and thrombotic microangiopathy. The other parts of the traditional pentad are later sequelae. Thus the key initial finding will be thrombocytopenia and a microangiopathic blood smear. Prolonged coagulation times are uncommon in TTP and suggest another diagnosis. TTP is one thrombocytopenic condition where transfusion of platelets may worsen the situation and are contraindicated. Exchange transfusion has reversed the poor prognosis of past decades into a quite favorable one today. It should be remembered that plasma infusion itself has beneficial effect and should be administered while waiting for the logistics of exchange transfusion to be completed
3. The answer is B. The most significant morbidity of TTP is thrombotic, with a thrombosis rate in untreated patients of 50% in the 30 days after diagnosis. Direct thrombin inhibitors address this and are indicated in therapy. LMWH, through a less common inciter of HIT, will cross-react in established cases and is contraindicated. A vast majority of patients will revert to ELISA negativity by day 100, but will quickly and frequently morbidly recur if rechallenged with heparin. HIT is another thrombocytopenic entity in which platelet transfusion is relatively contraindicated and should be avoided in most situations.

4. The answer is D. Immediate and mucocutaneous bleeding patterns are suggestive of platelet-related bleeding. Aspirin and Plavix are antiplatelet agents, which create platelet dysfunction on occasion severe enough to elicit clinical bleeding of this type. Hemophilia A, coumadin anticoagulation, and hepatocellular dysfunction are more associated with coagulation factor deficiency and a different deep delayed bleeding pattern. Sickle cell is not a hemorrhagic disorder.

5. The answer is E. Coumadin exerts its anticoagulant effect by interfering with the vitamin K mediated posttranslational carboxylation of factors II, VII, IX, and X. Such noncarboxylated factors are nonfunctional and bestow the anticoagulant properties of the drug. Aspirin is an antiplatelet agent. Heparin is an indirect thrombin inhibitor while Lepirudin is a direct (no need for antithrombin III mediation) thrombin inhibitor. Fondaparinux exerts its anticoagulant effect mainly by inhibiting factor Xa.

CHAPTER 25

FRANCIS C. CORDOVA, NICOLE R. HILBURT, AND JOSEPH I. BOULLATA

Nutrition Assessment and Nutrition Therapy in Intensive Care Unit Patients

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Describe the neurohormonal changes of the body during stress and its effect on fuel utilization by the body.
- Describe the indications for nutrition therapy in a critically ill patient.
- Explain the timing, route, and administration of nutrition therapy in the critically ill patient.
- List dosing parameters for macronutrients and micronutrients delivered enterally or parenterally to critically ill patients.
- Describe the monitoring parameters used to assess the therapeutic effect and adverse effects of nutrition therapy.

Malnutrition in the hospitalized patients is common especially in the intensive care setting. Critically ill patients often received less calories than prescribed due to fasting for diagnostic procedures, mechanical feeding tube problems, gastrointestinal (GI) intolerance, and inaccuracy of the pump.[1,2] Thus, many patients lose weight during their hospital stay. This, in combination with either preexisting or new onset malnutrition affects wound healing, musculoskeletal strength, cardiopulmonary function, and immunocompetence ultimately resulting in increased morbidity and mortality.[3]

The problem of malnutrition in critically ill hospitalized patients, particularly those who are undernourished due to chronic illness, is magnified several fold because of the profound

CASE STUDY: PART 1

AW is a 48-year-old man with a history of hypertension who presented to the emergency department (ED) with a 4-day history of increasing diffuse abdominal pain, associated with several episodes of vomiting, and constipation, alternating with diarrhea over the past week. He denied fever or chills. He has no known allergies and takes no medications at home. On physical examination, the abdomen was distended, diffusely tender with hypoactive bowel sounds. Radiographic findings of the abdomen revealed dilated bowel loops with multiple air fluid levels. He was admitted to the surgical service and underwent exploratory laparotomy, with lysis of adhesions and resection of 25 cm of jejunum with primary anastomosis, and upon recovery was transferred to the ICU.

metabolic alterations associated with critical illnesses. In essence, undernutrition is common in the ICU patient because of preexisting malnutrition compounded by the hypermetabolic response of injury and suboptimal food intake following admission to the ICU. Depending on the severity of the undernutrition and the underlying illness, and the adequacy of the nutrition therapy, the patient may continue to lose lean body mass, fat, and finally bone and viscera, all of which are detrimental to successful ICU resuscitation.

In this chapter, we describe the pathophysiology and clinical assessment of malnutrition and the approach to nutrition therapy in all critically ill adult patients. Specialized nutritional therapy in patients with specific organ dysfunction is also discussed.

Undernutrition is common in hospitalized patients, especially in the ICU setting. Critically ill patients often require specialized nutrition therapy, delivered enterally or parenterally, not as a substitute for food so much as to provide the needed substrate for a metabolism altered by their illness.

Critically ill patients often require enteral or parenteral nutrition (PN).

DEFINITION

Nutritional status is an expression of the degree to which an individual's nutritional needs are being met based on body composition and physiologic function. Poor nutritional status, or malnutrition, refers to any imbalance between nutrient intake and requirements (from starvation to obesity). Disease states obviously influence clinical outcome, but nutritional status is also a comorbid factor.

Undernutrition refers to a state of food intake inadequate to meet the daily nutrient requirements of the body. Starvation is the extreme example of the undernourished state, which can result from insufficient nutrient intake, malabsorption, or increased metabolic requirements due to disease or injury. Undernutrition can be defined as a body weight less than 90% of the predicted ideal weight or a body mass index (BMI) (body weight/height^2) less than 18 kg/m^2. Undernutrition is also said to exist with an unintentional weight loss of at least 10% that occurs over the preceding 3–6 months. The opposite extreme of nutritional imbalance is obesity, defined as a body weight above 130% of the predicted ideal weight, or a BMI greater than 30 kg/m^2. Individuals over 110% of ideal weight, or with BMI greater than 25 kg/m^2, are considered preobese or overweight. It is important to realize that undernutrition should be viewed not only as a decrease in body weight but also as an alteration in body composition in response to a perturbation in physiologic function. Various screening tools, devices, and nutritional indices have been developed to further define malnutrition. Clearly, there is no single best parameter to define undernutrition in every clinical situation, especially in the ICU. The actual body weight remains an objective, easy, and reproducible measure of undernutrition and is an important initial screening tool of nutritional status in the ICU. Different measures of nutritional health, such as midarm muscle circumference, triceps skin fold thickness, serum albumin, prealbumin, and delayed skin test reactivity, can then be used to further define and classify the degree of undernutrition and evaluate the response to nutrition therapy.

Malnutrition can occur either as undernutriton (BMI <18 kg/m^2) or obesity (BMI >30 kg/m^2).

The term specialized nutrition therapy refers to the provision of specially formulated nutrient products to maintain or improve a patient's nutritional status via the enteral or parenteral route. Enteral nutrition (EN) is the provision of therapy by nonvolitional delivery through a tube into the GI tract. Increasing use of this modality, also referred to as tube feeding, has followed innovations in both access and formulas. Parenteral nutrition (PN) is the provision of some or all nutrients through a central vein. Product osmolality and volume limit the effective administration of PN by peripheral vein. Still one of the most complex prescription drug products in terms of dosing and compatibility, PN has in the past been referred to as "hyperalimentation" and "total" PN.

EN is administered into the GI tract, and PN into a vein.

ALTERED METABOLISM IN THE CRITICALLY ILL PATIENT

Hypermetabolic State

The dynamics of fuel utilization by the body can be best understood by studying energy utilization during fasting. In the normal nonfasting condition, glucose is the main energy source of the body and is supplied by the breakdown of daily ingested food. During fasting in healthy subjects, serum glucose is maintained by the breakdown of hepatic glycogen stores, a process known as glycogenolysis. However, the glycogen store of the body is limited and is rapidly depleted within a 24-h period. During a prolonged fasting state, the body's energy utilization shifts from glucose to ketones, which are generated by the oxidation of body fat stores. Body tissues with an obligate need for glucose as the sole source of energy obtain their supply via hepatic gluconeogenesis. In this process, lactate, glycerol, and amino acids from muscle proteins provide the substrates for glucose production. In addition to the change in the pattern of energy utilization, the body also decreases energy expenditure by about 20%.

In contrast, in critically ill patients such as those with severe burns, trauma, or sepsis, energy expenditure remains high both during periods of adequate nutrition therapy and during periods of temporary suspension of nutrition intake. Indeed, the body's energy balance remains negative even with aggressive nutrition therapy.

The hypermetabolic state results from altered neuroendocrine response of the body during stress and is defined by increased tissue catabolism and energy expenditure.

During periods of metabolic stress, energy consumption may increase as much as 100% above the baseline depending on the severity of injury for a period of time. This increase in metabolic rate and energy expenditure commonly seen following injury is known as the hypermetabolic state. The hypermetabolic state is characterized by severe catabolism of muscle protein, resulting in a net negative balance of body nitrogen that may eventually lead to organ failure.[4] As seen during fasting, the fuel utilization of the body shifts from carbohydrate to fat as the glucose stores are rapidly depleted and as the synthesis of glucose by the liver cannot keep up with the body's high energy needs. Unlike malnutrition, where nutrition therapy is enough to induce positive nitrogen balance, only providing adequate nutrition therapy while treating the underlying disease process can reverse the metabolic derangement following injury.

Physiologic changes in the body following injury are high serum levels of catecholamine, cortisol and glucagon, and relative tissue insensitivity to insulin.

The metabolic response to injury impacts nutrient metabolism and nutritional requirements.

This altered fuel utilization and hypermetabolic state is largely brought about by a neuroendocrine response involving macromediators (e.g., catecholamines, cortisol, glucagon) and additional responses coordinated by micromediators such as cytokines, eicosanoids, and reactive oxygen and nitrogen species at the level of the leukocyte and endothelium. The body's stress response to injury creates a hormonal milieu that favors gluconeogenesis, and lipolysis despite increased insulin secretion. Although protein synthesis per se may increase, the rate of proteolysis is greater, and amino acid efflux from skeletal muscle supports the acute-phase response and gluconeogenesis. The resulting clinical picture is one of a hyperglycemic, hypertriglyceridemic, azotemic, and often edematous patient. Although the stress response to acute injury itself may be detrimental to the body's ability to recover, the use of nutritional support during this period may dampen the hypermetabolic state and allow proper wound healing, restitution of immune function, and recovery of musculoskeletal strength.

The goal of managing the stress response and the hypermetabolic state in these patients is to modulate its effect on organ functions. Although maximizing oxygen delivery and minimizing infectious complications therapeutically may improve outcome, nutrition therapy is just as necessary, in organ or visceral resuscitation, as it minimizes the detrimental effects on nutritional stores and provides substrate to the tissues.

Nitrogen Balance

A net negative nitrogen balance occurs when the rate of protein breakdown exceeds the rate of protein synthesis.

The amount of nitrogen in the diet and the amount of nitrogen excreted in the urine plus the small amount of nitrogen lost through the GI tract determine the overall nitrogen balance of the individual. A positive nitrogen balance means that the body's structural proteins are rebuilding and is a desired endpoint of all forms of nutrition therapy. Nitrogen balance studies are best used to determine whether the nutrition regimen provided has been adequate enough to prevent catabolism or to promote anabolism.[5,6] In normal subjects, a negative nitrogen balance up to approximately 4 g/day can be expected. In any kind of injury or stress, the negative

nitrogen balance invariably increases several fold beyond normal depending on the severity and duration of injury. In malnourished subjects, negative nitrogen balance increases to about twice normal, reflecting a loss of body cell mass to catabolism. In essence, the body is using its available fuel reserves (i.e., muscles and adipose tissue) as energy sources. In severe injury, as exemplified by a greater than 40% BSA burn injury, a nitrogen balance can approach −27 g/day. Because 6 g of protein contains approximately 1 g of nitrogen, burn patients can lose as much as 162 g protein/day. If this hypermetabolic rate goes on unabated, or is only partially attenuated by aggressive nutrition therapy, severe malnutrition will occur within 2 weeks. Other sources of nitrogen loss can occur in the critically ill patient through fistula or wounds, GI fluids, or renal replacement methods to name a few. The accuracy is affected by the presence of renal failure and insufficiency (creatinine clearance of <50 mL/min). Other disorders or factors that may also affect the accuracy of the results other than GI and wound losses include severe hepatic failure, diuresis, accuracy of the collection and protein intake data.

It is possible to achieve zero nitrogen balance in normal subjects or in malnourished patients by providing enough daily calories and protein to meet energy expenditure and obligatory protein losses from ongoing metabolic processes. Unfortunately, the negative nitrogen balance that occurs during sepsis and severe injury is resistant to even the most aggressive nutritional supplementation. A zero nitrogen balance can eventually be achieved as recovery from the initial injury is achieved. Several studies showed that providing early aggressive enteral feeding improved clinical outcomes compared to delayed EN therapy.[3,7-10] However, some observational studies suggest that early enteral feeding that achieves only 25–66% of the targeted caloric goal may be enough to improve clinical outcome. Other studies suggest that caloric deficits are common and when occurring within the first few days of critical illness increase morbidity including infection, and cannot be made up later.[1,3] PN used in combination with enteral feeding to achieve the calculated caloric goal confers no additional advantage.

Protein Metabolism

Amino acids from protein breakdown are used for gluconeogenesis.

Structural body protein serves as a large, readily available energy reserve that can be mobilized by the body during fasting or following injury. The amino acids released during catabolism of muscle proteins are mainly used as a substrate for gluconeogenesis and are made available for the synthesis of new proteins for tissue repair and immune response and for the synthesis of acute-phase proteins by the liver. In addition, the release of branched-chain amino acids serves as nitrogen donors for the synthesis of glutamine, which is the preferred fuel source of rapidly dividing cells such as intestinal mucosa or white blood cells. However, the increase in protein catabolism during injury is not without side effects. The increase in amino acid efflux from skeletal muscle results in increased urinary nitrogen excretion and a negative nitrogen balance. Because food intake immediately following injury is often limited, and because of the hypermetabolic state following injury, an increased negative nitrogen balance invariably follows injury and, if not reversed by nutrition therapy and treatment of injury, the condition results in severe malnutrition.

Glucose Metabolism

During injury, altered fuel utilization and perturbation in hormonal milieu commonly results in hyperglycemia, despite elevated levels of circulating insulin. Specifically, increased hepatic gluconeogenesis coupled with decreased glucose uptake by insulin-sensitive tissues such as skeletal muscle and adipose tissue are the main reasons for increased blood glucose levels following injury. The decreased uptake of glucose by muscle cells and adipose tissue is caused by stress-induced insulin resistance, thought to be mediated by elevated levels of counter-regulatory hormones (cortisol, catecholamines, and glucagon) and cytokines released during stress by inflammatory cells.

Stress-induced hyperglycemia is caused by increased circulating catecholamines and relative tissue insensitivity to insulin.

Hyperglycemia following injury is thought to be a biologically adaptive mechanism designed to provide adequate supply of glucose to poorly vascularized wounds. In addition, the brain obtains almost all its energy from glucose oxidation. Recent studies have shown that tight control of hyperglycemia with insulin resulted in decreased morbidity and mortality in select surgical and medical ICU patients.[11,12]

CASE STUDY: PART 2

Initial ICU data included the following:

- Medications: cefepime 2 g IV q12 h, famotidine 40 mg IV daily, lorazepam 2 mg IV prn, morphine 2 mg IV prn, and D5W/0.45 NaCl with 20 mmol KCl/L at 80-mL/h
- Vital signs: T_m, 100°F; BP, 135/88 mmHg; HR, 90/min; RR, 12/min
- Height, 5′9″; weight, 84 kg (usual weight, 88 kg; preoperative weight, 83 kg)
- Pertinent findings: sedated but arousable; intubated and mechanically ventilated; nasogastric tube to suction with over 600 mL out in the first few postoperative hours; abdominal distension; dressing intact; no bowel sounds or flatus/stool noted; adequate urine output; total fluid in/out 3,100/2,800 mL; left subclavian triple lumen catheter in place centrally as confirmed by chest X-ray
- Pertinent lab results: Na, 138 mmol/L; K, 4.1 mmol/L; Cl, 106 mmol/L; CO_2, 22 mmol/L; BUN, 18 mg/dL; Cr, 0.9 mg/dL; glucose, 128 mg/dL; triglycerides, 240 mg/dL; albumin, 2.8 g/dL; WBC, 9 K/mm^3; Hb, 9.5 g/dL; platelets, 240 K/mm^3; INR 1.1

Lipid Metabolism

Adipose tissue is the major fuel reserve of the body. During mild to moderate trauma, an increase in free fatty acids and glycerol can be seen as early as 2 h following injury. Fat becomes the predominant source of energy as the supply of glucose becomes limited. The respiratory quotient, that is, the ratio of carbon dioxide production to oxygen uptake (VCO_2/VO_2) is lower during stress compared to baseline, indicating the preferential use of lipids as an energy source; this may be advantageous because lipid has a sparing action on protein catabolism. The increased free fatty acids serve as a fuel source for tissues, except the red blood cells and the central nervous system. The increased rate of lipolysis is thought to result from a continuous stimulation of the sympathetic nervous system during injury.

Ketones derived from fatty acids serve as an alternate fuel source during stress.

In patients with severe trauma, both free fatty acids and ketones are decreased while the level of glycerol remains unchanged. This apparent discrepancy in the rate of lipolysis between mild to moderate trauma on the one hand and severe trauma on the other hand is probably caused by decreased perfusion of adipose tissue in severe injury.

NUTRITION ASSESSMENT

Poor nutritional status influences patient outcome from critical illness.

There is no single presenting sign or symptom, biochemical marker, or physical examination finding that defines nutritional status, least of all in the critically ill patient. However, most of these patients will be determined to be malnourished at presentation due to the underlying chronic illness or prior weight loss. Moreover, critically ill patients are at nutrition risk even during hospitalization due to their inability to eat, disease related alteration in nutrient utilization, and feeding interruption due to testing.

A nutritional assessment includes a good history, a nutritionally focused physical examination along with careful interpretation of height and weight, and laboratory markers. The history should be able to identify chronic disease states, most of which impact nutritional status: GI disorders, poor appetite, dental and oral health, surgeries, and recent weight changes.

A validated tool for nutrition assessment is the Subjective Global Assessment (SGA). Although indicated only for nonacutely ill patients, this tool nonetheless provides a good framework that takes into account both history and physical exam. It starts with a detailed review of food intake and any recent discrepancies. As most ICU patients are intubated, this data usually comes from family members. If the patient has been on EN or PN at home or from a previous hospitalization, the specific product, volume and rate should also be included in this section. The second part evaluates incidence, duration, and intensity of GI symptoms and includes an abdominal exam. Lack of bowel movements, diarrhea, and output from gastric or intestinal drainage tubes should also be included. The third part is the weight history. Whenever possible, the usual body weight (UBW) should be obtained for use in nutrient calculations. The patients' actual body weight will be of limited value if edema, anasarca, or pleural effusions are present. As already stated, UBW is the best measurement to use given the often severe fluid fluctuations in critically ill patients. Family members should be asked if there has

been any recent change in body weight that they are aware of, with particular attention being paid to past medical history and those conditions known to adversely increase or especially decrease weight. Obtaining daily weights and fluid ins/outs are best to trend fluctuations in the ICU. The fourth part focuses on the patients ADL status prior to hospitalization, i.e., independent, active, needing assistance, bed-ridden, etc., as compared to current status.

After this, a nutrition-focused physical exam should be performed in order to help determine if any nutrient deficiencies are present and to determine how the patient should be fed. Overall, general appearance should be evaluated (muscle mass, fat distribution), as well as specific markers of nutrient deficits. Examples of nutrient deficits include the following: temporal wasting (protein-calorie), xerosis (retinol), poor skin turgor (water), poor wound healing (protein-calorie, micronutrients), cheilosis and glossitis (B vitamins), and the presence of irregular or mottled nails (protein, iron). Abdominal exam and organ function is also addressed here to determine the route of feeding. Next, the clinical review is completed which presents the patients current condition, any treatments or surgeries underwent, any specific nutrition tests performed, and assessment of weight changes and clinical findings.

Use the clinical history, physical examination, and biochemical; markers for nutrition assessment.

Measurement of lean body mass using bioelectrical impedance (BIA) has been reported to be a better predictor of mortality in certain disease states compared to body weight. In the ICU setting, this test is primarily used to determine changes in extracellular fluid status and changes in lean body mass, but may also be helpful in providing guidance in fluid management in the critically ill patient if done serially. After collecting data from the history and physical exam, lab tests can be of some additional value.

Biochemical markers are also used to help determine the nutritional status and the presence of risks associated with undernutrition. Serum albumin has traditionally been used as a marker of nutritional status. However, in critically ill patients with reprioritization of hepatic protein synthesis and changes in fluid compartmentalization, hypoalbuminemia is common regardless of the nutritional status. Serum albumin has a long half-life (~20 days) and its level may be falsely low due to the presence of organ dysfunction, and systemic inflammatory response. Therefore, it is not a good indicator of nutritional status, although hypoalbuminemia in critically ill patients is associated with increased morbidity and mortality. Prealbumin, with a shorter half-life than albumin, can be used as a protein status marker. However, as is the case with albumin, prealbumin is another negative acute-phase reactant and is affected by disease state and organ dysfunction. In the absence of significant inflammation, prealbumin is used as an indicator of the nutritional state as well as to evaluate the response to nutritional therapy. C-reactive protein may help distinguish the presence of an acute-phase response from poor nutritional status as a cause for hypoprealbuminemia.

All the subjective and objective data available are then evaluated to make the best clinical assessment of nutritional status and determine each patient's risk. By definition, the severely ill patient with sepsis, organ dysfunction, extensive surgery, burns, or traumatic wounds has altered nutritional status by virtue of their altered metabolism and will likely need nutrition therapy.

INDICATIONS FOR NUTRITION THERAPY

Many institutions have a formal nutrition therapy team or a group of individuals (physician, nurse, dietitian, pharmacist, respiratory therapist) specializing in nutrition therapy available to the intensivist. As previously noted, a patient's nutritional status is evaluated on the basis of specific subjective and objective data. The potential risks vs. benefit from nutrition therapy depend on the nutritional status and the estimated time until resumption of usual diet. Generally, nutrition therapy may be required for patients with an alteration, or potential for an alteration, in nutritional status, who are otherwise unable to improve or maintain their nutritional status on their own. The critically ill patient may also be evaluated based on the severity of illness and premorbid nutritional status. The patient with adequate premorbid nutritional status who is expected to improve clinically and eat within a week is not likely to require specialized nutrition therapy. However, the patient with significant illness or injury, not expected to recover within a week, may need nutrition therapy. The threshold is especially

Specialized nutrition therapy is indicated in patients with altered nutritional status who are unable to improve their status on their own.

low for the patient with poor nutritional status on admission to the ICU, including undernourished and obese patients as well as those with imbalances in specific nutrients. The goal of providing nutrition therapy is to minimize the co-morbid effects of malnutrition and to prevent or manage specific nutrient imbalances. When an indication for nutrition therapy is established, the timing, route, and dosing become important.

TIMING OF NUTRITION THERAPY

When indicated, nutrition therapy is best administered as soon as possible in a hemodynamically stable patient with safe access.

When indicated, nutrition therapy should be initiated as early as feasible to minimize the adverse systemic effects of the injury response. Data suggest that delay for more than 48 h significantly increases the risk of infection, length of stay, and mortality in burn and trauma patients. A patient should first be hemodynamically stable, and with a safe enteral or parenteral access device in place. Timing of nutrition therapy along with the degree of malnutrition may influence outcome. Postoperative PN is no better than intravenous fluids in well-nourished or mildly malnourished patients and may actually be worse if the patient is not severely malnourished. The best outcome (fewer postoperative complications) results from initiating PN preoperatively in severely malnourished surgical patients. Initiation of early EN (within 24 h) decreases infection and mortality, and attenuates the systemic inflammatory response compared to delayed nutritional therapy (>5 days) in trauma, critically ill burn patients, and GI surgical patients. There are no data that show any advantage to delaying nutrition therapy when it is indicated, and in fact caloric and protein deficits increase the risk for morbidity.[13] Once indicated, the next decisions involve determining the route, access, and duration of nutrition therapy.

ROUTE AND ACCESS OF NUTRITION THERAPY

The enteral or the parenteral route is available to deliver specialized nutrient formulations. Decision-making about the route of nutrition therapy involves evaluation of GI tract function, anticipated duration of therapy, and the relative benefits of EN vs. PN.

The function of the GI tract and the expected duration of therapy help determine the route and access for nutrition therapy.

Although assessment of the premorbid status and the severity of illness determine the initiation of nutrition therapy, the function of and access to the GI tract determine the route of administration. The function of both the upper and lower GI tract should be determined. Whenever a functional GI tract can be safely accessed in a patient with an indication for nutrition therapy, the enteral route should be used. Adequate function requires absence of anorexia, nausea, vomiting, or excessive drainage from a nasogastric/orogastric tube. The presence of 200 mL or more of gastric output over 4–6 h (100 mL or more if gastrostomy) or documented tracheal aspiration of gastric contents would preclude using the gastric route for EN. Abdominal examination should reveal normal bowel sounds and absence of distension or tenderness. The passage of flatus or stools are good signs of intact bowel function. Surgery on the GI tract does not preclude the use of EN per se, but the presence of significant ileus, bowel obstruction, peritonitis, hemorrhage, high-output fistula, necrotizing pancreatitis, ischemic bowel, short bowel syndrome, documented malabsorption, or intractable vomiting or diarrhea point to the parenteral route as the preferred route for nutrient delivery until gut function is restored. However, it is important to remember that the small bowel is still capable of nutrient absorption despite the presence of poor gastric emptying, and consideration may be given to directly accessing the proximal small bowel for EN.

The small bowel may be considered for EN delivery even in the presence of poor gastric emptying.

Assuming safe access to the GI tract, there may be differences between gastric and intestinal feeding. Aspiration risk is greater for bolus feeding as opposed to continuous gastric feeding. Data do not consistently support the contention that the risk of tube feed aspiration is lower in patients fed postpylorus; however, the intestinal administration of an appropriate formulation reduces the time to achieve the goal dosing rate. Duodenogastric reflux may contribute to gastric volume, but reflux is less likely when the distal end of the feeding tube is beyond the ligament of Treitz. In any event, there is a lack of correlation between gastric residual volume and aspiration and pneumonia.[11] No single finding predicts success with the enteral route, but with a functional GI tract, the best test of EN tolerance is a trial of EN before

CASE STUDY: PART 3

On postoperative day 2 (POD 2), the patient was febrile and somewhat more agitated despite adequate analgesia. The same drug regimen had been continued and the patient had required increasing amounts of saline boluses to maintain adequate circulatory pressures. A pulmonary artery catheter was placed via the right subclavian vein for hemodynamic monitoring.

- Vital signs: T_m, 101.8°F; BP, 128/68 mmHg; HR, 108/min; RR, 18/min; CVP, 6 mmHg; PAOP, 12 mmHg, CI, 3.6 L/min · m^2; SVR, 850 dynes · s/cm^5.
- Pertinent findings: nasogastric suction, 1,000 mL (pH 3.5); abdominal distension, without flatus or stool; decreasing urine output, fluid in/out 4,200/1,800 mL.
- Pertinent lab results: Na, 141 mmol/L; K, 3.8 mmol/L; Cl, 110 mmol/L; CO_2, 20 mmol/L; BUN, 22 mg/dL (UUN 7); Cr, 1.4 mg/dL; glucose, 160 mg/dL; Mg, 1.1 mg/dL; P, 2.1 mg/dL; Ca, 7.5 g/dL; albumin, 2.1 g/dL; WBC, 14 K/mm^3.
- Nutritional therapy assessment/plan: Given a 6% weight loss before admission, NPO status for at least 6 days with a worsening clinical condition, and no expectation of resuming oral diet in the next few days, this patient was a candidate for nutrition therapy. The GI tract could not be used because of poor gastric emptying and no access to the small bowel. The patient was a candidate for short-term PN via a dedicated lumen of the central catheter. Nutrient dosing was based on the metabolically active weight of 74 kg. In the absence of indirect calorimetry, his caloric goal was 1,835 kcal/day (25 kcal/kg to start) based on an estimated basal energy expenditure of 1,667 and an activity factor of 1.1. The initial caloric therapy should be on the lower side with dextrose not exceeding 150–200 g/day and lipid not to exceed 1 g/kg/day. The empiric protein goal is 110 g/day (1.5 g/kg). Maintenance fluid needs are approximately 2,200 mL/day (30 mL/kg). The 1,000 mLPN, initiated at 42-mL/h, contained 75 g protein, 150 g dextrose, and 40 g lipid (providing 1,210 kcal). If tolerated, the goal volume can be ordered the following day at 1,600-mL at 67-mL/h containing 120 g protein (1.6 g/kg and 19 g nitrogen), 240 g dextrose, and 64 g lipid (providing 1,936 kcal/day), including 64 mmol NaCl, 48 mmol potassium acetate, 5 mmol calcium gluconate, 12 mmol magnesium sulfate, and 18 mmol sodium phosphate in that 1,600 mL along with 10 mL 13-multivitamin product, 3 mL 5-trace element product, and 40 mg famotidine (discontinuing the intermittent IV famotidine).

committing to the parenteral route. If the GI tract cannot be safely accessed, then PN is appropriate until the enteral route is usable. The weakest link in using EN is safe access, although there are a number of techniques to place EN access devices in critically ill patients.

Devices exist for obtaining enteral and vascular access. Placement of enteral access may be guided by endoscopy, fluoroscopy, laparoscopy, or surgically as well as by blind placement. Anticipating the duration of EN helps determine the most appropriate and comfortable enteral access for the patient. Generally, for short-term use (<3 weeks), the transnasal/transoral route is sufficient. If treatment for longer than 3 weeks is anticipated, percutaneous access of a gastrostomy, transgastric jejunostomy, or jejunostomy may be considered whether placed endoscopically, fluoroscopically, or surgically. A silicone or polyurethane tube of at least ten French with adequate internal diameter can be used for the transnasal/transoral enteral access device.

The transoral route is sufficient for short-term EN; percutaneous tube placement is considered for long-term EN (>1 month).

An intravascular catheter ideally with a dedicated lumen for PN placed through a central vein, with the distal tip in the vena cava, is required for PN administration. A peripheral venous access may be used for the short-term (<5 days) administration of PN in the absence of a central access or while titrating the rate of the EN to goal dosing. Peripheral PN necessitates low nutrient concentrations to maintain formula osmolarity at a tolerable level (<900 mOsm/L). Correct placement of both enteral and parenteral access devices should be confirmed before use. Placement of long-term indwelling catheters for continued PN administration at an alternate care site may be considered if transfer from the ICU with that therapy is possible. The use of either the enteral or parenteral route for nutrient therapy does not preclude the adjunctive use of the other route to best meet an individual patient's needs.

PN is associated with a higher incidence of infectious complications than EN, even when line-related infections are excluded.[14] This difference may result from altered GI mucosal function and mucosal lymphoid tissue at the respiratory and GI tracts. Whether this is a direct result of the route of administration that has been chosen, the nutrient composition that is delivered by that route (with subsequent impact on gene expression or the regulation of nutrient flow by the GI tract), or both remains unclear. The substrate delivered in the current parenteral formulations may be incomplete or unbalanced for that route of delivery.

Although the etiology is not yet entirely clear, infectious complications are usually fewer with EN than PN.

CASE STUDY: PART 4

On POD 3, infusion of dexmedetomidine was initiated to facilitate ventilatory management. Dopamine and norepinephrine infusions were started to maintain adequate perfusion. Antimicrobials were appropriately modified. An indirect calorimetry reading, under adequate conditions, provided a resting energy expenditure (REE) of 2,164 kcal/day for this patient.

- Vital signs: T_m, 101°F; BP, 180/20 mmHg; MAP, 78 mmHg; PAOP, 15 mmHg; CI, 4.4 L/min; SVR, 760 dynes · s/cm^5.
- Pertinent findings: weight, 90 kg; poor GI function continued (gastric pH 4.5); renal function stabilized; fluid in/out 3,900/2,000 mL.
- Pertinent lab results: Na, 142 mmol/L; K, 4.2 mmol/L; Cl, 110 mmol/L; CO_2, 21 mmol/L; BUN, 20 mg/dL; Cr, 1.4 mg/dL; glucose, 190 mg/dL; Mg, 21.1 mg/dL; P, 2.3 mg/dL; Ca, 7.7 g/dL; WBC, 17 K/mm^3, CRP, 24 mg/dL; prealbumin, 8 mg/dL.
- Nutrition therapy assessment/plan: Patient continues to require nutrition therapy via the parenteral route. Increased weight likely reflects fluid retention. The low prealbumin likely reflects both poor nutritional status and the response to inflammation. PN is well tolerated with titration to the goal rate. The empiric caloric dosing goal is similar to the results of indirect calorimetry (2,164 vs. 1,936; only 228 kcal less), so there is no need to alter the regimen, especially given ventilatory status, hyperglycemia, and use of vasopressors. Consider initiating an insulin infusion if serum glucose exceeds 150 mg/dL, with a goal of 100–120 mg/dL during the inflammatory response.

ADMINISTRATION OF NUTRITION THERAPY

Enteral

EN is initiated at 10–20-mL/h and titrated to goal as tolerated.

Slow advancement and stopping of infusion results in many critically ill patients not meeting their requirements.

Critically ill patients tolerate EN best when administered continuously into the stomach or proximal small bowel using a pump. The head of the bed should be elevated to 30°–45°, and the feeding can be administered at full strength starting at 10–20-mL/h. The dosing rate may be titrated up by another 10–20 mL/h every 4–12 h toward the goal rate as tolerated. Reports of initiating EN at goal rate in critically ill patients remain scarce. The goal rate would be the hourly volume of a formulation that over the course of a day would provide the patient's nutrient dosing needs. Patients who have been nil per os (NPO) for a week or longer, or those with severe malnutrition on presentation, may need to be advanced toward goal rate more slowly. Unfortunately, because of slow advancement, inappropriate stoppages, and under-dosing, half of critically ill patients do not meet their nutrient requirements during a course of EN therapy. Additives to the EN formulation are to be avoided because of limited compatibility data and to limit the risk of contamination especially as sterile closed EN systems are now widely used. A pharmacist should be consulted before administering any medication through the same access device as the EN formula to identify appropriateness. The ideal order for EN includes the product name (brand or generic name), the volume and accompanying rate, the route, with the patient's dosing weight. The administration bag and set should be changed as per policy related to the closed system used (up to 36 h) or open system (within 8–12 h), and any remaining formula should be discarded. Because of its propensity to therapy microbial growth, a volume of EN should not remain in an open system bag for more than 8 h. If a closed-system tube feed product is used, the container can hang for 24 h without being compromised. Avoid using tap water for administration via enteral access devices in the critically ill patient due to contaminants.[13,15-18]

Parenteral

PN can be initiated at 1-L the first day and advanced to goal by the second day as tolerated.

Limit infectious complications and interactions by using a dedicated catheter port for PN.

The PN formulation is prepared on a daily basis and administered in a single container at a rate not to exceed 42 mL/h for the first day and advanced to the goal rate by the second day, as tolerated to limit complications involving volume, glucose, or electrolytes. The PN should be infused through a catheter port dedicated for this purpose, with no breaks in technique for blood draws or to administer another medication or blood product, to limit infectious complications and interactions. Additional nutrients and medications may be prescribed for inclusion in the PN formulation if supported by both clinical and pharmaceutical data. For reasons of PN instability or institutional policies, occasionally, the lipid portion of the formulation is

administered separately from the rest of the PN; in those instances, an infusion pump should be used to administer the lipid dose over at least 20 h. The ideal PN order includes the volume and accompanying rate, the route, and the daily dose of each nutrient requested, with the patient's dosing weight. Transition from PN to EN (or oral diet) requires overlap of both routes, tapering the parenteral infusion rate as the patient tolerates EN. Once the patient tolerates approximately 75% of energy and protein requirements by the enteral or oral route, PN can be discontinued.

DOSING AND FORMULATION ISSUES

The dosing of macronutrients and micronutrients via nutrition therapy regimens is based on patient requirements and may differ with the route of administration and the formulation, given the issues of bioavailability, physiologic regulatory mechanisms, and physicochemical characteristics of enteral or parenteral products.

Macronutrients

Generally, critically ill patients require 25–30 kcal/kg and 1.5–2 g protein/kg daily. An appropriate dosing weight should be used.

General recommendations for dosing macronutrients in critically ill adult patients include 25–30 kcal/kg/day and 1.5–2 g protein/kg/day regardless of the route, although it is less likely that these needs could be met via a peripheral vein. The calories are delivered as carbohydrate and lipid, with dosing limitations of no more than 4–5 g/kg/day and ≤1 g/kg/day, respectively. Fluid maintenance is estimated at 25–35-mL/kg/day, individualized to a patient's age, fluid balance, and solute load. The dosing weight of each patient should be documented in the medical record and on the label of the nutrient formulation. The patient's actual body weight can be used if it is less than or similar to an estimated lean body weight and does not represent recent fluid imbalance. For an obese patient, dosing could be based on a metabolically active weight estimated with the following adjustment [(actual weight – lean weight) (0.3) + lean weight]. Of course, changes in fluid status must be taken into account when evaluating recorded weights, and an estimated dry weight should be obtained. The aforementioned dosing guidelines are empiric, based on population parameters. The specific requirements of an individual patient may vary with their clinical state and can be ascertained when clinically necessary. Basal energy requirements can be estimated using the Harris–Benedict predictive equations, which take into account weight, height, age, and gender:

Empiric energy requirements may be estimated by predictive equations although the measurement of energy expenditures via indirect calorimetry remains the gold standard when available.

Men: 66.5 + (13.7 × weight in kg) + (5 × height in cm) – (6.8 × age in years)
Women: 655 + (9.6 × weight in kg) + (1.8 × height in cm) – (4.7 × age in years)

These equations estimate the energy expenditure at rest and necessitate a factor to account for the patient's level of activity and hypermetabolism, which when multiplied with the basal requirement provides an estimate of the total energy expended (kcal/day). Factors may be of the order of 1 in the sedated patient to 1.6 in the agitated patient with significant burn injury. A factor of 1.1 provided the closest estimate to measured energy expenditure in critically ill patients.[5] Energy requirements can also be based on a calculated expenditure using the Fick equation or measured energy expenditures as determined by indirect calorimetry. No equation accurately predicts the energy expenditure in most hospitalized patients without a significant degree of error.

The Fick equation requires the use of a functional pulmonary artery catheter for the parameters needed to calculate oxygen consumption (VO_2). Energy expenditure (kcal/day) is then estimated as VO_2 (mL/day) × 7. This equation holds best for the hemodynamically stable, spontaneously breathing patient, and poorest for unstable, mechanically ventilated patients. Indirect calorimetry is preferred for this patient population.

Indirect calorimetry uses a portable, open-circuit calorimeter to measure the volume and concentration of the inspired and expired oxygen and carbon dioxide. The calorimeter uses the data to calculate VO_2 and carbon dioxide production (VCO_2), which are proportional to substrate utilization and energy expenditure. The relationship has been simplified into the following

equation: energy expenditure (kcal/day) = (VO_2 in L/day) (3.9) + (VCO_2 in L/day) (1.1). The findings from indirect calorimetry should take into account any limitations inherent in the methodology or calorimeter. Limitations may be based on unmet assumptions such as that all O_2 and CO_2 exchange occurs across the lung, is associated with ATP synthesis, and no O_2 or CO_2 is stored or retained. Measuring energy expenditures using indirect calorimetry may be of most benefit in obese critically ill patients or those not responding as expected to empiric dosing of macronutrients.

Empiric protein requirements can be based on nitrogen losses.

Patient-specific protein dosing can be based on the level of nitrogen elimination, which serves as a marker of the degree of hypercatabolism. The quantity of urea nitrogen eliminated in the urine of a patient with adequate renal function can be used to determine the catabolic index: urinary urea nitrogen (g/day) – [(nitrogen intake (g/day) × 0.5) + 3]. A value of 0–5 indicates mild catabolism and a value >5 indicates severe catabolism requiring higher doses of protein. As steady state is approached following several days of nutrition therapy, nitrogen balance can be determined: (nitrogen intake (g/day) – [urinary urea nitrogen (g/day) + 4]. Keep in mind that this does not take into account abnormal losses (e.g., drains, wounds). A value of 0 to +4 is ideal, but unrealistic in a critically ill patient. Values between 0 and −10 are considered an interim success in the ICU.

EN products vary in nutrient content, source, and cost.

A large number of commercially prepared enteral formulations exist, varying in nutrient content, nutrient source, osmolality, and cost. Guidelines for use depend on access to the GI tract and patient tolerance. The various products can be classified into several categories (Table 25-1). Each health care institution or system carries only a select number of products on their formulary. Intact macronutrient (polymeric) and hydrolyzed macronutrient (monomeric/oligomeric) formulas are always represented. Polymeric formulas are divided into those that are isotonic, some containing fiber, which usually provide about 1 kcal/mL, and those that are more concentrated in calories or protein and often provide 1.2–2 kcal/mL. The more concentrated a formulation is, the less free water it contains, which may be of value in fluid-restricted patients. The hydrolyzed formulas are typically reserved for patients with malabsorption or previous GI intolerance to tube feed. The role of formulations designed for specific disorders (e.g., diabetes, organ dysfunction) remains unclear on the basis of the current data. These specialized products vary in caloric density and composition, and may serve as a standard intact formula for patients

TABLE 25-1

SELECTED ENTERAL NUTRITION FORMULAS

CATEGORY	PATIENT CHARACTERISTIC	EXAMPLES
Intact		
Isotonic Standard Low calorie Hi fiber Low electrolyte High calorie High protein	Functional gastrointestinal tract	Isocal, Isocal HN, IsoSource, IsoSource HN, Nutren 1.0, Osmolite, Osmolite HN; (fiber containing) Fibersource, FiberSource HN, Jevity, Jevity. Plus, Nutren 1.0 with Fiber, ProBalance, Ultracal
Concentrated Hi fiber Low electrolyte High protein	Fluid restricted, increased metabolic requirements	Deliver 2.0, Magnacal, Nutren 1.5, Nutren 2.0, ReSource Plus, Two Cal HN
Hydrolyzed	Maldigestion, malabsorption, or intolerance to intact Formulas	AlitraQ, Criticare HN, Crucial Peptamen, Reabilan, Reabilan HN, Subdue, Vital HN, Vivonex TEN
Disorder specific	Critically ill/immune	Advera, AlitraQ, Crucial ImmunAid, Impact, Perative Promote, Replete, TraumaCal
	Organ dysfunction	AminAid, HepaticAid II, Magnacal Renal, Nepro, NutriHep NutriVent, RenalCal, Pulmocare Respalor
	Diabetes	DiabetiSource, Glucerna, Glytrol

regardless of the presence or absence of a disorder. A formula is selected that meets a patient's energy, protein, and fluid needs most closely. Additional factors include the patient's past medical history and organ function, as well as the physicochemical characteristics of available enteral formulas.

EN products are selected to most closely meet a patient's requirements.

Some EN formulations have been enriched with one or more specific substrates for a targeted therapeutic effect. Use of specific nutrients for pharmacologic effects rather than meeting nutrient requirements has been termed nutritional pharmacology or nutrient pharmacotherapy. Certain substrates (lipids, amino acids, micronutrients) may modulate injury response. The greatest benefit of using substrate-enriched formulations to enhance patient outcome appears to be a reduction in major infectious complications.[19,20] Data in trauma patients suggest fewer infections, less antibiotic use, fewer days on mechanical ventilation, and shorter length of stay with glutamine and/or arginine. Patients with adult respiratory distress syndrome (ARDS) may benefit from EN enriched with gammalinolenic acid (GLA) and eicosapentanoic acid.[21] The benefits of substrate-enriched EN in other critically ill patients remain less clear. The specific nutrient combinations and dosing parameters are not yet clear, but benefit seems to require 4–6 days of therapy. Wider use awaits results from additional trials of specific substrate-enriched formulations in defined critically ill subpopulations. Specific nutrients and metabolites include amino acids (e.g., arginine, cysteine, glutamine), fatty acids (e.g., γ-linolenic acid, α-linolenic acid, eicosapentanoic acid, docosahexanoic acid), and others (e.g., nutrient antioxidants, ornithine α-ketoglutarate, nucleotides). As with any other therapeutic intervention, vigilant monitoring is necessary to assess progress whether using traditional or substrate-enriched EN therapy. Substrate-enrichment of PN formulations is less common thus far in the U.S., although data exist to support this practice in specific settings.

TABLE 25-2

DAILY ELECTROLYTE REQUIREMENTS

ELECTROLYTE	ENTERAL	PARENTERAL
Sodium	500 mg (22 mmol)[a]	1–2 mmol/kg
Potassium	2 g (51 mmol)[a]	1–2 mmol/kg
Chloride	750 mg (21 mmol)[a]	As needed to maintain acid–base balance with acetate
Calcium	1,200 mg (30 mmol)	5–7.5 mmol
Magnesium	420 mg (17 mmol)	4–10 mmol
Phosphorus	700 mg (23 mmol)	20–40 mmol

[a]Estimated minimal requirements for healthy adults

TABLE 25-3

DAILY VITAMIN REQUIREMENTS

VITAMIN	ENTERAL	PARENTERAL
Thiamin	1.2 mg	6 mg
Riboflavin	1.3 mg	3.6 mg
Niacin	16 mg	40 mg
Folic acid	400 μg	600 μg
Pantothenic acid	5 mg	15 mg
Vitamin B_6	1.7 mg	6 mg
Vitamin B_{12}	2.4 μg	5 μg
Biotin	30 μg	60 μg
Choline	550 mg	Not well defined
Ascorbic acid	90 mg	200 mg
Vitamin A	700–900 μg	1,000 μg
Vitamin D	15 μg	5 μg
Vitamin E	15 mg	10 mg
Vitamin K	90–120 μg	120 μg

TABLE 25-4

DAILY TRACE ELEMENT REQUIREMENTS

TRACE ELEMENT	ENTERAL	PARENTERAL
Chromium	25–35 μg	10–15 μg
Copper	0.9 mg	0.3–0.5 mg
Fluoride	3–4 mg	Not well defined
Iodine	150 μg	Not well defined
Iron	8–18 mg	Not routinely added
Manganese	1.8–2.3 mg	60–100 μg
Molybdenum	45 μg	Not routinely added
Selenium	55 μg	20–60 μg
Zinc	8–11 mg	2.5–5 mg

The PN admixtures are prepared aseptically by a pharmacy from commercially available stock solutions on a daily basis for the ICU patient. Some health care institutions develop standard base formulations that contain amino acids, dextrose, lipids, and possibly water in defined proportions to which the remaining micronutrients are added as clinically necessary and pharmaceutically appropriate. Although somewhat more expensive, parenteral formulations allow the flexibility for meeting patient-specific dosing requirements as stability and compatibility allow. PN formulations can be maximally concentrated as is often necessary in the critically ill patient. The choice of specific EN or PN formulations should also consider the patient's organ function.

PN formulations can be manipulated to closely meet a patient's requirements.

Micronutrients

The dosing of electrolytes, vitamins, and trace elements for critically ill adult patients follows general guidelines for the use of nutrient therapy available in the literature.[22] Tables 25-2–25-4 provide guidelines for dosing micronutrients. For enteral dosing, the adult recommended dietary allowance/adequate intake levels established by the Institute of Medicine are used as an initial guide, although they are intended for otherwise healthy individuals obtaining nutrients from a mixed oral diet and vary with age and gender. Commercially available EN formulations contain fixed micronutrient levels that often meet the guidelines when administered in volumes of 1–2 L daily. Parenteral dosing guidelines are intended for patients with increased requirements. The dosing level for nearly each micronutrient in a PN formulation can be altered if clinically necessary. Individual patient requirements may vary with clinical condition and monitoring parameters.

Micronutrient dosing is based on published guidelines.

Specific nutrients may have a role in modulating the injury response at pharmacologic doses in subgroups of the critically ill patients.

EN products may contain a greater variety of nutrients than do PN formulations.

Overall nutrient composition differs between EN and PN, with the latter being far from complete. The EN products are much more comprehensive in included nutrients. For example, intravenous lipid products used in the United States for making PN consist of soybean oil, which contains significant amounts of ω6 fatty acids, considered to be immunosuppressive and enhancers of the stress response, and very low amounts of ω3 fatty acids. In contrast, EN formulations may contain a better balance of ω6 and ω3 fatty acids, which may dampen the response to injury and limit immunosuppression. The clinically relevant ratio or dose of each class of fatty acid is not yet clear.

Other

The complex and beneficial interactions between the GI flora and human tissues including the mucosal surfaces are still incompletely understood. However, there is growing interest in prebiotics and probiotics for patient care.

Prebiotics, in the form of soluble plant fibers (e.g., pectins, gums, fructo-oligosaccharides) are indigestible making them a useful substrate for microbial fermentation in the lower GI tract. Additionally, most prebiotics delay gastric emptying and intestinal transit time. Some research has shown positive benefits of supplementing surgical patients with a mix of several different fibers given the quick and significant reduction of commensal flora that occurs in their management. Caution is necessary in the patient who has received antimicrobials or in whom abdominal distension may be contraindicated. A few EN products

CASE STUDY: PART 5

On POD 5, the patient went to the OR the previous day for open drainage of intraabdominal fluid collections (identified on CT scan). Intestinal tissue appeared healthy without anastomotic leak. A dual-lumen, nasojejunal feeding tube was placed intraoperatively above the anastomosis to replace the nasogastric tube. Clinical improvement continued postoperatively, weaning down requirements for norepinephrine; dexmedetomidine was discontinued as ventilatory status improved.

- Vital signs: T_m, 100°F; BP, 105/70; HR, 85/min; PAOP, 14 mmHg; CI, 3.2 L/min; SVR, 920 dyne · s/cm^5.
- Pertinent findings: nasogastric output below 600 mL, abdomen less distended, patient noted to pass flatus, urine output continues to improve, in/out 3,600/3,200 mL.
- Pertinent lab results: Na, 141 mmol/L; K, 4.2 mmol/L; Cl, 108 mmol/L; CO_2, 22 mmol/L; BUN, 20 mg/dL (UUN 13); Cr, 1.2 mg/dL; glucose, 180 mg/dL; Mg, 2.1 mg/dL; P, 2.4 mg/dL; Ca, 7.7 mg/dL; WBC, 12–14 K/mm^3.
- Nutrition assessment/plan: The patient has improved clinically, and is less catabolic, based on a catabolic index of 1.5. Although the patient is still unable to initiate an oral diet, an attempt at initiating EN is practical at this time. The enteral access device placed allows small bowel feeding with simultaneous gastric decompression. PN will continue to meet the patient's needs until tolerance of EN can be determined. A concentrated, polymeric formula (1.2 kcal/mL, 65 g protein/L) is initiated at 20-mL/h via the nasojejunal tube. The administration rate may be advanced to 40 mL/h after 8 h in the absence of nausea, vomiting, increased intragastric volumes, abdominal distension, cramps, or diarrhea. The patient may be advanced to the goal administration rate of 70 mL/h (providing 1,680 mL total volume, 2,016 kcal and 109 g protein). The goal will only provide about 1,350 mL of free water; the remaining 850 mL can be provided by IV fluids and/or water flushes via the tube.

contain prebiotics in low amounts, but more often they are administered independently as a medication, typically limited to the management of a critically ill patient's bowel regimen.

Probiotics are live, nonpathogenic microorganisms (bacteria or yeast) including lactic acid bacteria (e.g., *Lactobacillus* sp) and *Bifidobacterium* sp. They are intended to maintain or replenish the body's gut flora in order to support GI and immune function. Only a few specific species and strains have been studied and are not usually contained in the products available for use in the U.S. Rare complications of these dietary supplement products include bacteremia and sepsis.

MONITORING NUTRITION THERAPY

Therapeutic and adverse effects of nutrition therapy need to be monitored regularly.

Regardless of the route or rationale for providing a nutrition regimen, such patients must be appropriately monitored. Monitoring is an ongoing process in the critically ill patient receiving nutrition therapy to assess both efficacy and the potential complications of the regimen. Subjective and objective data are collected at baseline and routinely during the course of therapy as dictated by clinical status. Physical findings including vital signs, hemodynamics, and fluid status are readily available, and the status of the GI tract, access devices, and access sites should also be obtained daily. Laboratory findings include a comprehensive metabolic panel at baseline to include serum electrolytes (consider ionized calcium and ionized magnesium if available), serum urea nitrogen, creatinine, glucose, albumin, prealbumin, C-reactive protein, triglycerides, a complete blood count, and INR. Until the patient is stable, obtain serum electrolytes, urea nitrogen, creatinine, and glucose (or fingerstick glucose) on a daily basis. Serum electrolytes should be maintained in the normal range. A weekly serum prealbumin and triglyceride along with body weight is valuable in monitoring the SNS regimen. The arterial blood gas may be used to evaluate $PaCO_2$ as an indicator for excessive caloric dosing with an inability to eliminate the metabolic by-product. Other markers including urinary nitrogen and electrolytes can be obtained as clinically necessary.

Therapeutic Effect

A goal of specialized nutrition therapy is to limit the comorbidity of malnutrition.

The effect on clinical outcome of providing metabolic substrate, or of modulating the injury response with nutrients, in critically ill patients requires further investigation. The general goal is to maintain or improve nutritional status as determined by body weight and serum protein markers, but in the critically ill patient, supporting metabolism during the injury to limit associated morbidity and mortality is the predominant goal. Benefits that are sought in

CASE STUDY: PART 6

POD 7, the patient is resting comfortably while completing his course of antimicrobials. He has been weaned from vasopressors and continuous infusion sedation and analgesia, requiring only intermittent IV doses. A ventilator weaning trial is under way. The patient continues a similar PN formulation at 42 mL/h, while also continuing EN at 55 mL/h.

- Vital signs: T_m, 99°F; BP, 132/84; HR, 94/min; RR, 18/min.
- Pertinent findings: nasogastric output minimal today on intermittent suction; the abdomen is nontender, nondistended; two stools passed yesterday; incisional wound is healing well; urine output is adequate, fluid in/out 2,900/2,500 mL.
- Pertinent lab results: Na, 142 mmol/L; K, 4 mmol/L; Cl, 106 mmol/L; CO_2, 28 mmol/L; BUN, 20 mg/dL; Cr, 1 mg/dL; glucose, 172 mg/dL; Mg, 2.2 mg/dL; P, 2.5 mg/dL; Ca, 7.8 mg/dL; WBC, 10 K/mm^3.
- Nutrition assessment/plan: The patient continues to require nutrition therapy to maintain nutritional status as the inflammatory response resolves. He is tolerating the enteral route, now at 80% of goal dosing. The PN may be discontinued to avoid overfeeding and associated hypercarbia, which may hinder weaning from the ventilator. Once the patient has been successfully extubated, the enteral device may be removed, and the patient may begin a trial of oral soft diet and liquids. If he has no difficulty in swallowing, he can be advanced to a normal healthy diet.

these patients include improved weaning from mechanical ventilation, wound healing, fewer infections, shorter ICU length of stay, and return to oral diet. More specific markers may include a serum prealbumin above 15 mg/dL and a nitrogen balance between 0 and −10 g, although renal dysfunction may falsely elevate both parameters. There appears to be a strong correlation between the C-reactive protein/prealbumin ratio within the first 5 days and the severity of subsequent organ dysfunction: best at <1, worse at >4.

Adverse Effects

Complications of nutrition therapy include mechanical, infectious, metabolic derangement, and GI problems.

Complications can occur with both EN and PN. These complications may be classified as mechanical, infectious, metabolic, or GI. Management of complications is specific to the varied etiologies and patient variables. Safe practice guidelines exist for EN and for PN.[23,24]

The access device used for EN may cause local irritation, be misplaced or become dislodged, alter the risk for aspiration, become clogged, or be involved in GI obstruction. The EN formulations are excellent growth media for microorganisms and care should be taken when preparing, storing, or connecting them for administration. Flushing the tube after interrupting and before restarting the feeds, as well as between each medication administered via the tube will significantly reduce the risk of clogging. Metabolic complications include poor glycemic control, and dehydration often manifests with rising serum sodium and urea nitrogen/creatinine ratio. Patients with severe malnutrition (e.g., >10% weight loss ≤6 months; NPO status >7 days) are particularly at risk for refeeding syndrome. It is characterized by drastic intracellular shifts of potassium, magnesium, and phosphorus, as well as alterations in glucose metabolism and fluid status acutely following reinstitution of feeding (enteral or parenteral) to therapy tissue anabolism. Vitamin deficiencies may also occur, especially thiamin due to its role as a cofactor in carbohydrate metabolism. Paresthisias, convulsion, coma, and cardiac decompensation have also been reported. The nutrition team should be consulted if refeeding risk is noted as therapy needs to be specifically tailored to prevent this sequalae.

The occurrence of refeeding syndrome should be monitored during nutritional therapy in patients with severe undernutrition.

Adverse GI effects include nausea, vomiting, elevated gastric residual volumes, abdominal cramps, bloating, distension, constipation, and diarrhea. Diarrhea is another common condition seen in the critically ill patient during EN, although medication and local infection are the most common cause. Diarrhea may be characterized as bacterial, viral, osmotic, or other. It is typically defined as >500 mL watery stool output in 24 h or greater than 5–7 stools/day. Ruling out drug or infection (e.g., *C. difficile* toxin) should be performed while feeds continue until the testing is complete. If the diarrhea persists despite addressing other potential causes the EN formula should be evaluated. High osmolar tube feeds can be changed to an isotonic one, a fiber-containing formula can be tried to bulk stool (or stopped if contributing to the diarrhea), or an elemental formula can be used for easier gut absorption. If stools described above persist despite changes for 3–5 days, bowel rest is recommended and switching to PN is an option.

Both the mechanical and infectious adverse effects associated with PN result from the intravenous access device and can be significant. Complications include pneumothorax, hemothorax, vascular injury, air emboli, fracture, thrombosis, malposition, and line-related infection. Metabolic complications to be prevented or managed include hypertriglyceridemia (triglycerides >400 mg/dL), hyperglycemia (glucose >150 mg/dL), electrolyte abnormalities, gallbladder stasis, and gut atrophy.

NUTRITIONAL THERAPY FOR SPECIFIC ORGAN DYSFUNCTION

Certain disease states need special nutritional therapy because of altered macro and micronutrient metabolism. Standard formulas for enteral therapy and total PN regimen maybe inappropriate or inadequate in certain specific disease states and may need to be modified accordingly. As such, the dose and profile of proteins, the nonprotein calorie to nitrogen ratio, and the type of fat (medium chain vs. long chain triglyceride) given during nutritional therapy may need to be modified.

RESPIRATORY FAILURE

Undernutrition is common in patients with underlying chronic pulmonary diseases especially when they develop acute respiratory failure. In patients with chronic obstructive pulmonary disease, the incidence of undernutrition has been reported to be between 30 and 40% and as high as 60–70% of COPD patients admitted to the ICU for acute respiratory failure. The causes of undernutrition in COPD patient are multifactorial in part due to poor oral intake and high energy demand of breathing. The normal physiologic response to undernutrition is decrease in oxygen consumption ventilatory demand, and in REE. In contrast, the REE in undernourished COPD patients is usually 15–20% higher than predicted by the Harris-Benedict equation. The observed increase in REE in COPD patients is thought to be due to an increase in ventilatory demand related to thermogenic increased CO_2 production, and increased work of breathing due to inefficient respiratory muscle function or the presence of a chronic inflammatory process. In undernourished COPD patients, tumor necrosis factor α (TNFα) is tenfold higher compared to control healthy subject.[25]

Systemic inflammatory response and increased work of breathing contribute to undernutrition in patients with acute or chronic respiratory failure.

In patients with acute respiratory distress syndrome, the hypermetabolic response due to systemic inflammatory response leads to higher oxygen consumption, and increase ventilatory demand. This hypermetabolic state occurs in the setting of respiratory muscle weakness due to catabolism, and electrolyte abnormalities. Nutritional therapy is essential for weaning from prolonged mechanical ventilation.

Nutritional therapy in patients with respiratory failure and limited ventilatory capacity needs to be tailored to the patients needs. Providing too much calories and higher percentage of carbohydrate as nonprotein calorie energy source may lead to higher CO_2 production and higher ventilatory demand. The large increase in CO_2 production following nutritional repletion may precipitate respiratory distress or hinder successful weaning in patients who have limited ventilatory capacity. Because of respiratory muscle weakness, reduced ventilatory drive, and underlying parenchymal lung disease, patients may not be able to increase their minute ventilation appropriately to maintain normal PCO_2 levels.

The amount of caloric intake has been shown to be more important in increasing VCO_2 than the amount of carbohydrate given. However, some studies showed that when 40% of the caloric intake is provided as fat, carbon dioxide production increased only by 10% in depleted patients and 30% in stressed hypermetabolic patients. If no fat was given, the increase in CO_2 production was twice as high. It is recommended that overfeeding or high carbohydrate diets should be avoided to prevent excessive increase in CO_2 production and ventilatory requirement in patients with respiratory insufficiency. Excessive increase in CO_2 production may precipitate respiratory failure or problems with weaning. As long as the carbohydrate load is less than 50% of the total calories given, it does not appear to result in clinically significant changes in respiratory status.[26,27] Accordingly, there is little to suggest that higher proportion of 50% fat 30% CHO is superior to 50% CHO/30% fat.

Underfeeding and overfeeding should be avoided in patients with acute respiratory failure that require mechanical ventilation to facilitate weaning.

In sepsis associated ARDS, there is emerging data that specialized nutritional support using a combination of low carbohydrate, high fat formulation with antiinflammatory and vasodilatory properties of eicosapentaenoic acid (EPA), GLA, and antioxidants improves lung microvascular permeability, oxygenation, and decreases lung inflammation. In a prospective randomized controlled trial of 146 patients with ARDS due to sepsis, patients were randomized to receive either enteral feeding with diet enriched with EPA and GLA or standard iso-caloric diet at a minimum caloric delivery of 75% of the calculated caloric requirement for at least 4–7 days. There was no difference in the severity of illness between the 2 groups. The patient group that received enteral formula enriched with EPA and GLA had significant improvement in gas exchange parameters starting at day 4 with sustained improvements up to day 7 compared to baseline. In addition, patients fed with EPA and GLA enriched formula had fewer ventilator days (11 vs. 16, $p>0.11$) and decreased ICU days (12.8 vs. 17.5, $p>0.16$) compared to patients fed with standard enteral formula. Moreover, fewer patients in the EPA/GLA group developed new organ failure during the study.[28] Similar beneficial results were obtained in a separate single center trial using similar study design and diet enriched with EPA/GLA. The study included 165 patients with ARDS due to severe sepsis and septic shock who were randomized to receive either enteral diet enriched with EPA/GLA with antioxidants principally vitamin E and C or iso-caloric, iso-nitrogenous standard diet. The patients who received the study diet experienced significant improvements in oxygenation status, more ventilator free days (13.4 ± 1.2 vs. 5.8 ± 1.0, $p<0.001$), and more ICU free days (10.8 ± 1.1 vs. 4.6 ± 0.9, $p<0.001$), and fewer development of new organ dysfunctions. More importantly, the patient who were fed with enriched enteral formula had significant reduction in 28 day mortality compared to patients who received control diet (67.3 vs. 47.9%, $p>0.037$).[21] The absolute mortality reduction was 19.4%. Based on these two randomized, double-blind, placebo controlled trials, the use of early enteral feeding with EPA/GLA enriched formula should be considered in patients with ARDS due to sepsis.

LIVER FAILURE

Protein-calorie malnutrition is common in patients with cirrhosis. The incidence of malnutrition approaches 100% in hospitalized patients with alcoholic liver cirrhosis. In patients with nonalcoholic liver cirrhosis, the incidence of malnutrition has been reported to be between 10 and 40%.[29] In a study of 123 patients with different causes of liver cirrhosis, malnutrition increased mortality by twofold.[30] The liver is crucial in the maintenance of normal coagulation, in the fluid distribution between intracellular and extracelluar body compartments, between interstitial and intravascular space, and in providing adequate nutrients during starvation or stress. Thus, the end result of hepatic injury includes bleeding, edema, hypoperfusion state, metabolic encephalopathy, and if severe, multisystem organ dysfunction. In patients with chronic liver disease, portal hypertension also alters renal electrolyte regulation. Moreover, since the liver is the central organ for nutrient metabolism, macronutrient metabolism is invariably altered.

Liver disease alters glucose, protein, and fat metabolism. Persistent hypoglycemia is a sign of advanced liver disease.

The metabolic changes due to liver disease are complex and the severity of its manifestations is in part due to the severity of the hepatic injury. Except in fulminate hepatic failure, hepatic injury usually results in hyperglycemia due to gluconeogenesis and glucose intolerance from decreased insulin:glucagon ratio, impaired hepatic clearance of cortisol and epinephrine. Persistent hypoglycemia is a poor prognostic sign due to impaired gluconeogenesis and decreased insulin clearance. Protein and fat metabolism are also impaired in patients with liver disease. Structural proteins are used for gluconeogenesis leading to the depletion of protein stores. In addition, there may be an accumulation of aromatic amino acids relative to branched-chain amino acids. These aromatic amino acids (i.e., tryptophan, tyrosine, phenylalynine) in conjunction with elevated ammonia levels may play a role in hepatic encephalopathy.[31,32]

Because of the concern for worsening hepatic encephalopathy, protein restriction was previously an important intervention in hospitalized patients with hepatic encephalopathy. This is no longer recommended since studies have shown that a low protein diet paradoxically produces a plasma amino acid profile similar to patients who were receiving high protein diet.[33] This is thought to be due to poor hepatic glycogen stores and earlier onset of gluconeogenesis during starvation which promotes the breakdown of the skeletal proteins.[34] Therefore, provision of adequate protein has protein sparing effect.

Several enteral and parenteral formulations (Table 25-1) specifically developed for patients with liver cirrhosis and hepatic encephalopathy are commercially available. Both parenteral and enteral formulas are designed to reverse the imbalance of the branch chain amino acid relative to the aromatic amino acids. In a study of hospitalized patients with chronic liver cirrhosis, a modified amino acid PN regimen without lipid emulsion showed significant improvements in hepatic encephalopathy and mortality when compared to concentrated dextrose and neomycin regimen.[35] This study highlights the benefit of nutritional support in patients with liver cirrhosis. Metaanalysis of the use of modified amino acid solutions shortened the duration of the hepatic encephalopathy. However, the effect on mortality was not clear because of contradictory results from the pooled studies. The inclusion of additional data suggested that there was also a reduction in mortality.[36] The current guidelines recommended using whole protein formulae. The current recommended protein intake is 1.2–1.5 g/kg/day with a total calorie of 35–40 kcal/kg/day. Branched-chain amino acid formulae are recommended when the patient developed hepatic encephalopathy while receiving EN. Tube feeding is the recommended route of delivery even in patients with esophageal varices. Placement of percutaneous enteral gastrostomy tube is not recommended due to high risk of complications due to the presence of ascites or varices.

Enteral formulae containing higher concentration of branch chain amino acid is useful in patients who develop hepatic encephalopathy while on whole protein formulae.

Micronutrient deficiency in common in patients with cirrhosis due to poor oral intake or malabsorption. Zinc deficiency is the most common trace element abnormality in patients with hepatic failure. Zinc is important in cerebral function including membrane depolarization, receptor function, and urea synthesis. Cirrhotics exhibit excessive urinary losses, and Zinc supplementation up to 600 mg/day orally has been suggested.[29]

ACUTE RENAL FAILURE

Acute renal failure or acute-on-chronic renal failure is common in critically ill ICU patients. Nutritional therapy in patients with renal failure requires special attention to altered protein metabolism, fluid balance, electrolyte and acid–base abnormalities, and micronutrient deficiency. The aggressiveness of the nutritional therapy is further modified based on whether the patient is receiving dialysis or not. The type of hemofiltration and/or dialysis is also important in tailoring the nutrient prescription since each influences nutrient losses differently. For example, patients receiving peritoneal dialysis may absorb up to 500–800 calories in dextrose from the dialysate. Protein intake can be increased to 1.2 g/kg in patients on hemodialysis and to 1.5–2.5 g/kg for patients who are on peritoneal dialysis. Although patients with acute renal failure are hypercatabolic, the recommended protein intake is 0.6–1.0 g/kg/day in patients with acute renal failure but not on dialysis therapy. In general, their recommended energy intake is 20–30 kcal/kg body weight/day. Dialysis and hemofiltration also increases the loss of micronutrients and water soluble vitamins during dialysis and should be supplemented.

Total protein intake, fluid and electrolyte balance are crucial parameters that need to be adjusted in patients with renal failure.

ACUTE PANCREATITIS

Acute pancreatitis is an inflammatory process of the pancreas that can vary from mild disease to a severe, necrotizing pancreatitis. The two most common causes in adults are gallstones and alcoholism, but it may also be hereditary. It usually manifests as acute upper abdominal pain after eating that then turns into a steady state of pain even without food consumption. This pain can last for days and is usually accompanied by nausea and vomiting, thereby preventing the patient from being able to take oral food. Due to the high percentage of pancreatitis cases that are caused by alcoholism, an accompanying, preexisting state of malnutrition also exists.

This disease also brings on enormous local and systemic inflammatory responses, making the patient extremely hypermetabolic and catabolic. Therefore, it is prudent to examine the patient, determine the disease severity, and proceed with nutrition therapy as recommended. In mild to moderate pancreatitis, nutrition therapy is rarely needed. It responds to short periods of bowel rest, usually 2–7 days with IV fluids and pain management. Once clinical conditions improve, oral intake can often be initiated with clear liquids and advanced to regular diet as tolerated. In severe and/or necrotizing pancreatitis (with or without the need for

Acute severe pancreatitis leads to extreme hypercatabolic state. Early nutritional therapy is advocated.

surgery) early nutrition therapy is being advocated more frequently in order to minimize nutrient deprivation and worsening of preexisting malnutrition.[37] This therapy has typically been of the parenteral route because these patients often have an ileus and to prevent abdominal pain by not stimulating the gut or pancreas. However, emerging evidence has shown that the patient can be fed in the distal jejunum, past the ligament of Treitz as it does not stimulate pancreatic enzyme secretion; therefore, causes little to no pain. Also it is of note that the presence of complications such as pancreatic ascites, fistulas, or partial ileus does not preclude the use of EN. The most important benefit of enteral therapy is its ability to maintain the intestinal barrier, thereby preventing possible bacterial translocation from the gut, which is potentially a major cause of infection in acute pancreatitis. Enteral feeding also decreases other sources of infection such as catheter lines as well as removes complications from pneumothorax, vein thrombosis, and catheter embolism. More prospective, randomized studies are emerging showing that early enteral feeding is safe, more cost-effective, and feasible in many of these patients.[38] Some studies have also shown reductions in hospital stay, duration of illness, severity trend, and a decrease in overall complications.[39,40] An elemental or semielemental formula has been used as this seems to be the best tolerated, but this is not definite at this point and research is still being done on optimal formula selection. The clinician should keep in mind the severe hypermetabolic state of these patients and choose a formula accordingly to meet their increased energy needs. Nutrition therapy should provide ~25–35 kcal/kg/day with the provision of carbohydrate being 3–6 mg/kg/day to prevent other metabolic complications from hyperglycemia. Nutrition therapy should not be advanced if blood sugars are >200 mg/dL. Protein should be provided ~1.2–1.5 g/kg/day with adjustments made for a severe nitrogen balance or if patients have associated renal or hepatic failure at the time of treatment. Fat should remain ~1 g/kg/day. If triglycerides are >400 mg/dL lipid should be removed from PN if this is the route of therapy. If a paralytic ileus exists and PN must be used, it is still recommended to give trophic feeds into the jejunum for its beneficial GI effects.

SUMMARY

Specialized nutrition therapy can play a significant role in managing selected critically ill patients. When appropriate, the nutrition regimen should be optimized in terms of timing, route, and dosing to maximize the benefits and minimize complications. Available nutrition therapy expertise in the institution should be utilized, whether as a formal consulting service or an individual physician, dietitian, nurse, or pharmacist. Regardless of the route or rationale for providing nutrition therapy to critically ill patients, this pharmacotherapeutic modality must be monitored for both therapeutic and adverse effects. Placing nutrition as a priority and being vigilant in its appropriate use may help identify individual patient and population outcomes.

REVIEW QUESTIONS

1. **Physiologic changes in the body in response to injury include**
   - **A.** Increased serum glucagon
   - **B.** Increased serum cortisol
   - **C.** Increased lipolysis
   - **D.** Increased protein catabolism
   - **E.** All of the above

2. **Nutritional therapy is indicated in each of the following ICU patient situations except**
   - **A.** Poor premorbid nutritional status and NPO for 7 days since admission
   - **B.** Adequate premorbid nutritional status and expected to eat within 5 days of admission
   - **C.** Adequate premorbid nutritional status, now with multiple organ dysfunction following extensive small bowel resection
   - **D.** Poor premorbid nutritional status, now ICU day 4 following severe head injury

3. **The best time to initiate nutrition therapy in a burn or trauma patient who is unable to improve the nutritional status on their own is**
   - **A.** Before the patient is hemodynamically stable
   - **B.** Within 48 h of the injury
   - **C.** After 5 days of conventional management
   - **D.** Following completion of any antibiotic regimens

4. The major determinant of the route of administration chosen for nutrition therapy is
- **A.** Function of the GI tract
- **B.** Cost of therapy
- **C.** Anticipated duration of therapy
- **D.** None of the above

5. The appropriate amount of calories to provide empirically in a critically ill patient who has no known glucose or lipid disorders is
- **A.** 2,000–2,200 kcal/day
- **B.** 100–120 kcal/kg
- **C.** 25–35 kcal/kg/day
- **D.** 5–6 kcal/kg/day

6. Which of the following adverse effects may be associated with either enteral or PN therapy?
- **A.** Hyperglycemia
- **B.** Hypokalemia
- **C.** Hypertriglyceridemia
- **D.** Hypomagnesemia
- **E.** All of the above

ANSWERS

1. The answer is E. The typical neurohormonal response of the body during the period of stress or body injury is characterized by increased blood levels of stress hormones, including glucagon and cortisol. Fat is mobilized via lipolysis as an alternative fuel source.
2. The answer is B. In patients with adequate nutritional status, withholding nutritional therapy for a few days has no negative clinical effect, especially if they are expected to eat within a few days. In all other patient situations, such as inpatients who have poor premorbid nutritional status before hospitalization (choice A), those in a hypermetabolic state such as patients with multiorgan dysfunction (C), and patients who are expected to have a protracted recovery, early nutritional therapy is recommended.
3. The answer is B. In patients with severe injury as in multiple trauma, severe burn, or sepsis, nutritional therapy is recommended as soon as hemodynamic stability is achieved.
4. The answer is A. EN is preferred if GI function is intact to maintain gut integrity and prevent bacterial translocation. Moreover, the risks associated with central venous access (infection, thrombosis, bleeding, pain) required for total PN are avoided.
5. The answer is A. In patients who are critically ill, the amount of calories is adjusted higher commensurate with the level of stress. Providing adequate calories promotes the utilization of proteins for rebuilding the body instead of being utilized as a fuel source.
6. The answer is E. Hypokalemia, hypomagnesemia, and hypophosphatemia may occur during the refeeding syndrome or because of inadequate replacement of electrolytes. Hypertriglyceridemia may occur during lipid infusion, especially in patients with diabetes mellitus or pancreatic insufficiency. Hyperglycemia commonly occurs in ICU patients as a result of elevated stress hormones.

CHAPTER 26

JOSEPH CROCETTI, MONTSERRAT DIAZ-ABAD, AND SAMUEL L. KRACHMAN

Oxygen Content, Delivery, and Uptake

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the principal determinants of oxygen content and appreciate the concepts of oxygen delivery and consumption.
- Understand the normal physiologic relationship between oxygen delivery and consumption.
- Understand oxygen supply dependency in critically ill patients.
- Understand goal-directed therapy and the controversies that surround it.

Normal cellular function in the body is critically dependent on oxygen. Therefore, it is important for the body to be able to deliver oxygen to the cells and for the cells to utilize the oxygen once it has arrived. A change in either of these variables could lead to the development of cellular hypoxia and result in end-organ failure and possibly death. In many disease states, changes in oxygen delivery (DO_2) and oxygen consumption ($\dot{V}O_2$) are noted to occur and may be responsible for the clinical presentation of these patients. Meeting the metabolic demands of the cells is, thus, an important component of therapy in the critically ill patient.

CASE STUDY: PART 1

G.C. is a 47-year-old alcoholic college professor who complained of 2 days of shaking chills, fever, cough producing yellow sputum, and left-sided chest pain. Initial examination in the emergency room revealed an acutely appearing man with a respiratory rate of 36 breaths/min, pulse of 122 beats/min, and blood pressure of 90/42 mmHg. His initial chest radiograph showed a left lower lobe infiltrate; arterial blood gas analysis demonstrated a metabolic acidosis and a respiratory alkalosis. His CBC was significant for a WBC of 22.0 with 24% bands and hemoglobin of 10 g/dL. The patient was treated empirically for community-acquired pneumonia with antibiotics and given 2 L of normal saline intravenously.

The critical level of oxygen in normal humans is a P_aO_2 of 20 mmHg.

In disease states, cellular hypoxia occurs at higher values of P_aO_2.

A change in oxygen delivery or consumption can result in cellular hypoxia.

OXYGEN UTILIZATION

At the cellular level, the most efficient means of generating ATP is through oxidative phosphorylation, which is a series of oxidation–reduction reactions in which oxygen serves as the terminal electron acceptor (Fig. 26-1). In the absence of oxygen the cell must depend on glycolysis, which is a very inefficient process to generate ATP, or depend on limited high-energy stores in the body such as creatine phosphate. The critical level of oxygen required by the cells for oxidative phosphorylation is unknown, yet it has been shown that mitochondria can continue to function normally so long as the partial pressure of oxygen (PO_2) is maintained at greater than 0.5 mmHg.[1] In intact animals and in humans, the critical level of oxygen appears to be an arterial PO_2 (P_aO_2) of 20 mmHg, as evidenced by changes in end-organ function and changes in the level of ATP.[2,3] Such findings suggest that humans are able

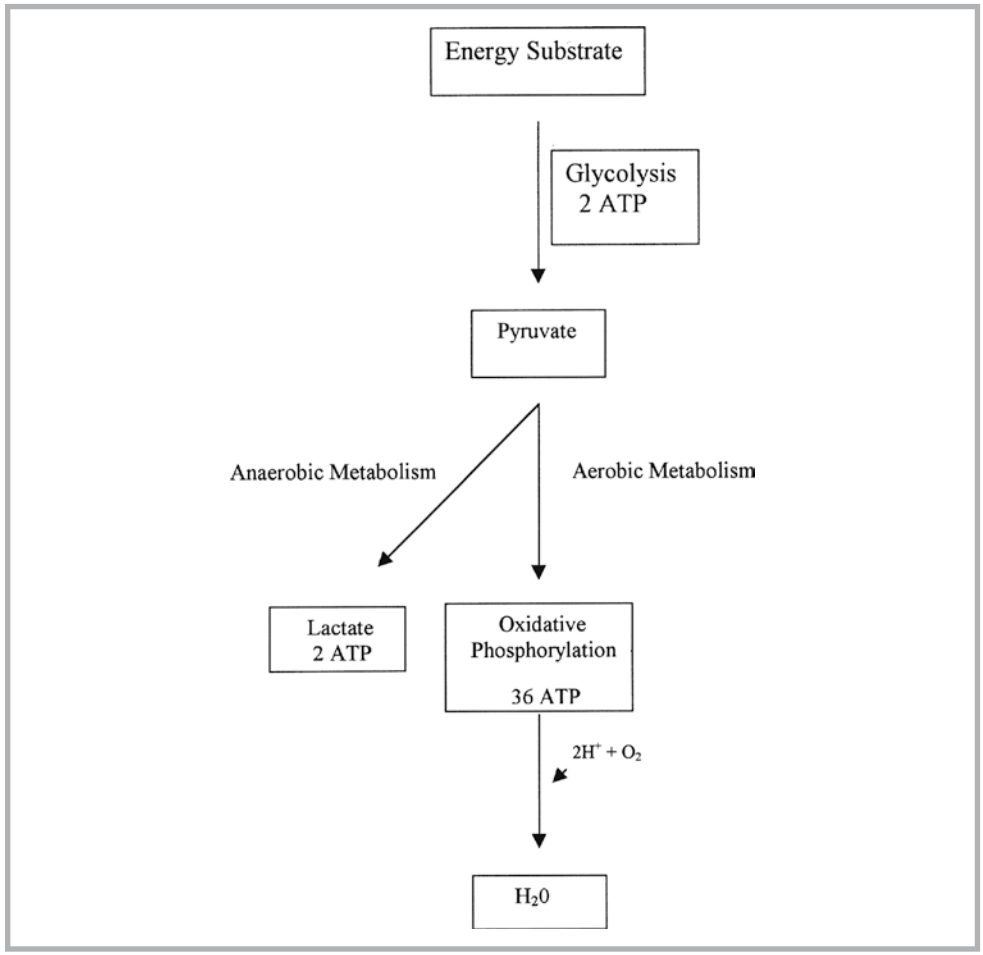

FIGURE 26-1

At the cellular level, the most efficient means of generating ATP is through oxidative phosphorylation, which is a series of oxidation–reduction reactions in which oxygen serves as the terminal electron acceptor. Under anaerobic conditions, pyruvate is converted to lactate, which is a very inefficient mechanism for ATP production.

TABLE 26-1

DISTRIBUTION OF BLOOD FLOW AND OXYGEN UTILIZATION

ORGAN	CARDIAC OUTPUT (L/MIN)	OXYGEN DELIVERY (mL/MIN)	OXYGEN UPTAKE (mL/MIN)	RESISTANCE (mmHG/MIN)
Brain	14	840	52	7
Heart	5	300	34	20
Splanchnic bed	28	1,680	83	3.6
Kidney	23	1,380	19	4.4
Skeletal muscle	16	960	57	6.3
Skin	8	480	12	12.4

to tolerate severe hypoxia before cellular and end-organ dysfunction develop. In disease states such as sepsis or in the acute respiratory distress syndrome (ARDS), however, cellular hypoxia and end-organ dysfunction can occur at much higher levels of P_aO_2, possibly because of the changes in DO_2 and oxygen utilization at a mitochondrial level that occur with these disorders.

OXYGEN REQUIREMENTS OF THE VARIOUS TISSUES

Each organ system in the body has different oxygen requirements that must be met to make it function properly and maintain normal homeostasis (Table 26-1). To meet the oxygen demands of the different organ systems, changes occur in cardiac output and microcirculatory flow. The microcirculatory system consists of the arterioles, capillaries, and the venous system. Although 80% of the blood in circulation is stored in the venous system, local control of DO_2 to the organ systems occurs at two levels: (1) the small muscular arterioles, which are the major resistance vessels in the body and dilate in response to tissue hypoxia and; (2) the precapillary sphincters, which regulate the number of capillaries that are available for gas diffusion into the tissue cells. It would be ideal if we could directly measure the DO_2 to each organ system to ensure that it is adequate. Unfortunately, this is not possible, and at present, we can only obtain measurements of total body DO_2 and $\dot{V}O_2$, thereby indirectly assessing overall body oxygen requirements from these less sensitive and specific values.

OXYGEN CONTENT

The oxygen content of arterial blood (CaO_2) is the sum of two components, the oxygen bound to hemoglobin and the oxygen dissolved in blood:

$$CaO_2 = (1.3 \times Hgb \times SaO_2) + (0.003 \times PaO_2) \quad (26\text{-}1)$$

where Hb is hemoglobin, SaO_2 is the arterial oxygen saturation, and PaO_2 is the arterial partial pressure of oxygen. The first part of the equation states that each 1 g of hemoglobin binds 1.3 mL of oxygen when the hemoglobin is completely saturated ($SaO_2 = 100\%$). The second part of the equation measures the amount of oxygen that is actually dissolved in the blood, which is of the order of 0.003 (mL/dL/mmHg). As can be seen, under normal physiologic conditions the oxygen that is dissolved in the blood contributes little to CaO_2. Most of the oxygen in the blood is bound to hemoglobin, and thus, SaO_2 is the most important blood gas variable for assessing the CaO_2 of arterial blood. Assuming a Hb of 14 g/dL, SaO_2 of 98%, and a PaO_2 of 100 mmHg, CaO_2 (Table 26-2) can be calculated as:

$$CaO_2 = (1.3 \text{ mL/g} \times 14 \text{ g/dL} \times 0.98) + [0.003(\text{mL/dL})/\text{mmHg} \times 100 \text{ mmHg}]$$

$$CaO_2 = 18.1 \text{ mL/dL} \quad (26\text{-}2)$$

TABLE 26-2

OXYGEN DELIVERY AND CONSUMPTION VARIABLES

VARIABLES	EQUATION	NORMAL VALUE
Oxygen content (CaO_2)	$CaO_2 = (1.3 \times Hgb \times SaO_2) \times (0.003 \times PaO_2)$	16–22 mL/dL
Mixed venous content ($C\bar{v}O_2$)	$M\bar{v}O_2 = (1.3 \times Hgb \times S\bar{v}O_2) \times (0.003 \times P\bar{v}O_2)$	12–17 mL/dL
Oxygen delivery (DO_2)	$DO_2 = Q \times CaO_2$	460–650 mL/min
Oxygen uptake ($\dot{V}O_2$)	$\dot{V}O_2 = Q \times (CaO_2 - C\bar{v}O_2)$	96–170 mL/min
Oxygen extraction ratio (O_2ER)	$O_2ER = \dot{V}O_2/DO_2$ $O_2ER = CaO_2 - C\bar{v}O_2/CaO_2$	22–32%
Arterial oxygen tension (PaO_2)	Measured	95 ± 5 mmHg
Arterial saturation (SaO_2)	Measured	97 ± 2%
Mixed venous oxygen tension ($P\bar{v}O_2$)	Measured	40 ± 5 mmHg
Mixed venous saturation ($M\bar{v}O_2$)	Measured	75 ± 5%
Systemic vascular resistance (SVR)	(Mean arterial pressure—central venous pressure)/$Q \times 80$	800–1,200 dyne/s/cm^{-5}
Pulmonary vascular resistance (PVR)	(Mean pulmonary artery pressure—pulmonary wedge pressure)/$Q \times 80$	150–250 dyne/s/m^{-5}

OXYGEN DELIVERY

Global oxygen delivery is calculated as the product of the cardiac output (Q) and the CaO_2:

$$DO_2 = Q \times CaO_2 \text{ or } DO_2 = Q\ (1.3 \times Hgb \times SaO_2) \times 10 \quad (26\text{-}3)$$

where DO_2 is oxygen delivery and Q is cardiac output. The equation is multiplied by 10 to convert volumes percent to mL/min. A DO_2 index (DO_2I) can be calculated by substituting the cardiac index (CI) for the cardiac output, which is simply the cardiac output divided by the body surface area (BSA):

$$DO_2I = Q/BSA \times (1.3 \times Hgb \times SaO_2) \times 10 \quad (26\text{-}4)$$

Assuming a cardiac output of 5 L/min, hemoglobin of 14 g/dL, and SaO_2 of 98%, a normal DO_2 (see Table 26-2) can be calculated as:

$$\begin{aligned} DO_2 &= 5\text{L/min} \times (1.3\text{ mL/g} \times 14\text{ g/dL} \times 0.98) \times 10\text{ (scaling factor)} \\ &= 900\text{ mL/min} \end{aligned} \quad (26\text{-}5)$$

Using a CI of 3 L/min, a normal DO_2I (Table 26-2) can be calculated as:

$$\begin{aligned} DO_2I &= 3\text{L/min/m}^2 \times (1.3\text{mL/g} \times 14\text{ g/dL} \times 0.98) \times 10\text{ (scaling factor)} \\ &= 540\text{ mL/min.m}^2 \end{aligned} \quad (26\text{-}6)$$

Local control of DO_2 occurs at the arterioles and precapillary sphincters.

Most of the oxygen in the blood is bound to hemoglobin.

Thus, from the foregoing equation it can be seen that oxygen delivery is simply the product of three main variables: arterial oxygen saturation, hemoglobin, and cardiac output.

OXYGEN CONSUMPTION

Oxygen consumption is defined as the quantity of oxygen consumed per unit time. Total body $\dot{V}O_2$ can be measured by two different techniques: the reverse Fick equation or indirect calorimetry using a metabolic cart. $\dot{V}O_2$ can be affected by many variables, including fever, anxiety, pain, and shivering, and thus, it is important for the patient to be relatively stable at the time the measurements are obtained.

The indirect Fick equation calculates $\dot{V}O_2$ by using the equation:

$$\dot{V}O_2 = Q\text{ L/min} \times (CaO_2\text{ mL/dL} - C\bar{v}O_2\text{ mL/dL}), \quad (26\text{-}7)$$

where Q is cardiac output and $CaO_2 - C\bar{v}O_2$ is the arteriovenous difference in oxygen content. $C\bar{v}O_2$ is the venous oxygen content [(1.3 ml/g × Hg × $S\bar{v}O_2$%)] and $S\bar{v}O_2$ is the saturation of venous blood. The indirect Fick method is usually employed in critically ill patients through the use of a pulmonary artery catheter. The cardiac output is determined by thermodilution technique. Mixed venous oxygen saturation ($S\bar{v}O_2$) is determined by a blood sample from the distal port of the pulmonary artery catheter; and SaO_2 is obtained by cooximetery. The equation can be rearranged as:

$$\dot{V}O_2 = Q \text{ L/min} \times (1.3 \text{ mL/g} \times \text{Hb g/dL}) \times (SaO_2 - S\bar{v}O_2\%) \quad (26\text{-}8)$$

Using a cardiac output of 5 L/min, hemoglobin of 14 g/dL, SaO_2 of 98%, and $S\bar{v}O_2$ of 75%, a normal $\dot{V}O_2$ (see Table 26-2) can be calculated as

$$\dot{V}O_2 = 5 \text{ L/min} \times (1.3 \text{ mL/g} \times 14 \text{ g/dL}) \times (0.98 - 0.75) \times 10 \text{ (scaling factor)}$$
$$= 244 \text{ mL/min.} \quad (26\text{-}9)$$

The equation is again multiplied by 10 to convert volumes percent to mL/min.

Indirect calorimetry uses a metabolic cart to obtain measurements of expired gas volumes of both O_2 and CO_2, and then calculate $\dot{V}O_2$ according to the formula:

$$\dot{V}O_2 = \left(\frac{1 - F_EO_2 - F_ECO_2)}{1 - F_iO_2} \right) \times F_iO_2 - F_EO_2 \times V_E \quad (26\text{-}10)$$

Oxygen delivery is the product of arterial oxygen saturation, hemoglobin, and cardiac output.

VO_2 can be measured by the reversed Fick equation or by indirect calorimetry.

where F_iO_2 is the fraction of inspired oxygen, F_ECO_2 is the fractional expired CO_2 cocentration, V_I is the inspired minute volume, F_EO_2 is the fractional expired oxygen concentration, and V_E is the expired minute volume. As is discussed later, this method has the advantage of actually measuring rather than calculating $\dot{V}O_2$ as is done using the indirect Fick method. Although indirect calorimetry may be more accurate in obtaining the $\dot{V}O_2$, it is also more cumbersome at the bedside, and thus, is not frequently done in the intensive care unit setting.

OXYGEN EXTRACTION RATIO

The oxygen extraction ratio reflects the tissue's avidity for oxygen.

The oxygen extraction ratio (O_2ER) is the fractional uptake of oxygen by the tissues from the capillary bed, and thus, reflects the tissue's avidity for oxygen. Under normal physiologic conditions, the tissues extract about 25% of the oxygen that is bound to hemoglobin in the circulation. A normal extraction ratio of 25% results in a $S\bar{v}O_2$ of 75%. The extraction ratio can be calculated as:

$$O_2ER = CaO_2 - C\bar{v}O_2/CaO_2 \times 100 \quad (26\text{-}11)$$

$$0.25 = (20 \text{ mL/dL} - 15 \text{ mL/dL})/20 \text{ mL/dL} \quad (26\text{-}12)$$

where O_2ER is oxygen extraction ratio, CaO_2 is arterial oxygen content, and $C\bar{v}O_2$ is venous oxygen content. Another equation that can be used to calculate the oxygen extraction ratio is

$$O_2ER = \dot{V}O_2/DO_2 \times 100 \quad (26\text{-}13)$$

If a normal $\dot{V}O_2$ of 250 (mL/min)/m^2 and DO_2 of 1,000 (mL/min)/m^2 are assumed, a normal oxygen extraction ratio (Table 26-2) can be calculated as

$$O_2ER = 250 \text{ (mL/min)/m}^2/1000 \text{ (mL/min)/m}^2 \times 100$$
$$O_2ER = 0.25 \text{ (mL/min)/m}^2. \quad (26\text{-}14)$$

CASE STUDY: PART 2

Despite volume resuscitation, the patient developed worsening hypotension with a blood pressure of 70/40 mm/Hg. The patient's urine output decreased, and his work of breathing increased requiring mechanical ventilation. A central venous catheter was placed, which showed a central venous pressure (CVP) of 5 mm/Hg. The patient was given another 2 L of normal saline, and despite an increase in the CVP to 10 mm/Hg, the patient remained hypotensive with a blood pressure of 75/55 mm/Hg (MAP=62 mm/Hg). The patient was then placed on norepinephrine starting at 2 μg/min, with an increase in blood pressure to 110/70 mmHg (MAP=83 mm/Hg).

NORMAL PHYSIOLOGIC RELATIONSHIP BETWEEN DO_2 AND $\dot{V}O_2$

Under normal conditions, DO_2 is determined by the oxygen requirements of the tissue cells, and thus, their $\dot{V}O_2$. Increases in cellular metabolic demand, as seen during exercise, are met by increases in both cardiac output and local perfusion to the associated organs. At maximal exercise, DO_2 can increase to 4–5 times the resting level.[4] This increase in DO_2 may not be sufficient to meet the cellular demands for oxygen, however, with increases to as high as tenfold during maximal exercise.[4] The cells attempt to compensate for this inadequate DO_2 by increasing their oxygen extraction from a basal level of 25% to as high as 80% during maximal exercise, but at some point the oxygen demands of the cells can no longer be met and anaerobic metabolism begins. This point is referred to as the anaerobic threshold, and in normal individuals it can occur when $\dot{V}O_2$ is as low as 40% of maximum.[5] The inefficient use of anaerobic sources of ATP leads to the production of such byproducts as lactate and the development of a metabolic acidosis. Thus, under normal conditions, $\dot{V}O_2$ is the independent variable with changes in DO_2 occurring in response to the oxygen needs of the tissue.

A different relationship between DO_2 and $\dot{V}O2$ can be observed in situations where DO_2 is the independent variable; this occurs when DO_2 is either decreased, as with anemia, hypoxemia, or decreased cardiac output, or increased, as when cardiac output is increased with inotropic medications. Under these conditions, a biphasic relationship between $\dot{V}O2$ and DO_2 is observed (Fig. 26-2).[6,7] In normal individuals, increases in DO_2 do not result in a significant increase in $\dot{V}O2$ because the cells do not require any additional oxygen. When DO_2 decreases, the cells initially are able to compensate by increasing oxygen extraction to meet their metabolic demands. Yet, as DO_2 decreases further, a point is reached, referred to as the "critical point" (DO_2 crit), where maximal oxygen extraction can no longer meet cell oxygen demands and $\dot{V}O2$ begins to decrease linearly with DO_2; this is referred to as supply dependency.[6,7] In healthy animal models in which DO_2 was slowly decreased, values for DO_2 crit have been found to be 6–10 mL/kg/min.[7]

The anaerobic threshold occurs when the oxygen demands of the cells are no longer being met.

OXYGEN SUPPLY DEPENDENCY IN THE CRITICALLY ILL

The normal biphasic relationship in DO_2 and $\dot{V}O_2$ is not observed in the critically ill.

Impaired O_2 extraction may result from direct endothelial or parenchymal cell injury.

In contrast to normal animals where supply dependency is noted only at very low values of DO_2, critically ill patients with sepsis and ARDS demonstrate supply dependency at much higher levels of DO_2.[8-13] In addition, the normal biphasic relationship between DO_2 and $\dot{V}O_2$ is not observed (Fig. 26-3). A number of mechanisms have been proposed to explain the linear relationship between DO_2 and $\dot{V}O_2$ observed in these patients. One such scheme suggests that the DO_2 crit is much higher than normal in these critically ill patients. Because of their disease state, these patients may not be able to increase DO_2 sufficiently to reach the supply-independent portion of the curve; a point where the increased oxygen demands of the cells can be met. Another explanation proposed for the observed supply dependency is the inability of cells to adequately increase the extraction of oxygen to meet the increased

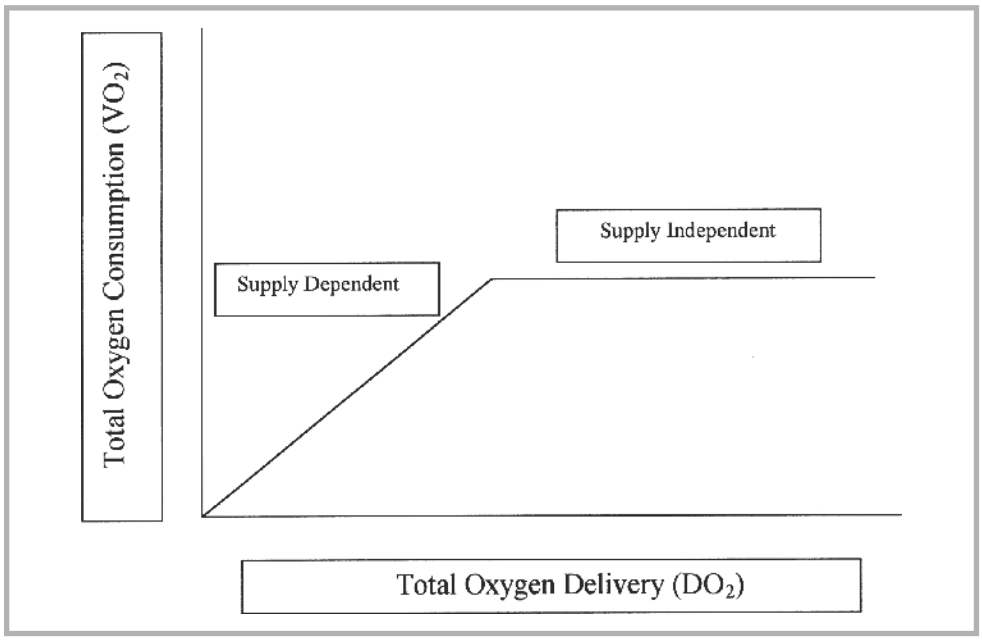

FIGURE 26-2

When DO_2 is the independent variable, $\dot{V}O_2$ remains unchanged in response to an increase in DO_2 (as with inotropic medications increasing cardiac output) as the oxygen supply to the cells is already adequate (supply-independent). However, when DO_2 is decreased (as with anemia or a decreased cardiac output), a biphasic response in $\dot{V}O_2$ is observed. Initially, as DO_2 decreases, the cells respond by increasing oxygen extraction to maintain $\dot{V}O_2$. A point is reached at which the cells can no longer increase their extraction of oxygen (critical DO_2), and $\dot{V}O_2$ becomes dependent on DO_2 (supply-dependent).

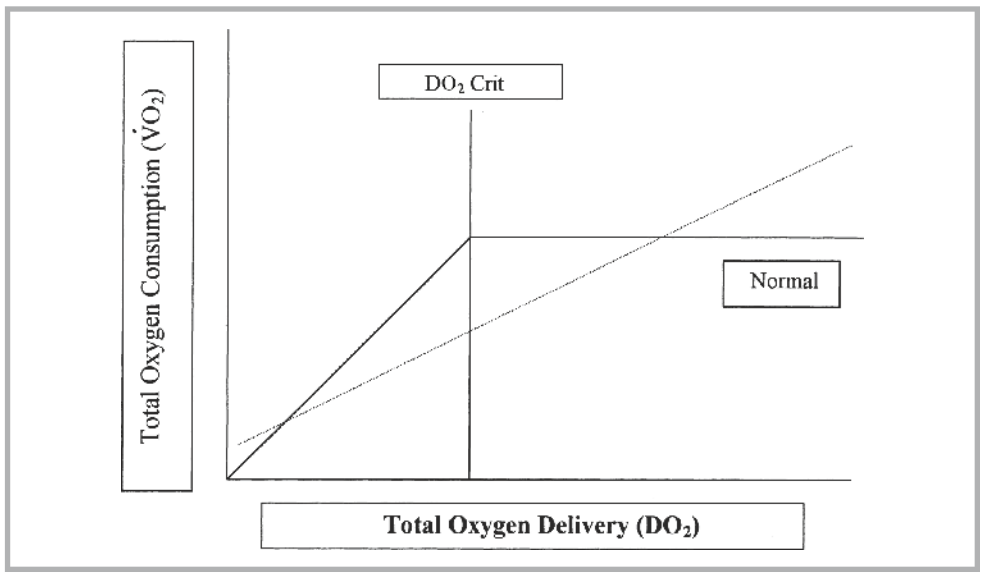

FIGURE 26-3

The *dotted line* represents pathologic supply dependency observed in patients with sepsis or the acute respiratory distress syndrome (ARDS). Oxygen consumption is observed to be continuously dependent on oxygen delivery with no evidence of a critical DO_2, above which a supply-independent state would exist.

demand. In other words, the extraction ratio remains unchanged whether DO_2 increases or decreases, and thus, the relationship between DO_2 and $\dot{V}O_2$ remains linear (Fig. 26-3). This inability to increase oxygen extraction can result from two main mechanisms: (1) alteration in organ blood flow distribution and (2) direct endothelial or parenchymal tissue injury.

Alteration in Blood Flow Distribution

An altered blood flow to the capillary beds could produce changes in the $DO_2 - \dot{V}O_2$ relationship similar to that observed in sepsis by means of several mechanisms, including a redistribution of cardiac output to organs with low oxygen extraction ratios. This change can occur when there is loss of the normal microvascular tone and the major muscular arterioles are no longer able to control blood flow distribution to the organs with the highest oxygen requirements (Fig. 26-4).[14] Changes can also occur in the precapillary sphincters

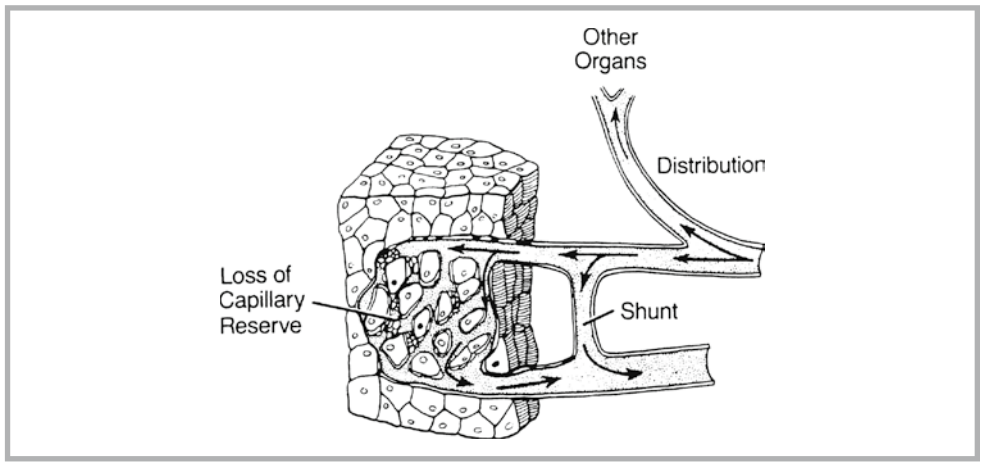

FIGURE 26-4

Alteration in blood flow distribution may lead to a decrease in blood flow to organs with increased oxygen demands, which may contribute to a state of supply dependency (reprinted with permission from ref[14]).

that control local organ blood flow. Despite compelling clinical evidence, neither of the proposed mechanisms for altered organ blood flow has been observed in animal models of septic shock.

Endothelial and Parenchymal Injury

Direct injury to the endothelium can impair the ability of the cells to directly extract oxygen from the blood (Fig. 26-5).[14] This impairment can occur in disease states that cause a systemic inflammatory response, such as sepsis and ARDS. The normal mixed venous oxygen levels observed in these disease states could be explained by this mechanism. Despite an apparently adequate DO_2, the injured endothelium cannot extract the amount of oxygen needed to meet cellular demand. Another proposed mechanism involves direct injury to the parenchymal cells themselves, which may impair oxygen utilization at any level of DO_2.

Studies Demonstrating Oxygen Supply Dependency

Earlier animal studies demonstrated that sepsis, and not isolated lung injury, was responsible for the apparent oxygen supply dependency. In dog models, it was shown that both bacteremia and endotoxemia, but not isolated lung injury, were responsible for the significantly increased DO_2 crit from 7 to 11 mL/kg/min.[15] More importantly, the oxygen extraction ratio at the point where oxygen consumption became supply-dependent fell from 70 to 51% in the bacteremic dogs. This result suggests a problem with end-organ tissue oxygen utilization,

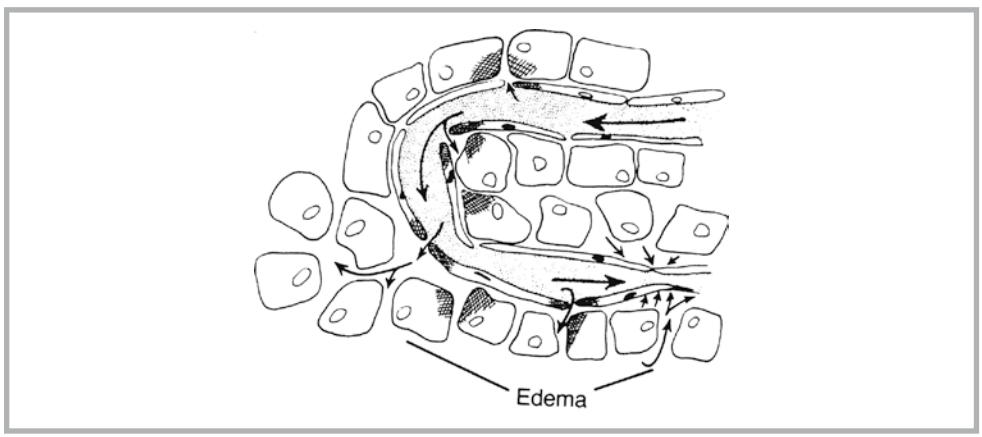

FIGURE 26-5

Oxygen extraction may be impaired secondary to endothelial or parenchymal cell injury, which may lead to a state of supply dependency (reprinted with permission from ref.[14]).

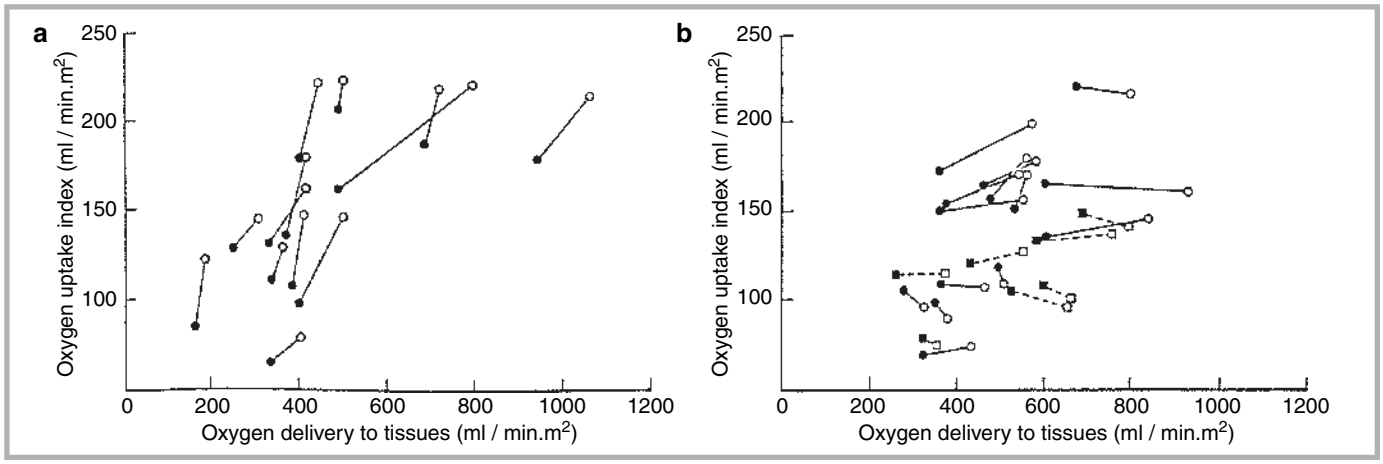

FIGURE 26-6

Effects of prostacyclin infusion on oxygen delivery and oxygen uptake in 27 patients with acute respiratory failure (*circles*) and 7 controls (*squares*). In the 13 patients who died (**a**), there was a significant increase in oxygen uptake in response to an increase in oxygen delivery. A similar increase in oxygen uptake was not seen in those patients who survived, as well as the controls (**b**) (reprinted with permission from ref.[10] ©1987 Massachusetts Medical Society. All rights reserved).

rather than a primary respiratory process. In addition to these animal experiments, there have been numerous studies in patients with respiratory failure and sepsis demonstrating oxygen supply dependency.[8-13]

Bahari et al.[10] studied the effects of increasing DO_2 in 27 critically ill ARDS patients. In those patients who died, there was a significant increase in $\dot{V}O_2$ and O_2ER in response to an increase in DO_2, whereas there was only a small increase in $\dot{V}O_2$ and an actual decrease in O_2ER in those who survived (Fig. 26-6). This finding suggested an existing oxygen debt in those patients who died, with the tissue cells deprived of the required oxygen needed for optimum aerobic metabolism. In contrast, those patients who survived appeared to have adequate oxygen delivery to the cells for aerobic metabolism, and thus, remained on the supply-independent portion of the $DO_2 - \dot{V}O_2$ curve. Other investigators have noted that additional markers suggesting an existing oxygen debt, such as the presence of a metabolic acidosis or increased serum lactate, predicted an oxygen supply-dependent state.[16]

Thus, based on clinical studies suggesting the existence of an oxygen supply-dependent state in critically ill patients, treatment strategies were designed with the aim of increasing DO_2 to supranormal values. It was hoped that by correcting any existing oxygen debt, multisystem organ failure could be prevented and mortality decreased.

GOAL-DIRECTED THERAPY

In the early 1970s, Shoemaker et al.[17] described a group of critically ill surgical patients with improved survival when supranormal values for DO_2 and $\dot{V}O_2$ were observed. Since then, studies have been designed for goal-directed therapy in which DO_2 and $\dot{V}O_2$ are increased to these previously noted supranormal values. This approach is based on three tenets: (1) that critically ill patients die of multisystem organ failure and that tissue hypoxia may be partially responsible for its development; (2) that tissue hypoxia may persist in critically ill patients, despite early resuscitation to normal hemodynamic end points; and (3) that increasing oxygen delivery can reverse tissue hypoxia.

Since this original observation by Shoemaker et al.[17] there have been a number of trials to evaluate goal-directed therapy. Many of the studies that have demonstrated favorable results involved trauma or surgical patients, where supranormal values for DO_2 and $\dot{V}O_2$ were

obtained before hemodynamic compromise or the development of organ dysfunction.[18-21] There is also concern that the improved outcome noted in both surgical and medical patients was based on a post hoc comparison of subgroups of patients who were able to reach supranormal values for DO_2 and $\dot{V}O_2$, regardless of whether they received goal-directed therapy to achieve these supranormal values.[21,22] More recently, Donati et al.[23] examined the effects of goal-directed therapy in a group of patients scheduled for major abdominal surgery. In those patients randomized to the protocol group, O_2ER was maintained at <27%, in addition to a mean arterial pressure >80 mmHg and urine output >0.5 mL/kg/h. While the protocol group demonstrated a decrease in end-organ failure and decreased hospital stay, there was no difference in mortality between the two groups.

There have also been several studies in critically ill medical and surgical patients that failed to demonstrate improvements with goal-directed therapy.[24-26] In fact, in one study the control group actually had a lower mortality than the goal-directed group, in which dobutamine was used to increase DO_2[24] (Fig. 26-7). Of note, in these studies only approximately 60% of the patients were able to reach these supranormal values for DO_2 and $\dot{V}O_2$ with therapy, while some of the control patients were able to meet these goals without intervention. In the largest study, Gattinoni et al.[25] randomized 762 critically ill medical and surgical patients to three groups with different hemodynamic goals: (1) a normal CI group (2.5–3.5 L/min/m^2), (2) a supranormal CI (>4.5 l/min/m^2), and (3) a normal mixed venous oxygen saturation group ($S\bar{v}O_2 \geq 70\%$); 94% of the normal CI group, 45% of the supranormal CI group, and 60% of the normal mixed venous saturation group were able to reach their goals. There was no difference in the survival or the development of organ dysfunction among the groups, even when only those patients who were able to obtain their assigned goals were analyzed.

What may be more important than achieving supranormal values for DO_2 and VO_2 is the timing at which the goal-directed therapy is initiated. In the above studies that have not demonstrated an improved outcome with goal-directed therapy, the protocol was initiated once the patient was in the ICU, often many hours following their admission. Russell et al.[27] examined the differences in DO_2 and VO_2 in survivors vs. nonsurvivors who had initial measurements obtained within 24 h of developing ARDS, often associated with septic shock. Survivors had greater values of DO_2 and VO_2, with the increased DO_2 secondary to an increased stroke volume. None of the survivors developed end-organ failure. More recently, Rivers et al.[28] examined the effects of early goal-directed therapy for 6 h while in the emergency room prior to the admission to the ICU in patients with septic shock. Rather than aiming for supranormal values of DO_2 and VO_2, the protocol involved maximizing the central venous pressure (CVP) to >8 mmHg, and if the mean arterial pressure (MAP) was still less than 65 mmHg, then vasoactive agents were started. Once MAP was stabilized, central

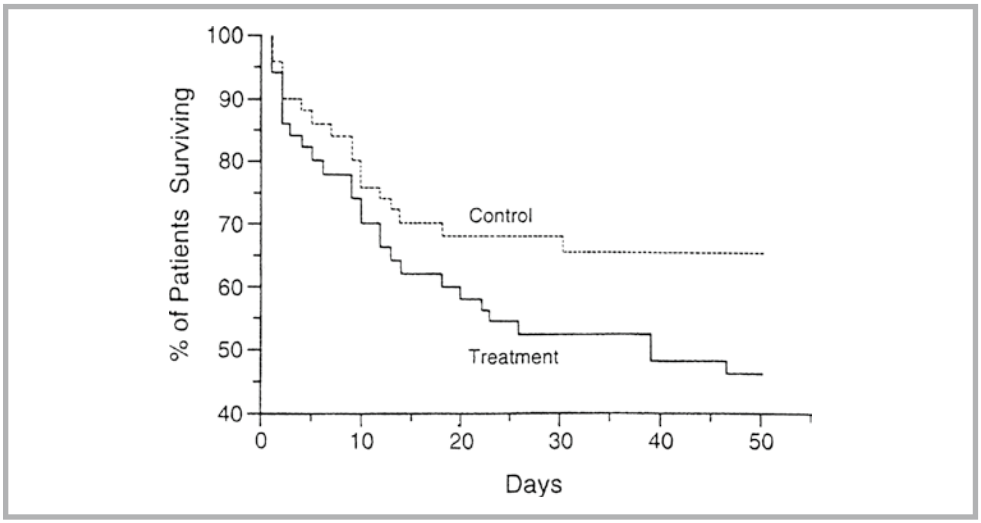

FIGURE 26-7

In-hospital survival was significantly better in the control group compared to the treatment group, which met certain hemodynamic goals in regard to oxygen delivery (reprinted with permission from ref.[24] ©1994 Massachusetts Medical Society. All rights reserved).

venous oxygen saturation was maintained at >70% using red cell transfusions to achieve a hematocirt of at least 30% and inotropic agents as needed. As compared to the control group, the protocol group demonstrated a significant 16% reduction in hospital mortality, as well as a significant difference in requiring mechanical ventilation, need for vasopressors, time in hospital, and overall cost.[28] The combined hemodynamic goals were achieved in 99% of the protocol group as compared to 86% of the control group which received standard therapy. Two more recent single center studies have demonstrated a similar decrease in mortality with early goal-directed therapy when compared to before the protocol was implemented.[29,30] While no difference in survival has been reported with more restrictive transfusions (maintaining a hemoglobin between 7 and 9 g/dL), only 6% of those studied had underlying sepsis.[31]

Early goal-directed therapy has been shown to improve survival in septic shock.

Therefore, in the early stages of septic shock, goal-directed therapy to improve DO_2 appears to be beneficial. However, the length of time that window remains open before detrimental effects are seen with goal-directed therapy remains uncertain. In patients with acute lung injury, a recent study demonstrated that conservative vs. liberal fluid management was associated with improved oxygenation, a shortened need for mechanical ventilation and ICU care, without an increase in end-organ failure.[32] Approximately 25 and 50% of these patients had associated sepsis and pneumonia, respectively. While there was no difference in mortality, these improvements in the secondary outcomes are clinically important, especially as they relate to when the protocol was implemented; an average of 40 h after they were admitted to the ICU, and after they were hemodynamically stable. Therefore, defining a timeline for goal-directed therapy has yet to be determined; with early intervention demonstrating improved survival, while therapy administered later in the course of illness resulting in no improvement or adversely affecting outcome.

The relative lack of success with goal-directed therapy that is not administered early may be partially explained by the results of a study by Ronco et al.[33] These investigators identified the DO_2 crit in nine septic and eight nonseptic patients by measuring DO_2 and $\dot{V}O_2$ as life support was being discontinued. They noted a significantly lower DO_2 crit than that previously found in animal experiments[7] and in humans using pooled data.[6,11] In addition, there was no difference in the DO_2 crit values for those patients with and without sepsis, at 3.8 and 4.5 mL/kg/min, respectively. Those studies that attempted goal-directed therapy[22-26] had patients with baseline values for DO_2 that were much greater than the DO_2 crit noted in the Ronco et al. study.[33] In addition, Ronco et al.[33] noted no difference in the O_2ER at DO_2 crit in those with and without sepsis, at 0.61 and 0.59, respectively, which are values similar to those at maximal exercise.[4] In an earlier study, Krachman et al.[34] were unable to identify a DO_2 crit in patients with ARDS due to sepsis, despite increasing DO_2 by 45% with the use of dobtuamine. These findings suggest that DO_2 is most likely adequate in the majority of critically ill patients, even those with sepsis. In addition, sepsis does not appear to significantly impair the tissue's ability to extract oxygen. Therefore, attempting to increase DO_2 to supranormal levels in all or nonselected critically ill patients to increase $\dot{V}O_2$ may be without benefit.

Increasing DO_2 to supranormal values is without benefit, and may be harmful.

CONTROVERSIES REGARDING OXYGEN SUPPLY DEPENDENCY

The presence of oxygen supply dependency, which has been reported in a number of studies,[8-13] should be interpreted with caution for the following reasons. First, concerns have been raised in regard to the methods used to determine $\dot{V}O_2$, which may produce an artifactual correlation between DO_2 and $\dot{V}O_2$. In many of these studies $\dot{V}O_2$ was calculated using the reverse Fick equation. Therefore, both DO_2 and $\dot{V}O_2$ were calculated using the shared variables of cardiac output and CaO_2. An increase or decrease in either variable could cause DO_2 and $\dot{V}O_2$ to change in the same direction, producing a linear relationship between the two variables and the appearance of a supply-dependent state. Since these

CASE STUDY: PART 3

While maintaining a stable blood pressure on 5 μg/min of norepinephrine, a central venous oxygen saturation was checked by drawing a blood sample from the distal port of the central venous catheter. With a $S\bar{v}O_2$ of 65% and a hematocrit of 24%, the patient was transfused 1 unit of packed red blood cells. Repeat measurements demonstrated a $S\bar{v}O_2$ of 73%, with a hematocrit of 27%. The patient was then transferred from the emergency room to the ICU. The patient's mean arterial pressure stabilized and his urine output increased. Subsequently, his blood cultures grew Pneumococcus and the patient completed a 14-day course of antibiotics for bacteremia and sepsis. The patient was able to be weaned and extubated on the third ICU day and the norepinephrine was eventually weaned off with no significant change in his MAP.

initial studies, investigators have directly compared the $\dot{V}O_2$ obtained with the reverse Fick equation to that measured using a metabolic cart.[35] In all these studies, no correlation was found between the calculated $\dot{V}O_2$ values and those obtained using the metabolic cart. Also, although there appeared to be a supply-dependent state when $\dot{V}O_2$ was calculated using the reverse Fick equation, this was not evident when $\dot{V}O_2$ was measured using the metabolic cart.

Another concern regarding the notion of supply dependency is that under normal conditions, spontaneous changes in O_2 demand result in changes in DO_2, as seen with exercise. In a number of studies involving septic and ARDS patients, data had been collected over a period of time (hours to days) and appeared to demonstrate a supply-dependent state, but this finding may represent only appropriate changes in DO_2 occurring in response to changing O_2 demands.[11] Finally, it should be noted that many of these studies, including those that attempted goal-directed therapy, were conducted without any knowledge of what is a normal DO_2 crit value in either healthy individuals or critically ill patients.

LACTIC ACIDOSIS

In sepsis, the lactate/pyruvate ratio remains unchanged.

Serum lactate is not an accurate marker for anaerobic metabolism in sepsis.

There has also been controversy regarding the significance of lactic acidosis in patients with sepsis. It has been assumed that the increased arterial lactate is the result of a decreased DO_2 and a tissue oxygen debt, resulting in anaerobic metabolism (Fig. 26-1). There is evidence, however, that arterial lactate increases as a result of an increase in glycolysis.[36] Sepsis is characterized by a hypermetabolic state with increased glucose uptake by cells. This increased uptake appears to be mediated by the Glut-1 membrane transporter, which is not insulin dependent. Glut-1 production increases in sepsis, with increased mRNA production for the Glut-1 glucose transporter, a process thought to be mediated by cytokines. The increase in cellular glucose leads to an increase in the production of pyruvate. If the oxidative metabolic pathway is unable to metabolize the increased pyruvate, the cells will convert it to lactate. Thus, unlike an anaerobic state in which the lactate/pyruvate ratio is elevated, in sepsis, it may remain unchanged, with lactate being produced because of an increase in the substrate pyruvate. These findings strongly suggest that arterial lactate is not an accurate marker for the presence of anaerobic metabolism in sepsis.

RECOMMENDATIONS

Initial management involves establishing hemodynamic stability.

The primary objective in the initial management of the critically ill patient is to establish hemodynamic stability, and thus, organ perfusion (Fig. 26-8). Organ perfusion can be gauged by several clinical indexes such as mentation, urinary output, skin perfusion, and blood pressure. When perfusion is subnormal, treatment is targeted at the pathophysiologic cause (i.e., cardiac performance, vascular resistance, or inadequate filling pressure). The initial

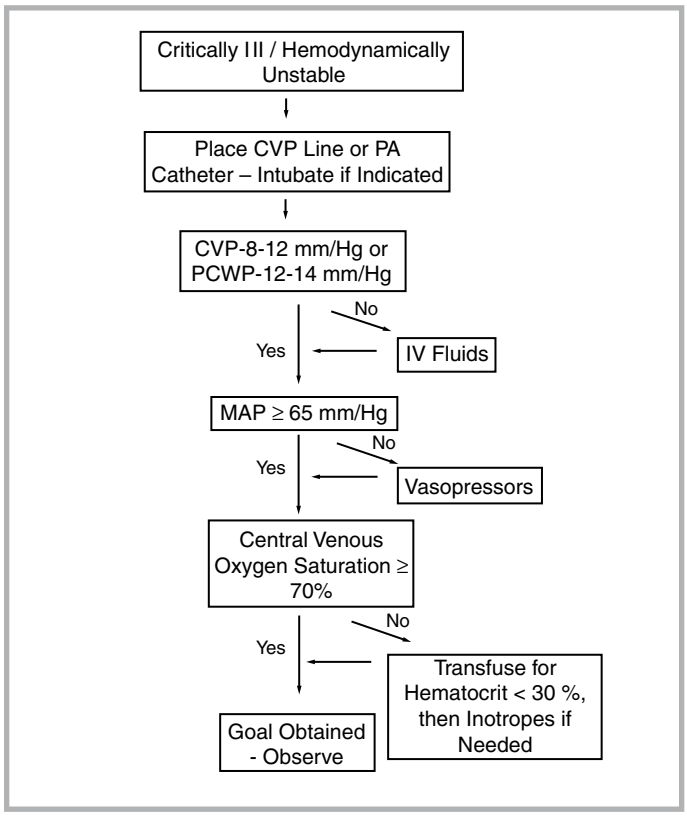

FIGURE 26-8

Algorithm for the treatment of the hemodynamically unstable critically ill patient with sepsis or septic shock using early goal-directed therapy (data from ref.[28]).

treatment for most patients is volume (crystalloid, colloid, or blood), and treatment is guided by the response to therapy, such as increased urine output, improved mentation, and increased mean arterial pressure. For patients with septic shock, early goal-directed therapy should be initiated immediately, often prior to transfer to the ICU. A central venous catheter should be placed, with the initial aim of optimizing the patient's volume status with a CVP of 8–12 mmHg with the use of IV fluids. If the patient's MAP remains low (less than 65 mmHg) despite an adequate filling pressure, vasoactive medications, such as norepinephrine or dopamine, should be initiated. Once the CVP and MAP are normalized, central venous oxygen saturation should be optimized to ≥70% by maintaining a hematocrit of ≥30% and/or the use of inotropic medications. If there is no response to initial therapy and/or there is uncertainty as to the type of shock the patient is in, then placement of a pulmonary artery catheter can be considered. However, a recent study in patients with acute lung injury noted no difference in survival or organ dysfunction in those patients treated with a pulmonary artery vs. central venous catheter, even in those patients who were in shock.[37] However, the complication rate was twice as high, mostly due to dysrhythmias, in the pulmonary artery catheter group.[37] When a pulmonary artery catheter is used, in addition to the pulmonary capillary wedge pressure and cardiac output/index, DO_2 and $\dot{V}O_2$ are among the parameters that can be monitored in these patients during hemodynamic stabilization. Interventions aimed at optimizing DO_2 to values within the normal range should be the goal; this should result in adequate tissue oxygenation and metabolism as measured by O_2ER and $\dot{V}O_2$, respectively. However, the limitations of these measurements should be understood, because they are global measurements and because there are technical concerns in regard to shared variables. While early goal-directed therapy in patients with septic shock, as outlined above, has been shown to improve survival, there are no data to support improved outcome when used after a still undefined time period, or when values for DO_2 and $\dot{V}O_2$ are increased to supranormal values.

No data support the indiscriminate use of goal-directed therapy.

Interventions aimed at optimizing DO_2 to within the normal range should be the goal.

SUMMARY

Adequate oxygen delivery is crucial for normal cellular function. In critically ill patients, the normal relationship between DO_2 and $\dot{V}O_2$ is often disturbed and may be responsible for increased morbidity and mortality. Initial management should include efforts to normalize DO_2 to ensure that oxygen demands are met at the cellular level. In patients with septic shock, early goal-directed therapy is associated with improved survival, although the maximal time period before that benefit is lost has yet to be determined. Therapeutic interventions aimed at increasing DO_2 to supranormal levels in unselected patients have not been shown to improve survival, and may actually worsen outcome. Maintaining hemodynamic stability and treatment of the underlying disease process, thus, remain the primary goals in the management of the critically ill patient.

REVIEW QUESTIONS

1. What is the least important component of oxygen delivery?
- **A.** Hemoglobin
- **B.** Oxygen saturation
- **C.** Oxygen dissolved in blood
- **D.** Cardiac output

2. Which of the following has been associated with improved survival in patients with septic shock?
- **A.** Early goal-directed therapy
- **B.** Placing a pulmonary artery catheter in the patient
- **C.** Decreasing oxygen consumption
- **D.** None of the above

3. The normal physiologic response to an increased oxygen uptake during exercise is to?
- **A.** Increase oxygen delivery by increasing cardiac output
- **B.** Decrease oxygen extraction
- **C.** Increase oxygen content of the blood by hyperventilating
- **D.** All of the above

4. A 47-year-old woman with toxic shock syndrome remains hypotensive despite volume resuscitation with 2 L normal saline. The house staff decides to place a Swan–Ganz catheter; the initial numbers are CVP = 5 mmHg, RAP = 12/7 mmHg, PAP = 13/8 mmHg, PCWP = 8 mmHg, MAP = 40 mmHg, CO = 5.5, and SVR = 509 dyne/s/m^5. The next intervention for hemodynamic support would be to:
- **A.** Add norepinephrine to increase SVR
- **B.** Add dobutamine to increase cardiac output
- **C.** Administer more volume to increase the CVP and PCWP
- **D.** All of the above

ANSWERS

1. The answer is C. The least effective way to increase oxygen delivery (DO_2) is by increasing PaO_2. Recalling the equation for oxygen content as $[CaO_2 = (1.3 \times Hgb \times SaO_2) + (0.003 \times PaO_2)]$, note that PaO_2 contributes little to CaO_2. DO_2 is simply the cardiac output $\times CaO_2$. Thus, SaO_2 and hemoglobin make up most of the CaO_2, and these two variables should be normalized in managing septic patients to ensure an adequate DO_2.

2. The answer is A. Goal-directed therapy, when started early, often before the patient can even be transferred to the ICU, has been associated with improved survival in patients with septic shock. However, increasing DO_2 to supranormal values has not been associated with improved survival, and may actually be detrimental. A recent study has shown no difference in outcome whether a central venous catheter or a pulmonary artery catheter was used in patients with acute lung injury, including those with septic shock. Oxygen consumption would decrease based on cellular demand and cannot be easily manipulated clinically.

3. The answer is A. The normal physiologic response to increasing $\dot{V}O_2$ during exercise is to increase DO_2 by increasing cardiac output up to 4–5-fold that is seen at rest. Increased oxygen extraction occurs when cardiac output is unable to meet the increasing oxygen requirements, with $\dot{V}O_2$ noted to increase up to tenfold at maximal exercise.

4. The answer is C. The following patient has toxic shock syndrome that can manifest with profound circulatory shock. Many of these patients have profound volume depletion secondary to capillary leak and vasculature dilatation, and need large amounts of volume for hemodynamic support. In the following example, the initial 2 L of volume given was not sufficient to stabilize the patient. The numbers obtained from the Swan–Ganz catheter showed that the preload of the left ventricle was suboptimal and that the patient needed more volume. Increasing the CVP to 8–12 mmHg and/or the PCWP to 12–14 mmHg would be recommended in order to see if there is a concomitant increase in the MAP and CO. If increasing

the filling pressures to normal values has no effect on organ perfusion (as evidenced by increases in the MAP, CO, and urine output), then a vasopressor may be indicated.

Initial treatment with norepinephrine in this patient may be effective, but with the suboptimal PCWP, volume infusion would be the recommended first intervention. If there was hemodynamic instability after optimizing the PCWP, norepinephrine may be added. The administration of dobutamine will increase cardiac output, but may also decrease SVR, and for this reason, this would not be the first intervention.

CHAPTER 27

JOHN W. SCHWEIGER, JONATHAN D. DREIER, AND PETER D. RIVERA

Circulatory Shock

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Define circulatory failure.
- Recognize the major mechanisms of circulatory failure.
- Recognize the signs and symptoms of circulatory failure.
- Recognize the different types of circulatory failure.
- Know the major algorithms of circulatory failure treatment.

Circulatory shock represents the final common pathway of cardiovascular failure and manifests as a state of inadequate perfusion relative to tissue demands. Mortality has remained unacceptably high, despite improvement in clinical therapeutics, and remains in the range of 40–50% for critically ill patients with either cardiogenic or septic shock. Shock is characterized by low systemic blood pressure, and dysfunction of key vital organs. The clinical manifestation(s) of shock will vary depending on its nature, severity, and the underlying organ system(s) that are involved. Many aspects of shock, from its classification to its comprehensive treatment, remain somewhat controversial. In this chapter we attempt to cover the most established and agreed- upon principles of the pathophysiology, as well as therapeutic interventions for circulatory failure. We will begin by reviewing the definition and classification of shock, then examine what is known regarding its pathophysiology, and finally provide an overview of the major algorithms for treatment.

Although the clinical manifestations of shock will vary, shock is characterized by low systemic blood pressure, and dysfunction of the patient's vital organs.

DEFINITION OF SHOCK

Shock, by its very nature, remains difficult to define, because of its diverse presentations and the complexity of its pathophysiology. We define shock as a syndrome characterized by an acute, generalized disturbance in the normal perfusion pattern(s) within the body that leads to inadequate delivery of oxygen and metabolic substrates to the vital organs.[1]

CASE STUDY: PART 1

A 68-year-old man (85 kg) presented with a 4-day history of pneumonia. The patient had a limited past medical history which included hypertension (HTN) and benign prostatic hypertrophy (BPH). Over the past several days, he had complained of "an intermittent fever, sporadic chills, and progressive shortness of breath." The patient was treated by his family doctor with a course of oral antibiotics. On the day of presentation, the patient was found to be confused with an acute deterioration in his mental status and was pale and clammy. He was evaluated in the emergency department and found to have a HR=110 beats/min, RR=24, and noninvasive BP=80/60 mmHg. A Foley catheter was inserted and less than 15 ml/h of urine output was noted over the next several hours.

The physical signs and manifestations of circulatory failure depend on the underlying disease and the cause of the shock.

The key features of shock are hypotension, tachycardia, and tissue hypoperfusion.

This imbalance results in an insufficient oxygen supply that progressively fails to meet cellular/tissue requirements and ultimately causes profound dysfunction within critical organs. Classic symptoms of shock include altered mental status, hypotension, secondary tachycardia, oliguria, and hypoperfusion of the extremities. However, the spectrum of symptoms is vast and cannot be limited to those just listed, since a variety of others may present later in the course of the illness (Table 27-1). The clinical presentation of circulatory failure will vary depending on the type of organ failure. For example, metabolic acidosis occurs frequently as a result of anaerobic metabolism and lactic acid accumulate, especially in severe forms of systemic shock. Nevertheless, metabolic acidosis is not pathognomonic for shock, since it may be delayed or muted by compensatory mechanisms until late in the disease process.

PATHOPHYSIOLOGY OF SHOCK

Shock at the cellular level: (1) swelling of endoplasmic reticulum; (2) mitochondrial dysfunction leading to impaired oxidative metabolism.

The pathophysiology of shock is complicated and involves a cascade of neurohumoral and metabolic changes.

Hypoperfusion leads to intracellular hypoxemia followed by anaerobic metabolism. Liposomal disruption is a point of irreversible damage.

The cascade and pathophysiologic mechanisms involved in shock are demonstrated in Figure 27-1. Shock initially affects vital organs by altering their functional and/or structural integrity. Organ failure occurs through two major mechanisms: (1) hypoperfusion and (2) impaired oxidative metabolism. Hypoperfusion seems to be the initiating event leading to decreased delivery of oxygen. Systemic hypoperfusion affects the capillary permeability of cell membranes leading to capillary leak phenomena.[2] These and other changes lead to swelling of the endoplasmic reticulum, which is the initial manifestation of intracellular hypoxemia. The second organelle affected is the mitochondria. The citric acid cycle is no longer able to generate energy properly leading to a net deficit of 36 ATP molecules under anaerobic conditions. Continuous hypoperfusion and oxygen debt lead to progressive mitochondrial swelling. This injury may further potentiate the disruption in oxidative metabolism and worsen the systemic oxygen debt. Eventually, persistent cellular hypoxemia leads to rupture of the liposomal membrane, which releases multiple degradative enzymes into the cell. This likely perpetuates the vicious cycle of intracellular damage ultimately leading to patient death. At the very least, we believe that this process of liposomal disruption signals a point of irreversible damage.

TABLE 27-1

CLINICAL MANIFESTATIONS OF CIRCULATORY FAILURE

ORGAN/SYSTEM	SYMPTOMS
Central nervous system	Mental status changes, tremor, seizures
Heart	Hypotension, tachycardia, chest pain, new murmurs, arrhythmia, ↑JVD
Respiratory	Tachypnea, hypoxemia, ↑WOB
Renal	Oliguria, change in urine color
Gastrointestinal	Nausea, vomiting, diarrhea, ileus
Skin	Cold, clammy extremities

JVD jugular venous distension; *WOB* work of breathing

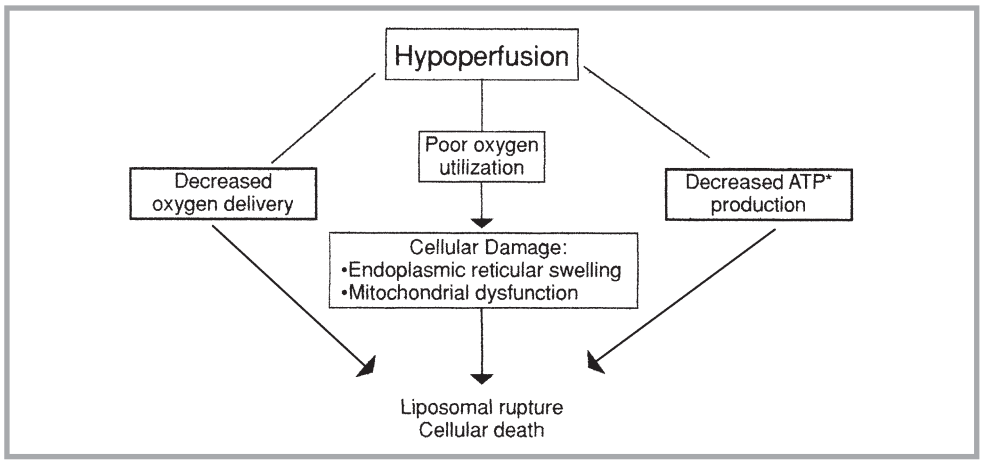

FIGURE 27-1

The key mechanisms and pathophysiology of circulatory failure. The core element of shock is hypoperfusion, which leads to inadequate oxygen delivery, ineffective aerobic metabolism, and eventual cell death (ATP adenosine triphosphate).

Neurohumoral Responses

All biological compensatory responses, including neurohumoral responses, are directed toward protecting the cells within the organs against the cumulative effects of (1) hypovolemia, (2) tissue hypoperfusion, and (3) oxygen debt. In healthy individuals, a moderate decrease in circulating blood volume triggers an increase in afferent impulses from the carotid and aortic baroreceptors and from mechanical receptors within the right atrium. These signals, in turn, lead to activation of the sympathetic nervous system, with reciprocal increases in heart rate, contractility, and peripheral vasoconstriction. Any detectable increase in arteriolar and venous tone will result in a shift of blood volume from the peripheral capacitance vessels inwards to the central circulation. Blood flow will, therefore, be directed away from skeletal muscle beds, subcutaneous tissues, and splanchnic circulation toward the vital organs (e.g., brain, heart, kidneys). This response is potentiated by the release of adrenocorticotropic hormone (ACTH) and antidiuretic hormone (ADH), as well as an increased production of cathecholamines, cortisol, and endothelin. The kidneys respond through activation of the renin-angiotensin-aldosterone system, which not only seeks to maintain blood pressure, but also aids in retention of salt, water, and conservation of circulatory blood volume. In severe hypovolemia, however, these compensatory mechanisms may be overwhelmed, leading to multiple organ dysfunction syndrome (MODS).

The major effect of neurohumoral change is to maintain adequate perfusion status.

Figure 27-2 demonstrates the effects of a variety of hormonal and nonhormonal mediators that are released into the circulation during shock, including bradykinin, beta endorphins,

Hormonal mediators released during shock include bradykinin, beta endorphins, histamine, prostaglandins, myocardial depressant factors, serotonin, and cachexin (tumor necrosis factor/TNF).

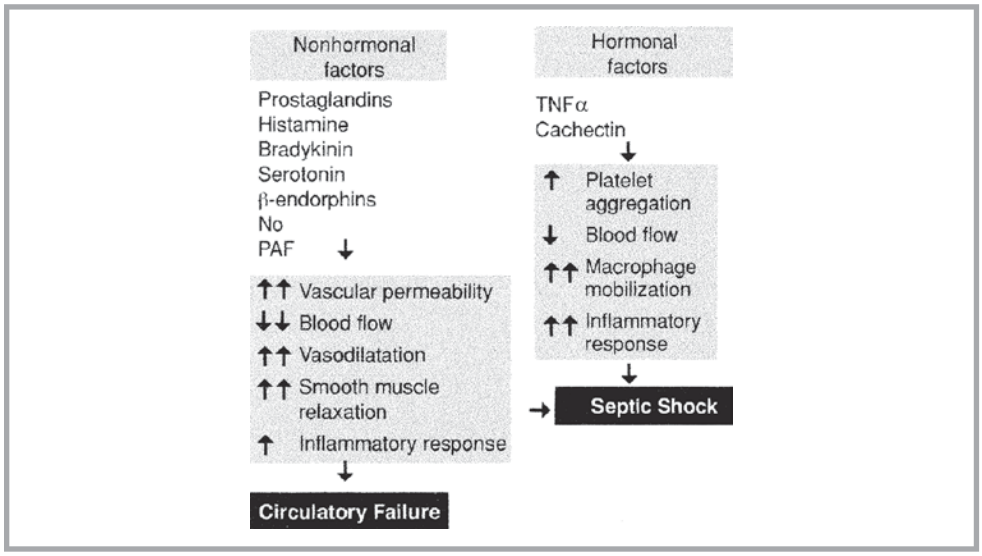

FIGURE 27-2

Hemodynamic, cellular, and inflammatory responses to a variety of hormonal and nonhormonal substances released into the circulation during shock (*NO* nitric oxide; *PAF* platelet-activating factor; *TNF* tumor necrosis factor).

histamine, prostaglandins, myocardial depressant factors, and serotonin. These substances alter blood flow distribution to the organs by increasing vascular wall permeability, and/or by affecting blood flow through enhanced red blood cell (RBC) rheology.[3] Hormones, such as the polypeptide hormone cachexin (tumor necrosis factor), are released from macrophages in response to endotoxemia. These hormones plus platelet-activating factors (PAF) slow blood flow by promoting platelet aggregation and potentiate inflammation through macrophage mobilization. These hormones appear to have a major role in the development of septic shock.

Vasoactive substances released in shock affect blood flow, vascular wall permeability, and inflammatory response.

Nonhormonal vasoactive chemicals, such as nitric oxide (NO), are capable of producing significant vasodilatation and seem to play an important role in the development of shock. NO may be produced by fibroblasts, mast cells, neutrophils, vascular endothelium, smooth muscle cells, and/or platelets. Besides smooth muscle relaxation, which plays an etiologic role in the development of hypotension during circulatory failure, NO also participates in platelet inhibition, the systemic inflammatory response syndrome (SIRS), [4] and neurotransmission.[5] High concentrations of NO, along with precursors and metabolites (e.g., peroxynitrite), have been found in patients with septic shock.

The SIRS is a state of inflammation on the continuum with shock. Criteria include the presence of two or more of the following: (1) HR >90, (2) temperature <36°C or >38°C, (3) RR >20 breaths/min or $PaCO_2$ <32 mmHg, or (4) WBC count <4,000 or >12,000.

Metabolic Responses

Neurohumoral perturbations may lead to very rapid metabolic responses (Fig. 27-3). During stressful states, catecholamine release results in decreased insulin secretion and insulin receptor function, as well as increased glycogenolysis and lipolysis. Glucocorticoids potentiate the effect of the catecholamines and promote gluconeogenesis, which further exacerbates hyperglycemia. Because of limited oxygen availability, hyperglycemia quickly contributes to anaerobic metabolism and lactic acid production. This tends to inhibit gluconeogenesis, and further limits the availability of energy resources for normal cellular function and repair. At some point, ketone bodies and the branched chain amino acids may be used as alternative energy sources. Unfortunately, without adequate oxygen supplementation, these sources become woefully insufficient to meet escalating cellular demands.

Lactic acid accumulation in shock results from limited oxygen availability causing anaerobic metabolism.

Certain types of shock (e.g., septic shock) manifest different metabolic responses within the cellular machinery. In stark contrast to hypovolemic shock, patients with sepsis develop early proteolysis, whereas lipolysis remains relatively inhibited until late in the disease. Specific metabolic responses will be discussed later in this chapter, during our discussion of the different types of circulatory failure.

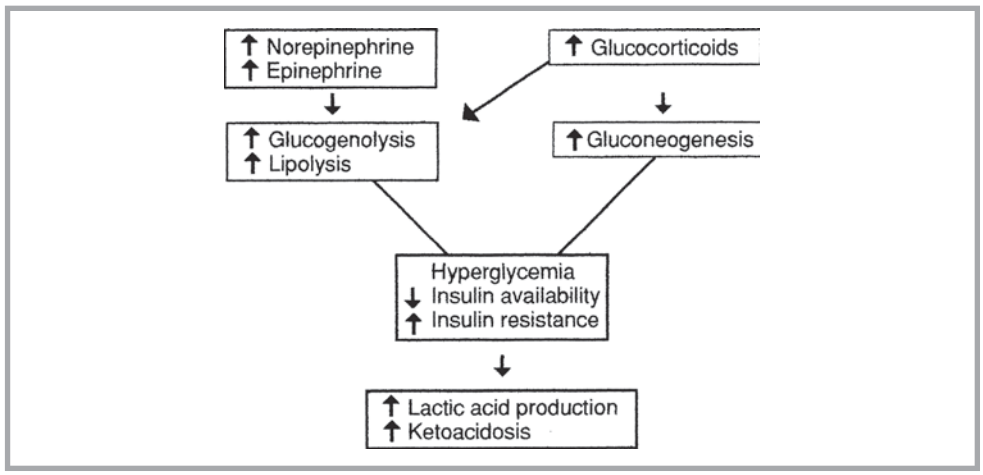

FIGURE 27-3

Major endocrine and metabolic responses in circulatory failure. Decreased insulin availability and progressive resistance of insulin receptors, secondary to enhanced production of glucocorticoids and catecholamines, lead to lactic and ketoacidosis.

CASE STUDY: PART 2

Following presentation, the patient was started on intravenous fluid resuscitation. A pulmonary artery catheter was inserted, revealing an elevated cardiac output (CO), low systemic vascular resistance (SVR), and relatively normal pulmonary artery occlusion pressure (PAOP). After several hours of fluid resuscitation, the patient's BP remained depressed at 70/50-mmHg, while his pulse was dramatically elevated to 150 beats/min, and RR=34. The patient remained anuric and eventually developed acute respiratory failure. An AP portable CXR demonstrated diffuse evidence of pulmonary edema as well as a new right lower lobe infiltrate. The patient subsequently required oral endotracheal intubation, and institution of positive pressure mechanical ventilation.

EFFECTS OF SHOCK ON SPECIFIC ORGANS

Heart

Sympathetic stimulation and hypotension occurring during shock can potentially result in cardiac ischemia.

Systemic shock introduces dual demands for increased myocardial oxygen extraction and increased oxygen delivery. The increased cardiac workload and energy consumption may result from the reflex sympathetic stimulation and peripheral vasoconstriction. These increased metabolic needs require a compensatory increase in the patient's coronary blood flow. Unfortunately, the systemic hypotension associated with many forms of shock tends to compromise coronary perfusion. This decreased perfusion may quickly result in coronary ischemia, regional wall motion abnormalities and, if uncorrected, myocardial necrosis and death. A variety of different chemical substances (e.g., myocardial depressant factor, PAF, and NO) have been reported to be released during shock. These, too, may play a contributory role in the progressive nature of shock. Obviously, any preexisting cardiac disease will tend to make the individual more susceptible to further cardiac dysfunction. CO may also be affected by underlying coronary artery disease, sympathetic stimulation, medication administration (e.g., beta-blocker, calcium channel blocker), systemic hypoxemia, and acidosis. At present, the exact composition of the myocardial depressant factor remains unknown. We hypothesize that it is likely to be a cytokine, prostanoid, or endothelin-derived substance (e.g., NO).

The heart may fail secondary to increased metabolic requirements.

Respiratory System

Shock is often associated with abnormalities in gas exchange (e.g., hypoxemia and hypercarbia), and respiratory mechanics (e.g., tachypnea and labored breathing).

Rapid, shallow breathing in response to the metabolic acidosis of shock can lead to dead space ventilation, pulmonary atelactasis, and CO_2 retention.

Shock is associated with changes in gas exchange (i.e., hypoxemia and hypercarbia), as well as respiratory mechanics. Since metabolic acidosis is one of the hallmark findings associated with shock, it forces the body to compensate via the lung through respiratory alkalosis. A marked increase in minute ventilation (V_E) is customarily achieved thorough tachypnea (↑RR) and increased tidal volume (↑V_T). This dramatic increase in V_E does not always correspond to a similar increase in alveolar ventilation (V_A), since the initial increase in V_T is usually followed by a progressive increase in respiratory rate and decrease in V_T resulting in an increase in dead space ventilation and fall in V_A (e.g., rapid shallow breathing pattern). An inflection point exists (<5 cc/kg) at which the increases in V_E and V_A produced by the increased RR are offset by the subsequent reduction in V_T. This is accelerated in cases of shock that are associated with diminished chest wall (C_{CW}), lung (C_L), and total thoracic wall (C_T) compliance. In fact, as the patient fatigues and begins to breath more rapidly (>35 breath/min), their V_T gradually approaches their anatomical dead space (V_{DS}) volume. When V_T falls below their inherent closing capacity (CC), pulmonary atelectasis will occur. Similarly, when the functional V_T approaches V_{DS}, then dead space ventilation occurs. This can result in retention of carbon dioxide and respiratory acidosis, even though overall V_E is dramatically increased two-to-threefold from the patient's baseline. Dead space ventilation may also be exacerbated

Acute respiratory failure occurs as a result of abnormal gas exchange, and/or impaired respiratory mechanics (e.g., pulmonary/thoracic compliance, increased workload and/or edema formation).

Pulmonary edema is a common cause of acute respiratory failure in shock and results from increased hydrostatic pressure and increased capillary permeability.

by concomitant circulatory failure and systemic hypotension due to a progressive imbalance between ventilation and perfusion.

Hypoperfusion, however, is not the only mechanism which contributes to gas exchange abnormalities. Intrapulmonary shunting frequently manifests when hypoxic pulmonary vasoconstriction (HPV) is overwhelmed within the lung, and perfusion is maintained to areas of poorly ventilated alveoli (i.e., shunt). Acute respiratory failure associated with systemic shock is typically a result of pulmonary edema and/or acute lung injury (ALI). Edema may occur from increased hydrostatic pressures and/or increased capillary permeability. The initial therapy of shock with massive fluid resuscitation or multiple blood transfusions may contribute to the development of pulmonary edema. ALI occurs as a result of inflammatory mediators and intrapulmonary capillary leak. Thus, increased work of breathing secondary to decreased lung compliance and direct impairment of respiratory muscle function is commonly observed in these patients.

Brain

The brain senses decreased perfusion by monitoring CO_2 and O_2 tensions. It autoregulates this perfusion by contraction or dilation of vascular smooth muscle.

Early in the course of shock, the brain function and structure are relatively spared as a result of compensatory mechanisms to protect vital organ function.

The brain is extremely sensitive to changes in perfusion. It depends almost exclusively on its perfusion to match its oxidative metabolic demands. Therefore, compensatory mechanisms are directed toward preserving brain perfusion. Several factors play a key role in regulation of brain perfusion. These factors include regional carbon dioxide and oxygen tensions, and contraction or dilation of vascular smooth muscle in the presence of increased or decreased intravascular pressures. Cerebral autoregulation plays a significant role, but if hypoperfusion continues, compensatory mechanisms may be overwhelmed. These factors may be affected by regional metabolic changes related to circulatory failure, as well as by drug administration and cellular edema. However, irreversible changes in the cellular structure of the brain occur relatively late in the process. Thus, irreversible brain dysfunction may be avoided through timely and appropriate resuscitation measures.

Kidney

Oliguria in shock is caused by hypoperfusion to the kidney, and after a point, is worsened by the body's compensatory mechanisms.

Hypoperfusion is one of the primary causes, but not sole cause of acute renal failure.

Acute renal failure associated with shock is not limited to glomerular dysfunction. More commonly, significant damage occurs at the tubular level. In either case, oliguria remains one of the sentinel manifestations of shock. Hypoperfusion is not the only mechanism attributable to shock-related oliguria, since blood flow to the kidney usually drops to only 40–50% of baseline. Initially, as mean arterial pressure (MAP) decreases, glomerular filtration rate (GFR) is maintained by increases in efferent arteriolar tone. During later stages, additional mechanisms play an important role in the reduction of GFR; these include sympathetic stimulation and release of catecholamines, angiotensin, and prostaglandins. All of these factors, both individually and collectively, contribute to an increased arterial vasoconstriction and redistribution of blood flow away from the renal cortex and toward the medulla (i.e., renal-cortical redistribution/shunt). In addition, there is an increase in salt and fluid reabsorption from the distal tubule secondary to increased aldosterone and ADH production. These compensatory mechanisms preserve intravascular volume, but at the expense of diminished urinary production. Unfortunately, this increase in afferent arteriolar tone eventually results in progressive renal ischemia and acute tubular necrosis (ATN). The pathogenesis of oliguria may be further complicated by the use of exogenous vasoconstrictors (e.g., neosynephrine, norepinephrine) administered to maintain an acceptable systemic blood pressure. These drugs, when used in high doses, have been associated with worsening the ischemic injury to the nephron.

Vasoconstrictors used to maintain BP during shock worsen injury to the nephron.

Three major pathologic mechanisms of tubular dysfunction have been described:

1. Direct tubular necrosis with concomitant poor diffusion of the glomerular filtrate.
2. Tubular damage and obstruction by casts and cellular debris, coupled with the direct cytotoxic effect of substances such as calcium or myoglobin. As a result of tubular epithelial damage, interstitial edema and tubular collapse may occur.
3. Ischemic injury of the tubular apparatus leads to impairment in its concentrating ability, leading to decreases in salt retention and urine osmolarity, which further decrease intravascular osmotic pressure and intravascular volume.

Gastrointestinal Tract, Liver, and Pancreas

Ischemic damage to the gastrointestinal (GI) tract plays a significant role in the pathogenesis of shock. Toxic mediators released from the wall of the damaged GI tract and gram-negative bacteria are able to penetrate the defensive boundaries of the mucosa and contribute to the systemic manifestations of shock.

Injury to the Gut

Ischemic injury associated with hypoperfusion is the major contributor to dysfunction of the GI tract in shock states.

In shock, ischemic injury to the gut lining allows bacteria and bacterial toxins from the gut to gain access to the central circulation.

The earliest manifestations of decreased splanchnic blood flow and ischemia of the gut mucosa are fluid sequestration/interstitial edema, hemorrhage, and/or necrosis of mucosal lining. The most prominent site of ischemic injury within the GI tract is the stomach. Splanchnic hypoperfusion related to shock or the use of vasopressor therapy may contribute to the development of stress ulceration, acalculous cholecystitis, and acute pancreatitis. Patients with underlying atherosclerotic disease of the mesenteric vasculature are especially prone to developing an ischemic injury. As a consequence of progressive systemic and regional hypoperfusion, the gut mucosa breaks down and manifests permeability.[6] This phenomenon allows for the translocation of bacteria (i.e., gram-negative organisms) and/or bacterial toxins within the intestinal lumen to gain entrance to the systemic circulation. These pathogens trigger an immune response known as the SIRS, which plays a pivotal role in MODS and multisystem organ failure (MSOF).

Liver

Ischemic injury to the liver occurs during shock and can be complicated by cholecystitis or biliary obstruction.

Hypoperfusion of the splanchnic system may result in mild-to-moderate transaminitis. Acute, fulminant hepatic failure, however, is not commonly seen. As shock evolves and/or the need for vasopressor therapy becomes necessary, injury to the liver parenchyma may become apparent. A characteristic pattern of centrilobular necrosis frequently is noted on necrobiopsy if the patient succumbs to shock.[7] As mentioned above, early markers of hepatocyte damage/hypoperfusion include the release of hepatic enzymes known as transaminases (e.g., AST, ALT) into the serum. If shock is complicated by acalculous cholecystitis or biliary obstruction, then bilirubin and alkaline phosphatase are commonly elevated. As a result of hepatic injury, Kupffer cells (also known as liver macrophages) are activated and inflammatory mediators will be released. This is to augment hepatic clearance, but often contributes to an increase in serologic markers and vasoactive substances.[8] Individually, or in combination, these factors exacerbate vasodilatation and distributive failure. The reticuloendothelial system (RES) may also be impaired; however, its involvement in shock is variable and not well understood.

Pancreas

Acute pancreatitis can complicate systemic shock, leading to hyperglycemia and release of inflammatory substances.

The pancreas is adversely affected by hypoperfusion, anaerobic metabolism, and mediators of inflammation. The precise role of pancreatic damage in shock remains to be definitively established. However, a strong association exists between systemic shock and the evolution of acute pancreatitis. Both ischemia and infection lead to structural and functional changes within the pancreas. Acute inflammation within the body and tail of the pancreas adversely affects islet cell function, thereby contributing to diminished insulin production and systemic hyperglycemia. These same factors have been hypothesized to contribute to the production of inflammatory and/or vasoactive substances, which may accelerate anaerobic metabolism in the tissue beds.

BLOOD AND COAGULATION

Blood flow within the microcirculation is impaired as a result of shock. There appears to be both a reduction in blood flow, as well as a redistribution of vascular supply. Although the initial derangement of blood flow is seen at the macro level (e.g., arteries, meta-arterioles,

veins, and venules), later perturbations affect the microcirculation. Expression of P-selectin and endothelial adhesion molecules lead to the formation of microaggregates which obstruct blood flow and affect nutrient and oxygen supply through the capillaries. Elevated levels of PAF lead to platelet dysfunction and abnormal platelet activation. Both quantitative abnormalities in platelet numbers and qualitative changes in platelet function are observed. Circulating platelets may be rapidly consumed (e.g., hemorrhagic shock), or sequestered (e.g., anaphylactic or distributive shock); in either case, thrombocytopenia will be the result. Likewise, platelet function may become progressively abnormal as a result of shock, or end-organ dysfunction (e.g., uremia seen with acute renal failure). Thus, platelet adhesion and aggregation are adversely impacted.

DIC is a common feature of septic shock.

DIC leads to clot formation in the microvasculature, compromising blood flow to vital organs and consuming circulating clotting factors.

Disseminated intravascular coagulation (DIC) is caused by microcirculatory stasis and abnormal platelet activation. Once platelet activation occurs, it results in the formation of platelet plugs throughout the microcirculation. As a result of normal coagulation, fibrinogen is activated and cleaved to form fibrin strands, which reinforce the structural integrity of the platelet plugs. Unfortunately, this process takes on a life of its own. Excessive clot formation propagates throughout the microvasculature. This not only results in the consumption of circulating clotting factors, but more importantly, impairs regional blood flow within the vital organs themselves (e.g., adrenal glands, brain, kidney). This phenomenon occurs commonly in septic and anaphylactic shock, and contributes significantly to hypoperfusion of the microcirculation. Eventual damage to the platelet membrane, coupled with the byproducts of fibrinolysis, leads to the release of vasoactive substances (e.g., prostaglandins and PAF). These substances are responsible for many of the clinical manifestations of shock (e.g., bronchospasm, hypotension).

In shock, the oxyhemoglobin dissociation curve usually shifts rightwards. This is seen as a result of the increased hydrogen ion (i.e., lactic metabolic acidosis) and reduction in 2, 3-diphosphoglycerate (DPG). Although most clinicians fear systemic acidosis, there is some inherent logic in the body's adaptation process to mild-to-moderate acidemia. The resultant rightward shift of the oxyhemoglobin curve favors enhanced unloading of oxygen from the RBCs to the cells at the tissue level. Hence, this increase in the availability of oxygen at the cellular level during shock serves as a survival mechanism, and compensates for decreases seen in arterial oxygen content (CaO_2), CO, and oxygen delivery (DO_2).

TYPES OF SHOCK

The four main types of shock are classified as; (1) hypovolemic, (2) cardiogenic, (3) obstructive, and (4) distributive.

Detailed descriptions of the various types of shock are provided in other chapters of this book. Here we discuss the characteristic features that distinguish one form of shock from another. Common hemodynamic patterns of shock are demonstrated in Table 27-2. Circulatory shock can be classified into two broad categories, "hypo"-dynamic and "hyper"-dynamic. The first category, hypodynamic, includes the following subsets: (1) hypovolemic; (2) cardiogenic; and (3) obstructive. The second category, hyperdynamic, is characterized by distributive shock.

TABLE 27-2

COMMON HEMODYNAMIC PROFILES IN CIRCULATORY SHOCK

TYPE	MAP	CO	SVR	PAOP	SVO_2
Hypovolemic	↓	↓ or N	↑	↓	↓
Cardiogenic	↓	↓	↑	↑	↓
Obstructive	↓	↓	↑	↑ or N	↓
Distributive	↓	↑ or N	↓	↓ or N	↑ or N

MAP mean arterial pressure; *CO* cardiac output; *SVR* systemic vascular resistance; *PAOP* pulmonary artery occlusion pressure; *SVO_2* mixed venous oxygen saturation; *N* normal

Hypodynamic Shock

Hypovolemic Shock

Grades of hypovolemic shock:
I – 15% blood volume loss, mild resting tachycardia.
II – 15–30% blood volume loss, moderate tachycardia, slow capillary refill.
III – 30–40% blood volume loss, tachycardia, hypotension, decreased urine output.
IV – 40–50% blood volume loss, above signs, profound hypotension.

Venous return (i.e., preload) to the heart may be inadequate for several reasons. Diminished intravascular volume may result from internal bleeding, overt hemorrhage, profound dehydration, decreased vascular tone, and sepsis. It may also be secondary to increased resistance to venous return, as can occur following obstruction of the inferior or superior vena cava (e.g., superior vena cava syndrome).

Hypovolemia is the most common form of shock caused by decreased venous return. If intravascular volume is decreased, it will lead to a marked decrease in atrial and ventricular filling. Since CO depends on end-diastolic ventricular volume (EDV), it will be reduced in the setting of hypovolemia. Sympathetic stimulation increases catecholamine release which can temporarily compensate for the decrease in EDV by increasing heart rate. In this manner, CO may be preserved for short periods (grade I–III shock). However, once ≥40% of intravascular volume is lost (grade IV shock), sympathetic stimulation can no longer maintain an adequate MAP. Moreover, the decrease in venous capacitance and return to the right side of the heart will manifest in frank shock. After sufficient time and/or severity, irreversible changes will occur in the end-organs. This is seen with the development of the "no reflow" phenomenon. This process implies that neutrophils become adherent to endothelial surfaces and become stagnant.[9] Thus, despite subsequent IV fluid resuscitation, the neutrophils remain adherent and facilitate platelet adhesion. This serves to block the capillary beds, and accelerates progressive tissue hypoxemia.[10] Within myocardial tissue, further damage occurs resulting in cardiac ischemia and the release of systemic mediators of inflammation. After an hour, diastolic dysfunction (i.e., lucitropic dysfunction) develops and further impedes the ability of the ventricles to accept appropriate volume loading. This cascade of events eventually leads to irreversible hypoperfusion, hypotension, and death.

The body's sympathetic response to hypovolemia can no longer preserve MAP once grade IV shock has been reached.

The classic example of hypovolemic shock is seen in blunt and/or penetrating traumatic injuries with concomitant exsanguination. Initially, intravascular volume is profoundly reduced as a consequence of the rapid blood loss. If the patient does not immediately exsanguinate, and if direct or indirect hemostasis is achieved, then redistribution of blood from the periphery to the vital organs is observed. Irrespective of the mechanism of trauma, timely IV resuscitation coupled with effective hemostasis is mandatory for patient survival. In our experience, delayed volume resuscitation (>2 h) or inadequate quantity of resuscitation fluid (e.g., <30 cc/kg of crystalloid for grade III–IV shock) will reduce the likelihood of successful resuscitation. In the event that the patient survives the initial phase of fluid administration and blood transfusion, a significant redistribution of plasma fluid from the intravascular space to the extravascular compartment (i.e., third-spacing of intersitial fluid) may subsequently be seen as a result of SIRS phenomenon.

Rapid loss of intravascular volume leads to marked decreases in atrial and ventricular filling pressures. Hypovolemic shock is caused by decreased venous return.

Survival of hypovolemic shock secondary to blood loss depends upon:
1. The body maintaining homeostasis by redistributing blood to vital organs.
2. Timely and adequate resuscitation.
3. Continued IV hydration to overcome third-spacing of interstitial fluid.

Cardiogenic Shock

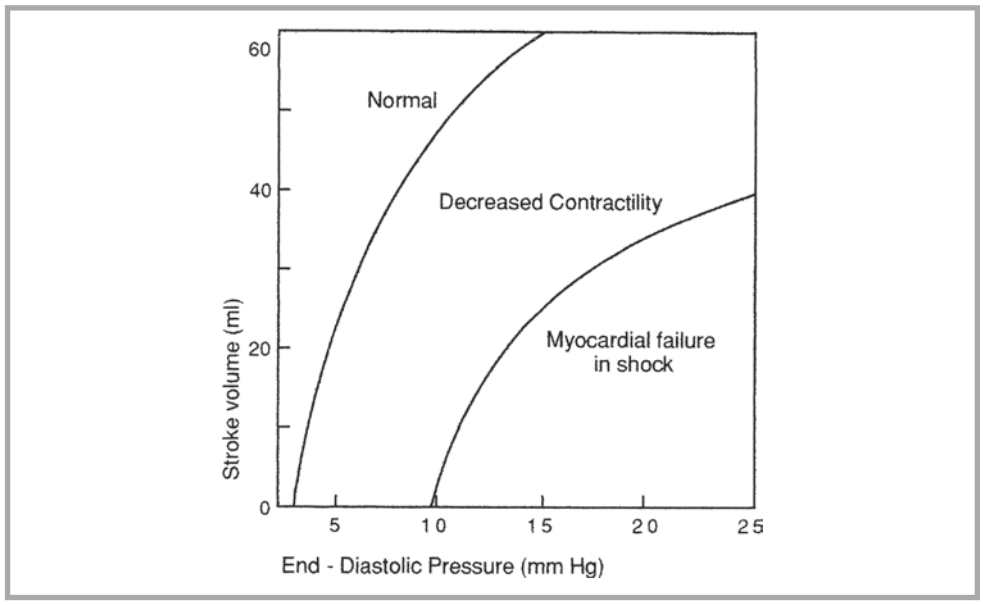
Cardiogenic shock is caused by "myocardial pump" failure. The etiology of cardiogenic shock is diminished (left>right) ventricular contractility.

Signs of cardiogenic shock include: cardiac index <2.2, PAOP ≥18 mmHg, $\downarrow SVO_2$, $\downarrow SaO_2$, and pulmonary edema.

By definition, cardiogenic shock results as a consequence of direct or indirect "myocardial pump" failure. It is defined by the presence of an inappropriately low CO, despite normal or even elevated ventricular filling pressures. Cardiogenic shock can be diagnosed when the cardiac index is less than 2.2 L/min/m^2 and the PAOP ≥18 mmHg. The pathophysiology of cardiogenic shock centers on decreased ventricular contractility, especially of the left ventricle. The end-diastolic pressure/ stroke volume relationship is shifted downward and to the right (Fig. 27-4). Thus, despite similar levels of ventricular preload, the ejection fraction is markedly reduced. As a compensatory mechanism, the ventricle attempts to become more compliant in an effort to increase stroke volume at the same end-diastolic volume/pressure. According to the Frank–Starling relationship, CO should increase in a linear fashion whenever end-diastolic volume (i.e., preload) increases. Eventually, however, there comes a point when the left ventricle is unable to maintain this enhanced workload, even at higher levels of preload. Once this state of "myocardial exhaustion" is reached, left ventricular performance and ultimately CO are adversely affected. The deterioration in cardiac function and

FIGURE 27-4

The Frank–Starling relationship between preload and contractility in normal state vs. circulatory failure. The pathophysiology of cardiogenic shock results from decreased left ventricular contractility. The end-diastolic pressure stroke volume relationship is shifted downward and to the *right;* therefore, despite the same level of ventricular preload, stroke volume must be reduced.



antegrade flow leads to the formation of pulmonary edema (i.e., cardiogenic edema), increased myocardial oxygen consumption (i.e., decreased mixed venous oxygen saturation [$S\bar{v}O_2$]), and then increased intrapulmonary shunt (i.e., decreased arterial oxygen tension [SaO_2]). Arterial desaturation further exacerbates anaerobic metabolism and cellular hypoxemia in the central and peripheral tissue beds, since the reduction in CO is reflected as a significant decrease in systemic oxygen delivery (DO_2).

Cardiogenic shock can be caused by: (1) MI, (2) valvular dysfunction, (3) increased diastolic stiffness, and (4) dysrhythmias.

Myocardial ischemia and/or infarction (MI) are the most common causes of left ventricular failure. Patients who suffer transmural infarction often experience subsequent circulatory shock. It has been estimated that a large myocardial infarction (e.g., ≥ 40% of ventricular mass) puts the patient at risk for cardiogenic shock. Anterior infarction of the left ventricle is more likely than either posterior or inferior infarction to be associated with overt cardiogenic shock.

Certain conditions cause cardiogenic shock by increasing diastolic stiffness; these include myocardial ischemia, pericardial tamponade, prolonged hypovolemic or septic shock, left ventricular hypertrophy, and/or restrictive cardiomyopathy. These states predispose the ventricles to both systolic and diastolic dysfunction. The latter condition, diastolic dysfunction, achieves particular importance when systolic contractility is markedly impaired. Failure of the ventricles to comfortably accept additional volume adversely affects the Frank–Starling compensatory response. Hence, progressive circulatory failure occurs, resulting in hypoperfusion and hypotension.

Valvular pathology (e.g., aortic valve regurgitation or stenosis) frequently leads to left ventricular dysfunction (i.e., low CO states), as well as cardiac rhythm disturbances (i.e., atrial fibrillation).

Valvular dysfunction may also cause LV dysfunction. The most frequent cause of valvular dysfunction is acute mitral regurgitation due to either rupture of the chordae tendinae or malfunction of the papillary muscle. Both occur as an end result of myocardial ischemia. Acute mitral regurgitation does not allow the atria time to compensate and leads to a significant and rapid rise in left atrial pressure, coupled with a reciprocal decrease in left ventricular end-diastolic volume. These changes produce acute pulmonary edema and cardiogenic shock.

Dysrhythmias related to shock:
- PACs and PVCs are related to cardiogenic shock.
- Sinus and supraventricular tachycardias are related to hypovolemic or septic shock.

Cardiac dysrhythmias may be the cause, or the consequence of myocardial hypoperfusion. Premature atrial and ventricular contractions, PACs and PVCs, are commonly seen on telemetry monitors during cardiogenic shock. They reflect ongoing ischemia and injury of myocardial tissue. Sinus and/or supraventricular tachycardia are seen in association with hypovolemic or septic shock. In and of themselves they do not require treatment, but instead serve as an indicator of the overall effectiveness of resuscitation. Ventricular dysrhythmias (e.g., ventricular tachycardia, ventricular fibrillation) mandate immediate attention and intervention. The clinician must quickly rule out the presence of systemic hypoxemia and/or

hypercarbia, which may account for metabolic or respiratory acidemia. Hypoxemia ($\downarrow SaO_2$) and hypercarbia ($\uparrow PaCO_2$) need to be treated immediately with manual or mechanical ventilation and delivery of supplemental oxygen. Next, attention needs to be focused on systemic perfusion pressure. Arterial monitoring needs to be implemented and carefully assessed either by invasive (e.g., arterial line) or noninvasive (e.g., oscillometric) blood pressure devices. Antiarrhythmic therapy (e.g., amiodarone, lidocaine) for ventricular dysrythmias will prove to be unsuccessful in the face of systemic hypotension and myocardial tissue hypoperfusion. Clearly, adequate volume expansion and vasopressor therapy are mandatory to reverse the deleterious effects of low MAP. With regard to the myocardium itself, special attention needs to be placed on the aortic root diastolic pressure, since it determines the perfusion pressure within the myocardial tissue.

Obstructive Shock

Obstructive shock is seen in relation to a variety of disorders (e.g., pulmonary embolism, pericardial tamponade, and tension pneumothorax). The unifying theme in all of these disease states is an outflow obstruction, which impairs ventricular emptying/filling and decreases ventricular compliance. Initially, the resultant increase in cardiac filling pressures may make it difficult to distinguish between obstructive and cardiogenic shock.

Hyperdynamic Shock

Distributive Shock

Distributive shock is defined as any pathologic state that results in a maldistribution of arterial, capillary, and venous blood flow in the absence of primary cardiac dysfunction. Common examples of this type of shock include septic, anaphylactic, and neurogenic (i.e., spinal injury) states, or adrenocortical insufficiency. The unifying theme in each case is paradoxical vasodilation of the capacitance vessels and arterial system. Systemic vasodilation results in a reduction of preload to the atria and ventricles and a reduction in CO, thereby potentially precipitating an imbalance in oxygen supply vs. demand.

All forms of distributive shock result in paradoxical vasodilation leading to diminished preload and CO.

Septic Shock

Septic shock, the most common form of distributive shock, is characterized by a dramatic reduction in arterial vascular tone and a hyperdynamic state with maldistribution of blood flow. The most common causative organisms are gram-negative bacilli, which are etiologically responsible for two thirds of all sepsis cases and for one third of the patients presenting in septic shock. However, gram-positive bacteria are becoming increasingly more common as the causative agents of sepsis and septic shock.[11] Characteristic clinical features of septic shock are hypotension with low diastolic and MAP, narrowed pulse pressure, warm extremities, good capillary refill, and hyperdynamic cardiac contractility. Sepsis is also often associated with fever, tachycardia, and leukocytosis (i.e., SIRS). Two subcategories of septic shock have been described: (1) warm shock and (2) cold shock. The latter is associated with a worse prognosis, since end-organ dysfunction and malperfusion are already well established. Thus, cold shock is much more resistant to therapeutic maneuvers and resuscitation.

Septic shock, frequently caused by the endotoxin released from gram-negative organisms, is the most common type of distributive shock.

Features of septic shock are narrow pulse pressures, warm extremities, good capillary refill, and low MAP. Activated Drotrecogin alpha (Xigris®), a recombinant form of activated protein C, has been shown to reduce 28-day mortality from severe sepsis.

Early in SIRS and/or sepsis, the CO is uniformly increased. This occurs for two reasons. First, the patient's left ventricular afterload and SVR are markedly reduced. Second, the sympathetic nervous system is activated with enhanced release of endogenous catecholamines into the circulation. During the later stages of sepsis and/or septic shock, the clinician may note a disturbing decrease in cardiac performance. Invasive hemodynamic monitoring as well as echocardiography demonstrate that cardiac contractility and CO become progressively depressed. This depression of systolic contractility is a key turning point in the course of septic shock. Impaired myocardial contractility is caused by the inability of the myocytes to extract the oxygen and/or substrates that are necessary for aerobic metabolism. Since the myocardium normally extracts high levels of oxygen from the circulating blood, it is

Septic shock initially results in increased CO, which eventually declines as myocytes become unable to extract sufficient oxygen to meet the high demand.

particularly vulnerable to any imbalance in oxygen supply vs. demand. With the increases in heart rate, stroke volume, and CO that take place during SIRS/sepsis, the demand for oxygen and aerobic metabolism soars. The eventual failure to satisfy this increased demand for aerobic metabolism within the myocardium may result in cellular and systemic metabolic acidosis (i.e., lactic acidosis).

Simultaneously an uncoupling process can be seen at the cellular level. This uncoupling process stems from the mitochondria's inability to appropriately utilize oxygen for oxidative phosphorylation. Hence, even when circulating oxygen levels (CaO_2) remain normal or are elevated, the cellular apparatus is unable to extract or utilize the oxygen.[12] If invasive monitoring is in place, this may observe a notable rise in mixed venous saturation ($S\bar{v}O_2$) at the same time that arterial oxygen saturation (SaO_2) is falling. In sepsis/septic shock, myocardial cellular oxygen utilization is grossly abnormal at the very time when oxygen demand is progressively and rapidly increasing.

Those patients who respond favorably to IV fluid administration have a higher likelihood of surviving septic shock.

Additionally, scientific evidence supports the presence of various myocardial depressant factors, which further impair systolic contractility and cardiac performance, irrespective of oxygen debt. If these patients recover from sepsis, the decreased systolic contractility usually reverses over a period of 5–7 days. The diastolic function of septic shock victims may be predictive of ultimate survival. For example, we have observed that patients who ultimately survive septic shock tend to maintain their diastolic function in a normal range and respond appropriately to IV fluid challenges (i.e., increased preload). In contrast, nonsurvivors of sepsis tend to demonstrate gross abnormalities of diastolic function. Their ventricles do not respond favorably to volume expansion, and demonstrate diastolic dilation. As a consequence, both stroke volume and CO diminish, resulting in a worsening of hypoperfusion and hypotension.

Decreased SVR, along with redistribution of fluid into the interstitial space, compromises venous return (preload) and leads to poor ventricular performance.

Decreased SVR is a hallmark of sepsis. This primarily affects the arterial and capillary vessels, but also impairs venous capacitance. The reduction in vascular resistance in the face of a high CO speaks for a disruption of vasogenic autoregulation. The etiology of this disregulation hinges on a variety of factors including gram-negative endotoxin, aromatic amino acids, prostaglandins, and other vasoactive substances. Redistribution of blood flow from the central circulation toward the periphery (e.g., skeletal muscles) results in venous pooling and decreased venous return. If left unchecked, increased hydrostatic pressure coupled with abnormal vascular permeability (i.e., capillary leak) leads to a redistribution of fluid from the endovascular compartment into the interstitial space. This, too, exacerbates the reduction in venous return mentioned earlier, and further contributes to decreased ventricular performance.

The abnormalities in the integrity of the microcirculatory vasculature contribute markedly to the fluid redistribution seen during septic shock. The microcirculation is affected in several ways by the inflammatory process. For example, an increased number of leukocytes adhere to the endothelial surface, RBC morphology may be altered by acidemia, and clots may form as a result of DIC. Recent evidence has suggested that activated Drotrecogin alpha (Xigris®), a recombinant form of activated protein C, reduces 28-day mortality from severe sepsis.[13] It is hypothesized that its mechanism of action is due to antiinflammatory and cytoprotective effects on the vascular endothelium, which ultimately allows for better blood flow and delivery of nutrients throughout the microcirculation.[14]

Anaphylactic Shock

As a result of antigen-antibody binding, mast cells degranulate and liberate cytotoxic substances. Anaphylactic shock occurs as a result of the effect of these inflammatory and immunologic mediators (e.g., histamine, leukotrienes) on the heart, circulation, and peripheral tissue. Similar to septic shock, CO initially increases as a result of the dramatic reduction in left ventricular afterload and SVR. Blood flow is redistributed to higher capacitance/lower resistance vascular beds, such as those within skeletal muscles. Significant increases in the permeability of the endothelium occur, in part, due to the loss of tight endothelial junctions. This results in a net movement of fluid and protein from the intravascular compartment into the extravascular space. If left unabated, this results in a state of relative hypovolemia within the intravascular compartment. Venous tone and consequently venous

return to the heart are reduced. The rapid reduction in ventricular preload impairs the ability to generate an adequate CO.

IV epinephrine is a rapid-acting and lifesaving intervention that must be given as soon as anaphylactic shock is recognized.

Appropriate treatment requires the rapid restoration of the preload by means of the administration of IV fluids (15–30 cc/kg balanced crystalloid solution) through large-bore peripheral IV access. This must be instituted as soon as possible to avoid catastrophic cardiac arrest. Epinephrine (0.25–1.0 mg IVP) should be immediately administered. Epinephrine provides a potent alpha-agonist effect, which reverses the vasodilation seen during an anaphylactic reaction. The beta-agonist properties of epinephrine play a secondary role in the resuscitation. A beta-agonist is useful if severe bronchoconstriction occurs and results in arterial desaturation, audible wheezing, and high peak airway pressures. The administration of epinephrine should never be delayed in favor of an antihistamine or glucocorticoid. Although each has a role in the eventual management of an allergic reaction, their onset is too slow to be considered useful in the face of life-threatening anaphylaxis.

Only after the aforementioned therapeutic interventions have been instituted and the "A-B-C's" of resuscitation followed, should standard dosages of an H_1-antagonist (e.g., diphenhydramine) and an H_2-antagonists (e.g., famotidine) be given. It is important to emphasize that parenteral steroids should not replace epinephrine during the initial resuscitation and treatment of anaphylactic shock. Many clinicians tend to forget that glucocorticoids, even when administered IV, normally have a time of onset between 6 and 8 h. Much like the advice concerning histamine receptor antagonists, parenteral steroids play a role in the long-term management of inflammation. Therefore, a tapered schedule of hydrocortisone or decadron may be considered, in order to reduce the systemic inflammatory changes, after initial resuscitation efforts have been instituted.

Neurogenic Shock

Unopposed vagal tone resulting from interruption of sympathetic nervous system pathways leads to profound hypotension and bradycardia seen in neurogenic shock.

Neurogenic shock is a less common form of distributive shock. In general, for this type of shock to manifest, neurogenic control and regulation of cardiovascular tone must be impaired. The classic findings are systemic hypotension and profound bradycardia (HR <40). This is very different from most types of shock, since systemic hypotension usually triggers a baroreceptor reflex in the carotid and aortic bodies resulting in reflex tachycardia. Neurogenic shock occurs following interruption of the sympathetic nervous system pathways within the spinal cord. This phenomenon is most pronounced when the cardiac accelerator fibers (i.e., T_1–T_4 level) are interrupted. Cervical spine injury results in unopposed vagal tone which slows the heart rate; at the same time, the lack of sympathetic input from the thoraco-lumbar chain reduces MAP and SVR. Hence, neurogenic shock is most often seen after devastating injuries of the cervical or high thoracic spinal cord with resultant sympatholysis. This phenomenon is often referred to as spinal shock. It occurs within 24–48 h of spinal injury, and tends to resolve within 4–6 weeks.[15] Initial treatment typically requires volume expansion with IV fluid administration and/or parenteral vasoconstrictors (e.g., dopamine, phenylephrine). Dopamine may be preferred since it has both alpha-agonist properties, which raise the MAP, and beta-1 agonist properties that increase the depressed heart rate.

Adrenocortical Shock

Stress-dose steroids should be given to patients with circulatory shock whose cause is even suspected to be adrenocortical in nature.

Certain chronic endocrine conditions may ultimately result in shock. Classically, Addison's disease or crisis (i.e., acute adrenocortical deficiency) may result in shock or may contribute to manifestations of shock.[16] The rapid withdrawal of steroid supplementation in a patient who has received long-term steroid treatment (glucocorticoids > mineralcorticoids) may precipitate an acute hypotensive episode. An ACTH stimulation test may be a useful adjunct for definitive diagnosis. Unfortunately, the acuity of the patient's condition often precludes the ACTH stimulation test. Instead, the pragmatic clinician is forced to draw a random cortisol level, and administers "stress-dose" steroids (e.g., hydrocortisone 100 mg IVP followed by an infusion of 10 mg/h) until the cardiovascular parameters stabilize.

Both hypo- and hyperthyroidism may contribute to sudden and unexpected cardiovascular dysfunction in the ICU. Untreated hypothyroidism may cause marked bradycardia and

hypotension. In contrast, hyperthyroidism or "thyroid storm" frequently results in profound tachycardia and hypertension. A patient with an undiagnosed pheochromocytoma may also present to the ICU in frank shock. The massive release of catecholamines results in profound, often uncontrollable hypertension and tachycardia. Invasive hemodynamic monitoring routinely demonstrates extraordinary increases in vascular afterload and SVR, with a paradoxical reduction in the venous capacitance system (i.e., ↓preload). Even more troubling may be the postoperative patient with pheochromocytoma who has just recently undergone surgical ligation and/or excision of the tumor. These patients routinely become dependent on the large volumes of circulating catecholamines in order to maintain HR and BP. Hence, if they have not been carefully optimized preoperatively with alpha-blockade and IV fluid expansion, their postoperative course can be extremely challenging and their morbidity/mortality unusually high.

TREATMENT OF CIRCULATORY FAILURE

In this chapter we are only able to discuss the general therapeutic approach to circulatory failure and shock. Specific treatment options for individual conditions are discussed elsewhere in this book.

The two major goals of resuscitation from shock are (1) to reverse systemic hypotension and (2) to provide adequate perfusion pressure to the vital organs.

The general goals of therapy in patients with circulatory shock can be summarized as follows: (1) maintain CO and oxygen delivery, (2) reverse systemic hypotension, and (3) correct functional hypovolemia. The clinician must be cognizant that every known therapeutic option has a unique risk-benefit relationship. Moreover, this risk-benefit ratio may vary depending on age, genetic profile, coexisting diseases, etc. For example, aggressive IV fluid resuscitation necessary to sustain MAP in distributive shock may eventually lead to the formation of pulmonary edema. This can occur as a consequence of the increase in capillary permeability throughout the vascular beds, low intravascular oncotic pressure, and increased hydrostatic pressure due to decreased left ventricular contractility.

The cornerstone of initial treatment for circulatory shock should always center on adequate and timely IV fluid resuscitation.

Therapeutic endpoints should be individualized to each particular patient's needs. In general, IV fluid and vasopressor infusion rates should be targeted at maintaining adequate MAP (i.e., 55–60 mmHg). This goal should be attainable and allow for sufficient perfusion of the vital organs (e.g., brain, heart, etc.) without reaching excessive ventricular filling pressure that could predispose to cardiogenic pulmonary edema. Likewise, high-dose vasopressor therapy should not be utilized until adequate preload and volume expansion have been achieved. High-dose vasopressor treatment should be directed toward maintaining an acceptable mean blood pressure within the tissue beds. Unwise titration of vasopressors to artificially high blood pressure measurements has been associated with extremity/digit ischemia, acute renal and hepatic failure, coronary ischemia, and even death.

FLUID THERAPY

Corrected CVP = measured CVP − expiratory change in intraabdominal (bladder) pressure (IABP). (Corrected CVP=measured CVP − ΔIABP).

Our approach to hemodynamic management is summarized in Figure 27-5. If a patient presents with clinical signs and symptoms of hypotension/hypoperfusion, an initial IV fluid challenge of 250–500 mL Ringers lactate or colloid-containing solution should be given over 15 min and repeated as necessary up to 30 mL/kg (i.e., approximately ≥ 2 L for a 70-kg adult). Caution should be exercised in the pediatric population (age < 8 year old), the elderly (age >70 year old), and those with significant comorbid diseases (e.g., congestive heart failure/CHF, diastolic dysfunction). If the mean arterial blood pressure does not respond to this initial therapeutic intervention and there are no clinical or radiographic signs of pulmonary edema, then a central venous pressure (CVP) catheter may be introduced to measure ventricular filling pressures. The clinician may use the CVP catheter to assess the patient's filling pressures, and to draw inferences concerning their ventricular volume status. If the patient remains functionally hypovolemic and the "corrected" CVP is < 8–12 mmHg [17], then

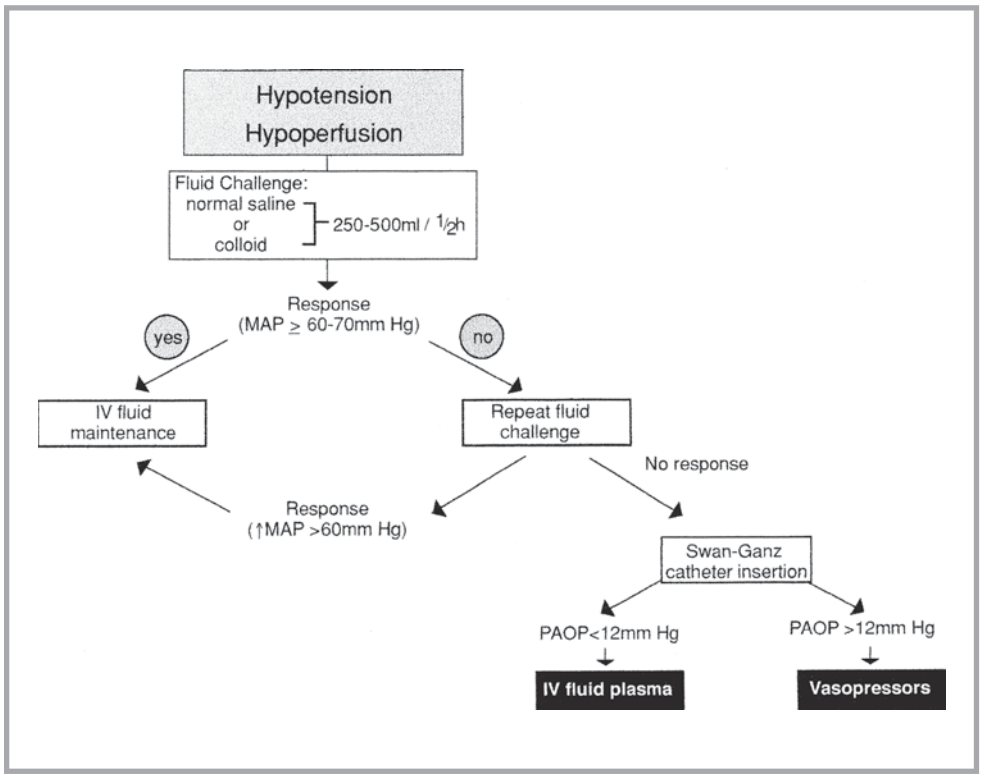


FIGURE 27-5

Hemodynamic management of shock (*MAP* mean arterial pressure; *PAOP* pulmonary artery occlusion pressure).

further IV resuscitation with an appropriate fluid (e.g., Ringer's lactate, albumin, or plasmanate) should be considered.

Transfusion of packed red blood cells (PRBCs) should be reserved for treatment when increased oxygen delivery is needed.[18] They should not be used simply for volume expansion. PRBC transfusion increases the oxygen-carrying capacity of the blood, and enhances oxygen delivery to the tissue beds. Clearly, this becomes essential in the face of severe anemia (i.e., Hgb < 7 g/dL). Despite decades of research and controversy, no one fluid has been proven superior to another in terms of resuscitation.[19] Each fluid choice has attendant pros and cons, and the clinician must weigh these in making an ultimate decision in favor of one or the other. In the final assessment, adequate circulatory volume can be achieved through various modalities. The type of replacement fluid should be selected based on the need for oxygen-carrying capacity, nature of the type of fluid lost from the vascular space, and the acuity of the problem; as well as potential risks of the product itself.

Vasopressor Therapy

If, despite normovolemia (CVP between 8 and 12 mmHg), the patient remains hypotensive, then vasopressor therapy should be instituted. Initially, we usually recommend dopamine at an infusion of >5 μg/kg/min, which should be titrated to a MAP between 55 and 60 mmHg. This range should be sufficient to provide adequate perfusion of vital organs, without many of the deleterious side effects (↑HR, ↓urine output) seen at higher doses. If high-dose dopamine (>15 μg/kg/min) becomes necessary to maintain adequate MAP, and/or there are signs of poor systemic perfusion, then norepinephrine may be added at 2–20 μg/min. Norepinephrine must be titrated with caution to avoid excessive vasoconstriction of the vascular beds in the organs and the peripheral tissue. Vasopressin at a rate of 0.04–0.08 U/min may also be added to enhance the effects of either dopamine or norepinephrine. Since its effect is often synergistic, it may allow for a reduction in the doses of other vasopressors.

For patients in circulatory shock, fluids should be administered until normovolemia is reached (CVP 8–12) and then dopamine infusion (±norepinephrine as needed) should be added to maintain MAP goal of 55–60 mmHg.

Dopamine has long been used for the treatment of cardiogenic shock. In addition, dobutamine and milrinone are inodilators which are frequently utilized to improve cardiac performance and reduce afterload in patients suffering from cardiogenic shock.

In the case where a patient presents in cardiogenic shock (e.g., low CO, high afterload), then inotropic support with an inodilator is necessary. Either dobutamine (2–20 μg/kg/min) or milrinone (initial load of 50 μg/kg over 20 min, followed by 0.375–0.75 μg/kg/min) may be administered by IV infusion and titrated to effect. Both of these agents increase contractility and simultaneously reduce arterial afterload (i.e., vasodilation). They are uniquely beneficial to the failing heart, since they improve forward flow (i.e., cardiac contractility) and diminish systemic vascular resistance (SVR). Thus, cardiac work is minimized and myocardial oxygen supply is optimized.

SUMMARY

Shock is a highly complex pathophysiologic process. It is mediated by a host of different substances that progress down a variety of pathways and cascades; compensatory mechanisms attempt to restore homeostasis. Our understanding of shock has advanced considerably over the past several decades; nevertheless, there are still areas of investigation that need to be pursued. The complexity of shock is exacerbated by its protean manifestations and the plethora of etiologic triggers. A solid understanding of the pathophysiologic mechanisms and the metabolic/humoral responses associated with shock will assist the clinician in choosing appropriate diagnostic tests, monitoring techniques, and therapeutic interventions. The ultimate goal of all of these maneuvers should be the restoration of circulating blood volume and support of adequate perfusion pressure within the vital organs.

REVIEW QUESTIONS

1. The major clinical signs that define "shock" include which of the following *except*:
- **A.** Hypotension
- **B.** Oliguria
- **C.** Tachycardia
- **D.** Fever

2. In the case of septic shock, which of the following substances is/are released by macrophages in response to endotoxemia?
- **A.** Tumor necrosis factor
- **B.** Prostaglandins
- **C.** Serotonin
- **D.** Histamine

3. ALL the following metabolic responses occur during shock, *except*:
- **A.** Glycogenolysis
- **B.** Gluconeogenesis
- **C.** Lactic acid production
- **D.** Increased insulin availability

4. A patient presents to the ICU in florid septic shock. The appropriate initial therapeutic maneuver for this patient should be:
- **A.** IV fluid bolus (15–30 mL/kg)
- **B.** IV dopamine (5–10 mg/kg/min)
- **C.** IV norepinephrine (2–10 μg/min)
- **D.** IV dobutamine (2–12 μg/kg/min)

ANSWERS

1. The answer is D. The major signs of shock – hypotension, oliguria and tachycardia – are caused by severe hypoperfusion of the vital organs, which is the defining pathophysiologic principle of shock. Fever may be present in septic shock, but is not characteristic of other types of shock. In fact, it may not even be seen in "cold" sepsis when the patient will actually present with hypothermia.

2. The answer is A. The major source of tumor necrosis factor is the macrophage. Sources of other vasoactive products listed in this question are platelets, smooth muscle endothelial cells, and mast cells, respectively.

3. The answer is D. Enhanced glycogenolysis and gluconeogenesis occur as a result of the surge in catecholamine and glucocorticoid during the shock state. Insulin production and release usually are insufficient to meet increased metabolic demands. The increase in lactic acid production reflects inadequate oxygen delivery and utilization in shock. Hyperglycemia and metabolic acidosis occur as a consequence.

4. The answer is A. The major pathophysiologic event in shock is hypoperfusion of vital organs. Thus, initial efforts should be directed at restoring adequate intravascular volume (i.e., preload). Parenteral administration of 10–30 mL/kg with a crystalloid solution (Ringer's lactate or normal saline) should always be the initial step in the treatment of septic shock. Vasopressor and/or inotropic support should only be instituted after adequate preload has been established.

Critical Care Neurology

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Recognize the signs and symptoms of selected neurologic conditions, and the approach to diagnosis.
- Discuss treatments used in selected neurologic conditions.
- Appreciate the diverse array of neurologic diseases that may be encountered in the intensive care unit.
- Recognize ethical aspects of selected neurologic disorders.

INTRODUCTION

Intensive care units (ICU) originated in the 1950s to provide respiratory support for the many victims of polio. It was soon recognized that a dedicated unit with well-trained staff could impact on the treatment of many serious illnesses. Recent estimates note that there are over 50,000 ICU beds in the United States, and about 3.5 million patients per year treated in this setting. Bleck et al have studied the neurologic complications encountered in the ICU, and have divided them between primary neurologic diseases and neurologic complications of serious medical illness.[1] Overall, about 20% of all patients in the ICU present with or develop some neurologic problem. One of the most common problems encountered is a change in mental status.

ALTERED MENTAL STATUS

The two main dimensions of mental status are level of alertness and content of thought. Level of consciousness is determined by wakefulness and awareness. Awareness is not possible without arousal. The levels of consciousness are listed in Table 28-1.

TABLE 28-1

LEVELS OF CONSCIOUSNESS

Awake: aroused and aware
Somnolent: easily aroused and aware
Stuporous: aroused with difficulty, impaired awareness
Comatose: unarousable and unaware
Vegetative state: aroused but unaware

Toxic Metabolic Encephalopathy

One of the most common causes of decreased alertness is a toxic metabolic encephalopathy. Typically, these patients range from having momentary lapses in alertness to hypersomnolence, where varying degrees of external stimulation are required to arouse them. It is often helpful to describe the patient's behavior literally, in addition to a term like somnolent. It is less ambiguous to know precisely which stimulus produced a response from the patient. Patients with a toxic metabolic encephalopathy are usually lethargic and confused. The exam typically shows no focal findings. Some patients with metabolic derangements (renal or liver failure) may have asterixis. The degree of somnolence usually parallels the degree of metabolic derangement, or amount of sedating medications. Some patients succumb to a seemingly additive effect of multiple mild derangements. The prognosis for most patients is favorable. In patients with severe hyponatremia (≤120 mEq/L), gradual correction is recommended, as rapid correction has been associated with osmotic demyelination and central pontine myelinolysis. There are several neuropsychological tests like "trailmaking A and B," which can be administered to help monitor the course of encephalopathy. The task in "trailmaking A" entails connecting numbers 1–25 displayed on a page, as quickly as possible. Normally this should take less than 30 s. "Trailmaking B" entails connecting numbers 1–13, but alternating sequentially with letters. This task is normally completed in less than 2 min. Either task can be administered repeatedly to assess performance day to day.

Delirium

Delerium is the most common mental disorder in hospitalized patients, and is accompanied by a neurobehavioral change.[2] According to DSM-IV, delirium is characterized by a disturbance of consciousness with impaired cognition, which develops over a short period of time. It is estimated to occur in 10% of all inpatients, and over 30% of patients in the ICU. Delerium can be defined as an abnormal mental status with disorientation, irritability, fear, and at times, hallucinations. Cognitive function is evaluated by assessing orientation, judgment, reasoning, and memory. Mental status fluctuates hour to hour and may worsen dramatically in the evening (sundowning). The presence of family members at the bedside may reduce the patient's susceptibility to develop delirium, especially in the evening. By contrast, dementia develops slowly over years. Risk factors for delirium include baseline cognitive impairment, older age, use of psychoactive drugs, severe comorbid illness, azotemia or dehydration, male gender, history of alcohol abuse, fever, infection, and metabolic derangements (see Table 28-2). Moreover, delirium is the result of the brain's response to a wide array of insults. Evaluation of mental status in patients who are receiving mechanical ventilation is challenging. Several new techniques have been devised to assess intubated patients, and data suggest that 60–80% of these patients are delirious. Furthermore, the presence of delirium is associated with increased length of stay, unplanned extubations, and increased morbidity and mortality.

TABLE 28-3

CAUSES OF DELIRIUM

CAUSE	EXAMPLES
Infectious processes	Encephalitis, meningitis, syphilis
Drug withdrawal	Alcohol, barbiturates, sedative-hypnotics, benzodiazepines
Acute metabolic disorders	Acidosis, alkalosis, electrolyte disturbance, hepatic failure, renal failure
Trauma	Heat stroke, postoperative severe burns, closed-head injury
Central nervous system pathology	Abscess, hemorrhage, normal pressure hydrocephalus, seizure, stroke, tumor, vasculitis
Hypoxia	Anemia, carbon monoxide poisoning, hypotension, pulmonary/cardiac failure
Vitamin deficiencies	B_{12}/niacin/thiamine; hypovitaminosis
Endocrinopathies	Hyperadrenocorticism or hypoadrenocorticism, hyperglycemia or hypoglycemia, parathyroidism
Acute vascular conditions	Hypertensive encephalopathy, shock
Toxins/drugs	Medications, pesticides, solvents
Heavy metal poisoning	Lead, manganese, mercury

The hypoactive variant of delirium is often unrecognized.

Yet another challenge is recognition of a hypoactive form of delirium. These patients appear to be apathetic and withdrawn, and may be misconstrued as depressed. Table 28-3 summarizes several causes of delirium. Table 28-4 lists both categories and specific drugs that can cause delirium.

Delerium is the most common cause of mental status change in hospitalized patients. Mental status may fluctuate widely through the day, even hour to hour.

The evaluation of the delirious patient should include a physical and neurologic exam, review of current and prior records if available, and laboratory and imaging data. In an alcoholic with ataxia, delirium, and ophthalmoplegia, Wernicke's encephalopathy should be considered and treatment with thiamine initiated. Sedating and antipsychotic medications are often effective in controlling agitation. Often these medications can be used for several days, and tapered down if the delirium is resolving. Certainly, oversedation and respiratory depression can be problematic, and the lowest effective dose should be sought. Some antipsychotics can induce their own complications, such as dystonic reactions and neuroleptic malignant syndrome (NMS).

Stupor and Coma

Stupor is a more profound impairment in consciousness in which patients are aroused transiently with intense stimulation such as sternal rub. If family members are present at the bedside, it is advisable to explain any provocative procedures such as testing corneal reflex or response to pain. Comatose patients are unarousable even with intense aversive stimulation. A partial listing of the causes of depressed consciousness is shown in Table 28-5.

Comatose patients lack both arousal and any awareness. Recent literature describes an entity known as a "state of minimal consciousness." In this condition, there is some level of awareness. Neurophysiologic tests such as somatosensory evoked potentials (SSEP) and newer imaging techniques such as cerebral PET scanning and functional MRI may help elucidate the structural basis and prognosis for these conditions that mimic coma. Another condition seen in the ICU is the persistent vegetative state (PVS). This is often the result of a hypoxic or traumatic insult. These patients show limited ability to arouse, with partial preservation of sleep–waking cycles, but they lack awareness. They may have roving eye movements, but do not fixate on an object and do not respond to visual threat.

Locked In Syndrome

Coma is a state of unarousable unresponsiveness.

The locked in syndrome is usually due to pontine infarction.[3] Patients are quadraparetic with bilateral facial and abducens palsy. However, these paralyzed patients are conscious, can hear what is said at the bedside, and retain the ability for upgaze and downgaze. For this

reason, patients who appear to be comatose may be asked to "look up" and "look down." EEG activity is largely preserved, and some patients may make a partial recovery.

The bedside evaluation of comatose patients is worth reviewing. Ocular motility and pupillary light reflexes should be assessed. Ideally, the light reflex should be examined with a bright light and magnifying lens to detect a small pupillary reflex. Conditions that may affect pupillary size and reactivity are listed in Table 28-6. Ocular motility may be examined with either oculocephalic (doll's eye) maneuver or caloric (oculovestibular) testing. If ocular motility is present with doll's eye maneuver, it is preferable to record this as "ocular motility could be induced by the doll's eye maneuver." Tonic deviation of the eyes away from the side of unilateral paralysis suggests a large hemispheric lesion like a complete middle cerebral

Oculocephalic and oculovestibular reflexes are supplemental techniques to evaluate brain stem integrity.

infarction. Spontaneous and induced movements should be scrutinized for symmetry. Decerebrate posturing (extension at the elbows with internal rotation of shoulders and lower extremity extension) usually signifies damage to multiple brainstem tracts. Decorticate posturing (flexion of the upper extremities, extension of the lower extremities) usually signifies bihemispheric damage or thalamic injury.

The Glascow Coma Scale (Table 28-7) is widely used to assess the degree of coma. It correlates with prognosis in patients with traumatic and nontraumatic etiology of coma

TABLE 28-8

PREDICTIVE VALUE OF THE GLASGOW COMA SCALE

	NEGATIVE PREDICTIVE VALUE POSTARREST

No response to verbal stimuli	67	75	94
Glasgow Coma Score 15	69	–	100

SOURCE: Data from Edgren et al[18]

(Table 28-8). There is excellent concordance between two trained observers. Recently, Wijdicks et al have reported on the FOUR (full outline of unresponsiveness) score, and compared it to the GCS.[4] It may be more discriminating in patients with lower GCS scores, but it lacks the broad familiarity of the GCS system.

Brain Death

Key diagnostic criteria for brain death:
- Coma
- Absent brainstem reflexes
- Apnea

Traditionally, the cessation of cardiopulmonary activity has defined death. With advancement in technology, cardiopulmonary function can be supported in patients with absent brain function. In 1981, the President's Commission for the Study of Ethical Problems in Medicine provided guidelines for the determination of brain death. Moreover, death is established when there is irreversible cessation of circulatory and respiratory function, or irreversible cessation of all functions of the entire brain, including brain stem function.[5] The key neurologic findings to support the diagnosis of brain death are: (1) absent cerebral hemispheric function manifested by coma, (2) absent brain stem function manifested by absent pupillary light reflex, corneal reflex, and ocular motility, and (3) absent spontaneous respiratory activity manifested by the "apnea test." Many hospitals have explicit brain death policies articulating the specific clinical requirements for the institution. For example, pediatric hospitals may have some unique policies such as a requirement for longer observation, evaluation by two independent examiners, and objective corroboration of the diagnosis by isoelectric EEG or absent cerebral perfusion. Objective support such as an EEG is also reasonable, but not mandatory, if a patient is being considered for organ donation.

Some family members have difficulty understanding the dichotomy between residual cardiac activity and the diagnosis of brain death. In such instances, prolongation of support may be desirable as the family comes to terms with the realities. Generally speaking, brain dead patients are susceptible to several types of terminal events such as cardiac arrhythmia, fluctuating blood pressure, and diabetes insipidus. That said, Bernstein et al have described the rare scenario of prolonged support of a brain dead mother to allow the fetus to attain a potentially viable gestational age.[6]

It is important to remember confounding factors that preclude the diagnosis of brain death. These include the presence of severe hypothermia, the presence of an intoxication such as phenobarbital, and major metabolic derangements. As mentioned, diabetes insipidus may cause precipitous rise in the serum sodium, which should be treated with aggressive fluid resuscitation and possibly (Desnopressin acetate) DDAVP.

Ethical Issues in Coma and Brain Death

One of the first issues to be addressed in comatose patients is whether the patient ever prepared a living will, or a similar document to address their wishes, or identify a surrogate decision maker. Recent literature notes the limitations and failings of living wills. It should be remembered that patients have the right to change their wishes. Yet another issue is the decisional capacity of the individual when he expressed his or her wishes. This topic was recently addressed by Paul Appelbaum who argues that patients should demonstrate comprehension of their general health, their acute illness, and treatment options and articulate the

basis of their decision.[7] When there is a surrogate decision maker, they should strive to choose therapy as the patient would want. It does not give the surrogate free reign to select what they would do themselves. One of the most common dilemmas in the intensive care is recognition of futile treatment. Ideally, there needs to be discussion with one designated family member to determine the course of action. Another common situation is an urgent need to perform an invasive procedure without a surrogate decision maker at that time. Once again, there will be differences from one institution to another, and state to state. If two attending physicians certify clinical urgency to some intervention, this may suffice. Yet another difficult matter is supportive care for patients in the PVS. Ropper has estimated that PVS may effect as many as 10,000–25,000 adults and 4,000–10,000 children in the United States.[8] The most common etiologies are hypoxic insult and severe head trauma. As detailed in an excellent review in the *New England Journal of Medicine* (1994), most patients attain a plateau within several months.[9] It does appear that younger patients and victims of traumatic brain injury have a greater prospect for meaningful recovery. The burden to distraught family members is immense. This issue was in the national spotlight with the case of Terri Schiavo.[10]

Occasionally, family may express a desire to harvest sperm from a brain dead patient.

There is debate in the available literature, but most seem to advocate clear compelling evidence that sperm retrieval was the patient's stated or explicit wish. Responsibility for the cost of sperm procurement and storage should be agreed upon, and some have advocated that the sperm be stored for a specified time frame, such as 1 year. There have been reports of successful impregnation with sperm retrieved posthumously.

Lastly, there is a serious crisis in the realm of organ donation. There are extensive waiting lists for many types or organs, and the supply falls far short of the needed quota. The Gift of Life organization urges consideration of all brain dead patients as potential organ donors. They recommend notification of the organization when there is a potential donor. They feel their trained counselors have greater success in organ procurement than well-intentioned but inexperienced attending physicians. Some surviving family members have identified the process of organ donation as a silver lining around the dark cloud of their relative's demise.

SEIZURES

About 3% of the general population has recurrent, unprovoked seizures (epilepsy). Some of these patients will develop seizures due to suboptimal anticonvulsant levels. It is not unusual for additional patients to experience new onset seizures during hospitalization, particularly in the ICU. Seizures may be the result of new pathology like a stroke (5% association with seizures) or cerebral hemorrhage (10% association with seizures). Seizures may be the result of an acute intoxication (cocaine use), or withdrawal from alcohol or medication (benzodiazepines, hypnotics, or analgesics). Seizure threshold may be lowered by concurrent medications or sleep deprivation in the ICU. Metabolic derangements such as uremia, hyperglycemia, and hyponatremia may provoke seizures. One of the most common causes of new onset seizures is posthypoxic encephalopathy. It has been estimated that 10% of patients in the ICU show a mental status change due to "subclinical seizures." An EEG is highly revealing and can be used to monitor the response to anticonvulsant medication. Jette and Hirsch of Columbia have even advocated that continuous EEG (cEEG) be a routine procedure in the ICU.[11]

The diagnosis of seizures begins with observation of the patient's behavior. The patient should be questioned about any premonitory aura sensations such as olfactory experiences (foul odor), lip smacking, or other automatisms. If the patient demonstrates normal cognition and responsiveness during the ictal phase, this indicates a partial seizure. Some patients with hyperglycemia will have recurrent stereotyped focal motor seizures, also known as epilepsia partialis continua. Patients who stare vacantly, lose awareness of their surrounding, and memory probably have a complex partial seizure. If they are given some stimulus such as a word or phrase to remember, they cannot recall it when requestioned. Patients with generalized seizures often show arching posture, and rhythmic tonic–clonic activity with teeth clenched,

TABLE 28-9

DRUG-RELATED SEIZURES IN THE ICU

Drug withdrawal	Pharmaceuticals
Barbiturates	Ciprofloxacin

Amphetamines	Tricyclics
Cocaine	
Phencyclidine	

and incontinence. They usually are somnolent after the seizure with confusion. As Dante wrote in The Inferno "As one who stares in consternation, bewildered by his late hard throws." It is not unusual for patients to have focal weakness after a seizure (Todd's paralysis). This may be misconstrued as a stroke. Patients who are promptly alert and interactive after an ostensible generalized seizure may have hysterical or nonepileptic seizures.

EEG data are correlated with the ictal behavior, and a presumptive diagnosis of seizure type is made. This assists in selecting an anticonvulsant appropriate to the seizure type, and the clinical context. Metabolic derangements that effect seizure threshold should be addressed. The level of medications such as theophylline which may lower seizure threshold should also be monitored and adjusted. See Table 28-9 for a list of drugs that may cause seizures.

STATUS EPILEPTICUS

Complications of status epilepticus:
Hyperthermia
Rhabdomyolysis and acute renal failure
Cerebral edema
Pulmonary edema and acute respiratory failure

Status epilepticus is a potentially life threatening emergency associated with high mortality and morbidity. [12] New onset of seizures may manifest with status epilepticus in 10–30% of patients. Status is defined as a seizure that lasts beyond 30 min, or that recurs without the patient regaining consciousness. Status epilepticus is the result of failed inhibitory mechanisms together with an overwhelming insult or injury. Noncompliance with prescribed anticonvulsants is one of the more common causes of status epilepticus. There is evidence that prolonged seizures may produce injury to the brain due to calcium mediated excitotoxicity. Seizures are often accompanied by sympathetic nervous system outflow resulting in hypertension and tachycardia. Postictally, there is lactic acidosis which can be profound, and persists for 30–60 min. Sequelae of prolonged generalized seizures included rhabdomyolysis, with risk for renal failure, and aspiration pneumonia. Protracted seizures can also cause hyperthermia and cerebral edema. Neurogenic pulmonary edema has also been described. Yet another recognized entity is sudden unexplained death in epileptic patients (SUDEP). This occurs in about 1/1,000 patients with epilepsy, and is another reason favoring optimal control of seizures.

Patients with status epilepticus should have an EEG when overt seizure activity ceases as 20–30% continue with electrographic seizures, which warrant aggressive treatment.

There are five aspects to the management of status epilepticus: supportive care, termination of the seizures, prevention of seizure recurrence, correction of precipitating causes, and prevention and treatment of any complications. Prompt initiation of treatment is crucial as outcome is related to seizure duration. Airway management is critical to avoid a hypoxic insult. Most patients require intubation and mechanical ventilation. Intravenous access should be secured and cardiac monitoring is also desirable. Treatment of hypotension should begin with volume replacement supplemented by pressors if hypotension persists. If patients are hypertensive, then specific treatment of this should be deferred, as treatment of the seizures often results in normalization of the blood pressure. If hypoglycemia is present, treat with 50 mL of 50% dextrose, together with thiamine. Laboratory studies should include CBC, metabolic panel, arterial blood gas, anticonvulsant level, urinalysis, and blood and urine toxic screen when appropriate. Lorazepam may be given as a 2 mg bolus IV as often as every 2 min for a total of five doses. This may cause respiratory depression so that ventilator support is desirable before administering repeated doses of lorazepam. The benzodiazepines often impact on seizures promptly, but have relatively short duration of effect. For this reason, a

TABLE 28-10

THE MOST WIDELY USED IV ANTICONVULSANTS

DRUG	LOADING DOSE mg/kg	MAINTENANCE DOSAGE	ROUTE OF METABOLISM	DIALYZABLE (% PROTEIN BINDING)	ADVERSE EFFECTS
Diazepam (Valium)	0.2–0.5 at 2–4 mg/min	None	Hepatic	>90	Respiratory depression, hypotension, sialorrhea
Lorazepam (Ativan)	0.1 at 2 mg/min	None	Hepatic	90	Same as diazepam
Phenytoin (Dilantin)	20 mg/kg at 50 mg/min	5 mg/kg/day	Hepatic	70	Cardiac depression, hypotension
Fosphenytoin (Cerebyx)	20 mg/kg PE at 150 mg/min	5 mg/kg/day	Hepatic	70	Cardiac depression, hypotension, paresthesias
Phenobarbital	20 mg/kg at 50–75 mg/min	1–4 mg/kg/h	Hepatic	50–60	Respiratory suppression
Pentobarbital	5–12 mg/kg over 1 h	0.5–5 mg/kg/h	Hepatic	59–63	Hypotension, respiratory suppression
Midazolam (Versed)	0.2 mg/kg	0.75–10 μg/kg/min	Hepatic	96	Hypotension, respiratory suppression
Propofol (Diprivan)	2 mg/kg	5–10 mg/kg/h initially, then 1–3 mg/kg/h	Hepatic	97–98	Respiratory depression, hypotension, lipemia, acidosis

PE, Phenytoin sodium equivalent

longer acting anticonvulsant is also administered. A summary of the most widely used IV anticonvulsants is in Table 28-10. While phenytoin given as a loading dose of 20 mg/kg is highly efficacious, the drug is highly alkaline in solution and can cause cardiac arrhythmia, hypotension, local pain at the injection site, and tissue necrosis with infiltration resulting in the purple hand syndrome. It is imperative that the drug be administered slower than 50 mg/min, with close monitoring of vital signs. Any changes in either heart rate or blood pressure should prompt holding further administration. Fosphenytoin is a more expensive alternative to phenytoin, which is as efficacious without the side effects noted above. Valproate can be given as an IV load of 20 mg/kg over 15–20 min. Phenobarbital 20 mg/kg can be administered if seizures persist after lorazepam and loading with a longer acting agent. Recently, levetiracetam has become available in parenteral formulation, and appears to be efficacious in refractory seizures. Those patients who continue to seize may be treated with pentobarbital 5 mg/kg IV, or midazolam 0.2 mg/kg, with the dose titrated to attain a burst suppression pattern on EEG. Ongoing EEG monitoring is desirable to exclude nonconvulsive status, which may be present in 20–30% after the termination of visible seizure activity.

Imaging with CT and MR when feasible is appropriate to identify a structural lesion. Patients with recurrent bouts of seizures should be evaluated by an epileptologist. There may be a role for alternative anticonvulsants, epilepsy surgery, vagal nerve stimulator, or intensive EEG/video monitoring.

STROKE

Most strokes are ischemic in nature. Subtypes of strokes include thrombotic, embolic, and lacunar.

Stroke is defined as the sudden occurrence of a nonconvulsive focal neurologic deficit due to cerebrovascular disease. It is estimated that there are 750,000 strokes per year in the United States. Stroke is considered the third leading cause of death. About 85% of all strokes are ischemic, and the remaining 15% are hemorrhagic. See Table 28-11 for characteristics of the different stroke types.

TABLE 28-11

CHARACTERISTICS OF DIFFERENT TYPES OF STROKES

TYPE OF STROKE	PERCENTAGE OF ALL STROKES	ONSET	PERCENTAGE TIAS (%)	SEIZURE AT ONSET (%)	COMA (%)	ATRIAL FIBRILLATION (%)	KNOWN CORONARY ARTERY DISEASE	MRI OR CT SCAN	OTHER FEATURES
Thrombotic	40	Stuttering Gradual	50	1	5	10	50	Ischemic infarction	Carotid bruit; stroke during sleep
Embolic	30	Sudden	10	10	1	35	35	Superficial (cortical) infarction	Underlying heart disease; peripheral emboli or strokes in different vascular territories
Lacunar	20	Gradual or sudden	30	0	0	5	35	Normal, or small, deep infarction	Pure motor or pure sensory stroke
Hemorrhagic	10	Sudden	5	10	25	5	10	Hyperdense mass	Nausea and vomiting; decreased mental status

TIAs transient ischemic attacks

Mechanistically, when blood flow falls beneath a critical threshold of 10 mL/100 g per minute, basic cellular functions can no longer be maintained. This leads to cell death. It appears that with an ischemic insult, there is a central core of irrevocably damaged tissue with a surrounding region of potentially salvageable tissue. The surrounding region has been referred to as the ischemic penumbra. Ischemic stroke can be further subdivided into thrombotic effecting either large or small vessels, and embolic. Predisposing risk factors for stroke include hypertension, atrial fibrillation, diabetes mellitus, cigarette smoking, and hyperlipidemia. Patients with coronary artery disease also have increased risk for cerebrovascular disease.

While there are a myriad of symptoms associated with stroke, the most common are unilateral weakness or sensory loss, speech and language impairment, ataxia and impaired coordination, and an acute visual disturbance. There are a number of common neurologic symptoms such as syncope and isolated vertigo, which are rarely the result of cerebrovascular disease (see Table 28-12). Identifying appropriate candidates for tissue plasminogen activator (TPA) is a daunting but important task. Recently, Weintraub has summarized the medico-legal issues surrounding either administration, or failure to administer TPA.[13]

TPA may impact significantly on a subset of patients based on rigorous selection criteria. While the "temporal window" is generally considered to be within 3 h of symptom onset, patients treated earlier (under 2 h from symptom onset) appear to derive even greater benefit. The phrase "time is brain" calls attention to the urgency of stroke patients being evaluated. There is a challenge to educate the community about stroke symptoms. There is a challenge to medical transport personnel, and to the emergency department staff. Institutions should scrutinize the time line to perform all requisite studies and reports from arrival to TPA administration. The history should note the time of the onset of neurologic symptoms, and their evolution over time. If the deficits are improving spontaneously, then TPA should be withheld. Generally speaking, patients awakening with a deficit are excluded from TPA administration. There is about 5% incidence of cerebral hemorrhage in patients receiving TPA, and this may be a lethal complication. Other exclusionary factors are anticoagulant therapy, recent major surgery, and severe hypertension, which fail to respond to treatment.

Language function is often affected by stroke. Ninety-nine percent of right-handers are left hemisphere dominant for language. About 70% of left-handers are also left hemisphere dominant for speech. Of the remaining 30% of left-handers, 15% are right hemisphere dominant, and 15% are "bi-hemispheric." Broca's area is situated in the frontal region near the motor strip. Most patients with expressive aphasia will also have some degree of focal motor

TABLE 28-12

SYMPTOMS THAT ARE SELDOM THE RESULT OF CEREBROVASCULAR DISEASE

weakness, often affecting the arm more than the leg. Patients with Broca's aphasia typically speak brief utterances with few adjectives or modifiers, and great effort. This has been called "telegraphic speech." They "know what they want to say." They may make paraphasic errors as well. Stroke in the posterior region of language control often produces Wernicke's aphasia, with maintenance of word production, but the words are incorrect, and the patient fails to recognize their errors.

For example, one patient was shown a pen, and when asked to name it responded "what an adorable vacuum cleaner." Sometimes these patients are misconstrued as being confused, when in fact they have a language disturbance. Because the lesion is usually in the postcentral gyrus parietal region, they often have little to no focal weakness.

Anterior circulation strokes usually cause weakness and numbness on one side, possibly neglect of the same side, and language and visual disturbances. Large middle cerebral strokes often cause tonic gaze to the side of the stroke due to involvement of the frontal eye fields. See Table 28-13 for the most common symptoms of carotid ischemia. The NIH Stroke Scale is a systematic exam that allows assessment of stroke severity. Posterior circulation strokes often produce ataxia, vertigo, and cranial nerve deficits at times with altered consciousness. See Table 28-14 for common symptoms of vertebral-basilar ischemia. All patients suspected for stroke should have CT scanning of the brain urgently. This serves two purposes. First, it addresses whether the patient has cerebral hemorrhage. Second, it may demonstrate the presence of structural pathology, like brain tumor or subdural hematoma, which may mimic a stroke. See Table 28-15 for conditions that may be mistaken for a stroke.

CT scan of the brain should be done urgently and will address the presence of intracranial blood or a mass lesion, but often fails to show the acute stroke for 8–12 h.

Unfortunately, a CT of the brain often fails to demonstrate an acute stroke initially, and may take 8–24 h before it is diagnostic. MR scanning reveals an acute stroke within as little as 30 min from symptom onset. The diffusion weighted imaging (DWI) allows one to image an acute stroke, and distinguish it from an older stroke. MR scanning is generally superior to CT in showing brain stem and cerebellar strokes, as well as lacunar strokes. Patients with a stroke should have routine blood work including complete CBC, with platelet count, blood glucose, coagulation profile, lipid profile, syphilis serology, serum homocysteine level, and an erythrocyte sedimentation rate. Young patients with a stroke should also be evaluated for a hypercoaguable state including anticardiolipin antibody, factor V Leiden, protein C, and S deficiency (see Table 28-16). Echocardiography is reasonable, especially if there is suspicion for an embolic source. EKG and cardiac monitoring should be done to exclude cardiac arrhythmia or a myocardial infarction. While the term cerebrovascular accident has been popular for years, in most patients the stroke is no accident. It is usually the culmination of one or several identifiable risk factors.

TABLE 28-16

TYPICAL DIAGNOSTIC EVALUATION OF STROKE

DIAGNOSIS	METHOD
Anterior circulation ischemia	Carotid duplex, echocardiography, CT scan (MRI if lacunar), MRA neck
Posterior circulation ischemia	Echocardiography, MRI (CT if unavailable), TCD, or MRA
The "unexpected stroke" (minimal risk factors or stroke in the young)	MRA (including cervical views) or conventional angiography echocardiography (TEE preferred), toxicology screen, prothrombotic workup

MRA magnetic resonance angiography; *TCD* transcranial Doppler; *TEE* transesophageal echocardiography

The goal of acute stroke treatment is to minimize the extent of ischemic injury. While there is evidence for an evolving cascade of events, we have not been able to salvage areas with a profound, prolonged ischemic insult. Nonetheless, hyperacute interventional trials continue.

For now, the management focuses on judicious control of blood pressure. Agents that lower blood pressure abruptly should be avoided. TPA should be considered provided patients satisfy the selection criteria and have no exclusionary data. A recent study noted up to 20% incidence of cerebral hemorrhage in patients receiving TPA who fail to satisfy protocol criteria. Those patients who do receive TPA should have a follow-up CT brain the following day to exclude cerebral hemorrhage. Patients should undergo carotid artery imaging with either duplex ultrasound, or MR angiography. Some patients may benefit from additional vascular imaging including CT angiography and CT perfusion imaging. Defining the subset of patients who derive the greatest benefit from these newer diagnostic modalities is yet to be clarified. Perfusion scanning may demonstrate a large "ischemic penumbra," which may improve with a revascularization procedure.

One area of considerable controversy is the role of full anticoagulation in the management of cerebrovascular disease. Heparin is considered appropriate for patients with cardiogenic embolization, such as in the setting of new onset atrial fibrillation (AF). AF is thought to increase stroke risk eightfold, and this increased risk is essentially eliminated with therapeutic anticoagulation. One notable exception to using full anticoagulation for cardiogenic cerebral embolization is in the setting of subacute bacterial endocarditis (SBE), where there is substantial risk for cerebral hemorrhage. Other settings where many consider Heparin reasonable are "stroke in evolution" with clinical progression in the deficit, and crescendo TIA, where focal neurologic symptoms occur more frequently for longer periods of time. Brain stem strokes that evolve raise concern for progressive basilar thrombosis, which is often fatal or devastating. Prompt vascular imaging with either MRA of brain, transcranial Doppler exam, or CT angiography can clarify the vascular anatomy. Interventional neuroradiologists may offer a procedural approach such as vascular stenting or retrieval of an embolism (Merci system). In patients suspected of having a hypercoaguable state, there may also be a role for anticoagulation. Some evidence suggests that lovenox may be superior to coumadin in treating the hypercoaguability seen in some cancer patients. It should be remembered that full therapeutic anticoagulation carries with it a risk of complications ranging from 5 to 10% per year. One should factor in the patient's age, mental status, compliance, concurrent medications, and risk for fall in determining if the benefit of anticoagulation outweighs its cumulative risk.

The WARS (warfarin vs. aspirin for recurrent stroke) study group addressed the comparative efficacy of warfarin vs. aspirin for atherosclerotic cerebrovascular disease.[14] Interestingly, aspirin was comparable in efficacy, and warfarin caused an increased risk of hemorrhagic complications.

Yet another issue in the management of cerebrovascular disease is the role and timing of carotid endarterectomy for patients with TIA or mild stroke, and high-grade carotid stenosis ipsilateral to the presenting symptoms. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) addressed the benefit of carotid surgery by highly competent surgeons for carotid stenosis ranging from 70 to 99%, and compared the results with

best medical therapy.[15] There was significant benefit for the 70–80% stenosis group, and greater benefits with higher grades of stenosis. The timing of the surgery is a subject of some debate. Traditionally, carotid surgery was deferred for about 6 weeks after a mild stroke. However, this delay was associated with recurrent strokes in some patients, so some have advocated surgery after a delay of several weeks. Patients with very high-grade stenosis (>90%) are at risk for the postcarotid endarterectomy hyperperfusion syndrome. This is associated with migraine-like headaches on the side of the endarterectomy, focal motor or generalized seizures, and cerebral hemorrhage postoperatively. Finally, there is debate over the role of carotid endarterectomy for asymptomatic carotid stenosis. The results of several studies are at variance with one another. The benefits of endarterectomy in the asymptomatic patient are less apparent, so the procedure is generally reserved for young patients with high-grade carotid stenosis, or documented progression of carotid stenosis. Coexistent coronary artery disease should be considered as this is common, and may cause an acute coronary syndrome during carotid surgery. For many patients with cerebrovascular disease, the cornerstone of medical management is assiduous risk reduction together with an antiplatelet agent. There is some evidence that clopidogrel bisulfate and asprin/extended release dipyridomol may confer some additional benefit compared to aspirin, but the cost of these medications is considerable, and in some patients, prohibitive. Optimal control of hypertension and smoking cessation are often pivotal to successful treatment.

INTRACEREBRAL HEMORRHAGE

An intracerebral hemorrhage causes abrupt focal neurologic deficits resembling those of an ischemic stroke, but also produces decreased level of consciousness. It is common for the neurologic deficits to evolve and for patients to deteriorate drastically over an hour or two. Many patients also report a severe headache. Because CT scan of the head is extremely sensitive for detecting intraparenchymal hemorrhage, it is heavily relied upon in the early diagnostic process. An elevation in blood pressure often occurs. It has been recommended that blood pressure be below a mean arterial pressure of 130 mmHg in patients with hypertension. Therapy focuses on reducing increased intracranial pressure by initially intubating and performing hyperventilation and then administering an osmotic diuretic agent such as mannitol or a loop diuretic such as furosemide. Neurosurgery is consulted in the event the patient requires ventriculostomy, or removal of the hematoma. In a small subset of patients, there may be a role for craniotomy if the prognosis appears favorable and intracranial pressure is life threatening. If more aggressive therapy is contemplated, such as high-dose barbiturates, an intracranial pressure monitor should be inserted. Corticosteroid therapy has not shown benefit and is generally not recommended because of numerous potential complications. Neurogenic pulmonary edema may occur during any acute intracranial condition. It is best to keep the pulmonary capillary wedge pressure close to normal in this setting. While cerebral hemorrhage may have substantial mortality, survivors may make a slow but significant recovery over several months.

Subarachnoid hemorrhage differs from other types of stroke in that it rarely causes focal neurologic findings. There are exceptions to this, such as third nerve palsy with posterior communicating artery aneurysm. Severe explosive headache, at times accompanied by loss of consciousness or near syncope, occurs. Most spontaneous subarachnoid hemorrhages arise from ruptured berry aneurysms. Cerebral angiography is often performed acutely to identify the site of bleeding, and to determine whether there are multiple aneurysms (20%) and the presence of vasospasm. A major determinant of patient outcome is the neurologic status on admission. Key management issues include maintenance of electrolytes and blood pressure control, maintaining systolic blood pressure at about 150 mmHg. Nimodipine, a calcium channel blocker therapy, is used to prevent cerebral arterial vasospasm. Patients undergo CT scanning, MR brain, and MR angiogram. In patients with subarachnoid hemorrhage, MR angiography is often helpful but not definitive.

MRA typically can detect aneurysms greater than 5 mm. Conventional catheter angiography remains the gold standard, and may have to be done repeatedly in patients with the

initial study negative. Three negative angiograms generally exclude a significant aneurysm. Fortunately, "angiogram negative" subarachnoid hemorrhage usually has a low rate of recurrent subarachnoid bleeding.

Subarachnoid hemorrhage often presents with severe headache and syncope, but is usually not accompanied by focal neurologic findings.

Some patients may have CT angiography, vs. conventional catheter angiography. There is a growing role for coiling by interventional neuroradiologists. Definitive therapy should be pursued expeditiously to avoid the dreaded and often fatal recurrence of subarachnoid bleeding.

NERVOUS SYSTEM INFECTIONS

Meningitis

Suspected meningitis should be treated immediately.[16] Some clinicians prefer to have a CT of the brain performed before doing the lumbar puncture. However, generally patients who are alert with normal fundi can undergo lumbar puncture. Patients who are somnolent, or show evidence of posterior fossa abnormality are best imaged to ensure no structural lesion. Cefotaxime or ceftriaxone should be used for empiric therapy. Vancomycin can be added until spinal fluid culture and sensitivities are available, particularly where pneumococcal resistance to third-generation cephalosporins has emerged. Chloramphenicol is often recommended for penicillin-allergic patients.

Blood cultures should be obtained before antibiotics are administered. If listeriosis is suspected, then ampicillin or sulfa-trimethoprim are acceptable alternatives. Antibiotic coverage for listeriosis should be added until an organism is isolated or blood and spinal fluid cultures have been negative for at least 3 days. Imipenem should be avoided in central nervous system infections because it is epileptogenic. The use of systemic corticosteroid therapy in adult meningitis remains controversial. There is a role for steroid therapy in more severe cases of TB meningitis. Increased intracranial pressure, hyponatremia, and cerebral venous thrombosis are all complications of severe meningitis. Additionally, seizures may occur and are initially managed with benzodiazepines and phenytoin.

Encephalitis

The most common and important cause of fatal sporadic encephalitis in the United States is herpes simplex virus. Most patients have a history of antecedent viral syndrome followed by mental status change, with new onset of seizures. Patients often show impaired short-term memory. CSF exam usually reveals pleocytosis, red cells, and protein elevation. CSF analysis for HSV PCR is confirmatory. Imaging often shows focal abnormality in the anterior temporal lobe. When encephalitis is suspected, acyclovir is begun as a workup proceeds. EEG may show periodic lateralized epileptiform discharges (PLEDS). However, PLEDS can also be seen in other clinical settings like brain abscess and brain tumor. While brain biopsy was recommended in the past, it is usually unnecessary in most cases. Unfortunately, Herpes simplex encephalitis still can cause fatality and severe morbidity even in patients diagnosed and treated promptly. Seizures, increased intracranial pressure, and cerebral edema are common complications of encephalitis.

SUMMARY

Numerous neurologic issues and problems are found in critically ill patients. Consultation with a neurologist or neurosurgeon is often necessary, but the intensivist must be able to recognize the conditions and initiate treatment appropriately.

REVIEW QUESTIONS

1. **Risk factors for delirium include all of the following, except one:**
   - **A.** Advanced age
   - **B.** Antecedent cognitive impairment
   - **C.** Use of psychoactive medication
   - **D.** Metabolic derangement
   - **E.** Presence of family members at bedside

2. **The persistent vegetative state (PVS) is associated with which pattern of responsiveness?**
   - **A.** Unarousable and unaware
   - **B.** Arousable but unaware
   - **C.** Arousable and aware
   - **D.** Unarousable but aware

3. **What type of stroke is associated with paroxysmal atrial fibrillation?**
   - **A.** Lacunar
   - **B.** Hemorrhagic
   - **C.** Embolic
   - **D.** Thrombotic

4. **Which condition is rarely associated with focal neurologic deficit?**
   - **A.** TIA
   - **B.** Ischemic stroke
   - **C.** Intracerebral hemorrhage
   - **D.** Grand mal seizure
   - **E.** Subarachnoid hemorrhage

5. **The risk of cerebral hemorrhage following TPA administration is:**
   - **A.** 1%
   - **B.** 5%
   - **C.** 10%
   - **D.** 20%

6. **Therapeutic anticoagulation with heparin is reasonable for each of the following situations, except one. Choose the exception.**
   - **A.** Stroke in evolution
   - **B.** Crescendo TIA's
   - **C.** Lacunar infarction
   - **D.** Hypercoaguable state
   - **E.** Progressive brain stem ischemia

ANSWERS

1. The answer is E. Presence of family can provide a deterrent to developing delirium.
2. The answer is B. Patients with PVS do have some evidence for arousal, including partial preservation of sleep–waking cycles. However, they are not aware of themselves or their surroundings.
3. The answer is C. Cardiac arrhythmia such as PAF is associated with embolic strokes.
4. The answer is E. Subarachnoid hemorrhage differs from other types of stroke because it rarely causes neurologic deficits, but does cause headache and syncope.
5. The answer is B. It is important to recognize this potentially fatal complication of TPA.
6. The answer is C. Lacunar disease is due to small vessel lipohyalinosis, and thought to be unresponsive to anticoagulant therapy.

CHAPTER 29

FRANCIS C. CORDOVA, MARIA ROSELYN C. LIM, AND GERARD J. CRINER

Neuromyopathies in the Critically Ill

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Be aware of the different neuromuscular disorders that are encountered in the ICU.
- Know the effects of neuromuscular dysfunction on the respiratory system.
- Know the proper initial evaluation and management of patients with neuromuscular dysfunction and respiratory failure.
- Be aware of the various therapies used to treat neuromuscular disorders that are most commonly encountered in the ICU.

INTRODUCTION

Neuromuscular disorders, especially acquired ICU neuromyopathy, are important contributors of morbidity and mortality in the intensive care unit (ICU). As more patients survive their acute illness due to advances in critical care medicine, acquired ICU neuromyopathy has emerged as the most common cause of muscle weakness in the modern ICU. In approximately a third of cases, an acute presentation or an acute exacerbation of the underlying chronic neuromuscular disease occurs. Guillain–Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, and myopathy (acquired before ICU admission) account for the majority of chronic underlying neuromuscular disorders that are most commonly observed in the ICU.

CASE STUDY: PART 1

N.C., a 38-year-old self-employed businessman, sought neurology consultation for progressive limb numbness and weakness over the past week. His symptoms started 10 days before consultation when he experienced numbness and a tingling sensation in both feet. Because he had never been sick and had always lived a healthy lifestyle, he ignored the symptoms and attributed them to the tight new moccasins his wife had given him on their tenth wedding anniversary. However, 2 days later, he began to have difficulty climbing stairs and doing his usual 10 km run. Three days before consultation, he experienced the same symptoms and weakness in both hands. He denied any swallowing difficulty. His past medical history was unremarkable except for a bout of diarrhea 2 months ago following a business trip to China.

In the ICU setting, neuromuscular dysfunction usually presents as acute respiratory failure, acute-on-chronic respiratory failure, or failure to wean from mechanical ventilation.

Although neuromuscular diseases are varied in etiology and pathogenesis, all can potentially lead to life-threatening respiratory failure, primarily by affecting the pump function of respiratory muscles and impairing the ability to generate an effective cough. Thus, neuromuscular dysfunction typically presents in the ICU setting as acute respiratory failure, acute-on-chronic respiratory failure, or failure to wean from mechanical ventilation after the resolution of the acute illness. In patients with known neuromuscular disorder, acute respiratory failure is either precipitated by disease progression or an exacerbation of the underlying neuromuscular disease, or by an infection such as a community-acquired pneumonia. In patients who fail to wean from mechanical ventilation, the incidence of neuromuscular dysfunction has been reported to range from 10 to 25% in US ventilator rehabilitation units (VRU).

The severity of respiratory muscle dysfunction caused by neuromuscular diseases depends on the pattern and extent of respiratory muscle involvement (inspiratory or expiratory muscle involvement) and availability of effective medical therapy (plasmapheresis in Guillain–Barré syndrome; anticholinergic agents in myasthenia gravis). The respiratory pump may be impaired at the level of the central nervous system, spinal cord, peripheral nerve, neuromuscular junction, or respiratory musculature. Neuromuscular disorders seen in the ICU and their corresponding site of injury are listed in Table 29-1.

A thorough understanding of the neuroanatomical and pathological changes caused by the various neuromuscular disorders is fundamental in learning the essential steps toward appropriate diagnosis and treatment. In this chapter, the etiology, pathophysiology, and treatment of selected neuromuscular diseases most commonly observed in the ICU are reviewed in detail.

TABLE 29-1

NEUROMUSCULAR DISEASES CAUSING MUSCLE WEAKNESS IN THE ICU SETTING

LEVEL OF THE MOTOR UNIT	DISORDER
Motor neuron	Amyotrophic lateral sclerosis
	Poliomyelitis
Peripheral nerve	Guillain–Barré syndrome
	Critical illness polyneuropathy
	Shellfish poisoning
	Porphyric neuropathy
Neuromuscular junction	Myasthenia gravis
	Botulism
	Hypermagnesemia
	Lambert–Eaton syndrome
Muscle	Acquired disorders
	Myoglobinuric myopathy
	Hypokalemic paralysis
	Toxic myopathy
	Acute myopathy of intensive care
	Congenital disorders
	Acid maltase deficiency
	Mitochondrial myopathy

PATHOPHYSIOLOGY OF NEUROMUSCULAR DISEASES THAT AFFECT THE RESPIRATORY FUNCTION

Various neuromuscular diseases can impair the different functional components of the respiratory system. Some diseases may affect the cortical center of breathing, whereas others predominantly affect the pump function of the respiratory muscles and chest wall to drive air in and out of the lungs. In addition, upper airway muscle weakness can lead to swallowing difficulty and recurrent aspiration that results in hypoxemia and aspiration pneumonia. The end result of the pathophysiological impairments caused by neuromuscular weakness on the respiratory system is respiratory failure (Fig. 29-1). The most typical changes in the respiratory system observed in patients with moderately advanced chronic neuromuscular dysfunction are listed in Table 29-2.

Control of Breathing

Respiratory muscle weakness is the most common cause of chronic respiratory failure.

Chronic respiratory insufficiency in patients with chronic neuromuscular disorder is primarily due to respiratory muscle weakness. However, several studies have shown that some patients afflicted with congenital myopathies exhibit hypoventilation out of proportion to the severity of their respiratory muscle weakness, suggesting the possibility of impaired central respiratory drive.[1]

Several studies have shown that the hypoxic and hypercapnic ventilatory responses are blunted in patients with congenital myopathies.[2,3] In normal individuals, the relationship between oxyhemoglobin desaturation and ventilation is linear; that is, a fall of oxygen saturation by 1% is approximately associated with a 1-L/min increase in minute ventilation. A much steeper linear increase in minute ventilation is seen during hypercarbic challenge. Thus, for every 1 mmHg rise in pCO_2, ventilation increases by 2.5–3 L/min. This normal predictable increase in minute ventilation in response to hypoxia and hypercapnea may be altered in certain neuromuscular disorders. In addition to a decrease in central neural drive, a blunted ventilatory response to hypoxia and/or hypercapnia may be related to other factors such as respiratory muscle dysfunction and/or abnormal chest wall and lung mechanics.

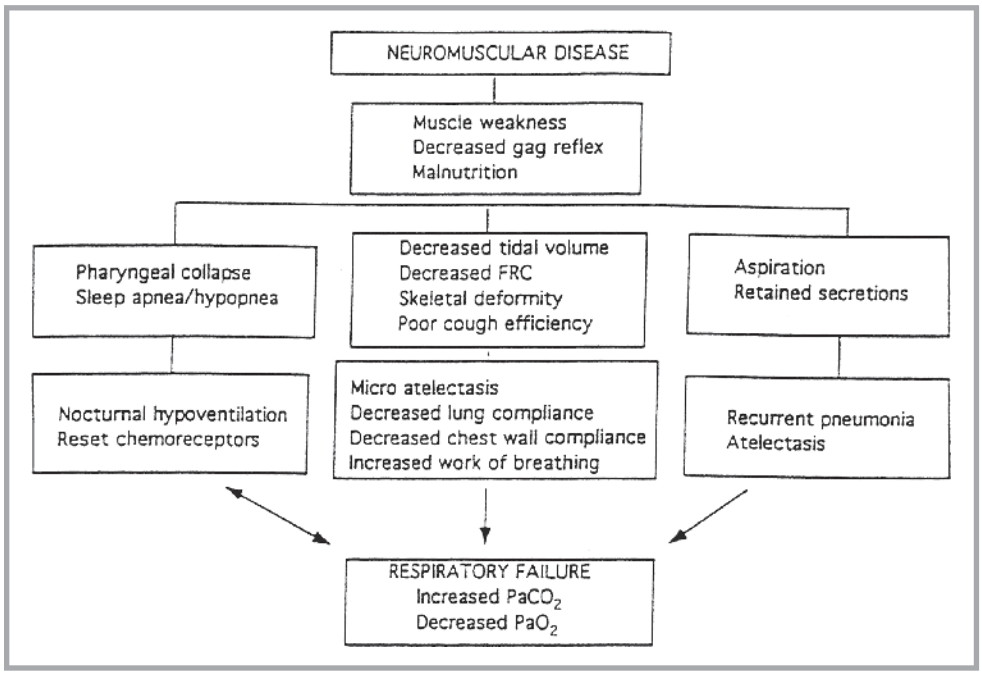

FIGURE 29-1

Schematic diagram of pathologic changes induced by neuromuscular disease on the respiratory system. The severity of these pathologic changes depends on the type and clinical stage of the neuromuscular disorder. *FRC* functional residence capacity.

TABLE 29-2

PATHOPHYSIOLOGIC EFFECTS OF NEUROMUSCULAR DISORDERS ON THE NEURORESPIRATORY AXIS

CONTROL OF BREATHING	NORMAL/INCREASED PM100
Respiratory muscle function	Decreased PI_{max} and PE_{max}
Lung and chest wall mechanics	Decrease in lung and chest wall compliance
Gas exchange abnormalities	Hypercapnia and hypoxemia
Sleep-related breathing disorder	Nocturnal hypercapnia and hypoxemia with normal daytime arterial blood gas

Mouth occlusion pressure, or Pm_{100}, is the maximum amount of negative pressure generated during early inspiration and is an index of central neural drive.
